PUBLISHER'S NOTE

Animals have always been a source of fascination for humans. We have sought to explain the origin and evolution of life, to classify the planet's many organisms in a logical manner, and to study the forms and behavior of creatures as diverse as jellyfish and elephants. *Magill's Encyclopedia of Science: Animal Life* offers accessible, easy-to-understand scientific information for high-school, undergraduate, and general readers on a subject of significant popular and academic interest. This illustrated, four-volume encyclopedia refocuses and expands on *Magill's Survey of Science: Life Science*. *Animal Life* revises and updates 108 articles from that 1991 set and its 1998 *Supplement* and then adds 277 new main entries, as well as more than three hundred textual sidebars, fact boxes, and biographies. Photographs, tables, and maps complement the text.

Animal Life concentrates on science in its discussion of nonhumans from the kingdom Animalia: invertebrates, insects, arthropods, amphibians, reptiles, fish, birds, and mammals. The 385 entries, ranging from 1,000 to 3,000 words each, survey a wide range of topics: anatomy (*Antennae*, *Feathers*, and *Tails*); behavior (*Defense mechanisms*, *Hibernation*, and *Nesting*); classification (*Bears*, *Crustaceans*, and *Mammoths*); ecology (*Herbivores*, *Poisonous animals*, and *Symbiosis*); evolution (*Fossils*, *Mutations*, and *Natural selection*); fields of study (*Biogeography*, *Paleontology*, and *Zoology*); geography and habitats (*Fauna: Australia*, *Fauna: Galápagos Islands*, *Deserts*, and *Rain forests*); physiology (*Cold-blooded animals*, *Reflexes*, and *Smell*); reproduction and development (*Asexual reproduction*, *Life spans*, and *Metamorphosis*); and scientific methods (*Breeding programs* and *Population analysis*). The emphasis of this encyclopedia is on animals in nature; the entries on domestic animals also cover their wild kin (*Chickens, turkeys, pheasant, and quail*; *Pigs and hogs*; and *Dogs, wolves, and coyotes*), and while there are entries on *Domestication* and *Zoos*, pets and farm animals are not discussed as such. Early humans are addressed in an evolutionary context, and modern humans are included only for interspecies comparison or for their efforts to coexist with other species.

All entries begin with ready-reference information about type of animal science and fields of study. Next is a list of principal terms, with brief definitions. Numerous creative subheads guide the reader through the main text of the entry. Every essay ends with an annotated bibliography; those reused from *Magill's Survey of Science* have been updated with recent sources. Species overviews, at 1,000 or 2,000 words, discuss notable anatomy and physiology, habitat, behavior (food sources, social groups), and reproduction and include an "Animal Facts" sidebar listing classification, geographical location, habitat, gestational period, life span, and special anatomy. Numerous biographical entries—on such prominent figures in the study of the natural world as John James Audubon, Charles Darwin, and Jane Goodall—appear as 500-word sidebars within main entries, as do some issue-oriented discussions such as habitat destruction and poaching. In addition, most longer entries provide one or more brief sidebars highlighting interesting subjects relating to the text.

A complete Alphabetical List of contents appears in the back of all four volumes, as does a Category List using the following headings: amphibians, anatomy, arthropods, behavior, birds, carnivores, cell biology, classification, ecology, evolution, fields of study, fish, genetics, geography, habitats, herbivores, human origins, insects, invertebrates, mammals, marine biology, marsupials, omnivores, physiology, population biology, prehistoric animals, primates, reproduction and development, reptiles, and scientific methods.

Volume 4 offers many useful appendices. The Glossary provides important terms with succinct definitions. A table of Animal Terminology gives the names applied to the males, females, young, and groups of various animals. The Time Line is a graphic depiction of the evolutionary tree across geological periods. The Classification Table lists all phyla, subphyla, superclasses, classes, subclasses, superorders, orders, infraclasses, suborders, superfamilies, and families in the kingdom Animalia. A Geographical List of Animals breaks species down into various areas: All continents (except Antarctica), all oceans, Africa, Antarctica, the Arctic, Asia, the Atlantic Ocean, Australia, the Caribbean, Central America, Europe, the Galápagos Islands, Madagascar, the Middle East, North America, the Pacific Islands, the Pacific Ocean, and South America. The Biographical List of Scientists consists of brief profiles of fifty-one important figures in animal science, past and present. A General Bibliography offers annotated sources, and both the Journals and the Organizations appendices provide contact and general information. The encyclopedia concludes with a comprehensive subject Index.

The contributors to this work are academicians from a variety of disciplines in the life sciences. We thank them for generously sharing their expertise; their names and affiliations are listed in the front matter to volume 1. Special acknowledgment is extended to the Editor, Carl W. Hoagstrom, Ph.D., from Ohio Northern University, for his invaluable guidance.

AARDVARKS

Type of animal science: Classification
Fields of study: Anatomy, zoology

The aardvark is the only member of the order Tubulidentata and is found only on the continent of Africa.

Principal Terms

NOCTURNAL: active at night
TUBULE: filled with cavities of pulp

The aardvark differs from the anteater, sloth, armadillo, and all other mammals. It is the only member of the order Tubulidentata (tubule toothed), so named because of a permanent set of twenty teeth that have tubular pulp cavities extending through them from top to bottom. The teeth are rootless. Dutch farmers who first encountered the animal in South Africa called it an aardvark, which means "earth pig" in the Dutch language. It is also sometimes called the African ant bear. It looks like a giant, hump-backed rat with the head of an anteater, the nose of a pig, and the ears of a rabbit. It is unrelated, however, to any other mammal.

Physical Characteristics of Aardvarks

The typical aardvark is about 7.5 feet long and weighs between 110 and 150 pounds, though the largest may weigh up to 180 pounds. It has a long, ratlike tail and a foot-long, sticky tongue that usually hangs out of its mouth. The tongue is curled like a coiled spring and is unleashed quickly as the aardvark sucks in its meal of ants or termites. It is perfectly suited for inserting into nests, and the termites adhere to the sticky surface. Adult aardvarks have one- to two-inch-long whitish hairs growing from each nostril, and twenty teeth along the sides of the mouth, that are always growing. The nose hairs protect aardvarks from dust and dirt while they are digging. Young aardvarks have front teeth that fall out as the animals reach maturity. Aardvark teeth are unique in the animal kingdom, as they are rootless, lack dentine, and have hollow tubes running through them.

Thick brown hair covers aardvarks' pinkish-gray skin. The hair serves to protect members of the species from insect bites. They have short, stocky legs and small feet with long, straight, very strong, blunt claws. Their front feet have four toes, while rear feet have five toes. The rear toes are webbed at the bottom. An aardvark looks like no other animal on earth.

The Life Cycle of Aardvarks

During most of the day, aardvarks live in burrows in the ground. They live singly or in small groups. They usually come out only at night, when they begin searching for termites and ants, which are the major part of their diets. They can rip open ant and termite nests and quickly lap up the insects with their sticky tongues. Aardvarks have tremendous ability to dig burrows in the ground very quickly. One aardvark can dig much faster than several human beings armed with shovels. Their powerful front claws can tear through hard ground and mud-covered termite nests with very little difficulty. They dig like dogs, pushing dirt and mud backward under their bodies.

They have a very good sense of hearing but very poor eyesight. When frightened, they usually run as quickly as possible for their burrows, but as they run, they frequently crash into trees and bushes. Sometimes they fight by using their powerful tails to hit their attackers, or by standing up on their back legs and slashing an opponent—usually a lion or a leopard—with their claws.

Aardvark Facts

Classification:
Kingdom: Animalia
Subkingdom: Eumetazoa
Phylum: Craniata
Subphylum: Vertebrate
Class: Mammalia
Subclass: Theria
Order: Tubulidentata (tubule-toothed)
Family: Orycteropodidae (ant bear)
Genus and species: Orycteropus afer
Geographical location: Africa, from Egypt to the Cape of Good Hope
Habitat: Open woodland, scrub, brushland
Gestational period: Seven months
Life span: Eight to ten years
Special anatomy: Chisel-shaped claws to break open hard clay of termite nests; a sticky tongue; twenty teeth that grow continually throughout its lifetime

Aardvark mothers usually give birth to only one or two offspring a year, usually in May, June, or July. They nurse their young in their burrows and spend most of the day with them, curled up in a tight circle. Aardvarks are able to dig their own burrows by time they are six months of age.

Aardvarks were formerly classified with anteaters, sloths, and armadillos in the order Edentata, but this is no longer the case. The order under which they are now classified, Tubulidentata, is at least sixty million years old, though its origins are unknown. Evidence of fossil remains indicates that the aardvark ranged over Europe and Asia until about five million years ago. At that time, a close relative lived on the island of Madagascar. Today there is only one order, one family (Orycteropodidae), one genus (*Orycteropus*), and, remarkably, only one species (*afer*), and it is exclusively African. It exists in relatively small numbers and does not respond well to captivity, but has survived in zoos for ten years.

Aardvarks and Humans

The chief importance of aardvarks is their keeping in check enormous, ever-multiplying hordes of termites. Some African peoples hunt aardvarks for food and claim the meat is very tasty. Aardvark burrows are large enough for a small-sized man to crawl into, but the hunter must kill the animal before it has time to escape by burrowing deeper. The animal can dig faster than the man and can throw up a wall of packed dirt between itself and the hunter—and then it is gone. Some African peoples believe that a bracelet of aardvark teeth can protect an individual against evil forces.

ADAPTATIONS AND THEIR MECHANISMS

Type of animal science: Ecology
Fields of study: Evolutionary science, genetics, invertebrate biology, zoology

Adaptations are structures, physiological mechanisms, or behaviors that are shaped by the environment and enable organisms to cope with specific environmental conditions. Studying adaptations helps scientists understand how organisms live with environmental constraints and allows them to examine the mechanisms of evolution.

Principal Terms

COEVOLUTION: joint evolutionary change caused by the close interaction of two or more species; each species serves as the natural selection agent for the other(s)

COMPETITION: striving for a limited resource

EVOLUTION: a process, guided by natural selection, that changes a population's genetic composition and results in adaptations

FITNESS: the ability of an organism to produce offspring that, in turn, can reproduce successfully; the fitness of organisms increases as a result of natural selection

NATURAL SELECTION: the elimination of individuals with hereditary characteristics that hinder the organism's ability to survive and reproduce, and the preservation of those with traits beneficial to survival

POPULATION: a group of individuals of the same species in a particular location

SPECIES: a group of organisms that can successfully interbreed to produce living, successfully reproducing offspring

Many of the features that are most interesting and beautiful in biology are adaptations. Adaptations are the result of long evolutionary processes in which succeeding generations of organisms become better able to live in their environments. Specialized structures, physiological processes, and behaviors are all adaptations when they allow organisms to cope successfully with the special features of their environments. Adaptations ensure that individuals in populations will reproduce and leave well-adapted offspring, thus ensuring the survival of the species.

Mutation and Natural Selection

Adaptations arise through mutations—inheritable changes in an organism's genetic material. These rare events are usually harmful, but occasionally they give specific survival advantages to the mutated organism and its offspring. When certain individuals in a population possess advantageous mutations, they are better able to cope with their specific environmental conditions and, as a result, will contribute more offspring to future generations compared with those individuals in the population that lack the mutation. Over time, the number of individuals that have the advantageous mutation will increase in the population at the expense of those that do not have it. Individuals with an advantageous mutation are said to have a higher "fitness" than those without it, because they tend to have comparatively higher survival and reproductive rates. This is natural selection.

Over very long periods of time, evolution by natural selection results in increasingly better adaptations to environmental circumstances. Natural selection is the primary mechanism of evolutionary change, and it is the force that either favors or selects against mutations. Although natural selection acts on individuals, a population gradually changes as those with adaptations become better represented in the total population. Predaceous fish, for example, which rely on speed to pursue and overtake prey, would benefit from specific adaptations that would increase their swimming speed. Therefore, mutations causing a more sleek and hydrodynamically efficient form would be beneficial to the fish predator. Such changes would be adaptations if they resulted in improved predation success, improved diet, and subsequently greater reproductive success, compared with slower members of the population. Natural selection would favor the mutations because they confer specific survival advantages to those that carry the mutations and impose limitations on those lacking these advantages. Thus, those individuals with special adaptations for speed would have a competitive advantage over individuals that can only swim more slowly. These attributes would be passed to their more numerous offspring and, in evolutionary time, speed and hydrodynamic efficiency would increase in the population.

Environment and Survival

Although natural selection serves as the instrument of change in shaping organisms to very specific environmental features, highly specific adaptations may ultimately be a disadvantage. Adaptations that are specialized may not allow sufficient flexibility (generalization) for survival in changing environmental conditions. The degree of adaptative specialization is ultimately controlled by the nature of the environment. Environments, such as the tropics, that have predictable, uniform climates and have had long, uninterrupted periods of climatic stability are biologically complex and have high species diversity. Scientists generally believe that this diversity results, in part, from complex competition for resources and from intense predator-prey interactions. Because of these factors, many narrowly specialized adaptations have evolved when environmental stability and predictability prevail. By contrast, harsh physical environments with unpredictable or erratic climates seem to favor organisms with general adaptations, or adaptations that allow flexibility. Regardless of the environment type, organisms with both general and specific adaptations exist because both types of adaptation enhance survivorship under different environmental circumstances.

Structural adaptations are parts of organisms that enhance their survival ability. Camouflage, which enables organisms to hide from predators or prey; specialized mouth parts that allow organisms to feed on specific food sources; forms of appendages, such as legs, fins, or webbed toes, that allow efficient movement; protective spines that

Image Not Available

make it difficult for the organism to be eaten—these are all structural adaptations. These adaptations enhance survival because they assist individuals in dealing with the rigors of the physical environment, obtaining nourishment, competing with others, hiding, or confusing predators.

Physiological Versus Behavioral Adaptation

Metabolism is the sum of all chemical reactions taking place in an organism, whereas physiology consists of the processes involved in an organism carrying out its function. Physiological adaptations are changes in the metabolism or physiology of organisms, giving them specific advantages for a given set of environmental circumstances. Because organisms must cope with the rigors of their physical environments, physiological adaptations for temperature regulation, water conservation, varying metabolic rate, and dormancy or hibernation allow organisms to adjust to the physical environment or respond to changing environmental conditions.

Desert environments, for example, pose a special set of problems for organisms. Hot, dry environments require physiological mechanisms that enable organisms to conserve water and resist prolonged periods of high temperature. Highly efficient kidneys and other excretory organs that assist organisms in retaining water are physiological adaptations related to the metabolisms of desert organisms. The kangaroo rat is a desert rodent extremely well adapted to its habitat. Kangaroo rats do not drink, but rather can obtain all of their water from the seeds they eat. They produce highly concentrated urine and feces with very low water content.

Adaptation to a specific temperature range is also an important physiological adaptation. Organisms cannot live in environments with temperatures beyond their range of thermal tolerance, but some organisms are adapted to warmer and others to colder environments. Metabolic response to temperature is quite variable among animals, but most animals are either homeothermic (warm-blooded) or poikilothermic (cold-blooded). Homeotherms maintain constant body temperatures at specific temperature ranges. Although a homeotherm's metabolic heat production is constant when the organism is at rest and when environmental temperature is constant, strenuous exercise produces excess heat that must be dissipated into the environment, or overheating and death will result. Physiological adaptations that enable homeotherms to rid their bodies of heat are the ability to increase blood flow to the skin's surface, sweating, and panting, all of which promote heat loss to the atmosphere.

Behavioral adaptations allow organisms to respond appropriately to various environmental stimuli. Actions taken in response to various stimuli are adaptive if they enhance survival. Migrations are behavioral adaptations because they ensure adequate food supplies or the avoidance of adverse environmental conditions. Courtship rituals that help in species recognition prior to mating, reflex and startle reactions allowing for quick retreats from danger, and social behavior that fosters specialization and cooperation for group survival are behavioral adaptations.

Because organisms must also respond and adapt to an environment filled with other organisms—including potential predators and competitors—adaptations that minimize the negative effects of biological interactions are favored by natural selection. Many times the interaction between species is so close that each species strongly influences the others in the interaction and serves as the selective force causing change. Under these circumstances, species evolve together in a process called coevolution. The adaptations resulting from coevolution have a common survival value to all the species involved in the interaction. The coevolution of flowers and their pollinators is a classic example of these tight associations and their resulting adaptations.

Adaptation in Theory and Practice

Charles Darwin and Alfred Russel Wallace, the mid-nineteenth century biologists who formulated the theory of evolution by natural selection, found much of the evidence for their theory in the adaptations they observed in nature. They reasoned that organisms with similar body forms and structures were closely related evolutionarily and had common ancestors which are now extinct. The modern study of relatedness among species and the evolutionary history of organisms is called systematics, and this discipline aids in understanding evolution and adaptations.

The methods used to study adaptations are largely the same as those used to examine the theory of evolution. Evolution, however, is a slow process, and, as a result, it is extremely difficult to test the theory. Instead, evidence must be collected from the past, and closely related organisms must be examined carefully to reconstruct how adaptations may have come into being. Scientists can then speculate on how adaptations occurred and how they helped organisms to survive.

Fossils, because they are a historical record of evolutionary change, are used by scientists to reconstruct evolutionary histories. Similar structures in different living organisms with essentially the same function are used by comparative anatomists to show how adaptations for a specific mode of life arose. The fins of some ancient fish and the limbs of mammals, for example, have strikingly similar bones that have a common origin, but the appendages have been modified for locomotion in very different environments. Adaptations are also studied in relation to biogeography, the geographical distribution of organisms. On the Galápagos Islands, fourteen species of finches now known as Darwin's finches are distributed geographically on the basis of their adaptations. Although the species that gave rise to these fourteen species is extinct, the existing species and their distributions suggest how evolution proceeded and how the adaptations came about.

A classic example of recent evolutionary change and adaptation comes from England. The peppered moth, with a mottled gray color, is well adapted to resting quietly on pale tree bark, with which it blends nicely. This adaptive coloration (camouflage) enhanced the moth's survival because the moths could remain largely undetected by predators during daylight hours. Between 1850 and 1950, however, industrialization near urban centers blackened tree trunks with soot, making the gray form disadvantageous, as it stood out on the contrasting background. During this period, the gray moths began to disappear from industrial areas, but a black-colored variant, previously rare, became increasingly common in the population. These circumstances made it possible for scientists to test whether the peppered moth's camouflage was adaptive.

In a simple experiment, moths were raised in the laboratory, and equal numbers of gray and black moths were released in both industrial and unpolluted rural areas. Sometime later, only half of the gray-colored moths could be recovered from the industrial sites, while only half of the black forms could be recovered from the rural sites, compared with the total number released. These results enabled the scientists to conclude that increased predation on the gray moths in industrial areas led to a greater fitness of the black moths, so the frequency of black moths increased in the population. The reverse was true at the rural sites. This is the first well-documented case of natural selection causing evolutionary change, and it illustrates the adaptive significance of camouflage.

The various ways of examining adaptations (by evolutionary history, comparative anatomy, and biogeography) demonstrate how adaptations are structurally and functionally important. These approaches also give scientists insight into the survival benefits of various adaptations.

The Function of Adaptation

Adaptations can be general or highly specific. General adaptations define broad groups of organisms whose general lifestyle is similar. For example, mammals are homeothermic, provide care for their young, and have many other adaptations in common. At the species level, however, adaptations are more specific and give narrow definition to those organisms that are more closely related to one another. Slight variations in a single characteristic, such as bill size in the seed-eating Galápagos finches, are adaptive in that they enhance the survival of several closely related species. An understanding of how adaptations function to make species distinct also furthers the knowledge of how species are related to one another.

Why so many species exist is one of the most intriguing questions of biology. The study of adaptations offers biologists an explanation. Because there are many ways to cope with the environment, and because natural selection has guided the course of evolutionary change for billions of years, the vast variety of species existing on the earth today is simply an extremely complicated variation on the theme of survival.

Rose, Michael R., and George V. Lauder, eds. *Adaptation*. San Diego, Calif.: Academic Press, 1996. The first comprehensive examination of how adaptational biology has confronted the critiques made over the last twenty years by Stephen J. Gould, Richard Lewontin, and others. A variety of often conflicting viewpoints is presented. For readers who already have a background in the topic and its controversies.

Weibel, Ewald R. *Symmorphosis: On Form and Function in Shaping Life*. Cambridge, Mass.: Harvard University Press, 2000. Addresses the ways that numerous mammal species have adapted their respiratory systems to the requirements of supplying oxygen and fuel to muscles. A case study in how an evolutionary hypothesis (in this case, "symmorphosis" or "the precise tuning of all structural elements to each other and to the overall functional system") is tested and modified.

Whitfield, Philip. *From So Simple a Beginning: The Book of Evolution*. New York: Macmillan, 1995. An authoritative guide to the major aspects of evolutionary theory, written for a general readership. The topics, covered in two-page summaries, are organized around the themes of life and change, the rules of change, adaptation, and current frontiers of evolutionary theory. Explains key assumptions, scientific processes, and current controversies in the field. Abundant state-of-the-art graphics and color photographs assist in making the narrative clear to nonspecialists.

ADAPTIVE RADIATION

Type of animal science: Evolution
Fields of study: Ecology, genetics, invertebrate biology, zoology

Adaptive radiation is a process by which new species can emerge from a common ancestor. If members of one population travel (or radiate) to new environments and are sufficiently isolated from other populations of their species, they may gradually adapt to their new environments and evolve into new species.

Principal Terms

ALLELE: an alternative form of a gene that is located at the same position on a chromosome

FOSSIL: any recognizable remains of an organism preserved in the earth's crust; it may be a footprint, bones, or even feces

GENE: the biological unit of heredity, which is composed of DNA and is located on a chromosome

GENOTYPE: the total genetic composition of an organism

HABITAT: the place where an organism normally lives or where individuals of a population live

NATURAL SELECTION: the process of evolution whereby organisms that are the best adapted are the most successful in reproducing and therefore in passing along their genotypes to successive generations

NICHE: the role of an organism in an ecological community—its unique way of life and its relationship to other biotic and abiotic factors

PHENOTYPE: the visible expression of the genetic makeup of an individual

SPECIES: a taxonomic subdivision of a genus, containing populations of similar organisms that interbreed and that usually do not interbreed with other species

In 1898, Henry F. Osborn developed the concept of adaptive radiation. According to Osborn, many different forms of evolutionary adaptations may occur among animals that started with a common ancestor. In this way evolutionary divergences can take place, and the occupation of a variety of ecological niches is made possible according to the adaptive nature of the invading species. As may be seen with certain forms of animal life, however, the ability to adapt is not shared by all species. Therefore, in many instances, either evolutionary divergence has been modest or the species involved has become extinct.

The Principles of Natural Selection

In order to understand how adaptive radiation operates, it is necessary to become familiar with the principles of natural selection. The concept of natural selection, frequently expressed as "survival of the fittest," is at the core of Charles Darwin's theory of evolution. Darwin did not mean to suggest that there was a physical struggle among organisms in order to survive. Instead, he meant that organisms compete for food, space, shelter, water, and other things necessary for existence. Only those organisms best adapted for a particular habitat will survive. According to the concept of natural selection, all organisms of a given species will show variation in color, size, physiology, and many other characteristics; in nature, all organisms produce more offspring than can survive, so the offspring must therefore compete for the limited environmental resources. Organisms that are the best adapted (most fit) to compete will live to reproduce and pass their successful traits on to their offspring. The others, which are less fit, will die without reproducing. When different parts of an animal population are faced with slightly different environments, they will diverge from one another and in time will become different enough to form new species. Natural selection also has the effect of producing different patterns of evolution. It may bring about widely different phenotypes (variable characteristics) in closely related animals, for example, or similar phenotypes in distantly related organisms. The organisms themselves may also become forces of selection through their interrelationships with other species.

The process of adaptive radiation illustrates how natural selection operates. The most frequently cited example is the evolution of Darwin's finches on the Galápagos Islands, off the west coast of South America. The islands were formed from volcanic lava about one million years ago. At first they were devoid of life, but bit by bit, several species of plants and animals migrated to them from the South American mainland. Since the nearest island is about 950 kilometers from the coast of Ecuador, it is anybody's guess how the different species arrived. It has been suggested that the birds may have been carried to the islands by strong winds, since finches are not known for their lengthy flights. Other organisms may have been carried by floating debris. In any event, the islands became populated. The mainland ancestor of the finches is not known, but it was no doubt a nonspecialized finch (a finch is about the size of a sparrow). Since there were no other birds with which to compete on the islands, the original population of finches began to adapt to the various unoccupied niches. The early off-

The evolution of white, arctic-dwelling, almost completely carnivorous polar bears from the largely vegetarian, forest-dwelling brown bear is a classic example of adaptive radiation. (PhotoDisc) shoots of the original population were modified again and again as adaptations continued. This process resulted in the evolution of fourteen species of finches. The main feature that makes each species different is the size of their beaks, which have adapted for the various types of available foods. Today the finches live on fifteen different islands. Some of the species are found in the same area (sympatric), while others occur in different areas (allopatric). The most noteworthy example of an adaptation to a particular niche is the woodpecker finch. A true woodpecker has an extremely long tongue that it uses to probe for insects. Since the woodpecker finch does not have a long tongue, it has learned to use a cactus spine for insect probing, and it can therefore occupy a niche normally filled by true woodpeckers.

A more recent example of adaptive radiation in its early stages has taken place in an original population of brown bears. The brown bear can be found throughout the Northern Hemisphere, ranging from the deciduous forests up into the tundra. During one of the glacier periods, a small population of the brown bear was separated from the main group; according to fossil evidence, this small population, under selection pressure from the Arctic environment, evolved into the polar bear. Although brown bears are classified as carnivores, their diets are mostly vegetarian, with occasional fish and small animals eaten as supplements. On the other hand, the polar bear is mostly carnivorous. Besides its white coat, the polar bear is different from the brown bear in many ways, including its streamlined head and shoulders and the stiff bristles that cover the soles of its feet, which provide traction and insulation, enabling it to walk on ice.

Evolution

All the genes of any population of living organisms at any given time make up its gene pool, and the ratio of alternative characteristics (alleles) in the gene pool can change because of selection pressures during the passage of time. As the ratio of alleles changes, evolution occurs. Evolution may be a random change, or it may occur because of the directive influences of natural selection. In the former case, occasional and unpredictable permanent random changes called mutations take place in the DNA molecules that compose the genes. These mutations also may be selected for by the environment or selected against by the environment. It is simply an accident if the newly mutated genes help the organism to become better adapted to its particular habitat niche. Genes may not change or become mutated through several generations (the Hardy-Weinberg law), but may change in terms of survival value if the environment changes or the species population is subjected to new mutations or natural selection. The relative numbers of one form of allele decrease in a divergent population, while the relative numbers of a different gene increase. This progressive change is all-important in the evolutionary process that takes place between the origin of a new gene by random mutation and the replacement of the original form of the gene by descendants having the newer, better-adapted form of the gene. The result in the long term is that enough of the DNA changes, either slowly or rapidly, through divergent populations or organisms, that the new generations have become so different from the original population that they are considered new species. Many times in earth's history, a single parental population has given rise not to one or two new species but to an entire family of species. The rapid multiplication of related species, each with its unique specializations that fit it for a particular ecological niche, is called adaptive radiation, or divergent evolution.

Studying Adaptive Radiation

Not all scientific information is gained by experimentation: A considerable portion of science is descriptive and is based upon observation. In determining that adaptive radiation has occurred and is indeed taking place among living species, much supporting evidence has come from the study of fossils and from observations of the structural, physiological, and behavioral adaptations of current animals. Clearly, wide-scale experimentation would be out of the question. No matter how well an experiment may be designed to test the concept of adaptive radiation, the scientist could not be around thousands or millions of years from now to gather the data. Therefore, scientific observation of animal remains is the best method.

Based upon scientific observations, it has been well established that the phenomenon known as adaptive radiation is a general feature of the evolution of most organisms. Studies of the morphological features of fossilized remains help determine relationships among prehistoric animals and enable the scientist to trace adaptive radiations from a more primitive ancestral stock. In order to establish time intervals, techniques such as radioactive carbon dating, potassium-argon dating, and fluorine dating have been used.

Zoologists have also made use of the uneven distribution of blood groups (A, B, AB, and O) among different groups of animals. As more blood subgroups were discovered, they became useful in helping chart migrations and indicating relationships between species.

The Evidence and Its Implications

Adaptive radiation as an important aspect of evolution means that modern organisms have attained their diversity in form and behavior through hereditary modifications after having been separated from ancestral populations. Adaptive radiation, therefore, is attributable to the genetic changes in isolated groups of organisms or, more specifically, to a change in the relative frequency of their genes from one generation to the next that eventually results in the formation of new species.

Evidence in several areas supports the concept of adaptive radiation as an important aspect of evolution: the fossil record (the most direct evidence), biogeographic distribution of organisms, comparative anatomy and embryology, homologous and analogous structures, vestigial organs, and comparative biochemistry. Regarding comparative biochemistry, scientists agree that blood group similarities confirm evolutionary relationships among the nonhuman primates. It has been shown that the blood of higher primates, such as orangutans and chimpanzees, is closer to human blood than to that of the more primitive monkeys.

AGING

Types of animal science: Development, physiology
Fields of study: Anatomy, cell biology, developmental biology, genetics, neurobiology, pathology, physiology

Aging is the process of progressive and irreversible change common to all living organisms. There are striking similarities in the physical process of aging among all animal species.

Principal Terms

AGING: a process common to all living organisms, eventually resulting in death or conclusion of the life cycle
COGNITION: ability to perceive or understand
DEATH: the cessation of all body and brain functions
FUNCTION: ability, capacity, performance
LIFE SPAN: length of life from birth to death
LONGEVITY: length of life

Progressive and irreversible change has been called the single common property of all aging systems. When change is reversible or self-maintaining, such as one would see in a forest, for example, the effects of aging are often not observable. Growth of the forest is evident, but with the right conditions, trees within the forest may grow for hundreds of years in the absence of disease. Certain conditions of the forest system help to regenerate, renew, and reverse changes that happen within that system.

However, in animals some change is not reversible. The changes in the cells of the body accumulate over time and result in a steady downward trend. The end point of this trend is the death of the organism. Aging is a normal part of the life cycle. This is known to be true because aging changes within populations are rather predictable. The changes associated with aging that are seen in all animal species may occur for similar reasons. These may include chemical aging, extracellular aging, intracellular aging, and aging of cells.

Aging occurs within body systems as a result of unseen changes at the molecular and cellular levels. Although the mechanisms through which aging occurs may be understood, the causes are less clear. The fact remains that due to changes in chemical balances such as those of hormones, and to the dying of cells within the body, each of the bodily systems shows deterioration over time.

Changes that occur in domestic animals over the life span can be similar to those that occur in humans. Dogs experience the graying of their hair, a decrease in vision, and a slowing of movement with age. They also experience cataract formation, arthritis, skin problems, cancer, and diabetes. Certain breeds of animals may demonstrate a tendency toward specific illnesses or diseases. For example, German shepherds often develop hip problems, and collies commonly develop progressive arthritis that may seriously inhibit mobility by around ten years of age.

Common Effects of Aging

There are many variations in the effects of aging among the species of animals. The life span of animals may range from a few days (among insects) to thirty years or more, with great variation depending upon many factors. Animals that live in captivity, as pets or in zoos where they are sheltered from the effects of predation, disease, and adverse climate, also tend to live significantly longer than animals in the wild.

Graying hair is a sign of aging in most mammals. The pattern of graying varies with species; in dogs, it usually begins around the muzzle. (Corbis)

Physical function or capacity tends to decline with age. This is largely due to the atrophy of muscles, which is more common as the body gets older. The joints tend to become stiffer and less mobile. Range of motion may be restricted. Changes in bone density may lead to loss of teeth, osteoporosis, and subsequent fractures. Tooth loss and osteoporosis have been documented in monkeys over the age of twenty years. Pictures of such older monkeys reveal a stooped posture, with shoulders hunched forward, similar to the kyphosis observed in many older human women.

Physical function among animals has been less studied than that in humans, but certain physiological characteristics are similar. For example, survival times after severe physical injury with blood loss and trauma decreases in both humans and animals as age increases. Male monkeys do not lose reproductive capabilities until toward the end of the life span, while females have a more restricted period of time to bear offspring. Fertility among all females tends to decline with age after its peak.

The immune system functions less effectively as age increases. This leaves the body more susceptible to a range of illnesses and diseases. Neoplasms, or tumors, are most common among mammals as they age. An impaired immune system allows various types of tumors or cancers to spread more rapidly in the older body. Response to stress and ability to adapt to stressors also decline with age. For example, older mice become less able to adapt to cold temperatures.

Social roles and behaviors among animals may also change with age. Longitudinal studies on animals in the wild are scarce, so only generalities may be speculated upon. Even studies done within controlled laboratory settings yield only broad suggestions, since numbers of animals available for study are limited. Males generally

Very little research has been done on the aging of most animal species. The reasons for this include the difficulty of observing animals over a long period of time in their natural habitat. Aging in monkeys has been studied more than that in other animals because of the notion that aging patterns may closely reflect those of humans.

Aging monkeys show changes in their circulatory systems similar to those found in humans: There is notable atherosclerosis and arteriosclerosis, or hardening of the arteries. The heart pumps less effectively, and vessels show buildup of plaque. These changes often result in cardiac problems, including heart attacks. The respiratory system also shows a decrease in elasticity. Senile emphysema has been noted. The kidneys show signs of atrophy and sclerosis in aged monkeys. The kidneys of humans may lose up to half of the functioning nephrons with advanced age and thus become less effective in filtering waste products from the body.

tend to dominate the females in both physical strength and social ranks. Some nonhuman primates show different characteristics with advanced age. That is, some monkeys and baboons allow older males to remain part of the social group, while other species support the male leader in the group only as long as the female harem supports him, whether younger or older. Individual monkeys in stable groups have been observed to resort less frequently to aggressive behavior to maintain their status within the group.

Causes of Death

Among nonhuman primates, the leading cause of spontaneous death is digestive problems. Older animals that die do not always show advanced signs of tissue aging. Since much less research has been done on aging among animals than among humans, data about causes of death are rare. However, it appears that there is an increased probability of dying from trivial illnesses, perhaps due to decreased resistance factors, as animals age.

Predator-prey relationships among animals are particularly significant as causes of death. Thus, the effect of the environment on animal aging and death requires more investigation. Do animals age more quickly if they are objects of prey? Do animals relate to stress in ways similar to those of people, thus showing signs of wear and tear that are seen with premature aging under stress? Are there risk factors among animals that affect their life span? These are some of the questions that remain to be answered on the topic of aging among animals.

ALLOSAURUS

Type of animal science: Classification
Fields of study: Evolutionary science, paleontology, physiology

Allosaurus *is the archetypal allosaurid, and was the dominant carnosaur of the Late Jurassic.* Allosaurus *is best known from the remains of at least sixty specimens collected at the Cleveland-Lloyd dinosaur quarry in Utah.*

Principal Terms

CARNOSAURS: the largest meat-eating animals to have lived on land

MESOZOIC ERA: the middle era of the Phanerozoic eon, 250 million to 65 million years ago

SAUROPODA: large, quadrupedal herbivorous dinosaurs that lived from the Early Jurassic to the end of the Cretaceous

THEROPODA: "beast foot"; dinosaurs that lived from the Late Triassic to the terminal Cretaceous extinction event; most predatory and carnivorous dinosaurs belong to this group

Carnosaur theropods are divided into two principal families, the Allosauridae and Tyrannosauridae. The allosaurids include all carnosaurs of the Early Jurassic to Early Cretaceous age that have been studied thoroughly enough to be assigned a family lineage. All mature allosaurids were five meters or more in length, had large skulls, short, powerful necks, very short forelimbs, massive hind limbs, and long tails. *Allosaurus* is the best-known carnosaur genus and the archetypal allosaurid.

Remains of *Allosaurus* ("different reptile") were first recovered in Grand County, Colorado, in 1869, but a full skeleton was not discovered until 1883, in the Garden Park Quarry, Fremont County, Colorado. Since these initial discoveries, numerous allosaur remains have been recovered in North America, most notably from the Morrison Formation in the western United States. The most spectacular discovery occurred in Utah in 1927 at the Cleveland-Lloyd Quarry, where some ten thousand bones, representing at least sixty individual allosaurs, were identified. The quarry has provided examples of individual allosaurs ranging in size from twelve-meter-long adults to three-meter-long juveniles. It is speculated that the quarry may have been a predator trap, similar to the Pleistocene-age Rancho La Brea Tar Pits in Los Angeles, California. One unfortunate feature of the Cleveland-Lloyd Quarry's collection of bones is that no articulated skeleton has been recovered there. The stratigraphic range and large numbers of allosaur fossils recovered in North America suggest that packs of allosaurs pursued prey animals all across the Jurassic topography, and that allosaurs were the dominant predator for nearly twenty-five million years.

A unique feature of *Allosaurus* was its lightly constructed skull, which had distinctive sham-rimmed ridges above and along the nasals and a tall, triangular hornlet in front of and above the eye orbits. The skull in an adult was about ninety centimeters long, relatively long in comparison to both its body size and to the skulls of other carnosaurs. Allosaur skulls have loose joints between some of the lower skull bones and also between several bones of the lower jaw. These flexible jaw joints probably allowed for expansion of the gullet so that large chunks of food could be swallowed. Above the jaws, the skull was lightly constructed, with several large, lateral spaces in front of and behind the eye. These spaces may have helped to lighten the skull, making it easier

Image Not Available

for *Allosaurus* to move its head. Allosaur eyes were twice as large as those of any other carnosaur, suggesting the animal hunted in both dim light and bright sunshine. Allosaurs had back and front serrated, recurved teeth, positioned far forward in the jaws and in front of the eye sockets, that could be used for stabbing, killing, and dismembering prey. Like tyrannosaurs, allosaurs had an enlarged transverse crest at the back of the skull, atop the braincase, supporting powerful cervical muscles. These muscles allowed the head to be held almost above the shoulders rather than extended forward. Allosaur forelimbs were large and powerfully muscled, having three large, sharply pointed, curving claws, the inner being the largest. These claw-tipped arms were probably used for mating, slashing, holding prey, and dismembering carcasses. Allosaur hind limbs were massive, with five-toed feet, of which only three toes supported weight. The allosaur body was rather squat and was balanced over the hip structure by a massive, muscular tail. Allosaurs were well-adapted predators, but their physiology suggests to many paleontologists that, individually, they may not have had the power or speed to overtake and kill large Late Jurassic sauropods. It has been suggested that allosaurs may have hunted in packs, ambushed prey, or been simply advantageous predators and carrion scavengers. The Cleveland-Lloyd Quarry discoveries suggest that, in that locale, allosaurs and other predatory theropods engaged in feeding frenzies when sauropods and other theropods wandered into a muddy bog and were trapped in slimy ooze. The immobilized prey were then swarmed by predators, who in turn became trapped in the bog and died.

ALTRUISM

Type of animal science: Behavior
Fields of study: Evolutionary science, genetics, zoology

Altruistic behavior involves an individual's sacrifice of self in order to help others. In some animals, altruism appears to be genetically determined.

Principal Terms

ALTRUISM: sacrifice of self to aid another; subjugation of the needs of the individual to the needs of another or to the needs of the group

EGOISM: self-interest

HYMENOPTERA: an order of highly specialized insects (including bees, ants, flies, and wasps) that often associate in large colonies and have a complex social organization

KIN SELECTION: a phenomenon by which acts of altruism can help pass on genes for altruism by improving the survival of kin and their offspring

RECIPROCAL SACRIFICE: one explanation for acts of altruism among unrelated animals; an individual sacrifice is made under the assumption that a similar sacrifice may in turn aid the individual in the future

SELECTION: a process that prevents some individuals from surviving and propagating while allowing others to do so

TRAIT: a genetically inherited characteristic

Those who study behavior have observed that on occasion individuals act altruistically. In other words, they appear voluntarily to put the needs of their group or of another individual ahead of their own needs. According to some scientists, there have been examples in nature where a particular species might not have survived had there not been sacrifice by some on behalf of the many. One important question is whether this so-called altruism has been a matter of voluntary choice or whether it has occurred as a part of the selection process, making it, therefore, an involuntary response.

Group Dynamics

Of interest to a wide group, including psychologists, sociologists, philosophers, and political scientists, are the questions of whether altruism is desirable behavior—perhaps even to the exclusion of egoism—and whether altruism may be necessary for human survival. Some wonder whether such behavior is necessary, whether it can be learned, and whether humans will voluntarily choose to learn it. Biologists and geneticists have been left the problem of determining, if possible, whether the tendency for altruism is inherited, that is, instinctual, or learned. Unfortunately for scientists, the study of human beings in social groups in the wild is virtually impossible. However, the study of animal behavior, primarily in native habitats, has provided some insight, although it must be recognized that different species have solved problems of survival in different ways.

Animals of the same species are bound to consort, if only for mating purposes. Most species are, in fact, found to live in groups, not only for purposes of reproduction but also because sources of food attract individuals to the same places and because congregation provides better protection from predators. It is common in nature for groups to form because their individuals have the same physical needs, and such groups may stay together as long as the needs of those individuals can be met. This does not necessarily mean that there exists in the group any loyalty or even any recognition of individuals as members of the group. In more highly developed societies, however, groups such as families or tribes develop. In animal life, two or more adults and their offspring often form close bonds and tend to exclude those who are not related. Each recognizes the others as being members, and membership is restricted to those who are among the founders or who are born into the smaller group and who conform in recognizable ways to the norms of the group. Hierarchy or rank is recognized, and often there is a division of labor within the group.

It has been demonstrated that those species which spend a large amount of time providing for their young tend to have developed higher social orders. Humans, for example, must care for their young much longer, before these young are able to become independent, than must many of the lower forms of animal life. Humans are aware of a bond that almost always exists between parent and child and of the spirit of mutual support and a cooperation that may exist even in the extended family. Cooperative behavior within such a familial group may be considered to benefit all members. Because such behavior is not consistent, however—there are times when such bonds do not exist and when families are not cooperative—such behavior cannot necessarily be attributed to predisposition. Some have argued that in primitive animal societies, so-called altruism may have evolved of necessity in order to achieve reproductive success, but that in human society there may be no evolutionary explanation for the phenomenon. Indeed, it could be argued that pure altruism, for humans, might be self-defeating and therefore unlikely to have developed as an inherited trait.

Kin Selection and Reciprocal Sacrifice

Evidence has been gathered in the study of Hymenoptera, which provide food for their young, that certain members of the population forage for the group while others lay eggs and remain at the nest to guard them. Where such behavior has evolved, through the necessity of feeding and protecting those who will propagate their kind, the foragers may be labeled altruistic: They have sacrificed their own reproductive possibilities for survival of the group. Some have questioned whether this phenomenon can truly be labeled altruism, however, because the donor appears to have no choice (conscious purpose is very difficult to assess in animals). Moreover, some researchers wonder how the traits that favor altruistic behavior can survive and become dominant in a group if those having the traits deemed desirable are not allowed to reproduce. With the use of mathematical models, it has been demonstrated that such traits can be preserved only within the family unit. Among close relatives, the traits appear with enough strength that they will be reproduced in a greater concentration, thereby compensating for the loss suffered by the sacrifice of the donors. This phenomenon has been referred to as kin selection, because it occurs in groups that have strong recognition of membership—to the extent that there exists aggressive defense against intruders, even of the same species. Discrimination against outsiders is an important facet of altruism of this type. The willingness of an individual to provide for others at the expense of its own interests diminishes as the degree of relatedness decreases.

Most parental behavior would not be labeled altruistic, since it is in the interests of the parent to care for the offspring in order to ensure the survival of the parent's genes. Of perhaps more interest than what happens among closely related members of a group and even between parent and offspring is the question of what motivates sacrifice on the part of an individual when no close relationship with the recipient exists—for example, a male animal coming to the rescue of an unrelated male animal who is being attacked by a third male of the same species. One theory maintains that these acts of personal sacrifice are performed on the chance that reciprocal sacrifice may occur at some future time. Whether this type of altruism can occur through natural selection, which acts through individuals, is an interesting question.

Models have shown that in a population where individuals are likely to encounter and recognize one another on a frequent basis, it is possible that reciprocal exchanges can take place. Individual A might be the donor on the first encounter, individual B on the second. This theory requires that the two must have a high probability of subsequent encounters and that the tendency for altruism must already have been established through kin selection. Because animals are usually suspicious of strangers on first encounter, it is necessary to speculate that in its beginning, altruism was a selected-for trait in very small groups where strangers were not only nonhostile but also likely to be relatives and likely to be met again. This type of behavior, in which individuals act in a manner not to their own advantage and not in order that their own genes or the genes of relatives will survive, is done, in theory, with some expectation of imagined reciprocal gain. How this type of behavior has come about, however, is a matter requiring further study.

Another question concerns how much culture is an influence on the development of a hereditary tendency toward altruism. Some have suggested that after generations and generations of cultural emphasis on the need for altruism, it might come to have a genetic basis. There is little hard evidence that this would occur. On the other hand, humans have had a very rapid cultural evolution, and it is possible that they may have had strong genetic propensities for altruism, which have been culturally overlaid. Some argue that biology and culture evolve simultaneously—that the culture is formed as a result of the imposition of genetic factors while, at the same time, genetic traits are evolving in response to cultural change. In order to understand the source of altruism in humankind, one must study such behavior in the context of many factors in human development—biological as well as social, cultural, economic, and ecologic.

Studying Altruistic Behavior

Those investigating the sources of altruism usually begin with a thorough understanding of whatever organism is the subject of the study. When the insect or animal cannot be studied in the wild, the ethologist tries to simulate the important features of the natural habitat in a captive environment, at least in the beginning. Models are devised, based on observable data; formulas are employed; and projections are made which provide a basis for speculative argument when absolutes cannot be assured.

By observing, it is possible to determine whether various bits of evidence of altruism exist within a population. Altruism may be manifested in as simple a way as the sharing of food when there is a scarcity. In some populations, one might observe a division of labor in which some forfeit their reproductive possibilities in order to care for the offspring of others. This phenomenon introduces the question of how altruism can survive in a population in which the genetic traits favoring the behavior are most evident in the individuals that do not reproduce themselves. It has been shown that the tendency for altruism can be perpetuated only within the family unit, where the same genetic tendency exists to some degree in members that engage in reproductive activity; this can be demonstrated by a mathematical formula.

Each individual bears the inheritance coefficient or relatedness coefficient r. Offspring share with each parent an average of half of the genetic traits of each ($r = \frac{1}{2}$). Offspring share with each grandparent one-fourth of the genetic traits of each of the older generation ($r = \frac{1}{4}$); the same coefficient exists with cousins. Were the altruists not to reproduce, it would be required, in order for the trait to be passed on, that the reproductive chances of their siblings more than double or that the reproductive chances of their cousins more than quadruple. For the sacrifice to be of value, the genetic relationship must be close, according to the demonstration. The case has been made that in societies having evolved according to this principle, there is a diminishing willingness to put the interests of others ahead of one's own as the degree of kinship decreases.

In societies where males are produced from unfertilized eggs and females from fertilized ones, female offspring of a mated pair have a high relatedness coefficient ($r = \frac{3}{4}$). The altruists among the female siblings will benefit more, regarding their genetic potential, by caring for their sisters than for their own offspring, and it can again be observed that sacrifice is more likely to be made on behalf of the member that is more closely related.

The Value of Altruism

If altruism exists in nature, and if it has come about through natural selection, then one can argue that it must be a behavior with value. When applying the human connotation to the term altruism, however, one must consider the role of choice in the manifestation of the behavior. Humans claim to admire acts of unselfishness that are seemingly done with no expectation of reward. The admiration would diminish or become nonexistent, however, if there were to be proof that the act was performed because of some primitive biological predisposition rather than because of a decision on the part of the donor. Therefore, it is necessary to make the distinction, when discussing the importance of altruism, as to whether one is referring to the acts of human beings that are performed in the face of emergency or tragedy, where a sacrifice is made as a matter of choice, or whether the intent is to consider altruism as it occurs in other creatures and seems to be involuntary.

In the case of nonhuman forms, altruism as an act of voluntary sacrifice is infrequent—if indeed it exists at all. Altruism, however, as an act which is dictated by genetics, is observable, and it has been shown to have been necessary for the survival of certain species. Where animal societies have formed in which some members of the society have spent their lives caring for the offspring of others or performing other sacrificial behavior which benefits the group, there can be little doubt that such altruism has been dictated by nature for its own unique purposes. Moreover, the fact that voluntary self-sacrifice on the part of human beings does exist does not automatically make it desirable human behavior any more than aggressive, even warlike behavior is automatically undesirable. The case can be made that both types of behavior are important. Perhaps the larger question is when and under what circumstances certain types of human behavior should be acceptable or desirable for the individual and for the group, and, even more important, who is qualified to decide what type of behavior is appropriate.

Points out similarities and differences in the existing approaches, theoretical and methodological, to the study of aggression and altruism.

AMERICAN PRONGHORNS

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, zoology

Pronghorns live in grasslands of plains and deserts. Almost driven to extinction, protection and good wildlife management have allowed these herbivores to become more numerous.

Principal Terms

BUCK: a male pronghorn
DOE: a female pronghorn
FAWN: a newborn pronghorn
GESTATION: pregnancy or its length
HERBIVORE: an animal that eats only vegetation
KERATIN: a tough protein plentiful in hooves and outer coverings of horns
RUMINANT: a herbivore that chews and swallows food, which enters its stomach, is partly digested, is regurgitated and chewed again, and reenters the stomach for more digestion

The pronghorn, or American antelope, can sprint sixty miles per hour and run at forty miles per hour. Pronghorns are fast almost from birth. For example, two-day-old pronghorns can outrun humans. Pronghorns are the only living members of the artiodactyl sub-family Antilocapridae, related to antelope. They are not true antelope and reportedly are almost unchanged from ancestors of two million years ago.

Pronghorns inhabit open grasslands in plains and semideserts and depend on keen eyesight to detect enemies (wolves and coyotes) and on speed to escape them. When pronghorns are afraid, their white rump hairs rise and are visible for miles. An endangered pronghorn also emits warning odors from rump scent glands. This gives other pronghorns time to seek safety.

Pronghorns are ruminant herbivores. In the summer they eat herbs, sagebrush, and grasses. During winter, pronghorns dig under the snow for hidden grass and woody plant twigs. When water is scarce, they get needed moisture by eating cacti. Pronghorns are sociable creatures, and their groupings reflect living conditions. In summer, males form single-sex groups, and females live with offspring. In winter, pronghorns form large herds containing both genders

Physical Characteristics of Pronghorns

Pronghorns are graceful, tan to reddish-brown animals, with solid, chunky bodies, strong but slender legs, and short tails. Their bellies, rump patches, and throat bars are very white. Male pronghorns (bucks) grow to body lengths of 4.5 feet, shoulder heights of 3.5 feet, and weights of 155 pounds. Bucks have back-curving horns with prongs, which is the source of the species name. The horns are up to 1.5 feet long and made of a bone core over which a black horny covering grows. The covering is shed and renewed every year, and horn core is retained. Females have much smaller horns and also shed the coverings. Pronghorns are the only known animals that shed horn covers.

Pronghorns are artiodactyl herbivores (others include cattle, pigs, goats, deer, and antelope), which walk on two toes. Their ancestors had five toes, but evolution removed the first toe, and the second and fifth toes are vestigial. The support toes—the third and fourth toes—each end in a hoof. Many artiodactyls are ruminants that chew and swallow vegetation, which enters the stomach for partial digestion, is regurgitated, chewed again, and reenters the stomach for more digestion.

Bovids, including pronghorns, have true horns (called horns henceforth). They are permanent, hard, pointy skull outgrowths that usually occur only on heads of males. Horns of females, where present, are smaller. All have bone cores, and atop the core is a tough skin layer rich in keratin, a durable covering for underlying bone. In pronghorns, horn coverings are shed and regrown every year, allowing horns to enlarge.

American Pronghorn Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Artiodactyla
Family: Antilocapridae
Subfamily: Antilocaprinae
Genus and species: Antilocapra americana
Geographical location: Throughout North America
Habitat: Open grasslands in plains and semideserts
Gestational period: Eight months
Life span: Ten years in the wild, up to fourteen years in captivity
Special anatomy: Back-curving, pronged bone horns over which a black horny covering grows; the covering is shed and renewed every year, and the core is retained

The Life Cycle of Pronghorns

In the spring, pronghorn herds separate according to age and gender. Does live in small herds and bucks live in breeding territories that they mark with scent from glands under their ears. Each buck tries to attract mates and scare away rivals by bellows or charges. Sometimes very violent battles arise over territories.

In August and September, does begin to pass through individual male territories. Some stop and mate with a buck; others move to the next breeding territory. Gestation lasts eight months and usually produces twin offspring (fawns). Fawns weigh 7 to 8.5 pounds at birth. They develop quickly and are weaned in five months. Pronghorns live about ten years in the wild and up to fourteen years in captivity

When North America was settled by Europeans, over fifty million pronghorns lived on the continent. In the early twentieth century, it was estimated that their population was only twenty thousand to twenty-five thousand, due largely to indiscriminate hunting. At that time pronghorns were protected by severely limiting their hunting. This control and careful wildlife management have raised the pronghorn population to 500,000. Wyoming, Montana, and New Mexico permit limited hunting of pronghorns.

AMPHIBIANS

Type of animal science: Classification
Fields of study: Anatomy, evolutionary science, physiology, systematics (taxonomy), zoology

Amphibians are cold-blooded animals with backbones. From an evolutionary standpoint, they link aquatic fish with terrestrial reptiles. Living forms include frogs and toads, salamanders, and caecilians.

Principal Terms

ADAPTIVE RADIATION: rapid speciation that occurs as the result of a particular group being able to exploit a new resource

CONVERGENCE: a state that occurs when two forms that are not closely related evolve structures that appear similar

DISJUNCT: pertaining to the geographic distribution pattern in which two closely related groups are widely separated by areas that are devoid of either group

METAMORPHOSIS: the complex developmental process of morphological change in which larval amphibians are transformed into adults

NEOTENY: the retention of larval features by adults; this process has played a major role in the evolution of the amphibians

PHYLOGENY: the determination of the evolutionary history of a particular group of organisms

The term "amphibian" is derived from the Greek word *amphibios*, which means "to live two lives." The majority of amphibians do this by spending the first part of their lives as aquatic, gill-breathing larvae and then transforming into terrestrial adults. The larval stage can be as short as a few weeks or as long as several years. Completion of the larval stage is triggered by hormonal events that initiate some dramatic developmental processes that are collectively termed metamorphosis.

As adults, most amphibians seek out aquatic environments in which to deposit their eggs. These can range from fast-flowing mountain streams to ephemeral roadside ditches. Most male frogs have species-specific mating calls that serve both to attract females and to prevent interbreeding. Frogs have external fertilization, in which the male typically grasps the female and encourages her to deposit her eggs, which he promptly fertilizes. Normally, both parents abandon the eggs, but some variations of this pattern exist. In contrast, most salamanders have internal fertilization, accomplished after the male has performed a stereotypical species-specific courtship "dance," which culminates with the deposition of a packet of sperm cells that is called a spermatophore. The female squats on the spermatophore, transferring the spermatozoa to a specialized holding structure called a spermatheca. The spermatozoa can be used to fertilize her eggs up to several months after mating.

Evolution of Amphibians

Amphibians were the first vertebrates to possess adaptations that allowed them to spend considerable periods of time out of the water. The earliest fossil amphibians, Ichthyostegalia, appear in the geologic record during the Devonian period, about 320 million years ago. Among experts, there is a general consensus that the ancestor of the amphibians is to be found in the primitive, lobe-finned fish (class Osteichthyes, subclass Sarcopterygii). This conclusion is based on a detailed analysis of the comparative anatomy of hard body parts that fossilized, such as the vertebrae, shoulder girdles, teeth, and skulls. Characteristics that the first amphibians shared with their fish ancestors included internal nasal openings (nares); a strange, hinged skull; and a distinctive tooth structure, in which the enamel was folded into intricate patterns.

The environmental conditions that led to the abandonment of the aquatic habitats in favor of a more terrestrial existence remain a major topic of discussion. One scenario envisions the early amphibian ancestors in an environment that was gradually becoming more and more arid. To survive, it would have been advantageous to be able to crawl on land for short distances to escape drying pools in favor of more permanent bodies of water. Those that could migrate would have survived in higher numbers than those that lacked this adaptation. A second scenario suggests that heavy predation pressures from the jawed, carnivorous fish that are known to have been abundant in the shallow freshwater lakes of the time may have selected for individuals that could leave the water, even if only briefly. A third scenario depicts competition for food as strong in the aquatic environments and much weaker on land, where several groups of invertebrates were known to be abundant.

Taxonomy of Fossil Amphibians

The taxonomy of fossil amphibians is confusing because of a series of problems. First, as a whole, the group has been conservative in the range of morphological variations that its members possess. Striking differences of taxonomic value (which would have to fossilize) are not numerous. Second, many of the skeletal elements that are important in determining the relationships of living amphibians are composed of cartilage rather than bone, and this material does not fossilize well. Because of this limitation, bony elements such as the vertebrae and skull have played a major role in determining amphibian phylogeny. The molecular techniques—electrophoresis, immunology, karyotyping, and deoxyribonucleic acid (DNA) sequencing—that have greatly assisted modern taxonomists cannot be used on fossilized materials.

The class Amphibia is further divided into orders. The number of orders recognized by various authorities ranges from eight to thirteen. All but three of these are extinct. One extinct order is the order Ichthyostegalia, which included the earliest recorded fossil amphibians. Most were small, with elongate bodies and weakly developed limbs. Many were almost assuredly aquatic, but at least some were capable of spending extended periods of time out of the water. By the time they appear in the fossil record (in the Devonian period), they were already diverse, with several different genera and species present. Another extinct group is the order Temnospondyli, which was abundant during the late Permian period and persisted until the end of the Triassic period. Most in this order were of moderate size (0.5 to 1.0 meter in body length), with low, stout profiles and flattened skulls. Some were highly aquatic and had short, weak appendages. One group, the Trematosaurs, was marine, and they are apparently the only amphibians to have been successful at invading the oceans.

The order Anthracosauria appeared in the fossil record during the Carboniferous period and was extinct by the end of the Permian. Common names of members of this group include the seymouriamorphs and the embolomeres. This order contained a mixture of terrestrial and aquatic amphibians. From an evolutionary standpoint, this order is important because from it the ancestors of the reptiles arose. Members of the order Aistopoda were eel-like, aquatic amphibians that had elongate, limbless bodies. Members of this group are characterized by a large number of vertebrae (more than one hundred) that were clearly divisible into cervical, trunk, and caudal regions.

The order Nectridea consisted of fully aquatic, salamander-like amphibians that persisted during the Carboniferous period. Appendages were weak or absent, and most fossils indicate body forms that were flattened dorsiventrally. They probably persisted by slowly crawling about the bottoms of ponds and lakes, where they preyed upon unwitting animals that crossed their paths. Amphibians of the order Microsauria were a diverse group of elongate, weak-limbed amphibians. Fossils of this group are fairly abundant from habitats that were swamplike during the Carboniferous period. The remarkable similarity in the appearance of some microsaurs with some of the earliest reptiles is considered by most authorities to be the result of convergence of body form rather than a depiction of a true evolutionary relationship. The order Proanura consists of a single froglike fossil that dates from the Triassic period on the island of Madagascar. The skull is distinctly froglike, but a tail was present, and the hind limbs had not been modified for jumping.

The taxonomy of the living members of the class Amphibia is still under considerable debate. A central question revolves around whether all currently living amphibians were derived from a single common ancestor (are of monophyletic origin) or whether they could have arisen independently from two or more separate stocks of fish (polyphyletic origin). Based on the presence of unique features, such as pedicellate teeth, a distinctive part of the inner ear, and specialized eye receptors, most experts have concluded that all living amphibians are monophyletic and can be grouped in the superorder Lissamphibia. As recognized, living amphibians are placed in the orders Caudata, Anura, and Gymnophiona.

Salamanders

Salamanders are grouped in the order Caudata. They are distributed over temperate parts of Europe, Asia, and North and South America. There are approximately three hundred species recognized, which are placed into eight separate families. Eastern North America has the greatest overall diversity, with fully seven of the eight described families represented there. One family (Plethodontidae) invaded South America and underwent a period of such tremendous speciation that approximately 60 percent of the living species of salamanders are members of this family.

Amphibians, such as this bullfrog, must keep their skins moist in order to take in oxygen and expel carbon dioxide. (PhotoDisc)

Almost everyone is quick to recognize a frog, simply by its appearance, but the same cannot be said for salamanders. The families Proteidae, Cryptobranchidae, Sirenidae, and Amphiumidae are entirely aquatic. The family Cryptobranchidae is disjunctly distributed and occurs today only in eastern Asia and eastern North America; it contains the largest living salamanders (Andrias), which attain lengths of 1.5 meters. Members of the family Proteidae are today isolated in Europe and eastern North America. They are commonly called "water dogs" and are frequently dissected in comparative anatomy classes. Members of the families Sirenidae and Amphiumidae are restricted to the southeastern United States, where they are called sirens and amphiumas, respectively. Sirens have external gills and two front legs, while amphiumas have minute front and back legs and lack external gills.

The family Ambystomatidae is entirely North American in its distribution. Most species are highly secretive and are only encountered under objects or intercepted as they migrate during spring rains to breeding ponds.

The family Hynobildae is exclusively Asian in its present distribution. Reproduction in this family is considered to be primitive, in that females lay eggs that are enclosed in a loose sac and are subsequently fertilized externally by the male.

The family Salamandridae is widely distributed in Europe, North Africa, Asia, and North America; the greatest diversity of salamandrids is found in the Eastern Hemisphere. Many species have developed highly toxic skin secretions to protect themselves from predators (human fatalities have been recorded from eating only one salamander). Many species advertise their toxicity by being very brightly and distinctly colored (this is known as aposematic coloration), and members of other, less-toxic families have also converged on these color patterns for protection from predators, a process called mimicry.

Members of the family Plethodontidae all share the unique feature of being lungless—respiration is accomplished by diffusion across their moist skins. Many species have abandoned laying eggs in water in favor of damp, terrestrial nests. Females guard the eggs until they hatch as miniatures of the adult, having completed their abbreviated metamorphosis while still in the egg.

The order Gymnophiona, on the other hand, consists of a highly specialized group of wormlike amphibians that are limbless. They inhabit tropical regions of North and South America, Asia, and Africa. Most are terrestrial burrowers and are rarely observed. Some primitive forms have dermal scales embedded in their skin. All caecilians possess a unique sensory organ called a tentacle. Fertilization is internal, and male caecilians possess a copulatory organ that is derived from the cloaca. The life history of most forms is incomplete, but in at least some, females retain eggs in the oviduct and give birth to fully developed young. Fossil caecilians are unknown.

Frogs

Finally, the order Anura is composed of tailless amphibians called frogs. Their hind legs are typically modified for jumping, their presacral vertebrae are usually eight in number, and their postsacral vertebrae are fused to form a coccyx. Frogs occur on all continents except Antarctica but reach their greatest diversity in the tropics of South America, Africa, and Asia. They have successfully invaded deserts, rivers, cold mountain streams, and arboreal vegetation. Several families have undergone tremendous adaptive radiation in the tropics, so that today almost 80 percent of the living amphibians are anurans.

Families that are widely distributed include the Bufonidae (toads), Hylidae (tree frogs), Microhylidae, and Ranidae (true frogs). These families are almost worldwide in their geographic distributions except for Australia (which lacks Bufonidae, Ranidae, and Microhylidae) and Africa (which lacks Hylidae). Toads often have dry, warty skins containing numerous glands that produce noxious, protective secretions. Tree frogs have expanded disks on the tips of their toes that have allowed them to occupy arboreal habitats unavailable to many other families.

The families Leptodactylidae, Brachycephalidae, Rhinodermatidae, Pseudidae, Centrolenidae, and Dendrobatidae reach their greatest abundance in Central and South America. The leptodactylids are a diverse assemblage that consists of nearly seven hundred species. Many of these lay eggs in specially constructed foam nests; other species have taken this a step further and deposit their eggs in damp, terrestrial situations, thereby avoiding aquatic predators almost completely. The dendrobatids are often small, brightly colored frogs that have been given the common name of poison arrow frogs because of their extremely toxic skin secretions. These secretions have been used by some Indian tribes to poison the tips of hunting arrows. Members of the family Pseudidae are unique in producing very large tadpoles that metamorphose into rather small frogs. The rhinodermatids consist of only two species, but one is unique in that the larvae do not feed and are carried in the mouth of the adult until they complete metamorphosis.

The Discoglossidae are European and Pelodytidae are Asian in their distribution patterns. The midwife toad (*Alytes obstetricians*) has an unusual reproductive mode, in that after fertilizing the eggs, the male cements them on his back and carries them to and from the water until they are ready to hatch.

The Rhacophoridae are a moderate-sized family (about 180 species), distributed over southern Africa and southeast Asia. Most members have expanded terminal digits, and some even have extensive webbing between their toes, which allows them to glide between arboreal perches. Diverse reproductive tactics also occur in this family. Several species use water-filled tree holes in which to deposit their eggs.

The family Myobatrachidae consists of a diverse group of about ninety-nine species that occur in Australia and New Zealand. One species (*Rheobatrachus silus*) is unique in its reproductive mode, which includes brooding eggs in the stomach of the female.

The family Leiopelmatidae is a small group of frogs that are disjunctly distributed in western North America and New Zealand. The tailed frog (*Ascaphus truei*) is the only frog to possess an intromittent organ that is used to transfer sperm to the female for internal fertilization. This organ has apparently evolved in response to the swift, cold streams in which the frog lives.

Bases of Characterization

As a group, amphibians are easier to characterize by the morphological features that they lack than by the unique characteristics that they possess. Missing are the scales that cover fish and reptiles (although these are not closely related structures), as are the hair and feathers associated with mammals and birds. Amphibians' skin is relatively thin, and it contains numerous glands. Large amounts of water can be lost or gained via the epidermis. In many forms, the skin serves as a major organ for respiration. Amphibians are ectothermic, which means that they do not have internal physiological mechanisms for maintaining a constant body temperature. The circulatory system is closed, and the heart is composed of three chambers (two atria and one ventricle).

The taxonomic relationships of salamanders are based primarily on the arrangement of bones of the skull, which of these bones possess teeth, and the shape of the centrum of the vertebrae. Living forms are further compared by the manner of reproduction. In general, salamanders have been relatively conservative, and characters such as the number of chromosomes have not proved especially useful in determining phylogenetic relationships. However, modern molecular techniques, such as electrophoresis, immunology, and the use of restriction enzymes, are adding to the understanding of selected groups. With these techniques, it has been possible to show that several forms (sibling species) that were indistinguishable based on morphological data are in fact genetically isolated from one another and are really distinct species.

The taxonomic relationships of frogs are also centered on differences in bony anatomy. Skull morphology, the shape of the vertebral centrum and its manner of development, and the arrangement of the bones that make up the pectoral girdle are important diagnostic characters. In living forms, molecular techniques are also shedding new light on relationships. The number of chromosomes is more variable and has more value as a diagnostic tool in frogs than it does in salamanders. The morphology of the larvae also is an important taxonomic tool.

The Importance of Amphibians

There are about three thousand recognized species of living amphibians. Yet, this number represents only a small fraction of the number of species that have been present on the earth over the past 350 million years. In many habitats, however, they still represent a major portion of the biomass, and, because ecologists often relate a group's "worth" to its biomass, amphibians can be considered major members of many terrestrial communities, often serving as keystone species for their ecological niches. Amphibians often exhibit traits such as low mobility, fidelity to breeding sites, and species-specific behaviors that are sought by ecologists and animal behaviorists for their studies. As a whole, salamanders and frogs represent some of the most thoroughly studied vertebrates.

Areas to which amphibians have contributed a significant portion of current knowledge include the evolution of mating systems, sexual selection, reproductive isolation mechanisms, niche partitioning, and community structure. Embryologists have long used amphibians to gain a basic understanding of complex development processes.

One area of extreme interest is the apparent decline of many populations of frogs and salamanders over large geographic areas, which is notably the case in western North America. The reasons for this decline are not yet known, but loss of breeding sites through habitat modification, acid rain, and competition from exotic species have all contributed to their demise.

Covers evolution, classification, development, reproduction, population, and environmental issues, and introduces the history of the field. Maps and bibliography.

ANATOMY

Types of animal science: Anatomy, physiology

Fields of study: Anatomy, anthropology, developmental biology, embryology, entomology, evolutionary science, herpetology, human origins, invertebrate biology, marine biology, neurobiology, ornithology, paleontology, physiology, systematics (taxonomy), zoology

Anatomy is the branch of natural science that focuses on the structural organization of living organisms. Physiology, which is closely related to anatomy, is the study of function, activities, and processes of living organisms. It is concerned with such basic activities as reproduction, growth, metabolism, excitation, and contraction as they are carried out within structures such as the cells, tissues, organs, and organ systems of the body.

Principal Terms

COMPARATIVE ANATOMY: the study of relationships between the anatomies of different species

DEVELOPMENTAL ANATOMY: the study of the anatomical changes an animal undergoes in the process of growth

One common approach to the study of anatomy is from the viewpoint of a classification system that is based on the type of organisms studied, generally plant anatomy and animal anatomy. Animal anatomy can be further subdivided into human anatomy and comparative anatomy. Other anatomy subdivisions are developmental, pathological, and surgical anatomy and anatomical art. An example of developmental is the study of embryos, and an example of pathological is the study of diseased organs. Examples of applied anatomy are surgical anatomy and anatomical art. Anatomy encompasses the following systems: musculoskeletal, nervous, circulatory, immune, respiratory, digestive and excretory, endocrine, reproductive, and integumentary. These systems differ widely among animals, but most animals need to fulfill the functions of these anatomical structures in one way or another. For simplicity's sake, anatomy of warm-blooded vertebrate creatures will be discussed here.

Musculoskeletal System

A muscle is a tissue composed of fibers capable of contracting and relaxing to effect bodily movement. The skeleton is the internal supporting structure of a vertebrate, composed of bone and cartilage. Skeletons are bound together by tough and relatively inelastic connective tissues called ligaments. Ligaments allow the limbs, connected by joints, to move freely. Movements of the bones of the skeleton are effected by contractions of the skeletal muscles, to which tendons attach the bones. These muscular contractions are controlled by the nervous system.

Nervous System

The nervous system in vertebrates is a network of cells, tissues and organs that regulates the body's responses to internal and external stimuli. The nervous system has two divisions: the somatic, which allows voluntary control over skeletal muscle, and the autonomic, which is involuntary and controls cardiac and smooth muscle and glands. The autonomic nervous system has two divisions: the sympathetic and the parasympathetic. These divisions tend to have opposing effects. For example, the sympathetic system increases heartbeat, and the parasympathetic system decreases heartbeat. However, the two nervous systems are not always antagonistic. For example, both nerve supplies to the salivary glands excite the cells of secretion. Voluntary movement of head, limbs, and body is caused by nerve impulses arising in the motor area of the cortex of the brain and carried by cranial nerves or by nerves that emerge from the spinal cord to connect with skeletal muscles. Movement may occur also in direct response to an outside stimulus. These involuntary responses are called reflexes. Muscular contractions do not always cause actual movement. A small percentage of the total numbers of fibers in most muscles are usually contracting. This serves to maintain the posture of a limb. This slight continuous contraction is called muscle tone.

Circulatory System

The circulatory system is composed of the heart, blood vessels, and lymphatic system of the body. Blood is pumped by the heart through the right chambers of the heart, into the lungs, where it picks up oxygen, and back into the left chambers of the heart. From these, it is pumped into the main artery, the aorta, which branches into increasingly smaller arteries until it passes through the smallest, known as arterioles. Beyond the arterioles, the blood passes through a vast number of tiny, thin-walled structures called capillaries. Here, the blood gives up its oxygen and its nutrients to the tissues and absorbs from them carbon dioxide and other waste products of metabolism. The blood completes its circuit by passing through small veins that join to form increasingly larger vessels until it reaches the largest veins, the inferior and superior venae cavae, which return it to the right side of the heart. Contractions of the heart working with the contractions of the skeletal muscle propel the blood and contribute to circulation. Valves in the heart and in the veins ensure blood flow in one direction.

Immune System

The immune system is an integrated system of organs, tissues, cells, and cell by-products (such as antibodies) that differentiates self from non-self and neutralizes potentially pathogenic organisms or substances. The body defends itself against foreign proteins and infectious microorganisms by means of a complex dual system that depends on recognizing foreign patterns. The two parts of the system are termed cellular immunity, in which lymphocytes are the effective agent, and humoral immunity, based on the action of molecules.

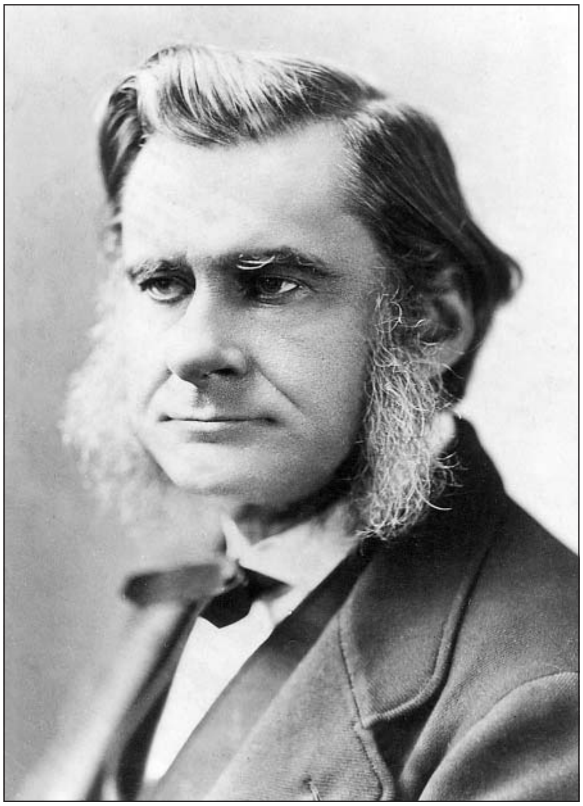
When particular lymphocytes recognize a foreign molecular pattern, termed an antigen, they release antibodies in great numbers; other lymphocytes store the memory of the pattern for future release of antibodies should the molecule reappear. Antibodies attach themselves to the antigen and mark it for destruction by other substances in the body's defense system, such as enzymes and phagocytes. The latter are cells that engulf and digest foreign matter.

Respiratory System

The respiratory system comprises the organs involved in the intake and exchange of oxygen and carbon dioxide between an organism and the environment. Respiration is carried on by the expansion and contraction of the lungs; the process and the rate at which it proceeds are controlled by a nervous center in the brain. In the lungs, oxygen enters tiny capillaries, where it combines with hemoglobin in the red blood cells and is carried to the tissues. Simultaneously, carbon dioxide, which entered the blood in its passages through the tissues, passes through capillaries into the air contained within the lungs. Inhaling draws into the lungs air that is higher in oxygen and lower in carbon dioxide; exhaling forces from the lungs air that is high in carbon dioxide and low in oxygen. Changes in the size and gross capacity of the chest are controlled by contractions of the diaphragm and of the muscles between the ribs.

Digestive System

The digestive system is composed of the alimentary canal, along with glands such as the liver, salivary glands, and pancreas that produce substances needed in digestion. Digestion starts with the ingestion and chewing of food mixed with saliva. The food passes down the esophagus into the stomach, where the gastric and intestinal juices continue the process. Thereafter, the mixture of food and secretions, called chyme, is pushed down the alimentary canal by peristalsis, rhythmic contractions of the smooth muscle of the gastrointestinal system. The contractions are initiated by the parasympathetic nervous system and can be inhibited by the sympathetic nervous system. In ruminants, the stomach has multiple sections, and chyme is passed back and forth several times between the stomach sections and the mouth for rechewing and redigestion. Absorption of nutrients from chyme occurs mainly in the small intestine; unabsorbed food and secretions and waste substances from the liver pass to the large intestines and are expelled as feces. Water and water-soluble substances travel via the bloodstream from the intestines to the kidneys, which absorb all the constituents of the blood plasma except its proteins. The kidneys return most of the water and salts to the body, while excreting other salts and waste products, along with excess water, as urine.



Thomas Henry Huxley's research in comparative anatomy helped establish the inductive method as the primary mode of scientific research. (Library of Congress)

Endocrine System

The endocrine system involves internal secretions related to the function of the endocrine glands such as the thyroid, adrenal, pituitary. Hormonal secretions from these glands pass directly into the blood stream. An important part of this system, the pituitary, lies at the base of the brain. This master gland secretes a variety of hormones, including hormones that stimulate the thyroid gland and control its secretion of thyroxine, which dictates the rate at which all cells utilize oxygen; control the secretion in the adrenal gland of hormones that influence the metabolism of carbohydrates, sodium, and potassium and control the rate at which substances are exchanged between blood and tissue fluid; control the secretion in the ovaries of estrogen and progesterone and the creation in the testicles of testosterone; control the rate of development of the skeleton and large interior organs through its effect on the metabolism of proteins and carbohydrates; and inhibit insulin—a lack of insulin causes diabetes mellitus.

The posterior lobe of the pituitary secretes vasopressin, which acts on the kidney to control the volume of urine; a lack of vasopressin causes diabetes insipidus, which results in the passing of large volumes of urine. The posterior lobe also elaborates oxytocin, which causes contraction of smooth muscle in the intestines and small arteries and is used to bring about contractions of the uterus in birth. Other glands in the endocrine system are the pancreas, which secretes insulin, and the parathyroid, which secretes a hormone that regulates the quantity of calcium and phosphorus in the blood.

Reproductive System

The union of male sperm and the female ovum accomplishes reproduction. In coitus, the male organ ejaculates millions of sperm into the vagina, with some making their way to the uterus. Ovulation is the release of an egg into the uterus; the uterus is prepared for the implantation of a fertilized ovum by the action of estrogens. In some primates, if a male cell fails to unite with a female cell, other hormones cause the uterine wall to slough off during menstruation. After childbirth, prolactin, a hormone secreted by the pituitary, activates the production of milk.

Integumentary System

Skin, the natural outer covering of the body, is an important part of the integumentary system. The skin is an organ of double-layered tissue stretched over the surface of the body and protecting it from drying or losing fluid, from harmful external substances, and from extremes of temperature. The inner layer, called the dermis, contains sweat glands, blood vessels, nerve endings (sense receptors), and the bases of hair and nails. The outer layer, the epidermis, is only a few cells thick and contains pigments, pores, and ducts, and its surface is made of dead cells that it sheds from the body. The sweat glands excrete waste and cool the body through evaporation of fluid droplets; the blood vessels of the dermis supplement temperature regulation by contracting to preserve body heat and expanding to dissipate it. Separate kinds of receptors convey pressure, temperature, and pain. Fat cells in the dermis insulate the body, and oil glands lubricate the epidermis.

ANIMAL KINGDOM

Types of animal science: Classification, ecology, evolution, geography
Fields of study: Ecology, evolutionary science, genetics, population biology, systematics (taxonomy)

Among all the species that have been identified, about 75 percent are animals. Animals flourish on land, in the seas, and in the air. Today, twenty-seven distinct phyla of animals come in diverse forms and shapes, and live in almost every habitat. Together, these animals make up a crucial portion of all ecosystems.

Principal Terms

CLASS: the taxonomic category composed of related genera; closely related classes form a phylum or division

INVERTEBRATES: animals lacking a backbone

PHYLOGENY: the evolutionary history of a group of species

PHYLUM: the taxonomic category of animals and animal-like protists that is contained within a kingdom and consists of related classes

SPECIES: a group of animals capable of interbreeding under normal natural conditions; the smallest major taxonomic category

TAXONOMY: the science by which organisms are classified into hierarchically arranged categories that reflect their evolutionary relationship

VERTEBRATES: animals with a backbone or vertebral column

Human perception of the animal kingdom tends to focus on relatively large vertebrates. However, these large vertebrates are true minorities, accounting for just a tiny fraction of the animal world. Over 97 percent of animal species are invertebrates, the earliest animals to emerge. Insects and arthropods make up the vast majority of animal species and a huge percentage of the individual animals on earth. Most other animal phyla are also far more diverse and numerous than vertebrates. All vertebrates together constitute only part of a single phylum, Chordata. In simple terms, the small and boneless creatures called invertebrates dominate the animal kingdom. They live bountifully in diverse habitats: in pond muck, on ocean bottoms, in treetops, beneath leaf litters, and in many other environments.

Animals are easy to identify but difficult to define due to the diversity and complexity of all creatures in this kingdom. The best approach relies on a set of common characteristics that distinguish animals from individuals of other kingdoms, a field called systematics. First, animals are multicellular (made up of many cells). Second, animals are heterotrophic, obtaining nutrients and energy by consuming other organisms. Third, animals are usually capable of sexual reproduction, although other reproductive styles may exist. Fourth, animal cells contain no cell wall. Fifth, animals are mobile during at least some stage of their lives. Finally, animals are usually capable of rapidly responding to external stimuli through their nerve cells, muscle, or contractile tissue. These six characteristics taken together distinguish animals from other living creatures.

Based upon evolutionary theories, animal phyla show trends toward increasing cellular organization and complexity. In the most ancient phylum of animals, sponges, individual cells may have specialized functions but act independently, hence are not organized into tissues or organs. Cnidarians (jellyfish and their relatives), the phylum most closely related to sponges, have well-defined tissues that coordinate movement and sensory information. Flatworms, the next phylum to emerge, have organs and organ systems, such as a reproductive system. Organ systems are also found in all the remaining, more recently emerged animal phyla. The trend toward increasing complexity goes beyond the level of cellular organization and specialization. It includes the presence and type of symmetry in body plan, the degree of development in sensory organs and brain, the presence and type of body cavity, the presence of body segmentation, and the structure of the digestive system. The members of the latest phylum, including vertebrate animals such as seals, whales, horses, and humans, also exhibit a trend toward increasing size and sophistication of the brain.

Based upon these traits, animals can be grouped into twenty-seven phyla. The nine major phyla include, from simple to more complex, Porifera (sponges), Cnidaria (hydra, anemones, and jellyfish), Platyhelminthes (flatworms), Nematoda (roundworms), Annelida (segmented worms), Arthropoda (insects, arachnids, and crustaceans), Mollusca (snails, clams, and squid), Echinodermata (sea stars and sea urchins), and Chordata (primarily vertebrates).

The Sponges, Hydra, Anemones, and Jellyfish

Sponges (phylum Porifera) are the simplest multicellular animals that lack true tissues and organs. They resemble colonies in which single-celled organisms live together for mutual benefit. However, individual sponge cells are able to survive and function independently. All sponges, whether single-celled or colony-like, have a similar body plan. The body is perforated by numerous tiny pores, through which water enters, and by fewer large holes, through which water is expelled. Water travels within the sponge through canals where oxygen is extracted and microorganisms are filtered into cells for digestion. Some sponges can grow more than a meter in height. So far, more than five thousand species of sponges have been identified, all of which are aquatic and most of which are marine.

The phylum Cnidaria is composed of hydra, anemones, and jellyfish. Clearly more complex than sponges, cnidarians have distinct tissues, including contractile tissue that acts like muscle and nerve net that spreads through the body and controls movement and feeding behavior. However, they lack true organs and a brain. Their beautiful and diverse body shapes are variations of two basic body plans: tentacled and jellyfish-like. Tentacles attach to rocks and reach upward for grasping, stinging, and immobilizing prey. A jellyfish-like body can easily be carried by ocean currents. Cnidarians are radially symmetrical, with body parts arranged in a circle around the mouth and digestive cavity. All cnidarians are predators, but none hunt actively. They rely upon their tentacles to grasp small animals floundering by chance into contact with them. Once stimulated by contact, special cells called cnidocytes explosively inject poisonous or sticky darts into prey. The immobilized prey is forced through an elastic mouth into a digestive sac. The undigested food is expelled through the mouth. Cnidarians may reproduce sexually or asexually. Of the nine thousand or more species in this phylum, all are aquatic and most are marine. One of these, the corals, is of particular ecological importance.

Diverse Forms of Worms

Flatworms (phylum Platyhelminthes) are more complex than cnidarians, yet are the simplest organisms with well-developed organs. Their bilaterally symmetrical bodies are an adaptation to active movement, as found in other, more complex organisms. Their sense organs, consisting of light-detecting eyespots and cells responsive to chemical and tactile stimuli, inform their bodies whether to feed, forge onward, or retreat. When the flatworm encounters smaller animals, it sucks its prey through a muscular tube called the pharynx, located in the middle of the body. Compared with more complex organisms, however, flatworms lack both respiratory and circulatory systems. They can produce sexually or asexually. Most flatworms are hermaphroditic, possessing both male and female sex organs within one body. Examples of flatworms include parasitic tapeworms and flukes.

Roundworms (phylum Nematoda) reside in nearly every habitat on earth. Of an estimated 500,000 species, only 10,000 have been named. They are largely microscopic, although some may reach a meter in length. They have a rather simple body plan, with a tubular gut that runs from mouth to anus. A fluid-filled hydrostatic skeleton provides support and a framework against which muscles can act. They also have a tough but flexible cuticle on the outside of the body and a simple brain that processes and transmits information. They do not have circulatory or respiratory systems. Most nematodes reproduce sexually, with the male fertilizing the female by injecting sperm inside her body. Nematodes play a crucial role in breaking down organic matter in ecosystems. Some are also parasites to humans or other animals, such as hookworms that infect human feet, *Trichinella* worms that cause trichinosis, and heartworms that attack dogs' hearts.

The prominent feature of the phylum Annelida is segmentation of the body into a series of repeating units; hence they are called segmented worms. Each body compartment is controlled by separate muscles, collectively capable of far greater complexity of movement than in other worms. A well-developed closed circulatory system distributes gases and nutrients throughout the body. Primitive hearts, in essence short, expanded segments of specialized blood vessels, can contract rhythmically. A simple brain located in the head plus nerve cords along the length of the body and within each segment control movement and other activities. Among the nine thousand or so species identified, the best known examples are the earthworm and its relatives, and leeches. However, the largest annelids, the polychaetes, live primarily in the ocean.

The Arthropods, Molluscs, and Echinoderms

The phylum Arthropoda comprises insects, spiders, and crustaceans. By any standard, whether number of individuals or number of species, arthropods are the most dominant animals on earth. A mere 10 percent of animals described in this phylum constitutes one million species, including insects (class Insecta), spiders and their relatives (class Arachnida), and crabs, shrimp, and their relatives (class Crustacea). The enormous success of arthropods is due to several adaptational features. The exoskeleton allows precision movement; segmentation generates specialized and more effective organ systems; these, in turn, allow higher efficiency in gas exchange, circulation, and information processing. Most arthropods have well-developed sensory systems, including compound eyes and acute chemical and tactile senses. Of the three classes, insects are the most diverse and abundant, accounting for 850,000 species identified. Insects usually have three pairs of legs plus two pairs of wings. Their ability to fly helps them escape from predators and find widely dispersed food. Insects normally go through radical changes in body form through metamorphosis, from egg to larva to pupa and finally to winged adults that mate and lay eggs.

Spiders and scorpions are examples of the class Arachnida. They typically have eight walking legs and are mostly carnivores, living on either a liquid diet of blood (ticks and mosquitoes) or predigested prey (scorpions). Simple eyes equipped with a single lens are extremely sensitive to movement, which helps in catching prey or escaping from predators. There are about fifty thousand species of arachnids. Crab, shrimp, crayfish, and their relatives make up the class Crustacea, comprising roughly thirty thousand species. They are largely aquatic, with a wide variation in size. Except for two pairs of sensory antenna and mostly compound eyes, they are highly variable in body form.

As their name suggests, members of the phylum Mollusca—snails, clams, and squid—have a moist, muscular body supported by a hydrostatic skeleton. Some have a shell of calcium carbonate to protect their body; others escape predation by moving swiftly or by being distasteful if caught. They have an open circulatory system. Their nerve systems are more advanced than those of arthropods in that more nerves are concentrated in the brain. Reproduction is sexual; some species have separate sexes, and others are hermaphro-

Coral Reefs: Beautiful Undersea Gardens

Coral reefs are created by the concerted activities of corals and algae. Reef-building corals are involved in a mutualistic relationship with single-celled algae, which live embedded in the coral tissue. The algae benefit from the high mineral levels in the coral tissues. In return, algae provide food for the coral and also help produce calcium carbonate, the limestone that forms the coral skeleton. The limestone persists long after the coral's death, serving as a base to which many other algae may attach. The cycle continues for thousands of years until massive coral reefs are formed.

Corals require warm temperatures and clear water to thrive, and thus are most abundant in the tropical waters of the Pacific and Indian Oceans, the Caribbean, and the Gulf of Mexico, where the maximum water temperatures range between 72 degrees and 82 degrees Fahrenheit. Coral reefs form undersea habitats that become the basis of ecosystems with stunning diversity and breathtaking beauty. They are home to bottom-dwelling animals and provide shelter and food for the most diverse collection of invertebrates and fish in the ocean. A single reef may be home to three thousand species of fish, invertebrates, and algae.

Coral reefs are extremely sensitive to certain types of disturbance, including silt caused by soil erosion, sewage and runoff from agriculture on nearby land, and overfishing. On December 11, 2000, it was reported that more than 25 percent of the world's coral reefs have been lost to these disturbances. Approximately 70 percent of coral reefs could be gone within fifty years without effective remedy. This would prove devastating to marine ecosystems, as well as to the economies of many nations.

ditic. Together, there are five thousand species identified, among which clams, octopuses, oysters, scallops, snails, and squid are the most familiar.

Sea stars, sea urchins, and sea cucumbers compose the phylum Echinodermata. These animals are mostly marine, and adults have radial symmetry and lack a head and distinct brain. They have very simple nervous systems, and hence move very slowly on numerous, tiny, tube feet. They feed on algae or small particles sifted from sand or water. Most species reproduce by releasing sperm and eggs into the water, where larvae develop upon fertilization. Another distinct feature of echinoderms is their endoskeleton, a hard shell of calcium carbonate enclosed by an outer skin.

Phylum Chordata: The Tunicates, Lancelets, and Vertebrates

Animals of this phylum exhibit tremendous diversity in form and size. They include small sea squirts and lancelets (invertebrates), and birds, fish, amphibians, reptiles, and mammals (vertebrates). Members of this phylum possess four characteristics at some stage of their lives: a notochord—a stiff yet flexible rod that extends the length of the body and provides an attachment site for muscles; a dorsal, hollow nerve cord at the anterior end of the notochord that becomes a brain; specialized respiratory openings called pharyngeal gill slits; and a tail that extends past the anus. There are only two classes of invertebrates in Chordata, lancelets and tunicates, both of which are small marine animals. Lancelets reside mainly in the sandy sea bottom and live by filtering tiny food particles from the water. Sea squirts, a member of the tunicates, send out a forceful jet of water in response to touch or danger. Their filter-feeding, saclike bodies move slowly via contraction.

Vertebrates are the most conspicuous animals on earth. Their backbones and other adaptations have contributed to their success. There are seven major classes of vertebrates.

Jawless fishes (Agnatha) were the earliest vertebrates to arise in the sea. Two examples are hagfishes and lampreys. The colorful hagfishes are strictly marine, living in communal burrows in mud, feeding on polychaete worms. Lampreys live in both fresh and salt water. Some lampreys are parasitic, attaching to fish with suckerlike mouths lined with rasping teeth. They live on blood and body fluids sucked from their hosts. Cartilaginous fishes (Chondrichthyes) are skillful predators, and include sharks, skates, and rays. Their skeletons are made up exclusively of cartilage, void of bone. Many shark species have several rows of razor-sharp teeth, with back rows moving forward as front teeth are lost to action or aging. Most sharks, as most skates and rays, are shy and retiring creatures that do not attack humans. A few species, however, can be deadly when irritated. Bony fishes (Osteichthyes), spread over a wide range of aquatic habitats, are the most diverse and abundant vertebrates on earth. As suggested by their name, bones rather than cartilage make up their skeletons. Of seventeen thousand species identified, all bony fishes have bladders that help them float effortlessly. Some have lungs and modified fins that work as legs, which help them to survive periodic drying in freshwater habitats.

Amphibians (Amphibia) live a double life between aquatic and terrestrial habitats. They represent the transition of life from water to land. Some adaptations, such as lungs, a three-chambered heart, and moist skin, help them live a temporary land life. However, other traits, requiring water for fertilization and juvenile development, restrict the range of amphibian habitats on land. Their double life and permeable skin have made amphibians particularly vulnerable to pollutants and environmental fouling. About 2,500 species have been identified, including frogs, toads, and salamanders. The seven thousand species of reptiles (Reptilia) identified have bodies of diverse forms. Turtles, snakes, lizards, alligators, and crocodiles are all reptiles, as well as the huge and now-extinct dinosaurs. Reptiles have more efficient lungs than amphibians, a tough, scaly skin that resists water loss and protects the body, a mechanism of internal fertilization, and a shelled egg. The diversity of birds (Aves) is revealed through nine thousand species, including the delicate hummingbird, the endangered spotted owl, and the largest bird, the ostrich. Their ability to soar gracefully in the air depends on many anatomical and physiological traits. These features include a light body with hollow bones, light wings with feathers that also provide protection and insulation, reduced reproductive organs during nonbreeding periods, a single ovary in female birds, acute eyesight, and a delicate nervous system that facilitates the extraordinary coordination and balance needed for flight. Birds, which are warm-blooded, also have four-chambered hearts that help to maintain high body temperature and a high metabolic rate, crucial for flight. The last vertebrate class, mammals (Mammalia), is represented by some 4,500 species. In addition to being warm-blooded with high metabolic rates, mammals normally possess hair, produce milk for their offspring, assume a remarkable diversity in form, and possess more highly developed brains than any other class. The bat, cheetah, elephant, mole, monkey, seal, and whale exemplify the radiation of mammals into nearly all habitats, with their bodies finely adapted to their lifestyles.

ANTELOPE

Type of animal science: Classification
Fields of study: Anatomy, ethology, genetics, physiology

More than seventy species of antelope exist, most in Africa but some also in Eurasia and North America.

Principal Terms

ASTRAGALUS: a pulley-shaped bone between the legs and ankles of antelope
BOVINE: relating to cows or oxen
BROWSER: an animal that feeds on leaves and twigs from trees
CUD: food regurgitated and chewed a second time after its initial ingestion
HERBIVORE: an animal that only eats vegetation
SAVANNA: a grassy expanse of land with few trees

Antelope are graceful animals that can run at speeds exceeding forty miles an hour and can sustain that pace longer than most of the predators pursuing them. With over seventy species of antelope observed and identified, there is a considerable range of characteristics among them. They range in size from the diminutive royal antelope (*Neotragus pygmaeus*) that stands about ten inches high and can weigh as little as four pounds, to the eland (*Tauratragus derbianus*) that, when fully grown, can stand six feet at the shoulders and weigh almost a ton.

Although most antelope live in grasslands, savannas, and forests, the tiny dik-dik (*Madoqua*) lives in semiarid regions. Whereas most antelope are gregarious animals that travel in herds for mutual protection, the bushback (*Tragelaphus scriptus*) is an elusive animal that travels alone and is active mostly at night. It avoids other antelope except for mating. The bongo (*Boocercus eurycerus*) travels in small groups, but often, particularly in old age, is solitary.

The names of various species of antelope reflect the colonial history of the parts of Africa in which they are prevalent. Settlers from the Netherlands named the dik-dik, the wildebeest (*Connochaetes*), the blesbok, and the duiker (*Sylvicapra grimmia*). The oryx and gazelle were named by French settlers. Impala (*Aepyseros melampus*) and kongoni are names drawn from the native Swahili language.

Physical Features of Antelope

Antelope of all species are generally slim, with long legs that can carry them at considerable speed when speed is necessary for survival. Antelope appear in a variety of colors—white, black, brown, gray, golden, orange, reddish, or a mixture of these colors. The red-orange bongo is particularly striking, sporting twelve thin white stripes down its side. Baby antelope frequently have white spots and stripes that disappear in adulthood.

Although they vary greatly in size, nearly all antelope, like all bovines and regardless of size, have two horns that are hollow inside and covered with a sheath, and that vary significantly from species to species. In the males of one species, the four-horned antelope (*Tetracerus quadricornis*), there are two sets of horns. One set, on the top of the head, is about five inches long, while a second set, on the forehead, is about two inches long.

Some antelope horns are quite long. The horns of the kudu (*Tragelaphus strepsiceros*) are shaped like corkscrews and can grow to five feet. In most species, both males and females have horns that, unlike the deer's, are not shed throughout the course of their lives. Usually the horns grow out of the top of the head and sweep backward. In the addax (*Addax nasomaculatus*), the horns have a spiral shape, while in the gemsbok (*Oryx gazella*), the horns are straight and swordlike.

Regardless of shape, horns are important to antelope. When they engage in mating competition, they use their horns extensively. Their chief defense mechanisms, however, are the protection gained from traveling in large herds and their ability to outrun most of their predators.

Because their diet consists of plants, which take longer to digest than meats, antelope have larger stomachs and longer intestines than carnivores. Like other bovines, an antelope has a rumen, a first stomach where food is stored when it is eaten and from which it is regurgitated for the animal to chew as cud.

Having lost their "thumbs" and "big toes" as they evolved, antelope developed split hooves from what are essentially overgrown toenails. They stand and run on the center hooves. They have a remarkable agility in running because they have a unique bone, the astragalus, located between the leg and the foot. It is pulley-shaped at both ends, giving antelope their speed and agility.

The History of Antelope

Some fossil remains of antelope date back to the end of the Cretaceous period, sixty-five million years ago. At that time some catastrophic event, not yet clearly identified, wiped out most complex life on earth, although the smaller species of antelope perhaps survived in limited numbers.

Early Bovidae were found in Eurasia and Africa, where antelope still live, although as northern Eurasia became cooler, antelope migrated gradually to more temperate climates, where the grasses and other plants they depended upon for food grew year around.

The American pronghorn (*Antilocapra americana*) roved the plains and grasslands as far north as Alberta, Canada, and as far south as northern Mexico, although its current range is much smaller. Fossil evidence suggests that the pronghorn lived alone or in small herds during the summer but that it became part of a large herd in winter, presumably to keep warm.

Migration and Eating Habits

All antelope are herbivores (vegetarians). They usually travel slowly within the security of their herds. Because of their numbers, they can anticipate danger as they travel and avoid it when it is imminent.

As they move through their habitats, some species, such as the wildebeest (also called the gnu), graze on the grass of the savannas in which they usually live. Species whose habitat is in forests tend to eat the leaves and slender branches of trees, often standing on their hind legs to reach these delicacies. Such antelope are called browsers.

Migrations are necessary for most antelope, as they exhaust the food supply in one area and are

Antelope, such as these springboks, usually live in herds for mutual protection against predators. (PhotoDisc) forced to move on to another. During dry periods, antelope usually move to wetter areas, where grass is more plentiful than in the arid regions. Such migrations are becoming increasingly difficult for these animals because of Africa's growing population. The development of large areas of land to accommodate the increasing human population is blocking the paths antelope once followed in their quest for food.

Having no permanent shelters, antelope follow cyclical routes that may cover more than two hundred square miles in any year. Their herds usually contain several hundred animals. Some antelope may be members of one herd in summer and of another herd in winter. Some, especially the old, the unattached, and the pregnant, may take time out from their herds for temporary solitude in marshes, along riverbanks, or in thick forests. Pregnant antelope who do this usually return to their herds as soon as their young are strong enough to follow them.

In order to assure the future of the antelope, reserves have been set up in some African countries. In these reserves, animals are protected from hunters and poachers. Attempts are made to guarantee that their food supply will not be compromised.

Antelope Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateral
Phylum: Craniata
Class: Mammalia
Subclass: Theria
Order: Artiodactyla
Family: Bovidae
Tribes: Reduncini (reedbucks, waterbucks, rheboks), Alecphalini (gnus, hertebeets, impalas), Hippotragini (horselike antelope)
Genus and species: Eleven genera and twenty-four species
Geographical location: Africa, North America, and parts of Asia
Habitat: Grasslands, savannas, and forests
Gestational period: Four to ten months, depending on the species
Life span: Between fifteen and twenty years
Special anatomy: Hooves, horns, slim legs

Mating and Reproduction

Within most antelope species there is no specific breeding season. Four to ten months following mating, the female antelope usually produces a single offspring, referred to in the larger species as a calf and in the smaller species as a fawn. Although single births are most common, the duiker frequently produces twins.

Once born, the offspring is usually hidden in grass or underbrush until it is strong enough to join the herd. This protective period lasts from four to eight weeks in most species, although among the reedbucks it lasts for four months. The young of some species, such as the wildebeest, are able to run within eight minutes of being born. Because of their vulnerability to predators, after the period of hiding young antelope are usually kept within the inner areas of the herd where their mothers can monitor them. Although infant mortality is high among antelope through both predation and disease, those that survive to adulthood can expect to live for up to twenty years. Human predators have been more threatening to antelope than such predators as tigers, lions, and cheetahs. As a result, some species, such as the bonetok (*Damaliscus pygarus*), currently exist only within the protection of animal reserves.

Farmers have indiscriminately shot many antelope because these animals eat the wild grasses that the farmers need to feed their livestock. As civilization has encroached upon areas once the sole domain of wild animals, domesticated animals have brought new diseases into those areas. Many antelope, especially calves and fawns, have succumbed to such diseases.

The Speed of Antelope

Although it is reasonably intelligent and has strong senses of sight and smell, the antelope's best defensive weapons are speed and agility. The impala has been known to jump nearly eight feet high and to bound as much as thirty-three feet in a

Antelope Relatives in North America

Some zoologists think that African and Eurasian antelope are misnamed. The pronghorn antelope (*Antilocapra americana*), the only species of antelope in North America, is, ironically, dismissed by many zoologists as not being a true antelope. It is the only living member of the family Antilocapridae and, as such, is not related to the Bovidae, unlike the species of antelope generally so designated.

African and Eurasian antelope are related most closely to bovines, as the name Bovidae suggests. Members of this group have three things in common: They are vegetarians; they eat their food, then regurgitate it and chew their cuds; and they have two horns, the only exception being the male four-horned antelope (*Tetracerus quadricornis*).

Bovines in North America include such animals as wild buffalo, American bison, cows, wild sheep, and mountain goats. Although antelope are smaller and sleeker than these animals, they are closely related to them.

Most zoologists agree that the closest relative of African and Asian antelope in North America is the Rocky Mountain goat (*Oreamnos americanus*), which is a bovid. Antelope are also remotely related to deer, giraffes, camels, and pigs.

single leap. The duiker, although it lacks the strength to jump as high and as far as the impala, can move very rapidly and, when it is being pursued, does so in a zig-zag pattern. It will finally elude its pursuers by diving into dense underbrush for protection.

What gives antelope their great propulsion in running is that they raise their two front legs, one after the other, and then their two hind legs. This gives them a forward thrust virtually unequaled in the animal world.

ANTENNAE

Type of animal science: Anatomy
Fields of study: Anatomy, conservation biology, developmental biology, entomology, herpetology, invertebrate biology

Antennae serve as a means of feeling and communication through pheromones, and are a criterion to distinguish between families in insect taxonomy.

Principal Terms

LIPOPHILIC: fat soluble or water insoluble
MASTER CONTROL GENE: a gene that singlehandedly triggers the formation of an organ or structure
MAXILLARY: pertaining to the upper jawbone
OLFACTORY: pertaining to the sense of smell

Many animals, insects, and crustaceans have antennae, which serve as feelers or communication tools. Together with the morphologies of the eyes, head, wings, legs, and body, antennae also serve as a criterion to distinguish between families.

Antennae have many forms in different species. All flies have antennae, which can be of two types. The first, found in the members of the suborder Nematocera, such as crane flies, midges, and gnats, is whiplike, with two basal segments called the scape and the pedicel, as well as a flagellum of many similar segments. The second type, encountered in all members of the Brachycera group, has a flagellum contracted into a compound third segment. Crayfish tend to shed the oldest, most distal parts of their antennule once their carapace reaches about seven millimeters in length, and new growth occurs from the proximal end of the flagellum. The antennal flagellum also serves as the multimodal sensory organ that contains mechanoreceptors and chemoreceptors in crickets.

Cockroaches use their antennae to locate a wall and to retain a constant distance from it as they move along it. While running, they may make up to twenty-five body turns per second in order to avoid collisions with outward projections. It is believed that exceptionally efficient sensory input from the flagellum of the antenna reports the exact distance from the wall in order to evoke those turns.

The trap-jaw ant, found in the warmer parts of the western hemisphere, has a jaw that moves one thousand times faster than the human eye can blink. These ants use their hair antennae to detect prey; the touch of the antenna against the prey triggers the jaws to snap shut immediately. Antennal contact appears to be prevalent also in the organization of ant colonies, especially when ants from another colony are nearby. The contact increase is proportional to the numbers of ants present, in agreement with the increased density of nest mates.

Antennae, Pheromones, and Sexual Selection

Pheromones appear to play a vital role in insect survival and in communication between members of the same species. The selection and transportation of these lipophilic messengers are achieved by carrier proteins moving through the hydrophilic sensillum lymph in the antennae toward the membrane receptors. Wing fanning appears to enhance the air penetration of silkworm moth pheromones, as well as their interception by antennae. Odor recognition and resultant behavior are achieved among the members of the

Image Not Available

Drosophila genus through sensory neurons that exist in either the antennae or the maxillary palp. A study using locusts has indicated, however, that insects fed for the final two stadia (the period of time between molts) on nutritionally adequate synthetic foods have fewer sensilla on the maxillary palps and antennae than insects fed on the normal diet of seeding wheat.

Experiments on Drosophila species indicated that homothorax homeobox genes are antennal selector genes. Biological clocks that monitor daily cyclical activity appear to exist in fruit fly tissues of the antennae and other organs. These genes showed an increasing intensity of the reporter protein as a function of adult age.

The relationship between antenna morphology and sexual selection in the cerambycid beetle (*Stenurella melanura*) indicates that males with antennal symmetry appear to win more battles with other males for a female, while females with more symmetrical antennae were much more desirable to males. Researchers have also discovered that the mating behavior in a male sphinx moth is the result of the reaction of nerve cells in his antennae to a pheromone that is emitted by a female moth's abdomen. The same scientists found out that once female moths absorb male nerve cells through the implantation of the males' antennae in their heads, these female moths exhibit male mating habits. This shows that transsexually grafted antennae alter the pheromone-affected behavior in a moth.

The olfactory blocking ability of the honeybee is severely hampered when input from one antenna is removed, resulting in the bee's inability to neutralize one odor through the effect of another odor. This is an indication that, although antennae sensory neurons are important, more central processing regions of the brain must be involved in this blocking phenomenon. Recent studies have also proposed that the chemical L-glutamate activates antennular grooming behavior (AGB) in lobsters through a mechanistic pathway that is nonolfactory.

ANTS

Type of animal science: Classification
Fields of study: Anatomy, ecology, entomology, invertebrate biology, physiology, reproductive science, systematics (taxonomy)

There are approximately 20,000 species of ants. Ants constitute almost 3 percent of the 700,000 insect species.

Principal Terms

caste: social division of an ant colony, including workers, soldiers, queens, and males
drone: a fertile male ant
myrmecology: the study of ants
soldiers: large workers who defend the colony and often raid other colonies
workers: sterile, wingless female worker ants

Ants are insects and like all insects have three body parts: head, thorax, and abdomen. Ants have six legs, which are covered with tiny hairs. These hairs are used to clean its two antennae. The antennae are used for touching and smelling. Ants' poorly developed eyes make these sensory organs all the more important. Myrmecologists contend that ants have a very elaborate communication system. For example, when ants locate food, they create a scent path with a chemical substance from the food to the nest, allowing other ants to travel from the nest and locate the food. Ants also touch each other's antennae to communicate.

Ants live in colonies. Each colony consists of a queen, workers, soldiers, and male ants. Ants build many different types of homes. Many ants build simple mounds of dirt or sand. Other ants use small sticks mixed with dirt and sand, which makes a stronger mound that offers protection from rain. Ant mounds consist of many chambers connected by tunnels. Different chambers are used for nurseries, food storage, and resting places for the worker ants.

Ants are found in almost all terrestrial habitats, with the exception of high altitudes and latitudes. Most ant species live in the soil, although some ants live in wood, like termites. Army ants do not make a home at all, but travel in large groups searching for food.

Image Not Available

Physical Characteristics of Ants

Ant coloration can be black, earth-tone reds, pale tans, and basic browns. Ant larvae are white and grublike. They have no legs and do not move about much on their own. Their large, dark stomachs can generally be seen through their cuticles. Ant pupae look like white adult ants, with their legs and antennae pressed close to their bodies. In some species, larvae spin silk, and the pupal stage is inside a cocoon. Newly emerged adult ants are often paler than older ones.

Without wings, a male can generally be distinguished from a worker by the larger size of his body, thorax, and abdomen. All workers are females.

Ants do not have lungs. Oxygen enters through tiny holes all over the body and carbon dioxide leaves through the same holes. There are no blood vessels. The heart is a long tube that pumps colorless blood from the anterior to the posterior then back up to the head again.

The Life Cycle of Ants

Ants go through four stages of metamorphosis—egg, larva, pupa, and adult—which can take from six weeks to six months to complete. Eggs are almost microscopic in size. After weeks of feeding and molting, larva enter the pupal stage. Pupae resemble adult ants but do not move around or feed and are often encased in a silky cocoon, which is protected fiercely by the soldier ants. Adults require several days to attain complete maturity after emergence from the pupal stage.

Male ants only serve one purpose, to mate with future queen ants. The queen grows to adulthood, mates, and then spends the rest of her life laying eggs. A variety of reptiles, amphibians, spiders, and other insects prey on ants. Bats and birds kill and eat the flying males and females.

Some ant species are considered pests because they inhabit human territory or consume resources that humans need. Many species of ants have poison sacs and/or stingers in the end of the metasoma for defense against predators. Worldwide, however, ants are one of the most important predators of small invertebrates, including other insects. Ants are important dispersers of the seeds that they harvest. Ants turn over and aerate the soil as much as or more than earthworms.

APATOSAURUS

Types of animal science: Classification, evolution
Fields of study: Anatomy, ecology, evolutionary science, paleontology, systematics (taxonomy)

Apatosaurus *was a quadrupedal, herbivorous dinosaur with short forelimbs and a long tail and neck. Although often depicted wading in deep water,* Apatosaurus *actually lived on dry land.*

Principal Terms

BRACHIOSAURIDS: long-necked, herbivorous dinosaurs, whose forelimbs were longer than their hind limbs

GASTROLITHS: stones found in the gut region, that aided in the digestion of coarse plant food

NEURAL SPINE: a projection extending off the upper side of a vertebra

ORNITHOPODS: bipedal, herbivorous dinosaurs

STEGOSAURS: herbivorous dinosaurs with vertical bony plates arranged along their backbones

In 1877, Othniel C. Marsh named a headless juvenile dinosaur skeleton collected near Morrison, Colorado, *Apatosaurus* and published a complete description of the material in 1878. *Brontosaurus* was named by Marsh in 1879 based on an adult skeleton collected at Como Bluff, Wyoming. Because *Brontosaurus* had no head, Marsh added one from a nearby site in 1883. Because the skeleton of *Brontosaurus* was more complete than that of *Apatosaurus*, its skeleton was mounted at a number of museums around the United States. In 1903, Elmer Riggs concluded that the specimens of *Apatosaurus* and *Brontosaurus* belonged to the same species and, using the rule of priority by which the first name assigned is the one used, combined them under the name *Apatosaurus*. In addition, he noted that the head that had been attached to *Brontosaurus* had a short snout and spoon-shaped teeth, and belonged to another sauropod, *Camarasaurus*. Many people still recognize this dinosaur as *Brontosaurus*, while *Apatosaurus* is the name accepted by most professionals.

Characteristics

Apatosaurus was confined to the Late Jurassic era (156 to 145 million years ago) of the western United States and, perhaps, adjacent Mexico. Adults were about 21 meters (70 feet) long and 4.5 meters (14.5 feet) tall, weighing 20 tons. The long, whiplike tail was lashed about in defense. Their maximum land speed is estimated to have been from twenty to thirty kilometers per hour. Since dry habitats predominated at this time in the western United States, *Apatosaurus* had to migrate long distances to find food. Its long, straight legs were highly suitable for walking. *Apatosaurus* was gregarious and traveled in herds.

Their heads were quite small relative to their large bodies. Only one partial skull of *Apatosaurus* has been found. Because the joint connecting the skull to the spine was very weak, the skulls were often lost before burial. The eyes were located at the back of the skull, as were the nostrils. The teeth were peglike and confined to the front of an elongate snout. Because the small head lacked both the teeth and the musculature for effective chewing, *Apatosaurus* nipped off leaves that were swallowed nearly whole. *Apatosaurus* probably held its head horizontally while feeding on shrubs and other low-growth vegetation. Contemporary stegosaurs and ornithopods ate the vegetation up to a height of about three meters. *Apatosaurus* foraged at heights above three meters. The tallest trees

Apatosaurus Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Reptilia
Subclass: Dinosauria
Order: Saurischia (lizard-hipped dinosaurs)
Suborder: Sauropoda (long-necked herbivores)
Family: Diplodocidae (quadrupeds whose forelimbs were shorter than their hind limbs)
Genus and species: Apatosaurus ajax, *A. excelsus*, *A. louisae*
Note: A number of competing classification schemes exist and will probably continue to do so in the future.
Geographical location: Western United States, including Colorado, Utah, and Wyoming
Habitat: The dry habitats that predominated in the western United States during the Late Jurassic
Gestational period: Although no eggs have been found, *Apatosaurus* was undoubtedly an egg layer; the frequency at which the eggs were laid, the time it took for them to hatch, and the reproductive life span of the adults are unknown
Life span: Based on mammalian models, sexual maturity would be reached after ten years, and the life span was probably in excess of one hundred years
Special anatomy: All the diplodocids, including *Apatosaurus*, had V-shaped neural spines on the upper side of the cervical (neck) vertebrae; a taut ligament running between the arms of the V held the neck rigid so that constant muscular exertion was not necessary to hold the head up against the pull of gravity

were eaten by brachiosaurids. Gastroliths helped grind up coarse plant parts prior to their being passed on to the stomach. Bacteria were present in the digestive tract to aid in breaking down food. Ferns, the chief herbaceous plants of the Late Jurassic, would have comprised the major part of their diet, although conifers, ginkgoes, and cycads were also eaten. Flowering plants, which made up a large part of the diet of Cretaceous herbivores, such as *Triceratops*, had not yet evolved. Although *Apatosaurus* browsed on low-growing vegetation, it could also rear up on its hind legs and tail to feed in the trees, engage in combat with other members of its species, defend its young, and, at least in the males, mate.

APES TO HOMINIDS

Type of animal science: Evolution
Fields of study: Anthropology, evolutionary science, genetics, systematics (taxonomy), zoology

Although the study of fossil apes has taught scientists much regarding certain aspects of primate evolutionary development, they cannot yet trace more than a general connection between the apes and hominids such as man.

Principal Terms

APES: large, tailless, semierect anthropoid primates, including chimpanzees, gorillas, gibbons, orangutans, and their direct ancestors—but excluding man and his direct ancestors

AUSTRALOPITHECINES: nonhuman hominids, commonly regarded as ancestral to man

DRYOPITHECINES: extinct Miocene-Pliocene apes; their evolutionary significance is unclear

HOMINID: an anthropoid primate of the family Hominidae, including the genera *Homo* and *Australopithecus*

HUMAN: a hominid of the genus *Homo*, whether *Homo sapiens sapiens* (to which all varieties of modern man belong), earlier forms of *Homo sapiens*, or such presumably related types as *Homo erectus*

PRIMATES: placental mammals, primarily arboreal, whether anthropoid (humans, apes, and monkeys) or prosimian (lemurs, lorises, and tarsiers)

STRATIGRAPHY: in geology, a sequence of sedimentary or volcanic layers, or the study of them—indispensable for dating specimens

Primates are an order of the class Mammalia. The Primate order is divided into two suborders. Suborder Prosimii (lower primates) includes lemurs, lorises, and tarsiers. Suborder Anthropoidea (higher primates), to which monkeys, apes, and humans all belong, is divided further into infraorders: Platyrrhini (flat-nosed New World monkeys, definitely not ancestral to man) and Catarrhini (down-nosed Old World monkeys, apes, and man). The infraorder Catarrhini includes two superfamilies: Cercopithecoidea (Old World monkeys) and Hominoidea (apes and man). Within the Hominoidea, finally, are three families: Hylobatidae (lesser apes), Pongidae (great apes), and Hominidae (man). As this classification suggests, it is now taken for granted that human ancestry—if it could be traced satisfactorily—would include forms that, on other genealogies, gave rise to lower and higher primates, Old World monkeys, and a series of now-extinct creatures that were ancestral to certain of the apes as well.

The lower primates (prosimians) first appeared about seventy million years ago. They still exist (as lemurs, lorises, and tarsiers) but have been declining for the last thirty million years, probably because of unsuccessful competition with their own descendants, the monkeys. Prosimians have five digits on each limb, but the digits have claws rather than nails, and the limbs are entirely quadrupedal. Prosimians also lack binocular vision, but they do have dentition anticipating the molar development of the higher primates.

The Higher Primate Fossil Record

The earliest evidence of any kind of higher primate—some tiny pieces of jaw found in Burma—dates from the Eocene epoch, about forty million years ago. Two creatures named *Amphipithecus* ("near ape") and *Pondaungia* ("found in the Pondaung Hills") have been proposed, each being a very primitive monkey or ape, but the evidence thus far is too sparse to ally these forms with any possible descendants. Some two million years later, in the Fayum Depression of Egypt (then a lush forest), *Apidium* and *Parapithecus* ("past ape") existed. Known only from jaws and teeth, they are the oldest known Old World monkeys presently recognized. Their dental pattern (arrangement of teeth), however, is the same as that of *Amphipithecus*. Other teeth from the Fayum, perhaps thirty-five to thirty million years old, have a different cusp pattern, more like an ape's (and a human's) than a monkey's. Possibly, then, *Propliopithecus* ("before more recent ape") is the earliest evidence of an ape line distinct from the monkey line.

The oldest apelike animal about which scientists know enough to regard it as a probable human ancestor is *Aegyptopithecus* ("Egyptian ape"), also found in the Fayum, in Oligocene deposits about thirty-two million years old. In addition to jaws and teeth, an almost complete skull and some postcranial bones (meaning those below the skull) have been recovered. Since the Fayum at that time consisted of dense tropical rain forest with little open space, *Aegyptopithecus* is assumed to have been an arboreal quadruped. (In 1871, before *Aegyptopithecus* was known, Charles Darwin had predicted that such a human ancestor existed.) It is the most primitive ape yet discovered.

Proconsul ("before Consul," Consul being a chimpanzee in the London Zoo in 1933) and *Dryopithecus* ("forest ape") were either closely related to each other or identical. *Proconsul* appeared in Africa at the start of the Middle Miocene (about twenty million years ago) and was contemporary with *Dryopithecus* in Europe and Asia about fourteen million years ago. The relatively abundant fossils of these forms have been classified by some researchers into three species, together forming an extinct subfamily, the Dryopithecinae. One species in particular, *Dryopithecus major*, regularly left its remains on what were then the forested slopes of volcanoes; males grew significantly larger than females (a situation known as sexual dimorphism). In both of these respects, Dryopithecus resembled the modern gorilla, to which it may be ancestral. Like the gorilla, *Dryopithecus major* probably walked on its knuckles. In size, it was somewhat larger than a chimpanzee. The other two species, *Dryopithecus nyanzae* and *Dryopithecus africanus*, were smaller than *Dryopithecus major* and more like the chimpanzee. Outside Africa, *Dryopithecus* has been found from Spain to China.

The Ancestors of Modern Apes and Humans

Limnopithecus ("lake ape"), found in deposits in Kenya and Uganda of about twenty-three to fourteen million years ago, is thought to be an earlier form of *Pliopithecus* ("more recent ape"). Its gibbonlike skulls, jaws, and teeth are plentiful in European sediments of Middle Miocene to Early Pliocene age—sixteen to ten million years ago. For some researchers, these two forms constitute a separate subfamily, the Pliopithecinae, which they consider to be part of the family Hylobatidae (lesser apes). In some respects, they resembled the modern gibbon, but other aspects of their anatomy were quite different. For example, *Pliopithecus* possessed seven lumbar vertebrae, whereas gibbons (and humans) have only five. It seems to have been primarily arboreal, swinging from branch to branch. *Pliopithecus* has been known since 1837 (in France), and since then some almost-complete skeletons have been recovered. *Sivapithecus* ("Siva's ape," Siva being a Hindu deity), found in India and later in Africa, is a closely related form, Miocene in age. Both the dryopithecines and the pliopithecines are often regarded as the ancestors of modern apes.

Ramapithecus ("Rama's ape," Rama being another Hindu deity), found originally as a jaw fragment in India, is remarkable for its human-looking teeth. Some researchers regard it as the earliest member of the hominid line and therefore ancestral to humans. Others, however, relate *Ramapithecus* and *Sivapithecus* to modern orangutans, seeing no direct connection to man. Though *Ramapithecus* has been recovered from Late Miocene deposits in Africa and Indian and Early Pliocene ones in India (about fourteen to ten million years ago), only teeth and jaws have been found. As a result, many opinions regarding *Ramapithecus* are highly conjectural. The most striking feature of this genus, for example, is the greatly reduced size of its canine teeth, as compared with those of earlier (as well as modern) apes. Presumably, this indicates a changed diet of some sort. However, primates also use their teeth for nondietary purposes, including weaponry and display. It has therefore been suggested that the reduced tooth size of *Ramapithecus* might indicate its having begun to use other tools or weapons; if so, none has ever been found. Another conjecture has been that climatic change brought the primates down from the trees. Once on the ground, *Ramapithecus* then developed a hunter-gatherer style of sustenance that eventually included the formation of family units (male-female bonds), tool making, and a rudimentary form of language—the beginnings of culture. Unfortunately, all that is really known about *Ramapithecus* is what can be observed from a smattering of its bones.

Finally, there was *Gigantopithecus* ("giant ape"), a huge simian with protohuman teeth (clearly not ancestral to man, however) that outlasted *Dryopithecus*, *Ramapithecus*, and *Sivapithecus* to survive in Asia for almost nine million years. The largest primate that ever evolved (exactly how large is not known), it was alive in China as recently as a million years ago. Known for its immense molars, *Gigantopithecus* was apparently the only successful ground-living savanna ape. It probably competed with early hominid forms and may have been exterminated by them.

In broad outline, then, these are the fossil apes. Since much of the evidence (all of it, in several cases) consists of teeth and jawbones, it is not surprising that conjecture has played a very active part in attempts to associate this evidence with the evolution of the hominids. Before 1980, there was widespread consensus among experts with regard to an evolutionary main line extending at least from *Aegyptopithecus* through *Dryopithecus* (or *Proconsul*) and *Sivapithecus* to *Ramapithecus*, the latter being regarded as the first hominid. However, portions of two *Sivapithecus* faces, recovered from Turkey in 1980 and Pakistan in 1982, impressed researchers with their orangutan-like characteristics. Since firm ties between *Sivapithecus* and *Ramapithecus* had already been established, it began to seem that the entire lineage pointed toward the orangs rather than toward man. Another problem is that formerly accepted dating has come into question for such important branchings of the lineage as those which separated monkeys from apes and apes from man. New genetic studies having nothing to do with either fossils or stratigraphy have presented compelling (but controversial) arguments to the effect that these branchings occurred much later than hitherto believed. A third, even more serious problem is that there is virtually no pertinent fossil evidence regarding the development of simian primates into humans for a period beginning about fourteen million years ago and lasting until the appearance of the australopithecines about four million years ago. While anthropologists and biologists continue to learn more about the ancestry of modern simians, therefore, it is certainly not the case that a reliable lineage (or even a timetable) leading from other primates to humankind has been established.

The Problems of Theorizing from Fossils

The study of fossil apes is a specialization within the broader field of vertebrate paleontology, or the study of fossil bones. Like all paleontologists, therefore, paleoprimatologists are necessarily concerned with fossils and their stratigraphic occurrence. Because primates still exist, however, it is also important to study the behavior of living examples. Since behavior reflects environmental conditions, it is further necessary to reconstruct the climate, flora, and fauna of the region and time in which the fossils were found.

No complete fossil ape has ever been found. Any understanding of what they may have looked like is therefore conjectural—an extrapolation from what has been recovered to what has not. Skulls are undoubtedly the most desirable evidence, but they are not the most durable of fossils. Teeth, which constitute the hardest parts of the primate body, are preserved more often than any other part. Some kinds of fossil ape are known either exclusively or primarily from their teeth and jaws. Ape teeth differ from human teeth in two significant respects: They are generally larger (the canines especially), and the cusp patterns on their molars differ. The arrangement of teeth in an ape's jaw, moreover, is angular, like a V; in a human, the arrangement is rounder, like a U. Inevitably, whenever jawbones or molar teeth are found, an attempt is made to place them somewhere on a continuum that runs between the purely simian (ape) and the purely human. This procedure not only distinguishes primitive apes from primitive humans, and one kind of fossil ape from another, but also gives rise to inevitable conjecture as to possible anticipations of the human line.

A major difficulty with evolutionary sequences based solely upon dental evidence is that the head and body of a given species have not necessarily evolved at the same rate. One may be surprisingly apelike, the other somewhat human. Even more specifically, the fact that jaws are changing does not necessarily mean that crania (or any other specific body parts) are changing also. On the whole, scientists do not yet understand the evolution of primate anatomy well enough to interpret present evidence or reconstruct missing parts with much reliability. In the absence of factual evidence, the form taken by prevailing reconstructions at any given time may owe as much to professional politics as to objective knowledge. The controversy regarding *Ramapithecus*, which (on the basis of facial bones) moved that genus from a central position at the base of the human lineage to a similar position on a separate orangutan genealogy, has been

Image Not Available

a valuable lesson in the folly of premature commitment.

Ancient Fossils and Modern Primates

Most paleoprimatologists are to some extent modern-day primatologists also, necessarily expert in the comparative anatomy of all members of the higher primates and as knowledgeable as possible regarding their behaviors and environments. It is assumed that a changing environment (one becoming increasingly arid, for example) requires behavioral modifications and that these modifications will then create selection pressures favoring some types of anatomical variation over others; thus, one species will eventually change into (or be replaced by) another. The process is not well understood, but the primates—being so intensely studied—are often regarded as test cases for competing evolutionary theories. Some researchers stress evidence to the effect that species are always changing; others believe that species are created precipitously and then tend to endure relatively unchanged until they are abruptly superseded. All that is really known at present is that the ancient apes generally conform to a partially ascertainable progression from hypothetical earlier forms to modern-day primates—with a ten-million-year gap in between.

The Importance of Fossil Apes

The fossil apes are important for four reasons: They are an important group in their own right; they are important to the development of the mammals; they are important to the development of the primates; and, they are thought to be ancestral to humankind and therefore uniquely important among all nonhuman fossil genera.

One of the unique characteristics of humans is the ability to create, preserve, and transmit knowledge. *Homo sapiens* has learned to value learning, to hoard and increase knowledge in the realization that it fortifies and enhances his existence. Humans attempt to know and understand all present-day forms of life; in order to do so, however, it must also be known how these forms came into being through time. Biology, then, is inherently evolutionary and does not sharply distinguish between plants and animals of the past and those of the present.

Insofar as an understanding of life itself is the goal of biological studies, no single form of life is inherently more important than any other. From this point of view, one would say that fossil and living apes are studied for the same reason that algae, sponges, or nematodes are. A number of biologists would maintain this view. Many others, however, believe mammals—and especially primates—to be a "higher" form of life, anatomically more complex than sponges (though not necessarily more nearly perfect) and certainly capable of more complex behaviors. No mere study of anatomy, this viewpoint suggests, can sufficiently explain a primate.

The outstanding characteristic of all primates is their intelligence. One can find surprising levels of intelligence in other animals, however: Among invertebrates, such cephalopods as the squid and the octopus have the highly developed nervous systems, senses, and brains that are normally associated with mammals. Together with some birds and social insects, all the mammals are capable of surprisingly complex behavior. Nevertheless, the higher primates constitute an intellectual elite even among the mammals. Impressive as gorillas and chimpanzees can be in this respect, it is apparent that the human mind has a capacity well beyond theirs. The brains of extinct apes are seen as having been ancestral not only to those of modern apes but also to the brain of man.

Scientists are fortunate in the number of fossil ape skulls that have been found, for they make the increasing mental capacity of the higher primates easy to establish. Limb bones and other less durable parts of the skeleton are much rarer. When available, they indicate the relative lengths of arms and legs; the nature of the shoulder (a key to arboreal existence); the relation of pelvis and femur (a key to posture); and the shapes, capabilities, and functions of hands and feet. Without such evidence, scientists have only conjectures based upon the presumed place of the genus in question within a supposed evolutionary sequence. When proposed sequences differ, though they are derived from the same sparse evidence, conflicting suppositions about the evolutionary sequence are at work.

Bibliography

Berger, Lee. *In the Footsteps of Eve: The Mystery of Human Origins*. Washington, D.C.: Adventure Press/National Geographic Society, 2000. Argues that humans originated in South Africa rather than East Africa, based on the author's own fieldwork with hominid fossils discovered in South African caves.

Campbell, Bernard. *Humankind Emerging*. 8th ed. Boston: Allyn & Bacon, 2000. See especially the chapters "Back Beyond the Apes" and "The Behavior of Living Primates." Though a college-level text, this book is useful to everyone because of its comprehensive scope. Older sources should be checked against it.

Conroy, Glenn C. *Primate Evolution*. New York: W. W. Norton, 1990. A very readable book for students and general readers. Emphasizes the evolution, phylogeny, and and classification of hominids, linking the fragmented fossil record with behavior and culture.

Jordan, Paul. *Neanderthal: Neanderthal Man and the Story of Human Origins*. Phoenix Mill, England: Sutton, 1999. A clearly written book for the general reader, highlighting all the ideas involved in the study of human evolution. Describes the discovery of Neanderthal Man, reconstructs the Neanderthal environment and way of life, and traces the emergence of modern humankind.

Lewin, Roger. *Bones of Contention: Controversies in the Search for Human Origins*. New York: Simon & Schuster, 1987. One rather involved chapter of this book reviews the *Ramapithecus* debate in detail.

Martin, R. D. *Primate Origins and Evolution: A Phylogenetic Reconstruction*. London: Chapman and Hall, 1990. A wide-ranging book for those interested in mammals and evolutionary biology in general. Covers classification of mammals, the fossil record of mammalian origins, continental drift and evolution, and the problems of phylogenetic reconstruction.

Szaly, Frederick S., and Eric Delson. *Evolutionary History of the Primates*. New York: Academic Press, 1979. Though not intended for beginners and somewhat dated in places, this remains a standard reference.

Tattersall, Ian, and Jeffrey H. Schwartz. *Extinct Humans*. Boulder, Colo.: Westview Press, 2000. Tattersall excels at explaining complex paleoanthropological topics for the general reader. This book presents the idea of a "bushy" human evolutionary history, with many branches, as opposed to the now-obsolete notion that humankind evolved in a single linear path. Discusses the similarities and differences among *Australopithecus*, *Paranthropus*, and *Homo*, and the importance of tools in hominid mental evolution.

ARACHNIDS

Types of animal science: Anatomy, behavior, classification, ecology
Fields of study: Anatomy, ecology, ethology, invertebrate biology, systematics (taxonomy), zoology

Arachnids are ancient members of the phylum Arthropoda and represent some of the first terrestrial animals. Arachnids are mainly beneficial to humans in that they prey upon insects.

Principal Terms

ARTHROPODA: animals having jointed legs, an exoskeleton, and a ventral nerve cord

BOOK LUNGS: a system of blood-filled diverticula that are surrounded by air pockets located in a chamber called the atrium

CHELICERAE: pincerlike mouthparts used in macerating food

PEDIPALPS: modified walking legs; these may be clawlike, as in scorpions, or have a modified structure, a palpal organ for sperm transfer, as in male spiders

PODITES: the parts of the jointed appendages of arachnids

SENSILLA: hairlike structures associated with nerves that act as mechanoreceptors and chemoreceptors

TRACHEAS: a system of branched tubes that, in some arachnids, deliver oxygen to the blood

Arachnids belong to the phylum Arthropoda, and as such have the basic characteristics of this assemblage. These characteristics include having jointed appendages, an exoskeleton, an open circulatory system, and a ventral nerve cord. The Arachnida are a subgroup within the subphylum Cheliceriformes, those arthropods with a pair of primitively pincerlike chelicerae mouthparts. Arachnids are considered to have an aquatic origin, but most present-day forms are terrestrial in nature.

Arachnids all have the following characteristics: a body that is divided primitively into a prosoma and an opisthosoma; a pair of chelicerae used as mouth parts, a pair of pedipalps that often end in pincerlike claws and are modified for prey manipulation and sperm transfer; four pairs of walking legs in the adult (juveniles may have three pairs) originating from the prosoma; absence of antennae; simple eyes in most; coxial glands at base of the legs and malpighian tubules extending between the hemocoels and gut tube used for excretion and osmoregulation; gut tube with diverticula; breathing accomplished by book gills (aquatic forms), book lungs, or tracheal tubes; and a dorsal heart.

The following orders comprise the Arachnida: Scorpiones (scorpions), Uropygi (whip-tailed scorpions), Schizomida (schizomids), Amblypygi (whip spiders), Palpigradi, Araneae (spiders), Ricinuleids, Pseudoscorpionida (false scorpions), Solpugida (wind scorpions), Opiliones (daddy longlegs), and Acari (ticks and mites).

Scorpions

The scorpions are considered to be among the earliest land animals. They are considered to be derived from water scorpions known as Eurypterids. Scorpions were established in the terrestrial environment by the Carboniferous era, but are thought to have invaded the land in the Devonian. Scorpions are mainly nocturnal and are common in desert and tropical regions. Northern climates are free of scorpions due to the extreme cold. Their bodies are segmented but are divided into three portions: an anterior prosoma (carapace) and an opisthosoma divided into mesosoma and a metasoma. The prosoma bears the mouth parts which are pincerlike chelicerae used to chew the prey and allow copious amounts of digestive juice to be poured externally over the prey. The next pair of appendages are the clawlike pedipalps that act to catch and hold prey. Scorpions have four pairs of walking legs, each usually with eight segments. The mesosoma bears the genital pores and a pair of comblike structures, the pectines, which are chemosensors for tracking prey as well as for digging burrows, along with the legs. Scorpions breathe through ventrally placed book lungs and thus avoid traveling in water. The tail segment or telson bears at least one stinging spine. A number of species are highly poisonous and their sting may be fatal.

Uropygi, Schizomida, Amblypygi, and Palpigradi

Uropygi, whip-tailed scorpions, look like scorpions, having chelicerae mouthparts and large pedipalps for capturing prey. Some species attain lengths of up to eight centimeters. Like scorpions, these forms are mainly nocturnal. Uropygans earn their name by elongating the telson into a whiplike structure, the flagellum. At the end of this organ are pair of glands that can spay acetic and caprylic acids at would-be predators. They range from arid climates to the tropics and subtropics of South America and southern United States. Some species have been introduced into Africa.

The Schizomida are small, under a centimeter in size. Like uropygans, they possess glands that spray acid, although the telson in these forms is short. The first pair of walking legs is sensory in nature. Schizomids are common in Asia, Africa, and the Americas, inhabiting leaf litter and secreting themselves under rocks and fallen trees. They are tropical and subtropical.

Amblypygi resemble whip-tailed scorpions in body form, although they lack the elongated telson. Internally they resemble spiders, but do not have fangs and use their chelicerae for tearing apart prey. The first pair of legs is sensory in nature and may be quite long in some species (up to twenty-five centimeters in length.) These whip spiders are found in tropical areas under tree bark, leaf litter, and in caves.

Palpigradi are small arachnids under three millimeters in length. About fifty-five species have been described since their discovery in 1885. Not only have they have undergone a reduction in size, but their exoskeletons are thin and colorless, facilitating the loss of respiratory organs. They have a whiplike flagellum similar to that of the Uropygi.

Arachnids have eight legs, as opposed to insects, which have six. (Corbis)

The Aranae

Spiders comprise a large arachnid group, with at least 35,000 known species. They inhabit all terrestrial environments, and some species have adapted to freshwater and estuarine areas. The body is normally in two parts, a prosoma and an opisthosoma. Spiders are organized into three subgroups: those with a persistent segmented opisthosoma, the Liphistiidae, and two groups included in the Opisthothelae, the mygalomorph or tarantula-like spiders, and the araneomorph spiders that are more familiar to most people. Spiders have fanglike chelicerae that inject venom and digestive enzymes into the prey that liquefy the internal organs in order that the spider may pump out the contents. Although all spiders are venomous, only a few species are dangerous to humans. Among these are the black widow and brown recluse spiders. Black widows, belonging to the Theridiidae or cobweb spiders, are capable of inflicting a fatal bite, owing to the neurologic aspects of their venom. Males, who are multicolored and small, are also venomous. The brown recluse spiders are fairly common throughout the southern United States. Their venom is mainly hemolytic; that is, it dissolves tissues and may create large lesions as the result of digestion of tissue. Their bite is rarely fatal. Other lethal spiders occur in Australia (the funnel web spiders) and in South America (the ctenid hunting spiders). Another major characteristic of spiders is their ability to spin silk through organs called spinnerets. The spinnerets are connected to silk glands. Silk is used for webs, cocoons for eggs and over-wintering, wrapping prey, and draglines.

Arachnid Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Arthropoda
Subphylum: Cheliceriformes
Class: Chelicerata
Subclass: Arachnida
Geographical location: All continents
Habitat: Mainly terrestrial, with some few freshwater forms found among spiders
Gestational period: Extremely variable depending upon group or individual species
Life span: Variable, but some members may live up to twenty-five years
Special anatomy: All have eight legs as adults; pincerlike mouthparts that may be modified into fangs in some groups; most members are free-living but parasites are found among the *Acarina*; includes some of the most venomous animals of the world, such as the African fat-tailed scorpion, the American black widow spider, and the Australian red back and funnel web spiders

Spiders have many sense organs that include hairs that sense vibration and touch. Other hairlike structures are hollow and are chemoreceptors. Slit organs that include the lyriform organs are slits in the cuticle that lead to sensory neurons. They are considered to be mechanoreceptors. Vision is variable in spiders depending upon the life habits of the spider, ranging from eight eyes arranged in two rows on the prosoma to a complete lack of eyes. The jumping and hunting spiders have the largest eyes capable of forming an image.

Spiders have interesting reproductive behaviors that range from rhythmic web tapping to flashing iridescent pedipalps. A male will pick up sperm deposited in a sperm web with a specialized structure on one of the pedipalps. If he is successful in approaching a female, he will mate with her by inserting the pedipalp tip into her seminal receptacle and beat a hasty retreat; otherwise the female may recycle him. The female will lay up to three thousand eggs sometime after the mating.

Opiliones

Harvestmen are found throughout the world. The carapace is broadly joined with the segmented abdomen without the usual constriction seen in spiders. The legs of most are long and spindly, hence their common name of "daddy longlegs." They are most abundant in the tropics. They have pincerlike but small pedipalps that are used to feed on small invertebrates and insect eggs. They also are scavengers. For defense, they have two repugnatorial glands that give off noxious chemicals to ward off would-be predators. Unlike other arachnids, these male spiders have a penis for sperm transfer and females have an ovipositor with which they deposit their eggs in the soil.

Acarina

Both the mites and ticks are included in this group and have the largest number of species—possibly over a million—of any arachnid taxon. They may not be a monophyletic group but one that has more than one ancestor. These forms are cosmopolitan in distribution and are either free-living or parasitic on both plants and animals. Mites are the most diverse members of this assemblage. They have opted for small size with a trend toward fusing the prosoma and opisthosoma together. Mites are predatory on other arthropods, including other mites. Many others are parasitic on plants and vertebrates. Some have become aquatic and can be found in many freshwater and ocean environments where they may parasitize mollusks, crustaceans, and aquatic insects; some are suspension feeders. Mites cause various aliments that include skin mange and other irritations, feather loss in birds, as well as subcutaneous tumors. Mites can also act as vectors in disease distribution, including wheat and rye mosaic viruses. Other mites may destroy stored grain products and thus have negative economic impacts. The ticks are parasitic, blood-sucking parasites on vertebrates, although one beetle is also parasitized by this taxon. The chelicerae are modified with teeth for anchoring the tick in the skin of the host, which makes it difficult to remove. Ticks are vectors for many diseases, including protozoan, bacterial, fungal, and viral agents. Ticks transfer Rocky Mountain spotted fever as well as Lyme disease.

Ricinulei

These secretive arachnids are small, ranging from five to ten millimeters in length. There are only about thirty-five species, found in Africa, the southern United States, and Brazil. They have pincerlike pedipalps, and their third legs are modified for sperm transfer in males. There is a hood structure in front of the prosoma where brooding of the single egg of one species occurs. The reproductive habits are largely unknown. These are secretive animals living under leaf litter and in caves. They are predatory on smaller arthropods.

ARCHAEOPTERYX

Types of animal science: Classification, evolution
Fields of study: Anatomy, evolutionary science, ornithology, paleontology

The oldest known bird is the Late Jurassic Archaeopteryx*, which is important as evidence for the generally accepted view that birds evolved from small carnivorous dinosaurs through the development of feathers into flight structures.*

Principal Terms

Archaeopteryx: the oldest known bird, from the Upper Jurassic Solnhofen Limestone of Bavaria

archosaurs: major subdivision of reptiles, which includes the crocodiles, birds, and dinosaurs

cladistics: a method of analyzing biological relationships in which advanced characters of organisms are used to indicate closeness of origin

Cretaceous: a period of time that lasted from about 146 to 65 million years ago, the end of which was marked by the extinction of the dinosaurs

furcula: fused clavicles, the wishbone of birds

Jurassic: a period of geological time that lasted from about 208 to 146 million years ago, during which the birds originated

theropods: carnivorous dinosaurs, and the group from which birds developed

The first *Archaeopteryx* ("ancient wing") fossil to be discovered was a single feather found in the Solnhofen Limestone Formation of Bavaria in 1860, during quarrying operations. Since then seven skeletons have been found, the most complete of which are the British Museum specimen (discovered in 1862) and the Berlin specimen (discovered in 1877). Although most of the specimens seem to belong to the same species, *Archaeopteryx lithographica*, a case has been made that the seventh specimen represents a different and smaller species, *Archaeopteryx bavarica*. The Solnhofen Limestone was deposited in hypersaline lagoons that formed along the northern margin of the Tethys Sea during the Late Jurassic, and the fine-grained limestones that formed in the lagoons contributed to the exceptional preservation of soft-tissue structures, including feathers. *Archaeopteryx* may have lived around the lagoons in bushes and shrubs, as there is no evidence of trees, and occasionally may have been blown out into the lagoons during storms, becoming waterlogged and sinking into the fine carbonate sediment.

Archaeopteryx was a small animal, about the size of a pigeon, and is considered to be a bird, as it has feathers, with those on the wings specialized for flight. However, many of its skeletal characteristics are dinosaurian, and if the feather impressions had not been preserved it would undoubtedly have been identified as a small theropod or carnivorous dinosaur. In particular, the skull has openings characteristic of dinosaurs, and toothed jaws are present rather than a beak. The arms still terminate in separate clawed fingers, unlike the fused wing of a bird, and its pelvis and long bony tail are similar to those of a theropod. All modern birds have a fused mass of vertebrae called the pygostyle rather than a long bony tail. However, *Archaeopteryx* does have a furcula, the wishbone of birds, which acts as a spring during flight; a broad platelike sternum for the attachment of the flight muscles; and feathers, which probably developed initially from epidermal scales as insulation and were only later adapted for flight.

Archaeopteryx Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Subclass: Archaeornithes
Geographical location: Southern Germany
Habitat: Probably low bushes and shrubs around marine lagoons
Gestational period: Unknown
Life span: Unknown
Special anatomy: Dinosaurian features, including teeth, forelimbs with separate clawed digits, saurischian pelvis, long bony tail; body covered by feathers, including asymmetric flight feathers

Significance of *Archaeopteryx*

The status of *Archaeopteryx* as the oldest known bird has made it extremely significant in ongoing discussions about the origin of birds and the origin of flight. At the time of its discovery, shortly after the publication of Charles Darwin's *On the Origin of Species* (1859), it seemed to be a perfect "missing link" between birds and reptiles, and was proposed as such by Thomas Henry Huxley. However, the apparent lack of a furcula was used to discredit this view, and rival views suggesting that birds were most closely related to crocodiles, basal archosaurs (dinosaur ancestors), and even mammals became more popular. This changed in the 1970's when John Ostrom cataloged numerous similarities between *Archaeopteryx* and theropod dinosaurs, particularly the advanced dromaeosaur *Deinonychus*. Subsequent analyses using cladistics, a method in which the distribution of advanced characteristics in related species can be assessed by computer, have fully supported this view.

Analyses of the wings of *Archaeopteryx* have shown that the feathers are adapted for flight and that the animal was probably capable of fast cruising flight, although it would not have been very manouverable. Specimens of feathered dinosaurs and early birds from the Lower Cretaceous of China have shown that feathers probably originated as insulating structures that were subsequently adapted for flight in animals such as *Archaeopteryx*. How that happened is still a matter for debate, but the two main possibilities are the arboreal hypothesis, which suggests that flight originated in gliders that started to flap, and the cursorial hypothesis, which suggests that flight developed in animals that were running and jumping after prey.

ARMADILLOS, ANTEATERS, AND SLOTHS

Type of animal science: Classification
Fields of study: Anatomy, physiology, zoology

Anteaters, armadillos, and sloths belong to the order Edentata ("without teeth"). The order includes the giant anteater and three smaller anteaters, two genera of sloths, and eight genera consisting of twenty species of armadillos.

Principal Terms

ARBOREAL: living in trees
HERBIVOROUS: plant-eating
NOCTURNAL: active only at night

Anteaters, armadillos, sloths, and several extinct species make up an order of mammals called Edentata ("without teeth"), now found only in the Western Hemisphere and chiefly in South America. Only one species of the order, the long-nosed armadillo, is found in the United States, chiefly in Texas. Although the name of the order means "toothless," armadillos and sloths do have a single set of teeth, which look like wooden pegs, lack enamel, and are constantly growing. Only the anteaters do not have teeth.

Edentates live in a number of habitats, including subtropical and tropical environments. Giant anteaters live in grasslands but also can be found in western South American forests. They feed on termites and ants, either at night or during the day. Lesser anteaters live mostly in tropical rain forests and are nocturnal in their habits, preferring to hunt at night. Tree sloths live in trees in humid tropical forests, where they feed exclusively on leaves and plants. Armadillos are found in grasslands and forests and live in burrows. They feed mainly on insects and worms.

Physical Characteristics of Edentates

The four genera of anteaters share several characteristics: They have long heads, long, tube-shaped mouths with long tongues, but no teeth. They are mammals and belong to the family Myrmecophagidae. The giant anteater, *Myrmecophaga tridactyla*, is sometimes called the ant bear. It can reach six feet in length and weigh up to eighty-six pounds and lives in swampy areas and open grasslands in South America. It is gray in color with a white-bordered black stripe on each shoulder. It has a long, bushy tail and sharp front claws used to tear open termite nests. The claws are so long that, in order to move, the ant bear must tuck its claws under its front feet and walk on its knuckles. The long, narrow tongue has a sticky surface; it flicks rapidly out of a small mouth and is perfectly suited for licking up termites and ants that adhere to its surface.

The pygmy anteater, *Cyclopes didactylus*, also called the two-toed anteater, is the smallest of the anteaters. It reaches about fifteen inches in length, but half of that is tail. The pygmy anteater weighs only four pounds on average. It has a small nose and silky golden fur that make it look like the seedpods of the main tree it inhabits, the silk cotton tree. It lives high up in the tree, where it feasts on termites and seldom comes to the ground. It uses its tail to help it jump from tree to tree.

There are two species of Tamandua, or lesser anteaters, *Tamanda tetradactyla* and *T. mexicana*. Both species have three toes, no teeth, and very sharp claws. They are about four feet long, shortsighted, and very hard of hearing. Their noses are much shorter than those of the giant anteaters. Both species are shorthaired and brownish, with a black area that looks like a vest on the front side. They live in trees and use their long, prehensile tails to help them hold onto branches. They sometimes come to the ground, where they walk extremely slowly. They do most of their feeding at night, eating ants, termites, and other small insects.

The armadillo, Spanish for "little armored thing," originated in South America more than sixty million years ago. It is found as far south as Argentinean Patagonia, where the pichi, *Zaedyus pichi*, is very common. One species of armadillo, *Dasypus novemcinctus* (the nine-banded armadillo), is found as far north as northern Texas. The armadillo is not toothless, but its teeth are simple, rootless pegs at the back of its mouth. The shell covering most of the animal is made up of hundreds of bony plates that are fused together. Across the middle of its back, the armadillo has a hinge that joins together its front and rear sections, which allows the animal freedom of movement. Armadillos can contract and curl up into a ball to cover their unprotected underbellies. A full-sized adult weighs between eight and fifteen pounds. There are nine genera and twenty species of armadillos. The three-, six-, and nine-banded armadillos (the genera *Tolypeutes*, *Euphractus*, and *Dasypus*) get their names from the number of bands in their armor. The armor protects the animal from flesh-eating predators.

Sloths are arboreal (living in trees), with six species found in the rain forests of Central and South America. They are herbivorous, meaning they only eat plants. There are two main kinds of sloths: the three-toed sloth, called an ai, and the two-toed sloth, known as the unau. The ai, or *Bradypus grisues*, got its common name from its cry of distress, "ai-ai." It is about two feet long, slender, and has long legs. Its feet are armed with three long, hooklike claws, from which it hangs from branches. It has small ears, a tail, and a bullet-shaped head. One unusual feature is its long neck, which contains nine vertebrae, two more than is usual in mammals. Its coat of hair is dull gray and in another peculiar feature, an algae grows in the sloth's hair that gives it a greenish color, making the animal difficult to see among the green leaves. Three-toed sloths eat only the leaves of the cecropia tree.

The two-toed unau, *Choloepus hoffmanni*, is larger than the ai. Its neck has only seven vertebrae, and the animal has no tail. It has two claws on its front feet but three claws on its hind feet. Unlike the three-toed sloth, the unau can come down a tree headfirst and stand upright on all four feet. Its diet consists mainly of leaves, stems, and fruits. The eyesight and hearing of all sloths are not very well developed, and they usually find their way mainly by touch.

The Life Cycle and Habitat of Edentata

Solitary habits and a low reproductive rate characterize all three species of anteaters. The young

Image Not Available

are born one at a time with a gestation period of approximately 190 days. A mother carries a single offspring on her back for most of its growth period, which can last up to a year in the case of the giant anteater. The giant anteater lives in the grassland and forest of South America; it is the only anteater that lives on the ground. It is an excellent swimmer, however, and is frequently seen in the Amazon River. When it lives near human populations, it is active only at night, but in the forest it can be found hunting ants and termites during the day. Its home is an old burrow abandoned by another animal, or a hollow log. The giant anteater is becoming rare due to the trade in exotic pets and through the destruction of its habitats.

The pygmy anteater rarely comes down from the tall trees it lives in, and is active only at night. It lives high up in trees in the rain forest and feeds on termites. Its breeding habits are not known. The lesser anteater lives in trees, hanging on to branches with its tail. It emerges at night to eat insects, ants, and termites. Its breeding habits also remain unknown. Lesser anteaters are hunted for their tails, which are used to make rope, and native Brazilians sometimes bring them into their homes to rid them of termites.

The armadillo lives alone, in pairs, or in small groups. It is primarily active at night, and lives in burrows. It is a strong digger, and also a good swimmer despite its heavy shell. If the animal encounters a small stream or water-filled ditch, it usually just walks right across the bottom, under the water. If an armadillo comes to a larger body of water, however, it will swallow enough air to double the size of its stomach. This increased buoyancy then allows the armadillo to swim across. Once across, it takes several hours for the animal to release all the extra air from its body.

In some species of armadillo, the mother bears one to twelve identical young, all of which develop from a single egg. The gestation period for armadillos varies from sixty-five days to four months, depending on the species. Armadillos are found in tropical and subtropical regions, primarily in South America. Most species live in open areas, but some live in forests. They have a very good sense of smell that enables them to detect insects up to five inches below the surface of the earth. Armadillos are easily frightened and are very quick to run away from danger. The arma-

Edentata Facts

Classification:
Kingdom: Animalia
Subkingdom: Eumetazoa
Phylum: Craniata
Subphylum: Vertebrate
Class: Mammalia
Subclass: Theria
Order: Edentata
Family: Myrmecophaga (anteaters), Dasypodidae (armadillos), Bradypodidae (three-toed sloths), Megalonychidae (two-toed sloths)
Genus and species: Anteaters—three genera and four species; armadillos—eight genera and twenty species; sloths—two genera and five species

Geographical location: South and Central America, with only one species of Edentata in North America

Habitat: Anteaters—savanna, parkland, thorn scrub, and forest; armadillos—savanna, pampas, arid desert, thorn scrub, and deciduous, cloud, and rain forests; sloths—lowland and upland tropical forest

Gestational period: Anteaters—190 days; armadillos—60 to 120 days; sloths—6 to 11.5 months

Life span: Anteaters—unknown in the wild, twenty-six years in captivity; armadillos—twelve to fifteen years in the wild, nineteen in captivity; sloths—twelve years in the wild, thirty-one in captivity

Special anatomy: Anteaters have long sticky tongues and long tails; armadillos have shells surrounding most of their bodies; sloths have long tails and claws that enable them to hang from trees dillo is the only animal, besides humans, known to carry leprosy. For that reason it is illegal to sell a live armadillo in Texas.

The tree sloth usually lives alone and spends most of its time sleeping. The brief time that remains, it spends eating leaves and moving about. It sleeps hanging by its tail from a branch, with its feet bunched together and head tucked into its chest. Its greenish color makes it look like a bunch of dead leaves, making it almost invisible to other animals. Even at night it moves slowly, so as not to attract the attention of its enemies.

Sloths do not make nests, and sleep wherever they happen to be. They are not aggressive, but if two males come together in the same area during mating season, they will fight until one is killed. Mothers give birth to single young during the summer. The baby lives with its mother, clinging tightly to her breasts for five weeks, and then begins to eat by itself.

Extinct Edentata

The evolution of the anteater is not clear, but its oldest ancestor is believed to be some unknown form of insect. The three suborders of anteaters were separate for much of their history because they emerged long before North and South America were joined by the Isthmus of Panama, about 3.5 million years ago. All of the North American species died out before that contact was made.

The fossil record of armadillos includes groups that were about the same size as contemporary species, as well as a South American species, *Macroeuphractus*, that was at least 6.5 feet long. The skeleton of another ancestor, *Pampatherium*, found in a deposit in Texas, was as big as a rhinoceros. All of the ancestors of armadillos appear to have been plant eaters.

In the past, many varieties of sloths roamed the Americas from New Mexico to the southern tip of South America. They ranged in size from small animals the size of a fox to a giant ground sloth, *Megatherium*, which was larger than a full-grown elephant. A bear sloth, *Nothrotherium*, and other extinct members of the sloth family lived in South America about one million years ago.

ARTHROPODS

Types of animal science: Anatomy, classification
Fields of study: Invertebrate biology, systematics (taxonomy)

Arthropods are the most numerous of all animal species, representing between 75 and 85 percent of all identified species. They are remarkably successful in all types of habitats and environmental realms.

Principal Terms

BIRAMOUS: having two rami; antennae are bifurcated

CUTICLE: a noncellular, secreted body covering

ECDYSIS: molting; the process of removing (escaping from) the old exoskeleton

EXOSKELETON: a protective system of external layers and joints that allows for antagonistic action of muscles

RAMI: the branches of an arthropod limb or appendage

SETAE: hairlike organs, typically sensory in nature, arising from the cuticle

TAGMATIZATION: functional specialization of groups of segments

UNIRAMOUS: having only one rami; antennae appear as a single, nonbifurcated structure

The phylum Arthropoda is the largest phylum in the animal kingdom and consists of myriad animals belonging to the subphyla Trilobita (extinct trilobites with biramous antennae, probably all marine), Chelicerata (horseshoe crabs, scorpions and pseudoscorpions, spiders, harvestmen, mites, ticks, and marine pycnogonids; all lacking antennae), Crustacea (all with biramous antennae), and Uniramia (insects, centipedes, millipedes; all with uniramous antennae). All of these subphyla are united by a common body plan similar to that of the annelids, in which the body is made up of a series of repeating segments, each bearing a pair of appendages. In contrast to annelids, however, arthropods have fused and modified segments for specialization. This fusion of groups of segments is known as tagmatization. The names for specific tagmata vary from subphylum to subphylum, but are most commonly recognized as the head, the thorax, and the abdomen. Appendages consist of articulated joints, moveable by muscles that insert onto specialized structures called apodemes that are attached to the cuticle.

Arthropods are found in all terrestrial and freshwater habitats and on all continents. They are also located in all marine realms, including in the abyssal depths and at hydrothermal vents, and are the only invertebrates to have conquered the aerial realm. Because of their widespread occurrence and their ability to occupy all niches on earth, they are considered the most successful animal phylum that has ever existed.

External Structure and Function

The first and last segments of the arthropod body differ in embryological origin from all of the rest and are considered as special segments. The first is called the acron and is preoral (lies before the mouth). The last is the telson and is postanal (occurs after the anus). Increase in segment numbers takes place in a growth zone immediately in front of (anterior to) the telson. Thus, the oldest segments are toward the head, while the youngest are toward the telson. The exoskeleton of each segment consists of two thickened plates, which are connected by a membranous cuticle. The cuticle is a nonliving, secreted material consisting of three layers: an inner endocuticle, an exocuticle, and an

Image Not Available

outer epicuticle, which is usually waxy. Despite this, the cuticle has many living structures that penetrate it and project beyond its surface. Chemical and mechanical sensory organs (setae) emerge generally as hollow projections from the cuticle and are typically hairlike in structure. Gland pores also penetrate the cuticle.

The cuticle is secreted by the epidermis and becomes hardened during a process of protein tanning and can be further strengthened by depositing calcium carbonate in the endocuticle (in Crustacea and Diplopoda). However, this hardened structure restricts growth and must be shed in a process called ecdysis (commonly called molting) in order for the animal to grow larger. Ecdysis is under neural and hormonal control. In preparation for ecdysis, the old cuticle is partially digested, particularly at joint locations and along specific lines of weakness. A flexible, untanned new cuticle is laid down under the old cuticle, and then the old cuticle cracks along the weak points so that the animal can emerge. The period between successive molts is known as intermolt, and the animal in each of these periods is called an instar; during this time cellular growth within the confines of the exoskeleton occurs. Some species of arthropods have terminal molts; that is, they molt a specific number of times and then cease all molting and growth. Other species retain the ability to molt and grow throughout their entire lives.

Internal Body Plan

The major, tubular blood vessel (heart) is dorsal, with blood flowing toward the head rather than toward the body. The circulatory system is greatly enlarged and occupies the space of the coelomic cavity, which is vestigial. In most arthropods, the circulatory system is open, so that all internal organs are bathed directly in blood rather than fed by smaller vessels (as is common in closed systems). The heart is pierced by a series of holes (ostia) which close when the heart muscle contracts so that blood can be propelled forward. Upon relaxation of the heart muscle, the ostia open and blood reenters the heart from the sinuses that feed into the sac surrounding the heart. The blood contains clotting agents, amoeba-like cells that act as phagocytic cells to attack pathogens, and oxygenating pigments.

Aquatic arthropods possess gills through which blood is circulated for gas exchange. Terrestrial forms have either book lungs or a series of cuticle-lined tubes called tracheas, which branch into smaller and smaller tubes to reach nearly all cells of the body. The tracheas open to the outside of the body via spiracles, which possess valves so that their opening and closing can be controlled to avoid water loss.

The arthropod gut has three divisions: a cuticle-lined foregut, a midgut, and a cuticle-lined hindgut. The foregut often is specialized for food storage and grinding and is separated from the midgut by a complex valve. The midgut has a large absorptive surface, which is called either the hepatopancreas or the digestive caecae. The hindgut serves as the area for water resorption and the formation of feces. Food and wastes are moved through the digestive system via muscular action due to the cuticular lining of the foregut and hindgut.

Osmoregulation and excretion of nitrogenous wastes are accomplished via one of two kinds of organs: the Malphigian tubules, or the nephridial coxal, antennae, or maxillary glands, all of which filter the blood for wastes. Marine forms excrete ammonia, while terrestrial forms conserve water through the excretion of uric acid.

The nervous system is of a ladderlike chain form, highly segmental, and ventrally located. Two longitudinal ganglia run along the midline of the animal. Paired ganglia arise in each segment and these are connected via lateral cords. The brain, composed of three pairs of ganglia, is found anteriorly above the esophagus; these ganglia then connect to the fourth set immediately below the esophagus. Sensory systems are highly evolved and include chemoreception (taste and smell), mechanoreception (vibration, touch, and deformation), and vision. Vision is accomplished via simple eyes (ocelli) and/or compound eyes, made up of a series of subunits called ommatidia. Compound eyes break up the image before it reaches the retina, and each ommatidium samples only a small part of the complete image.

Reproductive systems and strategies are highly variable. Sexes are usually separate, although hermaphroditism and parthenogenesis are known in some crustaceans and a few insects. Some arthropods display elaborate mating rituals; others do not. Some use direct copulation; others use indirect methods. Many arthropods pass through juvenile stages that are highly vulnerable to predators; hence the reproductive output of most arthropods is great. A few species, however, display direct development, where miniature adults are produced from eggs.

Phylogeny

Arthropods and annelids share a common ancestor, but it is unclear whether arthropods arose from an annelid ancestor or both shared an ancestor from another phylum. Some argue, based on molecular evidence, that annelids and crustaceans are not closely related at all. Traditionally, arthropods have been treated as a monophyletic group—all arose from a common arthropod ancestor. However, this idea is the subject of debate, with some arguing for a polyphyletic ancestry where each subphylum arose from a nonarthropod ancestor and then formed similar body structures via convergent evolutionary forces. Unfortunately, the fossil record does little to illuminate the phylogeny of arthropods, and current molecular evidence is contradictory.

ASEXUAL REPRODUCTION

Types of animal science: Development, reproduction
Fields of study: Cell biology, developmental biology, reproduction science

Asexual reproduction is any form of reproduction in which the fusion of haploid gametes is not the first step. There are many examples, such as the budding of a new hydra from the stalk of an existing one or the development of diploid eggs into larvae and, eventually, adults in aphids. The new organism formed is a clone of the original.

Principal Terms

CLONE: an organism that is genetically identical to the original organism from which it was derived

DIPLOID: having two of each chromosome; a normal state for most animals

HAPLOID: having one of each chromosome; a normal state for animal gametes

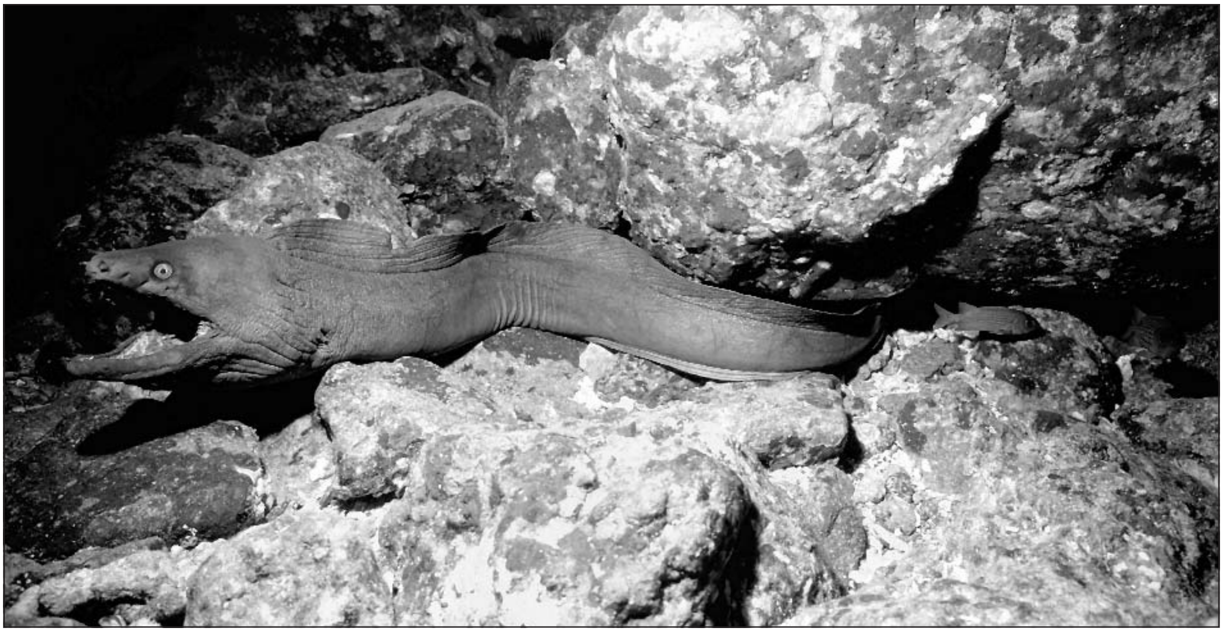
PARTHENOGENESIS: a form of asexual reproduction where the young are derived from diploid or triploid eggs produced by the mother without any genetic input from a male

TRIPLOID: having three of each chromosome; an abnormal state which is unable to produce normal haploid gametes

Although asexual reproduction is very common in organisms such as bacteria, protists, fungi, and plants, it is rarer among animals, especially among the more complex animals. In simple animals, such as sponges (phylum Porifera), the polyps of hydra, jellyfish, corals, and sea anemones (phylum Cnidaria), and many flatworms (phylum Platyhelminthes), asexual reproduction is common. Sponges can reproduce asexually when fragments break off and become established as new individuals or when mature sponges produce gemules, overwintering buds, that are produced and released by many freshwater and a few marine sponges. Cnidarian polyps frequently reproduce by budding. The buds start as small regions of less-differentiated tissue that differentiates into a new polyp. These new polyps can separate from the original to form new individuals or can remain attached and form colonies. The largest colonies to be produced asexually by budding are those produced by the reef-building corals. In some Cnidaria, the polyps release free-floating forms of the organism called medusae (jellyfish). The medusa form of the life cycle, which was formed asexually, reproduces sexually when it matures. Many species of flatworms reproduce asexually by fragmentation. When these worms are cut into fragments, most fragments can regenerate their missing parts, and thus form several organisms from the original one. Others, like many trematode flukes, asexually reproduce by polyembryony. In this mode of reproduction, larval flukes form many juveniles of the next larval stage internally, from the mature larva's own cells. The immature larvae that are produced, which are all genetic clones of the original larva, will be released to continue the life cycle.

Parthenogenesis

In higher organisms, asexual reproduction is much less frequent and far more complex. Rotifers (phylum Rotifera) are small aquatic organisms with rows of cilia around their mouths that seem to rotate as they beat. Rotifer populations are usually either mostly or entirely female. This happens because rotifers usually reproduce asexually by parthenogenesis. In this type of reproduction, the females produce diploid eggs instead of the haploid eggs that are needed for sexual reproduction.



Corals are among the many primitive species that reproduce asexually. (Digital Stock)

The diploid eggs have the same genes as the mother and are thus clones and mature into adults identical to their mother. In some rotifers, asexual reproduction is the only form of reproduction, and thus all of the organisms in these species are female. In other species, males are only produced during times of environmental stress, and sexual reproduction only occurs then.

Like rotifers, many populations of aphids (phylum Arthropoda), a common plant pest, are entirely or mostly female during parts of the breeding season. In spring and early summer, aphids reproduce parthenogenetically, with females producing diploid eggs that develop into adult female aphids. These eggs and the adults formed from them are clones of the original aphid. In late summer and early fall, the aphids reproduce sexually, producing haploid eggs that can be fertilized by haploid sperm from males.

Even among the very complex vertebrates, a few organisms can be found that reproduce asexually. The two most studied are the whiptail lizard, native to the deserts of the American Southwest and the northwestern part of Mexico, and the gecko, found on some tropical islands of the Pacific. These lizards exist in both sexually reproducing and parthenogenetic forms. Genetic study of their chromosomes has shown that the parthenogenetic species were first formed as diploid or sometimes triploid hybrids of two sexually reproducing forms. The hybrids could not undergo normal meiosis because different chromosomes inherited from each parent could not align properly. Thus, these lizards cannot reproduce sexually. They do, however, produce diploid or triploid eggs that can be triggered to start reproduction. The progeny that are produced are exact genetic duplicates of their mothers—clones.

With asexual reproduction, organisms do not have to waste energy in sexual activity. However, the energy savings is not without a price. With the exception of the rotifers, no populations of asexually reproducing organisms have very long histories, evolutionarily speaking. Unlike most sexually reproducing populations with varying degrees of diversity, all members of an asexually reproducing population are identical, except for mutations that arose after the population's inception. This lowered diversity makes the population much less likely to be able to adapt to change.

More or less water, higher or lower temperatures, introduction of parasites, or disease could more easily wipe out the entire population.

—Richard W. Cheney, Jr.

BABOONS

Types of animal science: Anatomy, behavior, classification, ecology, evolution
Fields of study: Anthropology, ecology, ethology, evolutionary science, human origins, systematics (taxonomy), wildlife ecology, zoology

Baboons are among the most widespread and adaptable of monkeys. Their behavior, ecology, and evolutionary history may shed light on human origins.

Principal Terms

COALITIONS: short-term alliances designed to gain access to a contested resource, often by fighting

MATRILINES: several generations of adult females all related by common descent from one foundress (female ancestor)

SEXUAL SWELLING: an estrogen-induced water retention that causes reddening and swelling in the perineal region and around the buttocks

Baboons are found as far north as the semidesert of Saudi Arabia (*Papio hamadryas*) and as far south as Cape Town in South Africa (*P. cynocephalus ursinus*). The regional variants of the cynocephalus (dog-headed) baboon (chacma in the south, Guinea in the west, olive in the north east, and yellow baboon in the southeast) are considered to be the same species by most experts. The northeastern variant, the hamadryas, is generally considered to be a separate species but can interbreed with the olive baboon of Ethiopia.

Baboons and Their Environment

Baboons are very numerous in Africa, and are among the most adaptable of all mammals. This adaptability also allows baboons to survive in wet forest and the driest semidesert regions. They eat almost any plant material or small animal they encounter. Baboons often survive quite well in and around human settlements. They sometimes cause severe crop damage when they visit farmers' fields, since they are capable of eating even the toughest roots, such as cassava and sweet potato,

Image Not Available

but they also forage on farmers' bananas and maize. Baboons can survive on garbage at tourist lodges, or find food in near deserts in Namibia, Ethiopia, and Saudi Arabia. Baboons sleep in trees or caves and cliff ledges, for protection from nocturnal predators.

Baboon Society

Except in the driest and coldest habitats, baboons form large groups and travel widely in the course of a day. Groups often exceed one hundred animals and contain scores of juveniles and females, plus a few adult males. These large social groups are composed of matrilines—a kin-group of sisters and their daughters who all descend from one female, plus their infant and juvenile male offspring—and unrelated adult males, who compete for mating access to females with sexual swellings. A large group can contain several matrilines, which may compete with each other over access to food, shelter, and male protection. The adult males in the group often fight fiercely among themselves, using coalitions to overcome single competitors. The typically calm life of moving in search of food is regularly interrupted by squabbles and mild competition over resources. More rarely, large fights break out within groups, and injuries follow. The most severe aggression is seen when a new adult male immigrates into a group, fights the other males to obtain high rank, and even harasses females and their young. Some cases of infanticide have been reported in such circumstances. The hamadryas baboons differ most in social organization. They do not build matrilines based on female kinship, but rather a female leaves the group in which she was born and bonds to a particular male as her future mate. This male plays an important social role as protector of a small group of one to three females. These small, one-male units travel and forage independently most of the time, but reunite with other units at night to form large herds often numbering in the hundreds.

Baboons have been studied extensively by biomedical researchers because of their physiological similarities to humans and because they are common animals in Africa. Baboons have also been studied intensively by anthropologists and evolutionary biologists interested in human origins. That is because the baboon evolved from an arboreal monkey that first exploited dry, open habitats some ten to twenty-five million years ago. In the past, anthropological theory suggested that our own ancestors followed a similar evolutionary pathway. Thus, baboons were seen for some time as a useful model for human evolution. This idea has changed somewhat over time as scientists have found that the group sizes, social organizations, and dietary habits of baboons probably do not mirror those of our ancestors. A more recent

Baboon Facts

Classification:
Kingdom: Animalia
Phylum: Vertebrates
Class: Mammalia
Order: Primates
Superfamily: Cercopithecoidea
Family: Cercopithecidae
Subfamily: Cercopthecinae
Tribe: Papionini
Genus and species: Papio cynocephalus (savanna baboon), *P. hamadryas* (hamadryas baboon), *P. leucophaeus* (drill), *P. sphinx* (mandrill)

Geographical location: Sub-Saharan Africa and parts of the Arabian Peninsula

Habitat: Mostly arid, tropical savanna-woodlands, but also temperate areas and rain forests

Gestational period: Six to seven months

Life span: In the wild, baboons older than fifteen years are rare, but in captivity adults may live to twenty-five or thirty years

Special anatomy: Reproductive females display a sexual swelling in the perineal region and around the buttocks that, at the time of ovulation, may contain several liters of fluid and turn bright red; adult males have extremely long canines which they use to threaten rivals, display their fighting ability to receptive females, or inflict wounds view holds that we can learn about antipredator behavior and habitat selection of our ancestors by observing baboons in similar habitats today.

Bibliography

Altmann, Jeanne. *Baboon Mothers and Infants*. Cambridge, Mass: Harvard University Press, 1980. This short book is highly readable and useful for a lay audience as well as the specialist reader. It takes an individual perspective and traces the life history of a remarkable set of individual yellow baboons.

Dunbar, R. I. M. *Primate Social Systems*. Ithaca, N.Y.: Comstock Publishing, 1988. This is a suitable textbook for undergraduates and contains a great deal of information about baboons mixed in with other types of primates. The author is an exert on gelada baboons.

Kummer, Hans. *In Search of the Sacred Baboon*. Translated by M. Ann Biederman-Thorson. Princeton, N.J.: Princeton University Press, 1995. An autobiographical account of Kummer's long career researching hamadryas baboons.

_______. *Social Organization of Hamadryas Baboons*. New York: Karger, 1968. Although old, this pioneering book has not been superseded by a more recent work. It remains the best description of the natural history of hamadryas baboons.

Smuts, B. B. *Sex and Friendship in Baboons*. Reprint. Cambridge, Mass: Harvard University Press, 1999. This very thorough and illuminating book describes baboon male-female social relationships in great detail. It is technical at times but rewards the diligent reader with unparalleled insights into the life of olive baboons.

BATS

Type of animal science: Classification
Fields of study: Anatomy, ecology, physiology, wildlife ecology, zoology

Over nine hundred species of bats have been identified, classified in the general order Chiroptera, the second largest order of mammals.

Principal Terms

INSECTIVOROUS: depending on insects as food
MAMMARY GLANDS: glands that, in the female, secrete milk
MARSUPIAL: an animal whose young shelter in the mother's abdominal pouch
NOCTURNAL: occurring in the night
PLACENTAL: an animal where the young are enclosed in a membrane inside the mother's body during pregnancy
TERRESTRIAL: relating to the earth
VERTEBRATE: having a spinal column

Bats are somewhat difficult to study because of their secretive, nocturnal habits and their flight capabilities. Although well over nine hundred species have been identified and catalogued, additional species have since been discovered, primarily from the South American rain forests. New ones remain to be discovered, and the classification of bats continues to be improved.

Bats are the most widely distributed kind of terrestrial mammal. They are found from Alaska to the tip of Argentina and from near the Arctic Circle to South Africa. They occur widely through the tropical regions and in the temperate zones.

Physical Characteristics of Bats

Although bats range in size from tiny hog-nosed bats that weigh less than a penny to flying foxes whose wing spans exceed five feet, the majority of bats tend to be small. Despite variation in size, all species of bat share the same body form, with certain similarities in fur and skin, wings, teeth, reproductive system and patterns, and visual and hearing systems.

The bat's skin is black or dark grayish brown in color, with tiny transparent hairs on the membrane surface. While most bats have small eyes, perhaps encouraging the misconception that bats are blind, their auditory system is developed to an extraordinary degree.

Of the bats who feed on animals, some feed on insects and whole animals; vampire bats, which occur from Mexico to Argentina, feed only on the blood. Plant-eating bats feed on fruit and flowers.

Female bats give birth at the roost site, frequently while hanging upside down. Bat young are born in a breech presentation and are helpless until they are large enough to fly. Brown bats reach adult size and begin to fly at three to four weeks of age.

The Behavior of Bats

The major behavioral pattern of bats is nocturnal activity. During nocturnal flight, bats are protected from being visually spotted by predators and from exposure to the sun and to high temperatures, which promote heat absorption and the loss of body water necessary for temperature regulation.

Bats routinely seek shelter during the daylight hours. Caves provide protection from the sun and predators and allow bats to conserve energy under consistent temperature and moisture conditions. Bats also shelter in tree cavities, crevices, buildings, and trees.

While tropical bats are active all year round, bats in temperate regions hibernate during the winter in order to accommodate the diminished food supply. Most hibernating bats spend the summer feeding heavily on insects, building up enough fat to provide energy during hibernation. During hibernation, the bat allows its body temperature to fall to that of the surrounding air, and as its pulse and breathing rates slow down, it essentially enters a state of suspended animation.

The sole characteristic that sets bats apart from other mammals is flight. Some bats fly high, fast, and far, while others fly more slowly, maneuvering around obstacles, catching their prey on the wing, or plucking it from the ground. Soaring is uncommon in bats, as is swift flight in comparison with birds. Bats fly in flocks sometimes numbering in the thousands, a precaution against predators.

Microchiropteran bats use echolocation, a pulse system of high-frequency sounds and their echoes, to navigate and to locate food. Bats emit sound, then receive and analyze the data from the returning echoes which provide information on direction and distance to the target. Best suited to short distances, echolocation is so accurate that some bats appear able to distinguish among individual species of insects.

Bats are allies of human beings in controlling the insect population. Most species of bats found in the United States feed on beetles, moths, and crickets, many of which destroy vegetation and are damaging to agricultural interests. Recent studies also suggest important uses for anticoagulent compounds, found in vampire bats' saliva, that hinder the clotting of blood.

Bat Facts

Classification:
Kingdom: Animalia
Subkingdom: Metazoa
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Theria
Order: Chiroptera (bats)
Suborders: Megachiroptera (flying foxes), Microchiroptera (bats)
Families: Pteropopidae (flying foxes, forty-four genera, 173 species); Rhinopomatidae (mouse-tailed bats, one genus, three species); Emballonuridae (sheath-tailed bats, thirteen genera, fifty species); Craseonycteridae (hog-nosed bats); Nycteridae (slit-faced bats, one genus, eleven species); Megadermatidae (false vampire bats, four genera, five species); Rhinolophidae(horseshoe bats, one genus, sixty-nine species); Hipposideridae (leaf-nosed bats, nine genera, sixty-one species); Mormoopidae (leaf-chinned bats, two genera, eight species); Noctilionidae (bulldog bats, one genus, two species); Mystacinidae (short-tailed bats, one genus, two species); Phyllostomidae (spear-nosed bats, forty-seven genera, 140 species); Desmodontinae (vampire bats, three genera, three species); Natalidae (funnel-eared bats, one genus, eight species); Furipteridae (thumbless bats, two genera, two species; Thyropteridae (disk-winged bats, one genus, two species); Myzopodidae (sucker-footed bats); Vespertilonidae (common or vesper bats, forty-two genera, 319 species); Molossidae (free-tailed bats, twelve genera, ninety-one species)
Geographical location: Every continent except Antarctica
Habitat: Mostly forests and deserts; some grasslands
Gestational period: Three to ten months, with delayed implantation
Life span: Generally three to five years; up to thirty years in captivity
Special anatomy: Head, body, tail, two wings, each supported by upper arm, forearm, hand; knee joints bend backward enabling the bat to hang upside down and still be ready to take flight easily

During the day, bats seek shelter in dark, enclosed spaces such as caves, tree crevices, and buildings, where they hang upside down until twilight. (PhotoDisc)

BEAKS AND BILLS

Type of animal science: Anatomy
Fields of study: Anatomy, ornithology

Ornithologists tend to use the terms "beaks" and "bills" interchangeably in referring to the horny part at the end of a bird's head. The terms also may be used to refer to a horny head part in other animals such as turtles or the duck-billed platypus. However, the vast array of sizes, shapes, and structures adapted for a multitude of functions is only seen among birds.

Principal Terms

ADAPTIVE RADIATION: the process by which many species evolve from a single ancestral species in adapting to new habitats

DISPLAY: usually a visible movement or behavior used as a social signal in the context of aggression, courting, etc.

EGG TOOTH: a hard, calcified structure on the tip of the bill of a bird embryo that is used to help the bird break its shell during hatching

POLYMORPHISM: the occurrence of two or more structurally or behaviorally different individuals within a species

SEX HORMONES: hormones—androgens in males, estrogens in females—which are associated with sex characteristics and sexual behavior

SEXUAL DIMORPHISM: a difference in structure or behavior between males and females

All birds have bills (or beaks), and these exhibit so much variation in their structure that they are useful as one of the distinguishing characteristics among species. Bills are toothless, except in embryos, and are covered with a horny sheath. Many of the variations in bill form are associated with specialized adaptations to different feeding habits. In addition to their obvious role in feeding behavior, bills have a function in a number of other behaviors. Some birds use their bills in different ritualized displays, including threat displays and appeasement displays. Some bills are used for digging, for nest-building, for "sewing," for drilling, and for many other activities.

Structure of the Bill

Anatomically, bills are a compact, modified layer of epidermal cells formed around the bony core of the upper and lower jaws, or mandibles. The bill is normally hard and thick, but it is not rigid, and different bills can be bent and twisted in different ways and to different degrees. For their size, bills actually are relatively light, one of the many adaptations in birds for flight. Although bills do not have teeth, adaptations in some forms have functions similar to those of teeth. Some bills have sharp edges, and these may function in cutting food, for example. There also are different specializations in the bony and muscular elements that operate in conjunction with bills to compensate for the different physical stresses imposed by feeding. It is interesting to consider where birds' nostrils are located. In most species, they are found near the base of the upper mandible, but there are some notable exceptions. In that unusual bird, the kiwi, perhaps the only species of bird with a well-developed sense of smell, the nostrils are located at the tip of the bill.

Some species of birds, including puffins and pelicans, have structures or projections on the bill that are present only around the breeding season and are then shed after reproduction. The brightly colored, triangle-shaped bill of the puffin has scales on both the upper and lower mandible, which seem to serve a role during courtship.

The bill of the developing embryo possesses an interesting structure: the egg tooth. The egg tooth is a hard, calcified structure on the tip of the bill of a bird embryo that is used to help the bird to crack and weaken the shell so that hatching can take place. The embryo also possesses a special muscle, the "hatching muscle" which provides the force behind the egg tooth. After hatching, the egg tooth either drops off or is absorbed.

Variations in Bill Structure

Given the variety of foods eaten by different bird species, it is not surprising that there are so many differences in the form and size of bills. What may seem surprising, however, is the observation that closely related species may have quite different types of bills. Two good examples of this phenomenon are seen in the finches of the Galápagos Islands and in the Hawaiian honeycreepers. Both of these examples illustrate nicely the process of adaptive radiation, by which many species evolve from a single ancestral species in adapting to new habitats. Similar to the Galápagos Islands, the islands of the Hawaiian chain are of volcanic origin and, moreover, they are even farther removed from any major landmass than are the Galápagos. It is thought that the ancestral form of the modern Hawaiian honeycreeper was a nectar-feeding honeycreeper type of bird that migrated to Hawaii from South America. The birds underwent a remarkable evolution, with new species formed as a result of adaptation to new feeding opportunities. Species became different not only in the shape of their bills but also in their coloration. Species were produced that were red, black, gray, yellow, and green. Beaks varied from those that were large and heavy for crushing seeds to long, thin beaks suitable for collecting nectar from flowers.

As remarkable as are differences in beaks among closely related species, even stranger are differences in bills among individuals of the same

Birds use their beaks much as other animals use their paws: to catch prey as this kingfisher has done, to preen themselves, and to build their nests. (Digital Stock)

Darwin: Beaks and Evolution

During its voyage around the world, the HMS *Beagle* visited the Galápagos Islands in 1835. It was there that Charles Darwin was able to observe the interesting variety of plants and animals. The Galápagos are removed from any large land mass, being situated about six hundred miles west of the coast of Ecuador. Darwin's observations of the islands' fauna contributed to the development of his ideas about evolution and the origin of species. The different animal species living in the islands were quite different from species anywhere else in the world. Of particular interest to him were the thirteen species of finches that he collected. Finches are small, sparrow-sized birds, and the thirteen species were similar to one another except for features related to their feeding habits, especially their beaks. Darwin noted striking differences in the size and shape of the beaks and observed that their structure was related to the type of food the birds ate. Short, thick beaks were suitable for crushing seeds. Long, thin beaks were useful for feeding on insects. Large beaks were effective in opening hard fruits. Each species appeared to be adapted to its own local food supply. Darwin reasoned that the finches in the Galápagos had descended from a single ancestral species that had come to the island from South America. The adaptive radiation of the finches was one of the cornerstones of his reasoning that adaptation to the local food supply was related to the origin of new species by the process of natural selection.

species. Bills of three different sizes are found in a finch from Africa, the black-bellied seedcracker. The bills occur in three discrete sizes, ranging from relatively small to relatively large, and the sizes appear related to the type of seeds eaten, with large bills being better suited for dealing with hard seeds and small bills being better adapted for soft seeds. Bills of intermediate size do not fare very well with either type of seed in comparison with either the small or large bills. However, the intermediates are necessary in order to have available the genetic capabilities for the other two sizes of bills. This type of selection is an example of disruptive selection, which in this case tends to produce individuals of the two extreme bill sizes.

Differences in bill structure between males and females of the same species are also known. The huia (probably extinct) is a bird in New Zealand with several unusual characteristics, the least of which is the structure of the bills in the two sexes. As is true of bills in general, the form of the bill appears related to its function. Males have a relatively straight and sharp bill, whereas females have a thin, downward curving bill which is much longer than that of the male. Males use their bills to dig open the burrows of grubs living in dead wood. After the tunnels are open, females use their bills to pull out the grubs. The different structures of the bills in males and females appear related to an interesting division of labor during feeding.

A final example of interesting variation in bills is a case in which the color of the bill changes seasonally within the same individual. The sex hormones, testosterone and estrogen, are responsible for the development of secondary sex characteristics and behavior in males and females, respectively. There are striking changes in behavior during the breeding season. The bills of male and female starlings change color, to yellow in the males and to red in the females, due to the action of these hormones during the breeding season.

Modifications of Bills for Feeding

As different species of birds are observed feeding, one has a sense of awe at the great diversity of dietary items and the variety of bills that are specialized to eat them. Foot items include nuts, hard seeds, soft seeds, insects, larvae, roots, flowers, sap, fungi, nectar, carrion, and other types of organic matter. The specializations observed in bills are adaptations for specific types of food. In a brief discussion, it is not possible to describe the many variations seen in the size and shape of bills, but even descriptions of a few representative examples provide the basis for appreciation of the exquisite designs and functions of bills.

In carnivorous birds of prey, such as falcons and owls, the beak is used as a meat hook. The birds typically seize their prey with their feet and disarticulate the cervical vertebrae by biting into the neck. The bill has a so-called tomial tooth on each side of the upper bill just behind the curved end of the beak. There is a notch or groove on the lower mandible that fits with the tomial tooth.

Birds that catch insects in flight, such as flycatchers, have beaks that are broad and slightly hooked. Frequently, there are long bristles or feathers at the base of the bill which facilitate the catching of the moving prey.

The bill of the crossbill shows some unusual features. The tips of the beak do not meet when they are closed. The tips are displaced to the side and move past one another as the mouth is closed. The end of the lower mandible may cross to the left or to the right of the upper mandible. This type of bill appears adapted for serving as a wedge to pry open the scales of pine cones, enabling the bird to insert its tongue and to remove the seeds from inside.

An interesting specialization is seen in the beaks of tropical fruit pigeons. These birds feed on large fruits, and their bills can open not only in the vertical plane but also in a horizontal plane, like the jaws of a snake when swallowing large prey.

It is evident from these examples that bills of birds have become adapted for their feeding. There are even some examples of species whose bills have become so specialized for their specific food that the number of birds is completely dependent on the availability of that food source.

BEARS

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, evolutionary science, wildlife ecology, zoology

Bears are large mammals making up the family Ursidae, that have adapted to habitats as diverse as the sea ice of the Arctic and the bamboo forests of China.

Principal Terms

CANID: a member of the dog family (Canidae)
CARNIVOROUS: eating meat
CARRION: the meat of dead animals
HERBIVOROUS: eating plants
OMNIVOROUS: eating both meat and plants
PLANTIGRADE: walking on the entire foot, not just the toes
TAXONOMIST: a scientist who classifies and gives technical names to plants and animals
UNGULATE: a hoofed mammal
URSID: a member of the bear family (Ursidae)

Bears are large mammals, and comprise eight species in Europe, Asia, North and South America, and the circumpolar Arctic. The earliest bears lived in North America and Europe during the late Eocene epoch, approximately thirty-seven million years ago. Bears are classified as carnivores, having evolved from small generalized predators. Functionally, however, bears range from the almost completely carnivorous polar bear to the almost completely herbivorous giant panda. The remaining six bear species are omnivorous, opportunistically feeding on a wide range of plants as well as mammals, fish, insects, and mollusks. A brown bear in Alaska, for example, emerging from its winter den in April or May, may feed on carrion (winter-killed moose or caribou), switch to grasses, sedges, and roots as spring progresses, and then eat mostly salmon as the summer salmon runs begin.

The Classification Controversy

While most taxonomists today recognize eight species of living bears, there has long been disagreement over whether to consider the giant panda (*Ailuropoda melanoleuca*) a true bear. The issue is complicated by the existence of the red (or lesser) panda (*Ailurus fulgens*). The red panda is raccoonlike in appearance, while the giant panda looks like a bear, yet the two pandas share some anatomical and behavioral features. The fossil record on pandas is scant. Recent molecular studies have shed new light on the issue but are not conclusive.

Anatomical, biochemical, paleontological, behavioral, and reproductive evidence is all relevant to this issue but is subject to differing interpretations by different authorities. Some place both pandas in the bear family (Ursidae); some put both in the raccoon family (Procyonidae); some consider the giant panda a bear and the red panda a raccoon; some put the two pandas in their own family, naming it either Ailuridae or Ailuropodidae; and some put the red panda in Ailuridae and the giant panda in Ailuropodidae. Clearly there is no simple answer to the question of how to classify the pandas. However, in general usage among both biologists and lay persons at the beginning of the twenty-first century, the giant panda is considered a bear, and the red panda is not.

Physical Characteristics of Bears

Bears are heavy-bodied, stout-legged, short-tailed mammals with long skulls and short snouts. Most bears have thick fur. All have five toes with nonretractile claws on each foot. Some have claws modified for climbing and some for digging. Bears are plantigrade, walking on the entire sole of the foot. Even lacking some of the modifications for speed possessed by canids and ungulates, some bears can run forty miles per hour. Bears have good, but not exceptional, eyesight and hearing. Their sense of smell, however, is excellent and greatly aids them in finding food.

Bears range in size from the sun bear, which weighs 60 to 145 pounds as an adult, to the male polar bear, which weighs up to 1,770 pounds. Large Kodiak bears (a type of brown bear) are almost as large as the largest polar bears. The extinct bear *Arctodus*, which lived during the Pleistocene epoch, was the largest bear ever, and may have reached fourteen feet tall when standing on its hind legs.

All living ursids have forty-two teeth. They have large canine and incisor teeth, the premolars are often reduced, and the molars in all except the polar bear form crushing platforms for grinding plant material.

Bear Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Suborder: Fissipedia
Family: Ursidae (bears)
Subfamilies: Ursinae, Tremarctinae, Ailuropodinae
Genus and species: Ursus arctos (grizzly or brown bear), *U. maritimus* (polar bear), *U. americanus* (American black bear); *Selenarctos thibetanus* (Asian black bear); *Helarctos malayanus* (sun bear); *Melursus ursinus* (sloth bear); *Tremarctos ornatus* (spectacled bear); *Ailuropoda melanoleuca* (giant panda)

Geographical location: Europe, Asia, North and South America, and marine areas of the Arctic

Habitat: Varies by species; temperate forests, subalpine mountains, tundra, grasslands, tropical rain forests, deserts, and sea ice

Gestational period: Seven to eight months for the American black, spectacled, brown, and polar bears; four to seven months for the Asiatic black bear, giant panda, and sun bear; unknown for the sloth bear

Life span: Wild bears typically live fifteen to twenty-five years; rarely, wild bears live past thirty, and captive bears have exceeded forty years

Special anatomy: All living bears except the polar bear have flat molars, which are adapted for crushing plant material; some bears have claws adapted for climbing and some for digging; although most bears eat a considerable amount of plant material, they have retained the short, simple gut of their meat-eating ancestors

Hibernation

During winter, in areas where food supplies are scarce, many bears den up for a winter sleep. This hibernation differs from that of such deep hibernators as ground squirrels. A ground squirrel's body temperature may drop to the freezing point (32 degrees Fahrenheit) or slightly below. A bear's body temperature drops only 5 to 9 degrees Fahrenheit from its normal level of 99 degrees Fahrenheit. Its heart rate drops from forty to seventy beats per minute to eight to twelve, and its metabolism drops by about half. This slowing of the body's processes combined with the heat-conserving properties of the den allow a bear to go up to eight months without eating or drinking. Stored body fat is the bear's only source of energy. Hibernating bears do not defecate or urinate. Brown bears and American and Asiatic black bears hibernate, as do pregnant female polar bears.

Reproduction

A brief mating season of one to two weeks occurs in spring or summer. Females in heat are followed and courted by males. There is often fighting among males, with the strongest and most aggressive winning the right to breed.

In bears there is a delay in the implantation of the fertilized egg in the wall of the uterus. In the polar bear, for example, mating may take place in April, but the embryo will not implant and begin to grow until October. Because of this delay, the cubs, when born in December, are small and relatively undeveloped, weighing 1 to 1.5 pounds. The female is in her winter den at this time and is living off her fat, and the needs of her cubs do not overwhelm her capacity to produce milk.

Bear cubs generally leave their mothers at 1.5 or 2.5 years, at which time the female is ready to breed again. Therefore, most female bears give birth to cubs every second or third year.

Behavior

Bears are intelligent, single-trial learners. They can remember where and when they have found food in the past—a trait that is very useful to them in the wild, but is a problem if they gain access to human food or garbage. Bears conditioned in this way can quickly lose their fear of humans and are potentially dangerous.

Cubs learn how to find food and other life lessons by observing their mothers. Other than family groups of a mother and her cubs, bears are usually solitary. However, a rich, concentrated food source, such as runs of spawning salmon in a river, may cause bears to gather in one area. In this case, a dominance hierarchy is established and maintained. Bears posture and threaten one another, communicating with body language and, to a limited degree, facial expressions. Fighting occurs and sometimes results in injury but is rarely fatal. Through this dominance hierarchy, prime fishing spots are claimed by dominant bears, as are breeding rights. Conflict is minimized as the bears concentrate on what is most important: eating.

Conservation

In many areas of the world, humans have converted wildlands into farms, tree plantations, oil fields, mines, suburbs, and cities. Many species of bears have been greatly reduced as a result. The giant panda, an endangered species, numbers only about one thousand in the wild. The other Asian bears—the sun, sloth, and Asiatic black bears, as well as the spectacled bear from South America—are also severely threatened. The American black bear, however, is thriving, with an estimated population of 450,000. Polar bear populations have been stabilized by a treaty limiting hunting to native peoples, but may now be threatened by global climate change. Efforts are being made to restore the grizzly (a type of brown bear) in some western areas of the United States.

The conservation of bears worldwide requires the protection of wildlands such as na-

Bears, such as this brown bear, are extremely intelligent mammals, and they learn from only a single exposure to a situation. (Corbis)

The Eight Species of Bears

The Brown bear (*Ursus arctos*) was once widespread in Europe, Asia, and North America, but is now much reduced. It is a large animal (up to 1,500 pounds) that has a varied diet, including grasses, roots, berries, insects, fish, rodents, moose, elk, caribou, and deer.

The American black bear (*Ursus americanus*) lives in the forested areas of Canada, the United States, and Mexico. It is the most numerous bear in the world, with an estimated population of 450,000. It is an excellent climber and feeds on a wide range of plant and animal species.

The Asian black bear (*Selenarctos thibetanus*) inhabits the forests of much of southern Asia. It is very similar to the American black bear in looks and habits.

The Polar bear (*Ursus maritimus*) lives in the marine areas of the Arctic, where its main foods are ringed and bearded seals.

The Sloth bear (*Melursus ursinus*) of India, Sri Lanka, Nepal, Bhutan, and Bangladesh digs into termite mounds and then sucks up the angry termites as they swarm out.

The Sun bear or Malayan bear (*Helarctos malayanus*) of the tropical rain forests of Southeast Asia eats fruit, honey, snails, eggs, lizards, rodents, termites, and earthworms.

The Spectacled bear (*Tremarctos ornatus*) of the Andes Mountains is the only South American bear. It is largely a fruit eater.

The Giant panda (*Ailuropoda melanoleuca*) survives only in limited mountainous areas of west-central China and in zoos. Its main food is bamboo.

tional parks, forests, and wildlife refuges, and the animals that inhabit them. In multiuse areas, careful management of bear populations can assure their survival.

BEAVERS

Types of animal science: Classification, ecology
Fields of study: Ecology, systematics (taxonomy), wildlife ecology, zoology

Beavers were almost wiped out in North America by the fur trade in the nineteenth century. Now thriving in many areas, beavers are a keystone species in their ecosystem because their activities modify habitats dramatically.

Principal Terms:

castoreum: a secretion from the castor glands, used in scent marking

Castoridae: rodent family to which beavers belong

sexual dimorphism: a marked difference between males and females in some aspect of animal morphology, such as body size

Beavers are semiaquatic mammals who live on ponds, lakes, or streams. Most live in groups called colonies, which together erect a home, called a lodge, constructed of mud and sticks. So-called bank beavers inhabit cavities in the sides of stream banks rather than lodges.

A beaver colony consists of a family comprising the breeding pair and their offspring from the previous two years. Typical colonies consist of four to eight individual beavers. Beavers appear to be monogamous, and females are dominant over males and juveniles, at least during parts of the year. Members of the colony work together to maintain the lodge, build dams, and defend their territory against other beavers. Beaver colonies occur in typical densities of 0.4 to 0.8 colonies per square kilometer, though they can occur at higher densities when suitable habitat is plentiful.

The Beaver Life Cycle

Beavers have a single breeding season, in winter, during which mating takes place. Females experience a period of estrus that lasts for about two weeks, during which they are receptive for ten to twelve hours. Gestation lasts for about 110 days. Litter sizes range from zero to nine, with an average of two to four young born each year. Beavers are born in a relatively well-developed state; their eyes are open and they are fully furred. Young beavers nurse from their mother for two or three

Image Not Available

months, though beavers begin eating some solid food at only a few weeks of age. Beavers reach sexual maturity at 1.5 to 2 years, at which time they are forced by their parents to leave the colony.

Beavers are herbivorous and eat the woody parts of trees and shrubs. Favorite foods include aspen and alder trees. Beavers will chew down large trees, not to gain access to the large trunks, which are impossible for beavers to move, but rather to gain access to smaller branches growing at the top of the tree, which the beavers then eat.

Active year round, beavers must plan ahead to provide food for themselves during the winter. During the warmer months, the beavers will group branches together in the water near their lodges. During winter, when the pond or stream ices over, beavers swim under the ice to gain access to these stick piles as a source of food. A beaver lodge is constructed with an underwater entrance. Thus, during the winter, beavers can enter and exit the lodge without ever coming up above the ice.

Beavers are known as important habitat modifiers due to their dam construction behavior. Beavers chew down trees and use the tree trunks and their associated branches to build dams along streams. Dams cause water pooling and slow the water flow behind the dam, increasing water depth and creating suitable areas for building lodges. Furthermore, beaver dams cause localized flooding that can dramatically alter landscapes. Once beavers have used all of the surrounding vegetation, either in dam construction or as food, they will relocate to a new area. The abandoned beaver pond eventually fills in to become a “beaver meadow” which supports a variety of plants that would not otherwise occur in that location.

Beaver Facts

Classification:
Kingdom: Animalia (Metazoa)
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Theria
Infraclass: Eutheria
Order: Rodentia (rodents)
Suborder: Sciurognathi (squirrel-like jaw musculature)
Family: Castoridae (beavers)
Genus and species: Castor canadensis (North American beaver), *C. fiber* (European beaver)

Geographical location: North America (*C. canadensis*), Europe and Asia (*C. fiber*)

Habitat: Ponds, lakes, and streams, except in southern Florida and the deserts of the southwestern United States

Gestational period: 100 to 110 days

Life span: Thirty-five to seventy years in captivity; ten to fifteen years in the wild

Special anatomy: Castor glands in both males and females are used for intraspecific communication; webbed hind feet and a broad flat tail allow for excellent swimming ability; dense, water-repellent fur

Physical Characteristics of Beavers

Beavers are one of the largest rodents, second in size only to the capybara. The two species in the family Castoridae are similar in many aspects. Both species show little sexual dimorphism and a normal range in body mass from twelve to twenty-five kilograms. Both male and female beavers have castor glands, which produce a substance called castoreum. Beavers deposit castoreum on piles of mud outlining the boundaries of their territories, in essence creating a message board for other beavers that pass by. Beavers also have broad, flat tails which are used not so much for packing mud, as is commonly believed, but instead as a means of communication. Beavers smack the water surface with their tails, producing a loud noise that can easily be heard by other animals. Beaver tails are also used for directional control while swimming.

Beavers are dark brown in color, and their thick fur coats contain a dense underfur that traps air and thus insulates the beaver. Long guard hairs provide a protective layer over the underfur. Their webbed hind feet function as excellent paddles when swimming. Forefeet are not webbed and thus are more capable of manipulating objects. Split claws on the first and second digit of the forefeet are used to groom the dense fur, thus maintaining its water repelling and insulating properties.

In North America, beavers have made a dramatic comeback in numbers after being hunted almost to extinction in the late nineteenth and early twentieth centuries. In Europe, beavers have fared less well and in some areas are listed as threatened or endangered, due mostly to destruction of suitable habitat.

BEES

Type of animal science: Classification
Fields of study: Anatomy, entomology, invertebrate biology

Over ten thousand species of bees form the order Hymenoptera. Honeybees, the best known, produce honey and beeswax.

Principal Terms

ABDOMEN: the hind part of a bee body, containing the stinger and most organs
PUPATION: the process whereby bee larvae metamorphose into bees
ROYAL JELLY: the protein- and hormone-rich food that workers feed queen larvae
THORAX: the midsection of the bee, from which legs and wings protrude

Over ten thousand bee species exist, classified in two groups. Social bees (for example, honeybees) live in groups of over ten thousand. Solitary bees (for example, carpenter and leaf cutter bees) live in smaller groups. Bees live from the tropics to the Arctic. Wild bees live in trees, bushes, and in the ground, building hives of beeswax, leaves, wood, or clay.

The best known and most plentiful bees are honeybees, imported to the United States during European colonization. Millions of U.S. honeybee hives produce hundreds of tons of honey yearly, one third of the honey made in the hives. The rest of the honey sustains the bees.

Honeybees—social bees—produce beeswax hives, each holding over ten thousand bees. Solitary carpenter bees tunnel into wood, such as trees or fence posts. Their colonies contain about one hundred bees. Another solitary bee class, the leafcutters, tunnel in wood and build from leaf bits joined by secreted glue. Miner bees live in sandy tunnels in groups of several thousands. Adult solitary bees are males or females.

Physical Characteristics of Bees

Bees are 0.1 inch to 3 inches long. There are three types of honeybees: workers, queens, and drones. In any given hive, 95 percent of the bees are immature female workers, 5 percent are males (drones), and one is a mature female (queen).

Image Not Available

The worker bee's main body parts are head, thorax, and abdomen. The head has five eyes, two antennae, and a mouth. Three small eyes sit atop the head, arranged triangularly. Two compound eyes at the front of the head contain many six-sided facets. Eye number, design, and arrangement give keen eyesight. Two antennae, organs of smell, protrude from the head. Their uses include finding food and recognizing bees that do not belong in a hive. The important mouth parts are the tongue and jaws. The tongue, a long, slender lower lip, is rolled in a tube used to sip flower nectar. Scissor-shaped jaws cut and shape things or bite defensively.

The thorax, behind the head, holds wings and legs. The four membranous wings beat over ten thousand times a minute. Front wings hook to rear ones to work as synchronized propellers. Wing speed and synchronization let bees fly precisely and carry loads of food outweighing the in-

René-Antoine Ferchault de Réaumur

Born: February 28, 1683; La Rochelle, France
Died: October 17, 1757; Saint-Julien-de-Terroux, France
Fields of study: Biology, entomology, chemistry, metallurgy
Contribution: Réaumur was the greatest entomologist of his time. He also made contributions to the biology of regeneration, metallurgy, chemistry and the early biochemistry of digestion.

René Antoine Ferchault de Réaumur was born in La Rochelle, France. Nothing is known about his early life. However, Réaumur became—among many other things—the foremost entomologist of his time. The fires that forged Réaumur began when he moved to Paris in 1703. In 1708, he was appointed to be a member of the highly prestigious French Academy of Sciences.

In 1710, King Louis XIV charged Réaumur with preparing a complete description of all the industries and natural resources of France. He was to prepare a document describing all the arts, industries, and professions present throughout the country. During this process, which concluded with his contributions to the Academie Royale des Sciences' publication of the *Description des Arts et Metiers* (1761-1798, 42 vols.; description of arts and handicrafts), Réaumur acquired a very wide knowledge of contemporary scientific and technological endeavors. This knowledge and the compilation of the huge report desired by Louis XIV were to stand him in good stead in many other scientific endeavors.

Among the wide-ranging scientific contributions arising from Réaumur's many activities in carrying out the king's charge were important contributions to metallurgy and to understanding the chemistry of iron and steel. He was the first scientist to recognize the importance of the carbon content of iron preparations that become steels of different types. In addition, in 1720 Réaumur invented the cupola furnace used for the melting of gray iron. Use of this furnace is still the most economical and widely utilized method for carrying out this process.

In 1734, Réaumur published the first volume of the work that was to make him the foremost entomologist of his time: *Mémoires pour servir à l'histoire des insectes* (1734-1742, 6 vols.; memoirs serving as a natural history of insects). The huge endeavor produced the first serious, complete, and comprehensive entomological work.

An overall naturalist, Réaumur's contributions to biology also included the discovery of the ability of crayfish to regenerate lost limbs. Furthermore, combining the known chemistry and biology of the day, Réaumur isolated gastric juice from animals and showed that its operation was chemical. He demonstrated the process in the laboratory in 1753.

In 1740, Réaumur's ability as a complete scientist led him to develop an opaque form of porcelain, still used, called Réaumur porcelain. He also invented, in 1731, a temperature scale or thermometer based upon the use of an alcohol-water mixture, in which water froze at 0 degrees and boiled at 80 degrees. This Réaumur temperature scale was widely used until the end of the twentieth century.

—Sanford S. Singer

dividual bee. The three legs on each side of the thorax end in claws and sticky pads, enabling bees to hang from flowers or walk upside down across hives. Bee legs and bodies are covered with fine hairs. They collect pollen (the second bee food after honey), which is transferred, via leg combs, to pollen baskets in the hindmost legs.

The abdomen, behind the thorax, contains the most organs. Beeswax, made in the abdomen, collects on abdomen wax plates harvested by mouth and used to build hives. At the rear of the abdomen is a stinger. It is 30 percent of the length of the bee's body. In worker bees the stinger is barbed, so that it remains in the animals it stings. This is fatal to the bee, because in freeing itself from its victim a bee rips away much of its abdomen. "Stingless" bees and drones lack functional stingers. Queens have barbless stingers.

Bee Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Arthropoda
Class: Insecta
Order: Hymenoptera (bees, ants, and wasps)
Suborder: Apocrita
Superfamily: Apoidea, with six families, four subfamilies, and tribes Bombini (bumblebees), Meliponini (stingless bees), Apini (honeybees)

Geographical location: Every continent except Antarctica

Habitat: All live on land in forests, plains, swamps, and deserts; colonies are in hives or tunnels, in trees, fallen logs, or sandbanks

Gestational period: Three to five weeks

Life span: Honeybee workers live six to eight months, queens live up to ten years, and drones live until winter; solitary bees do not live in hives kept warm year-round, so most die in winter

Special anatomy: Three legs on each side of the thorax; two pairs of synchronized, membranous wings; a poison stinger; a tongue for sipping nectar; pollen baskets

The Life Cycle of Bees

Every honeybee begins as an egg laid in a beeswax cell. In three days a grub hatches. Workers first feed all grubs royal jelly. Soon, worker grubs get a honey-pollen substitute. After several days, the queen grubs are sealed into cells and enter a third life stage, pupation, spinning cocoons and metamorphosing into queens. Drones, from unfertilized eggs, only fertilize queens leaving to begin new colonies. This kills the drones and gives each queen enough semen to fertilize all the eggs—often a million—she lays during her life.

Workers do all hive jobs except egg laying. They feed grubs, guard hives, keep air fresh by beating their wings to make air currents, gather pollen and nectar, seek bee glue (propolis) from trees, use propolis to mend hive-wall breaks, and build egg, honey, or nectar cells. They die six to eight months after birth.

Solitary bees differ from honeybees in several ways. First, all are functional males or females. Second, they make homes from leaves (leaf-cutter bees), wood (carpenter bees), or clay (mason bees). They lay eggs in cells holding pollen and honey, and larvae and pupae develop independently. Their colonies are smaller than honeybee hives because winter kills most inhabitants; colony continuation depends on female survivors. Finally, their jaws and stingers differ, enabling the use of different materials in building from their environment.

Destructive and Beneficial Bees

Bees pollinate most flowering plants, and thousands of plant species could not survive otherwise. In addition, the bee industry annually gleans hundreds of tons of honey and beeswax, earning sixty million dollars a year. Sweet, nutritional honey is used to flavor drinks, as a health food, and in salad dressings, is poured over pancakes, and is used in many other ways. Beeswax also has many uses, from candles to lipstick and eyebrow pencil components. Even "destructive" bee stings may have benefits; many people believe that stings cure arthritis and rheumatism.

BEETLES

Types of animal science: Anatomy, behavior, classification, ecology, geography, reproduction
Fields of study: Anatomy, ecology, entomology, reproduction science, zoology

Over 300,000 species of beetles have been identified, classified in the general order Coleoptera, the largest order of animals in the insect world. Beetles constitute more than 40 percent of the 700,000 known insect species.

Principal Terms

CUTICLE: outer nonliving layer of the beetle's body
ELYTRA: rigid front wings of beetles, that cover the second, functional pair of wings
EXOSKELETON: the external skeleton of beetles
MANDIBLES: insect jaws
MOLTING: the sloughing off of old body covering, which permits the beetle to grow
PARTHENOGENESIS: reproduction in which an unfertilized egg hatches
THORAX: the middle section of insects, from which the legs protrude

Beetles are the largest order of both the insect and the animal worlds. Approximately 300,000 species, some 26,000 of which exist in the United States, have been identified. Every year, however, thousands of new species are discovered and classified. Beetles are found on every continent except Antarctica. There is no reason to believe that some of these highly adaptable creatures do not exist on the somewhat temperate Antarctic Peninsula.

Although most beetles are land animals, some are aquatic, carrying air bubbles on their legs, which provide them with air when they are submerged. Most aquatic beetles live in freshwater, feeding on small fish and tadpoles, although a small number of beetles live in salt water. Other beetles live largely underground or beneath the bark of trees, while some species go through their life cycle in caves and are blind. The remarkable adaptability of beetles, which date to the Triassic period, has made them one of earth's most enduring species and accounts for their being found in a broad variety of geographical locations and climates.

Physical Characteristics of Beetles

With over 300,000 species of beetles cataloged and classified, the variations within each species are notable. These insects can range in size from very small to quite large. The fungus beetle is smaller than the period at the end of this sentence, never growing beyond one-fiftieth of an inch in length. The Hercules beetle, found in Central American rain forests, is typically six inches long and often exceeds that length.

Despite variations in size, each species of beetle shares anatomical characteristics with every other species. All beetles have three main body parts in common: the head, the thorax, and the abdomen. The head usually contains the mouth and the eyes, although some blind cave beetles have no eyes. All beetles have antennae that protrude from the front of the head and are vital to communication. Blind beetles have more fully developed antennae than sighted ones.

A beetle's mouth consists of three parts, the frontal mandibles, the maxillae or second jaw in four or five sections, which is jointed and has palpi (segmented appendages) on its outer side, and the labium or lower lip, which resembles the maxillae but has only three sections. In vegetarian beetles, the jaws point down, whereas in predatory beetles, they point forward.

The thorax is behind the head and consists of three segments. The first, the prothorax, larger in beetles than in other insects, has one pair of legs on its underside. The second segment has a second pair of legs and the elytra, the cutaneous wing covers found in all beetles. In some species of ground beetles that do not fly, the elytra may be joined as a single, hard piece of cuticle. The third segment bears the third pair of legs and the delicate hind wings used for flying by species that fly.

The abdomen, which contains most of the beetle's internal organs, is behind the thorax. It has nine segments, not all of which are visible. In most species the abdomen is covered almost entirely by the second pair of wings, although in a few species, up to half the abdomen is exposed. In most species, a straight line runs along the abdomen where the two elytra meet.

Regardless of size or species, all beetles share this basic anatomy. Individual differences, however, characterize various species. Ground beetles that tunnel into the earth have short, strong legs with projections that make them efficient diggers. Predatory beetles have long legs because they must move rapidly to trap their prey.

Image Not Available

The Life Cycle of Beetles

All beetles pass through four stages of development, called metamorphosis. Life begins within eggs laid by the female beetle, usually in a protected place such as beneath a rock, on the underside of a leaf, or inside the bark of a tree. The females in some species lay up to two thousand eggs at once, while in other species a single egg is laid.

When the eggs hatch, a small wormlike creature, called a larva or grub, emerges. The larvae of some species are mobile and have legs, while those of other species may be legless and can move about only by wiggling. Those with legs are predatory and move about easily in their quest for food. The legless larvae usually attach themselves to plants and survive by eating the leaves. Beetle larvae have huge appetites and frequently are destructive to crops. Their voracious eating causes them to grow rapidly, forcing them to shed their old skins, which they outgrow, in a process called molting.

When the larva reaches full size, it enters the next phase of its metamorphosis by becoming a pupa, sequestering itself in a safe place where it remains for about a month. Its body changes drastically as it evolves toward its adult stage. When the pupa cracks, the adult beetle emerges, its body soft and flexible. Within twenty-four hours, however, the body hardens and the metamorphosed beetle looks and acts like other adult beetles.

The integrity of the species is maintained in some types of beetles by the shape of the male sexual organs which allows them to enter only females of that species. Also, the white fringed weevils of Argentina and some other beetles are parthenogenetic, which means that their eggs are not fertilized by a male. This species is exclusively female.

Destructive and Beneficial Beetles

Many species of beetles are destructive, devouring everything in their paths, ruining crops, devastating forests by attacking the roots of trees, and wreaking general havoc wherever they exist. Japanese beetles were particularly destructive to farm crops in New Jersey during the 1930's. The boll weevil deposits its eggs in vegetables or in the blossoms of cotton plants. The resulting larvae quickly consume the plants in which they are hatched. Some types of beetles eat grain and flour, while the larvae of carpet beetles eat all kinds of fiber.

The predatory nature of some species of beetle can help solve ecological problems. St. John's wort, also called Klamath weed, is a rapidly growing plant that annihilates grasses that grow in the places where it takes hold. It also causes animals that eat it to have sore mouths and debilitating skin eruptions. When it was discovered that a leaf beetle the size of a pea would devour this intrusive plant, such beetles were introduced into the affected areas and within a few years had eradicated the plant.

Ladybugs contribute to agriculture by eating aphids and other pests from the leaves of plants. In many parts of the Third World, people depend upon the larvae of beetles to add protein to their diets. Many folk remedies, including aphrodisiacs and diuretics, are made from dried beetles. Scarabs and other beetles consume carrion and clear away dead material that is potentially infectious.

—*R. Baird Shuman*

Beetle Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Arthropoda
Subphylum: Unirama
Class: Insecta
Subclass: Endopterygota
Order: Coleoptera (beetles)
Suborders: Polyphaga (rove beetles, scarabs, stag beetles, metallic wood boring beetles, click beetles, fireflies, blister beetles, mealworms, ladybugs, leaf beetles, longhorn beetles, weevils); Adephaga (ground beetles, tiger beetles, predacious diving beetles, whirligig beetles); Archostemata (small, rare group characterized by wings coiled in a spiral)
Geographical location: Every continent except Antarctica
Habitat: Mostly land (forests, deserts), although some live in freshwater and a rare few in salt water
Gestational period: Varies greatly among species
Life span: Many exist for four months to a year; several species of ground beetles in Alaska, protected from subzero temperatures by an ability to produce glycerol that creates an antifreeze in their bodily fluids, survive for up to eight years
Special anatomy: Six legs, three on each side of the thorax; two pairs of wings, two hard, cutaneous wings on top that serve as armor, two more membranous wings underneath used in flying

Some Types of Beetles

Blister beetles, which are usually brightly colored, emit a strong chemical that blisters the skin of predators intent on harming them.

Carpet beetles live and breed in houses, often laying their eggs in carpeting. Their larvae eat carpets and other items of cloth.

Click beetles can arch their backs so that a protrusion pops out, stinging the mouth of any predator. If it is dropped on its back, it can click again and land upright.

Japanese beetles, brought into the northeastern United States on produce from Asia, are extremely destructive to plants of every variety.

Metallic wood borers, living largely beneath the bark of trees, have mouths designed for drilling into wood both for food and to provide a safe place to lay eggs.

Rowing beetles live on the surfaces of freshwater lakes and ponds, using their well-developed middle and hind legs like oars to move across the water at the rate of sixty strokes a minute.

Scarab beetles, also called Dung beetles, roll animal waste such as horse manure into balls—sometimes as large as baseballs—and lay their eggs inside; these balls provide food for their larvae.

Tiger beetles, unlike most other beetles, can fly immediately without first warming up in the sun or climbing to the edge of a leaf or end of a stem to take off.

BIODIVERSITY

Type of animal science: Ecology
Fields of study: Ecology, environmental science, population biology

Biodiversity refers to the total number of animals and other forms of life, including different species and genetic variants.

Principal Terms

AQUACULTURE: the artificial growth of animals or plants that live in the water; the culture of something living in water

BIODIVERSITY: the number and kinds of animals and plants and the variations in genetic material they possess

EXOTIC SPECIES: organisms that are not naturally found in a place but have been artificially introduced, whether by accident or intentionally

EXTINCT: no longer found anywhere on earth

EXTIRPATED: not found in an immediate local area but found elsewhere on earth

HABITAT: an assemblage of plants, animals, and the physical land, water, minerals, and other elements that support a life-form; usually refers to a single species

INVERTEBRATE: an animal without a backbone; for example, worms, clams, crabs, insects, and jellyfish

SPECIES: a group or groups of interbreeding natural populations of organisms that are reproductively isolated from other such groups

SUBSPECIES: a group or groups of interbreeding organisms that are distinct and separated from similar related groups but not fully reproductively isolated

THREATENED SPECIES: animals or plants so few in number that they may soon be endangered and then extinct

The study of biodiversity is relatively new. The word was coined by Edward O. Wilson in order to explain the biological living resources and wealth lost when whole areas of tropical rain forest were destroyed by clear-cutting and burning. Many, if not all, of these tropical rain forests were in remote areas, often in developing countries, untouched by modern civilization, and relatively unstudied by scientists. As a result, many of the plants and animals, especially insects, were unknown to scientists. Many of the species lived nowhere else on earth and, once destroyed, became extinct. Scientists realized that these tropical rain forests held a great wealth of species and that their destruction was removing large numbers, perhaps millions, of species, along with the DNA that made each species unique. Wilson referred to this loss of species as a loss of the forests' biological diversity, or biodiversity. The loss is not merely of the species that become extinct but also of the combination of highly specific genetic material in each species.

Because the study of biodiversity involves the study of individual species, their loss, and their habitat, the subject is closely tied to endangered species, ecology, and conservation biology. Endangered species are those plants and animals that are nearly extinct; threatened species are not yet at the point of being endangered but will be if measures are not taken soon. Both plants and animals, including insects, worms, clams, crayfish, and other creatures, may be considered either threatened or endangered. Specific habitats, especially those that are unique and found in only one location on earth, can also be considered threatened. Protecting individual species often means protecting the habitat the species needs for survival.

During the nineteenth century and the first part of the twentieth, some animals were hunted to extinction. Several other species were hunted to near extinction or were extirpated (removed) from large areas, largely by extensive changes to their habitats. As a result of the losses and near losses, some scientists, resource managers, and political leaders instituted programs and activities to prevent extinction and to restore species that were near extinction. Animals (and later plants) that were near extinction were officially designated as endangered and given legal protection to prevent their extinction. Eventually these efforts grew to encompass a much broader field of work by experts in many fields.

One of the more difficult aspects of protecting a single species is the importance of the habitat to the well-being of the species. This fact is one of the underlying principles driving the whole study of biodiversity. Scientists have learned that the habitat is critical for restoration of a species and that protecting the habitat is a powerful means of preventing species loss and protecting biodiversity. As a result, programs and individuals trying to protect or restore biodiversity or individual species have come into conflict with those who use or plan to use large areas of land and whole habitats for purposes such as housing or industrial development, harvesting, and aquaculture.

Threats to Biodiversity

Scientists generally believe that three major factors cause the loss of biodiversity: resource overharvesting, habitat loss, and introduction of exotic species. Overharvesting or excessive hunting and catching caused the loss of species such as the great auk, passenger pigeon, and Steller's sea cow. Some species of whales nearly suffered the same fate. However, for the vast majority of animals and plants, overharvesting is not a major cause of endangerment or extinction. Many animals that are commonly harvested have large and dispersed populations, so harvesting stops before it causes populations to decline to the point of endangerment and extinction. This does not mean that overharvesting is not a problem, but that it is seldom the sole cause of population declines and not the most frequent cause.

A number of international controls have been implemented to prevent, limit, or discourage the killing of some of the animals that are threatened by overharvesting in many countries around the world. Many such controls ban the import or shipping of either live animals (tropical birds such as parrots) or parts of them (elephant ivory and rhinoceros horn). The animals endangered by overharvesting—the rhinoceros, elephant, and parrot—tend to be long-lived and restricted in distribution. Their reproductive rates are low, and populations often require a large habitat. The habitats of many of these animals are threatened by human activities, which makes the effect of their being slaughtered for commercial reasons that much more pronounced. In 1997, one of the major international treaties governing commercial transactions in rare and endangered species was modified to permit some African nations to sell stocks of certain animal products that had been previously prohibited. Some experts worried that the change in the laws would again provoke illegal overharvesting.

Many animals are threatened in their native habitats by exotic species introduced into the area. These exotic species often cause biological pressures that the native species cannot handle. They may threaten native species directly by competing for food, living space, critical habitat (such as nesting space), or other necessary environmental resources. Some exotic animals are aggressive and drive away or attack the native ones. In the United States, sea lamprey were introduced into the Great Lakes and have driven populations of many native species to precipitously low levels or even extirpated them.

Exotic species may also present indirect threats by introducing diseases, parasites, or hitchhiker species that arrive with the exotic. In South Carolina and Texas, exotic shrimp are used in aquaculture, and they can carry a deadly virus that may threaten native shrimp if released into the wild by accident. Zebra mussels were carried into the Great Lakes water system in the ballast water of ocean tankers. With no natural controls, zebra mussels have multiplied to the point that they are not only a nuisance to human activities but also serious competition for native aquatic animals.

Habitat Loss and Degradation

The most significant threat to biodiversity, as occurs in tropical deforestation, is habitat loss or degradation, including poisoning. Habitat loss is the elimination of a habitat, often by cutting, plowing, filling, or other construction or harvesting methods. When all the trees in a forest area are felled for wood (a practice known as clear-cutting), the habitat is lost until the trees regrow, an event that may never take place. Degradation is the elimination or lessening of some characteristic of the habitat that is critical for one or more species. Changing the temperature or speed of the water flowing in a stream can render it no longer suitable for a particular fish or mussel. Filling or draining a wetland alters the moisture content of the soil and changes its suitability for plants or animals.

One of the earliest examples of habitat degradation was the poisoning of bald eagles and peregrine falcons in the United States by the pesticide dichloro-diphenyl-trichloroethane (DDT). DDT was widely used throughout the world (and still is in some countries), is highly persistent, and accumulates in animals at ever-increasing levels in a trophic system (a system in which one animal feeds on another that feeds on another, and so on). Falcons and eagles were some of the birds of prey that took in so much DDT that they were poisoned and their eggs became too thin-shelled to survive. Their populations began to decline from reproductive failure. Many species of freshwater mussels are highly sensitive to chemicals and do not survive even low levels in the water. Many of the mussel species have become rare and endangered as a result of this poisoning, and they are not the only species to suffer from environmental poisons.

Altering stream and river flow via dams, diversions, withdrawals, and dredging is another form of habitat degradation that can dramatically change the way animals and plants use the aquatic system. In river systems throughout the Pacific Northwest, salmon return from the ocean to spawn (lay eggs and reproduce) in the river where they grew from egg to fish before migrating to the open ocean. If a dam blocks the river or if the conditions in the river are no longer suitable, the salmon are not able to spawn. In salmon, the fish that spawn in a given river are distinct and genetically identifiable, almost forming a subspecies. Therefore, authorities in the Pacific Northwest have had to determine the relationship between individual spawning groups and the watershed habitat before altering streams and rivers.

The cutting of mature forests in the Pacific Northwest and in Alaska eliminated the habitat for the spotted owl. Great controversy resulted from limits, restrictions, or bans on logging in these forests, which were prized for the high quality lumber that could be made from the trees. These and similar conflicts formed the basis for many studies on scientific, legal, and policy matters concerning the Endangered Species Act in the United States.

Controversies have arisen over habitat protection programs and laws in the United States and other countries because of the restrictions and limitations imposed on development, logging, and other human activities. People on one side argue that the potential benefits from protecting a species are greater than any inconvenience or costs that might ensue, and those on the other side argue that the economic benefit from the activity that threatens the species outweighs any ecological concerns. However, in some cases, companies and governments have worked hard to preserve species believed to be of economic value.

Biodiversity Research

Biodiversity is studied at the level of populations, of individuals (including molecular biology), and in the interactions between organisms and their environment. Research on biodiversity includes genetic, ecological, and behavioral studies and investigations focusing on diseases and life histories.

Loss of habitat, often through clearcutting forests, is one of the greatest threats to biodiversity today. Many territorial animals require large ranges, and breaking up forest space (habitat fragmentation) is as destructive as cutting down the whole forest would be. (PhotoDisc)

Much of the work on any specific species, especially large vertebrates, is conducted in the field, using techniques for observing, counting, tracking, and monitoring the population. Most invertebrates cannot be studied other than by observation and counting. One of the goals of ecological research on biodiversity is to understand the life histories and ecology of individual species. Scientists seek to explain life span, reproductive patterns and strategies, food preferences, environmental requirements, and limits. Other major goals are to describe the habitat requirements and better understand the relationship between the species and the habitat.

The management and legal aspects of various programs are included in biodiversity studies. This research is closely related to the field of conservation biology. Such study entails examining areas such as how programs work; what money is spent, by whom, how, and for what use; whether habitats or species are protected, restored, or lost; and the time required for various activities. These considerations are generally part of program evaluation, a topic that can be more thoroughly researched in the field of management science. The legal aspects of preserving biodiversity and protecting endangered species have been studied by a number of legal and policy-making organizations, including the Environmental Law Institute and Environmental Defense Fund, both of Washington, D.C. The National Research Council, the operating arm of the National Academy of Sciences has published a number of reports on the Endangered Species Act, and these usually address legal, policy, and science issues.

Modern molecular genetic techniques are applied to the study of individual species of plants and animals and their restoration. Tissue, often a blood sample, taken from a single individual is analyzed to determine the genetic relations among members of a population. Scientists may then assess the potential of the remaining individuals to act as the beginning or nucleus for a new population. Modern techniques can determine the genetic makeup of animals and whether the individuals are distantly enough related to form a breeding pair without suffering the adverse consequences of inbreeding.

Artificial breeding and culture are techniques often employed with the few remaining members of a population. These animals may be brought in from the wild and confined, as were the last remaining California condors. The animals are kept in captivity so that artificial breeding and maintenance techniques can be used to raise additional members of the population. Once the population is large enough for release or other factors are favorable, reintroduction into the wild may be attempted.

Zoological parks and botanical gardens have been involved in maintaining the few remaining specimens of some species. With the help of such facilities, animal tissue has been stored in culture, and sperm have been frozen for later use in breeding. Parks and gardens now play an active role in species propagation and husbandry through breeding, nourishment programs, studying and preventing disease, and behavioral training to reintroduce zoo animals into the wild.

Increasing Awareness of Biodiversity's Importance

Human activities eliminated more than a few animals from the face of the earth before the second half of the twentieth century, when national and international laws were enacted to protect endangered species and the modern environmental movement began. Among the animals lost were the great auk in 1844 and the passenger pigeon in 1914. These animals were hunted to extinction under the mistaken belief that extinction could not happen, and because authorities lacked a way to limit the hunting of the animals. Despite international efforts to protect animals from extinction, in the latter part of the twentieth century many countries allowed or encouraged the wholesale destruction of tropical rain forests, along with the animals that lived there.

In 1973, amid growing awareness of the need to prevent further extinctions, the Endangered Species Act was passed by the Congress of the United States. The act gave the U.S. Fish and Wildlife Service the responsibility for enforcing the law and set procedures for determining which species should be listed as endangered. The act also established the category of threatened species to protect those that were close to becoming endangered. Subsequently, this protection was extended to the habitats on which the animals depend.

Studies by academic and government scientists revealed that most species are threatened by habitat loss or degradation, overharvesting, or exotic species. Most of the problems arise from habitat loss or degradation rather than overharvesting, which had been the cause in several of the cases that prompted passage of the Endangered Species Act. Scientifically, and eventually legally, one of the most difficult tasks is to determine habitat requirements and then ensure that the required habitat is protected. Identifying and protecting habitats became an important part of all programs aimed at protecting biodiversity. Loss or degradation of habitat became one of the criteria that federal agencies used to take legal action or make official decisions.

Many human activities such as logging, building, mining, and farming can destroy or degrade valuable habitats on which endangered species depend. As a result, endangered species protection programs and activities have been in conflict with some business interests seeking to carry out those activities that threaten species or their habitats.

Efforts, activities, and programs to protect biodiversity rely on the latest techniques and methods. These include electronic tracking of large animals, molecular analysis of genetic material, and cellular studies of tissues to help determine actual or potential threats to animals. Ecologists investigate life histories, including feeding habits, environmental requirements and limits, and migration patterns.

Bibliography

Burton, John, ed. *The Atlas of Endangered Species*. 2d ed. New York: Macmillan, 1999. This book, written by experts on various regions of the world, examines global aspects of species endangerment. It makes the topic real as it explains the causes and consequences of loss of species and the threat of loss throughout the globe. Beautifully illustrated. Includes references and an index of the species mentioned and some of the organizations working on the problem. The book deals with vertebrates, plants, and habitats.

DiSilvestro, Roger L. *The Endangered Kingdom: The Struggle to Save America's Wildlife*. New York: John Wiley & Sons, 1989. This book deals with endangered species and the efforts to save habitats and animals. It focuses on large vertebrates and birds and examines programs, case histories, and efforts by organizations and individuals.

National Research Council. *Science and the Endangered Species Act*. Washington, D.C.: National Academy Press, 1995. This volume is the report of the National Research Council study committee that was asked to resolve several difficult questions encountered in applying the federal Endangered Species Act. This well-written and thoughtful book is not overly technical because it discusses how the scientific information is applied. It includes a copy of the act, a history of the issue, causes of species extinctions, and numerous references, both technical and nontechnical. It deals with the scientific, legal, and policy aspects of endangered species.

New, T. R. *An Introduction to Invertebrate Conservation*. New York: Oxford University Press, 1995. This book covers the problem of endangered species of invertebrates, although in a somewhat technical fashion. The initial chapters explain the relation among biodiversity, endangered species, and conservation. The author directly addresses why protection of these animals is important. The book includes chapters on science, law, policy, case studies, and causes for invertebrate species endangerment. College level, extensively referenced.

Raven, Peter H., and George B. Johnson. *Biology*. 4th ed. Boston: McGraw-Hill, 1996. This introductory college biology textbook is a wonderful reference for general purposes at many levels. It comprehensively covers plant and animal biology in the context of environmental issues. The last of five chapters on ecological topics addresses such global environmental topics as loss of species and critical habitats. The chapters on genetics, heredity, and reproduction provide the basics in these related subjects. Study questions and additional readings make this a valuable reference.

Ricketts, Taylor H., et al. *Terrestrial Ecoregions of North America: A Conservation Assess-*

ment. Washington, D.C.: Island Press, 1999. A detailed assessment of North American biodiversity and the threats to it, by the U.S. and Canadian scientific staffs of the World Wildlife Fund. Includes maps and a glossary of technical terms.

Stefoff, Rebecca. *Extinction*. New York: Chelsea House, 1992. This book, written for the general reader, explains the nature of endangerment of species and compares loss of species through natural means with that from human activities. Photos provide both classic and modern images of species extinctions.

Tudge, Colin. *The Variety of Life: The Meaning of Biodiversity*. New York: Oxford University Press, 2000. A massive survey of biodiversity, dealing with the problems of cladistics, the craft and science of classification, and covering the entire spectrum of life on earth today, as well as a few extinct forms such as dinosaurs. References and index, as well as many illustrations and diagrams.

Wilson, Edward O., ed. *Biodiversity*. Washington, D.C.: National Academy Press, 1988. This volume is a collection of fifty-seven essays by nationally and world famous scientists who gathered at the Smithsonian Institution to present their views on the causes of species extinctions. Subjects range from international policy to the value of animal and plant species and the cause of species loss. Chapters 26 through 29 discuss how endangered species are identified and monitored. Chapters 30 through 37 specifically address activities to restore or recover endangered species.

BIOGEOGRAPHY

Types of animal science: Ecology, evolution, geography
Fields of study: Ecology, evolutionary science, paleontology, population biology

To understand the underlying geography of plant and animal distributions, biogeographers must integrate considerations of historical and current events and conditions.

Principal Terms

BIODIVERSITY: all of the different kinds of organisms living on earth or in a given area

DISPERSAL: the movement of organisms from one geographic area to another; movements may be the result of an animal's own efforts or the consequence of being passively transported by natural or human-mediated means; dispersal is limited by barriers

PLATE TECTONICS: often referred to as continental drift, the modern theory assumes that the current position of continents and oceans is the consequence of dynamic forces that involve land masses "floating" on the earth's molten core

PLEISTOCENE GLACIATION: a period from about 1.8 million years ago to the last 100,000 years, characterized by alternating glacial and interglacial cycles; during the glacial periods ice sheets many miles deep covered as much as a third of the earth's surface

VICARIANCE: an event involving the erection of a barrier to dispersal that splits the distribution of an organism and facilitates the differential evolution of the geographically separated descendants

Biogeography is the science that seeks to understand spatial patterns of biodiversity. By examining past and present distributions, biogeographers attempt to explain why certain groups of organisms occur where they do, what enables them to live there, and what factors prevent them from moving or living elsewhere. To address these issues, biogeographic investigations must consider the effects of climate, topography, and other kinds of organisms, as well as historical events such as tectonic effects and glaciation. Because such historical considerations are frequently important and conditions are constantly changing, a group's closest relatives and their distribution must be taken into account in order to accommodate evolutionary events.

Because biogeography is such a broad discipline, individuals can rarely address an entire spectrum of relevant questions. Consequently, most biogeographers become specialists. For example, phytogeographers study plant distributions, and zoogeographers examine those of animals. Historical biogeographers reconstruct origins, dispersal events, and extinction through time. Ecological biogeographers concentrate on interactions between organisms and their environments to explain distribution patterns, and paleoecologists try to bridge the gap between historical and current conditions. Also related to the breadth of the discipline is the necessity for biogeographers to be conversant in one or more related fields. A broad knowledge of biology is obviously fundamental, as is an understanding of physical geography, but geology, paleontology, and climatology, among others, may be equally important.

Trends in Biogeography

Several consistent trends have emerged from biogeographic studies. Communities in isolated regions (especially large islands that have not been in contact with continents for long periods of time) tend to be unlike those found anywhere else. More types of organisms are found in tropical than in temperate or arctic regions. Fewer types of organisms are found on oceanic islands, although the organisms that are present may be found in phenomenal densities. On the other hand, some inconsistencies are striking. For example, some groups of related organisms are found throughout the world, whereas other groups have very restricted ranges.

Generally speaking, groups of organisms that are broadly distributed are either very old (their ancestors were in place before the continents drifted apart) or very mobile. Mobile organisms may be able to disperse actively, that is, on their own power (some species of birds and large marine mammals are good examples), whereas others are dispersed passively. Seeds of many plants, microscopic planktonic organisms, and insects are often transported by wind, currents, or other organisms. Limits to the dispersal of organisms are myriad. Size limits the ability to be blown by the wind; for example, dandelion thistles are more readily dispersed by even mild breezes than are walnuts. If water is a factor, buoyancy is critical. Coconuts are found on tropical shorelines around the world in large part because they do not sink, nor are their hard shells easily penetrated by salt water. Physical barriers often limit dispersal. Deserts effectively block organisms that require moisture, land halts movement of aquatic forms, and mountains prevent the passage of plants and animals that cannot tolerate the conditions associated with high elevations. Some barriers even appear to be "psychological;" birds that could easily fly cross a stream or lake, for example, often will not.

Island Biogeography

In 1967, Robert H. MacArthur and Edward O. Wilson published a classic volume entitled *The Theory of Island Biogeography*. Although islands have figured prominently in modern biology (Charles Darwin and Alfred Russel Wallace both relied heavily on evidence from islands when formulating their theories of natural selection), only during the last third of the twentieth century was island biogeography recognized as a distinct discipline. Many of the principles that form the foundation of biogeography emanated from studies of islands. Among these are relationships between biodiversity and island size, ecological heterogeneity, and proximity to continents; between isolation and endemism (species evolving in a given area and found nowhere else in the world); and between island size and location and rates of immigration, colonization, and extinction. In addition, island biogeographers frequently have been at the center of debates arguing the relevance of dispersal versus vicariance. Central to these disputes is whether disjunct distributions of organisms are attributable to movement over barriers (dispersal) or to the creation of a barrier that separated a previously contiguous range (vicariance). Although both have undoubtedly played important roles, the debate rages over which was primarily responsible for the current distributions of many faunas, both on islands surrounded by water and on terrestrial "islands" surrounded by other inhospitable habitats.

BIOLOGY

Type of animal science: Fields of study
Fields of study: Cell biology, conservation biology, developmental biology, invertebrate biology, marine biology, neurobiology, population biology, zoology

Biology is the science that studies life and living organisms.

Principal Terms

BIODIVERSITY: the total of all living organisms in an environment

DEOXYRIBONUCLEIC ACID (DNA): the carrier of all an organism's genetic information

NATIONAL INSTITUTES OF HEALTH: the United States' governmental division that monitors and improves public health

XENOTRANSPLANTATION: the transplantation of organs from one species to another

Biology is an extensive field subdivided into categories based on the molecule, the cell, the organism, and the population. Molecular biology touches on biophysics and biochemistry. It is the branch of biology that deals with the structure and development of biological systems in terms of the physics and chemistry of their molecules. Cellular biology is closely related to molecular biology through understanding the functions and basic structure of the cell. The cell is the smallest structural unit of an organism that is capable of independent functioning, consisting of one or more nuclei, cytoplasm, and organelles, all surrounded by a semipermeable membrane. Botany is the science or study of plant life. Ecology, also referred to as bionomics, is the study of relationships between organisms and their environments.

Developmental biology encompasses a number of issues, including gene regulation, genetics, and evolution. These are concepts of importance to vertebrates, invertebrates, and plants. A gene is a hereditary unit that occupies a particular location on a chromosome, determines a particular characteristic of an organism, and can undergo mutation. Genetics is the branch of biology that deals with heredity, especially the hereditary transmission and variation of inherited characteristics. Evolution is the theory that groups of organisms change with the passage of time, mainly as a result of natural selection, so that descendants differ morphologically and physiologically from their ancestors. Population genetics, the study of gene changes in populations, and ecology have been established subject areas since the 1930's. These two fields were combined in the 1960's to form a new discipline called population biology, which became established as a major subdivision of biological studies in the 1970's. Central to this field is evolutionary biology, in which the contributions of Charles Darwin are noted.

Microbiology is the branch of biology that deals with microorganisms. The study of bacteria, including their classification and the prevention of diseases that arise from bacterial infection, is the primary focus of microbiology. This branch is of interest not only among bacteriologists but also among chemists, biochemists, geneticists, pathologists, immunologists, and public health professionals. Parasitology is the study of parasites, organisms that feed on or in different organisms while contributing nothing to the survival of their hosts. Ethology is the scientific study of animal behavior. Animal behavioral studies have developed along two lines. The first of these, animal psychology, is primarily concerned with physiological psychology, and has traditionally concentrated on laboratory techniques such as conditioning. The second, ethology, had its origins in observations of animals under natural conditions, concentrating on courtship, flocking, and other social contacts. One of the important recent developments in the field is the focus on sociobiology, which is concerned with the behavior, ecology, and evolution of social animals such as bees, ants, schooling fish, flocking birds, and humans.

Ethics is the study of the general nature of morals and of specific moral choices. Bioethics addresses such issues as animal experimentation, cloning, euthanasia, gene therapy, genetic engineering, genome projects, protection of human research subjects, organ transplants, and patients' rights.

Biotechnology is the industrial use of living organisms or biological techniques developed through basic research. Biotechnology products include antibiotics, insulin, interferon, and recombinant DNA, and techniques such as waste recycling. The Office of Biotechnology Activities of the National Institutes of Health monitors scientific progress in human genetics research in order to anticipate future developments, including ethical, legal, and social concerns, in basic and clinical research involving recombinant DNA, genetic testing, and xenotransplantation (the use of organs from other species of mammals for transplants). In addition to organs donated from humans, researchers are exploring the use of partially or wholly artificial organs manufactured in the laboratory.

Biodiversity focuses on such issues as conservation, extinction and depletion from overexploitation, habitat pollution, global patterns and values of biodiversity, and endangered species protection.

Well known pioneer biologists include naturalist and explorer Sir Joseph Banks (1743-1820), naturalist and explorer Charles William Beebe (1877-1962), biochemist Gunter Blobel (b. 1936), environmentalist Rachel Carson (1907-1964), biochemist Stanley Cohen (b. 1922), biophysicist and codiscoverer of DNA, Francis Crick (b. 1916), naturalist and father of evolutionary theory Charles Darwin (1809-1882), zoologist Richard Dawkins (b. 1941), marine biologist Sylvia Earle (b. 1935), bacteriologist Paul Ehrlich (b. 1932), bacteriologist and discoverer of penicillin Sir Alexander Fleming (1881-1955), microscopist Antonie van Leeuwenhoek (1632-1723), botanist and taxonomist Carolus Linnaeus (1707-1723), ethologist Konrad Lorenz (1903-1989), zoologist A. S. Loukashkin (1902-1988), botanist and geneticist Barbara McClintock (1902-1992) , botanist and genetic theorist Gregor Mendel (1822-1884), endocrinologist and inventor of the birth control pill Gregory Goodwin Pincus (1903-1967), naturalist Alfred Russel Wallace (1823-1913), biophysicist and codiscoverer of DNA James Watson (b. 1928), and sociobiologist Edward O. Wilson (b. 1929).

BIOLUMINESCENCE

Types of animal science: Behavior, physiology
Fields of study: Biochemistry, marine biology, physiology, systematics (taxonomy)

Bioluminescence is visible light emitted from living organisms. Half of the orders of animals include luminescent species. These organisms are widespread, occurring in marine, terrestrial, and freshwater habitats. Bioluminescence is used for defense, predation, and communication.

Principal Terms

LUCIFERASE: one of a group of enzymes that catalyzes the oxidation of a luciferin

LUCIFERIN: one of a group of organic compounds that emits visible light when oxidized

MELANOPHORE: a melanin-containing cell

PHOTOPHORE: a light-emitting organ consisting of a lens, reflector, and light-emitting photogenic cells

SYMBIOSIS: the intimate living together of two dissimilar organisms in a mutually beneficial relationship

Bioluminescence is the visible light produced by luminous animals, plants, fungi, protists, and bacteria, that results from a biochemical reaction with oxygen. Unlike incandescent light from electric light bulbs, bioluminescence is produced without accompanying heat. Bioluminescence was first described in 500 B.C.E., but the chemical mechanism of bioluminescence was not elucidated until the beginning of the twentieth century. The ability to luminesce appears to have arisen as many as thirty times during evolution. The chemical systems used by luminescent organisms are similar but not exactly the same. Most organisms use a luciferin/luciferase system. The luciferin molecules are oxidized through catalysis by an oxidase enzyme (luciferase). The oxidized form of luciferin is in an excited electronic state that relaxes to the ground state through light emission.

Animals may produce light in one of three ways. The bioluminescence may be intracellular: Chemical reactions within specialized cells result in the emission of visible light. These specialized cells are often found within photophores. These light-producing organs may be arranged in symmetrical rows along the animal's body, in a single unit overhanging the mouth, or in patches under the eyes, and are connected to the nervous system. Alternatively, the bioluminescence may be extracellular: The animals secrete chemicals that react in their surroundings to produce light. The third option involves a symbiotic relationship between an animal and bioluminescent bacteria. Several species of fish and squid harbor bioluminescent bacteria in specialized light organs. The symbiotic relationship is specific—each type of fish or squid associates with a certain type of bacteria. The bacteria-filled organ is continuously luminous. The animal regulates the emission of light either with melanophores scattered over the surface of the organ or with a black membrane that may be mechanically drawn over the organ.

Although bioluminescence is widespread in animals, its occurrence is sporadic. Most of the bioluminescent animal species are invertebrates. Among the vertebrates, only fish exhibit bioluminescence; there are no known luminous amphibians, reptiles, birds, or mammals. Although bioluminescence is found in terrestrial and freshwater environments, the majority of luminous organisms are marine. Scientists estimate that 96 percent of all creatures in the deep sea possess some form of light generation.

Image Not Available

Functions of Bioluminescence

There appear to be three main uses of bioluminescence: finding or attracting prey, defense against predators, and communication. Although visible light penetrates into the ocean to one thousand meters at most, most fish living below one thousand meters possess eyes or other photoreceptors. Many deep-sea fishes have dangling luminous light organs to attract prey. Terrestrial flies have also exploited bioluminescence for predation. The glow of glowworms (fly larvae) living in caves serves to attract insect prey, which get snared in the glowworms' sticky mucous threads. Fungus gnats (carnivorous flies) attract small arthropods through light emission and capture the prey in webs of mucous and silk.

Bioluminescence can serve as a decoy or camouflage. For example, jellyfish such as comb jellies produce bright flashes to startle a predator, while siphonophores can release thousands of glowing particles into the water as a mimic of small plankton to confuse the predator. Other jellyfish produce a glowing slime that can stick to a potential predator and make it vulnerable to its predators. Many squid and some fishes possess photophores that project light downward, regardless of the orientation of the squid's body. The emitted light matches that of ambient light when viewed from below, rendering the squid invisible to both predators and prey.

The best known example of bioluminescence used as communication is in fireflies, the common name for any of a large family of luminescent beetles. Luminescent glands are located on the undersides of the rear abdominal segments. There is an exchange of flashes between males and females. Females respond to the flashes of flying males, with the result that the male eventually approaches the female for the purpose of mating. To avoid confusion between members of different types of fireflies, the signals of each species are coded in a unique temporal sequence of flashing, the timing of which is controlled by the abundant nerves in the insect's light-making organ. Females of one genus of fireflies (*Photuris*) take advantage of this by mimicking the response of females of another genus (*Photinus*) to lure *Photinus* males that the *Photuris* females then kill and eat.

Some marine animals also utilize bioluminescence for communication. For example, lantern fishes and hatchetfishes (the most abundant vertebrates on earth) possess distinct arrangements of light organs on their bodies that can serve as species- and sex-recognition patterns; female fire worms release luminescent chemicals into the water during mating, beginning one hour after sundown on the three nights following the full moon; and deep-sea dragonfish emit red light that is undetectable except by other dragonfish.

BIRDS

Type of animal science: Classification
Fields of study: Anatomy, evolutionary science, ornithology, physiology, systematics (taxonomy), zoology

There are about 8,600 hundred living species of birds, in about twenty-eight taxonomical orders. All birds have feathers, a feature unique to them; most birds also have other evolutionary adaptations that enable them to fly.

Principal Terms

Archaeopteryx: the earliest known bird, known only from the fossil record; it lived during the Jurassic period

Aves: the class within the phylum Chordata to which all birds, and only birds, belong

crop: a specialized part of a bird's digestive system that holds and softens food

endotherm: an animal that, by its own metabolism, maintains a constant body temperature (is "warm-blooded"); birds and mammals are endotherms

gizzard: a part of a bird's stomach that uses ingested pebbles to grind up food

ornithology: the branch of biology that deals with the study of birds

thecodonts: extinct reptiles that lived during the Permian period; they were the ancestors of both dinosaurs and birds

Within the animal kingdom is a class of animals that has 8,600 living species, with each species having a feature found in no other class of animals: feathers. These animals, the birds, also have horny beaks, two hind limbs that allow them to walk, swim, or perch, and two forelimbs called wings, which often help them to fly or swim. Birds have anatomical systems that are quite similar to those of mammals, and both of these classes of animals are warm-blooded, or endothermic. Along with other vertebrates, birds have skeletal, muscular, circulatory, digestive, respiratory, urinary, reproductive, and nervous systems. They have an outer covering of skin and a variety of sense organs. Each system, however, has unique adaptations designed to enable birds to fly.

Avian Physiology

Feathers, found on all birds, are a lightweight body covering that insulates and protects the birds. The large, vaned feathers on the wings and tails provide most birds with the aerodynamic lift and maneuverability needed for flight. The shape, color, and size of some feathers is also important for camouflage, recognition, or behavioral displays. The skeletal systems of birds have many bones that are homologous to reptilian or mammalian bones, yet unique modifications give birds the strength, flexibility, and lightness to fly. Most birds have bones that are pneumatized, or filled with air. The supporting bones, however, are highly mineralized and very strong. Some bones that are found in reptiles and mammals are missing in birds; other bones are fused. There are also more cervical vertebrae in birds' necks, and they are unusually flexible, allowing great movement of the head and neck.

The circulatory systems of birds are very similar to those of mammals, and they have a four-chambered heart. The oxygen-carrying erythrocytes of birds are larger than those of mammals and, unlike those of mammals, have a nucleus. Heartbeat rates are a function of activity, environmental temperature, and size. A hummingbird's heart often beats more than one thousand times per minute.

The beak of a bird may serve a number of functions that include probing for, catching, crushing, tearing, and swallowing food. The toothless beak does not grind or chew food but passes it to the pharynx, next to the esophagus, and then to a storage chamber, the crop. Food eventually is passed to a glandular stomach, where digestion begins, and then to a muscular gizzard that, with the aid of a horny lining and grit or sand, grinds and digests it further. The gizzard leads to the intestine, where digestion is aided by secretions from the liver and pancreas. The feces empty into a cloacal chamber. The cloacal chamber is also the terminus of the urinary and reproductive systems. The cloaca is the only posterior opening in birds; since all sex organs are internal, including the penis and testes, the sex of a bird cannot usually be determined by examining this area.

The visual and auditory sense organs of birds are usually acutely developed. Senses of smell, taste, and touch, on the other hand, are often poorly developed. Pigeons can discriminate motions that are up to three times faster than any humans can distinguish; some hummingbirds can see ultraviolet light, which is invisible to humans. Eagles, hawks, and vultures can detect objects at remarkable distances; they have a retinal cell density that is twice that of humans. Oilbirds and some owls can locate prey in total darkness.

These anatomical systems, and the varied external sizes, shapes, and colors, as well as behaviors that include courtship patterns, migration, and vocalization, evolved during millions of years of avian evolution. Birds are thought to have evolved from reptiles, probably thecodonts, more than 150 million years ago. Several fossils of the earliest known bird, *Archaeopteryx*, have been dated at 150 million years old. The fossils clearly show feathers and wings on a crow-sized bird body that has teeth and some reptilian skeletal features.

Types of Birds

More than nine hundred species of birds can be found only in the fossil record. Two extinct bird groups were especially common about ninety million years ago—the large, toothed, diving bird *hesperornis* and the gull-like *ichthyornis*. Two groups of huge flightless birds have become extinct within historical times: the giant moas of New Zealand (about 3 meters tall), and the elephant birds of Madagascar (about 2.7 meters tall).

Birds belong to the taxonomical class Aves. This class is divided further, first into orders—groups of birds that have broadly similar characteristics. Orders are divided into families, families into genera, and genera (sing. genus) into species.

Flightless and Perching Birds

There are several surviving orders of large, flightless, running birds. These include Struthioniformes, with a single living species that is the largest living bird: the 2.5-meter-tall ostrich of Africa. Somewhat similar in appearance, but with differences great enough for them to be placed in a different order, are the two species of rheas, belonging to the order Rheiformes. Some of these South American birds stand 1.5 meters tall. Australia has two superficially similar groups of birds in the order Casuariiformes: the three species of tropical forest-dwelling cassowaries, which are sometimes more than 1.5 meters tall, and the single species of the slightly taller emu, which roams the open plains.

Not far away, in New Zealand, are the kiwis. Their order, Apterygiformes, contains three species of the smallest of the primitive flightless birds. Some stand about thirty centimeters tall; they have no visible wings (only vestigial flaps), have feathers that look somewhat like hair, and may lay an egg that is one-quarter their body weight—proportionally the largest egg of any of the living birds.

The largest order of entirely flightless birds, with fifteen living species, is Sphenisciformes, the penguins. This order includes the emperor penguin of Antarctica, at 1.2 meters tall, and, along the equator, the most northern penguins, the Galápagos penguin, at a little less than 60 centimeters tall.

With rare exceptions, all other birds are capable of flight. The forty species of tinamou, however, of the order Tinamiformes, are weak fliers. They are

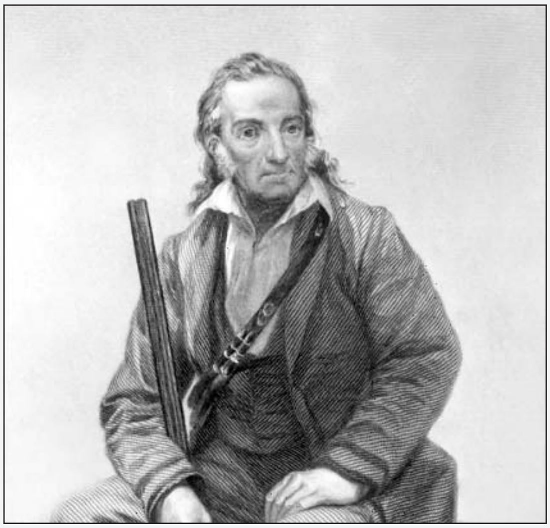
John James Audubon

Born: April 26, 1785; Les Cayes, Saint-Domingue (now Haiti)
Died: January 27, 1851; New York, New York
Field of study: Ornithology
Contribution: Audubon became famous for his beautiful, highly detailed paintings of North American birds and later through his naturalistic renderings of New World native animals.

Born the illegitimate offspring of a French merchant and planter and a Creole woman, Audubon was subsequently adopted by his father in 1794, after the elder Audubon took his young son to France. While growing up in the French countryside, Audubon developed a talent for drawing birds. At the age of eighteen, he was sent by his father to the United States to manage family business interests, thus avoiding conscription into the Napoleonic army. Audubon's commercial ventures did not prosper, and by 1820 he declared bankruptcy. Thereafter, Audubon supported himself through portrait painting and by teaching art, dancing, fencing, and French. He worked briefly as a taxidermist at the Western Museum Society of Cincinnati.

From the day he landed in the United States, Audubon found North American birds fascinating. He began drawing them during his wide-ranging travels whenever he could take time away from his business. Audubon explored the east coast from Labrador to Louisiana, visited the Mississippi Valley, and eventually ventured as far west as the Rocky Mountains. After 1820, Audubon decided to publish a portfolio depicting, in realistic color, the birds of his adopted land. A trip to Philadelphia in 1824 to investigate possible support for his projected publication proved a great disappointment; most of the city's naturalists and engravers refused to help. Audubon then realized he needed European backing to carry out his ambitious project of producing a series of full-color volumes, which he hoped to finance on a subscription basis.

Audubon found a warm welcome and indispensable subscribers in Edinburgh, Scotland, in 1826, and in London the following year. The London engraver Robert Havell, Jr., proved an effective collaborator during the eleven years (1827-1838) it took to produce the four-volume Elephant Folio edition of *The Birds of America*, with its 435 hand-colored plates displaying 1,065 life-size birds. The first volume received wide praise; thereafter, Audubon gained sufficient subscribers in Britain, France, and the United States to pay for the rest of the series. A young Scots naturalist, William MacGillivray, helped write the accompanying text, *Ornithological Biography* (5 vols., 1831-1839), describing the habits of the illustrated birds, and an index volume, *A Synopsis of the Birds of America* (1839).



John James Audubon was renowned for his detailed paintings of American birds. (Library of Congress)

Although his name is now associated with wildlife preservation, Audubon was an enthusiastic hunter. His usual practice was to shoot birds and either draw the fresh-killed specimen or stuff it for later use in the studio. Critics of Audubon have noted that some of his birds are posed in unlikely or fanciful positions, and the later plates in his series are crowded with dissimilar species as he strove to save costs and conclude the work. At their best, his bird portraits are both scientifically accurate depictions as well as carefully designed works of art. They won Audubon a reputation as the leading painter of American birds, gaining him wide popularity and his works enduring fame as valuable collector's items.

—*Milton Berman*

thought to be most like the ancestor of all living birds. Tinamous superficially look like quail, and they are found only in Central and South America.

The largest order of birds, with 5,200 species—60 percent of all living bird species—is Passeriformes. These birds are collectively called perching birds because of their grasping, unwebbed toes—three in front and one behind—all at the same level. Most Passeriformes have anatomical features that allow them to sing very well, and they are commonly referred to as songbirds. This diverse order includes finches, cardinals, grosbeaks, buntings, sparrows, orioles, blackbirds, tanagers, vireos, waxwings, thrushes, kinglets, mimids, warblers, wrens, shrikes, nuthatches, creepers, titmice, chickadees, swallows, crows, jays, larks, flycatchers, and starlings. Lesser-known Passeriformes include broadbills, ovenbirds, woodcreepers, antbirds, tapacolos, manakins, pittas, birds of paradise, bowerbirds, bubuls, babblers, honey eaters, white-eyes, sunbirds, honeycreepers, waxbills, cotingas, wagtails, and flower-peckers.

Aquatic Birds and Fowl

Two bird orders are most often associated with the open oceans or the marine coastlines of continents or islands. Procellariiformes, with ninety living species, contains albatrosses, shearwaters, and petrels. They all have webbed feet, long, narrow wings, and nostrils consisting of raised tubes. The fifty-two species of the order Pelecaniformes are the only birds with all four toes connected by webs; most also have an expandable throat patch. This order includes pelicans, tropic birds, boobies, gannets, cormorants, frigate birds, and anhingas.

Many types of birds generally inhabit areas that border bodies of water. The bays, estuaries, salt marshes, swamps, freshwater lakes, and rivers of the world teem with a multitude of birds. The largest of these orders, with 313 species, is Charadriiformes. This order contains three fairly common groups of birds. The shorebirds, often seen probing their long bills into sand or mud for food, include sandpipers, lapwings, plovers, avocets, stilts, phalaropes, oystercatchers, and jacanas. The gull-like group includes the web-footed gulls, terns, jaegers, skuas, and skimmers. Several of the forty-three species of gulls can be very cosmopolitan and are one of the most familiar sights at seaports and coastal resorts. The third group is the web-footed alcids—auks, murres, and puffins. They are northern oceanic birds that come ashore (mostly to rocky shores and cliffs) only to breed.

The eighteen species of grebes make up the order Policipediformes. These weak fliers are excellent divers and use their fleshy, lobed feet to dive for invertebrates or fish. The shallower waters of marshes and the edges of rivers and lakes are likely to have long-legged waders that belong to the order Ciconiiformes. These 110 species of herons, egrets, storks, ibises, bitterns, and spoonbills are usually fairly large birds with long necks and bills. They probe for mollusks, crustaceans, and fish, and sometimes for reptiles, amphibians, mammals, or birds.

The rails, gallinules, crakes, coots, and cranes are the aquatic groups of the 187 species in the order Gruiformes. Standing 1.5 meters tall, some of the cranes are among the tallest of the flying birds. The heaviest of all flying birds, the kori bustard, is also in this order. It weighs about twenty kilograms (approximately fifty pounds). The bustards, button quails, and several smaller families are terrestrial Gruiformes more often found in open plains or brushland.

The two smallest aquatic orders are Gaviiformes, the loons, and Phoenicopteriformes, the flamingos. The loons are excellent divers and breed only in or along cool northern waters. Flamingos, on the other hand, are found primarily in shallow, warmer, tropical, and temperate waters. With long legs and necks, these tall waders filter small aquatic organisms through their heavy, curved bill.

Anseriformes is an order of 151 species of semiaquatic birds that are hunted by people throughout the world. Several species have been successfully domesticated. This order includes a small family of stoutly built South American birds, the screamers, which resemble pheasant with wing spurs. The larger family of waterfowl includes ducks, swans, and geese, which are found worldwide except for Antarctica. They all have webbed feet and swim well; some are also excellent divers. Another order which has been hunted and domesticated for centuries is Columbiformes. The gentle doves of this order have long been symbols of peace and, along with pigeons and sandgrouse, give the three hundred species of this order worldwide distribution, except for polar regions. The pet bird trade has been especially interested in several of the 317 species of Psittaciformes. The birds of this order are primarily tropical or subtropical and include parrots, cockatoos, lories, parakeets, and macaws.

The bird order that has been the most exploited, however, both by hunting and domestication for food and eggs, is Galliformes, the fowl-like birds. The 253 species of this order include pheasant, grouse, quail, chickens, turkeys, guinea fowls, ptarmigans, megapodes, partridges, curassows, guans, chachalacas, and the hoatzin.

Predator Birds and Other Orders

Man is not the only efficient predator of birds: Many of the 271 species of the order Falconiformes are skilled at grasping a duck off a pond, a pigeon from the air, or a sparrow from a bird feeder. The order Falconiformes includes hawks, eagles, falcons, kites, kestrels, caracaras, vultures, condors, buzzards, and the osprey and secretary bird. All have strong, sharp claws and bills and are powerful fliers.

Another order of powerful predators of vertebrates is Strigiformes, the owls. The 131 species of owls are largely nocturnal, have large eyes with binocular vision, hear exceptionally well, and fly silently with unusually soft feathers. They do not tear mammals apart as the Falconiformes do, but usually swallow their prey whole and later regurgitate a pellet of hair and bones.

Some 1,200 more species are included within another 7 orders of birds. The order Cuculiformes, containing 143 species, includes the cuckoos, anis, roadrunners, and coucals. Most taxonomists also place the brightly colored touracos of Africa in this order. Most of the ninety-three species of the order Caprimulgiformes are either nocturnal or primarily active at twilight. This order includes night-hawks, nightjars, whippoorwills, frogmouths, potoos, and the oilbird.

Two small orders of medium-sized birds with long tails are Coliiformes (mousebirds) and Trogoniformes (trogons). While the six species of mousebirds are found only in Africa, the thirty-five species of trogons are distributed throughout tropical Africa, America, and Asia. Although the 191 species of the order Coraciiformes range from small to large in size, most are brightly colored and have a conspicuous bill. The kingfishers, todies, motmots, bee-eaters, rollers, hoopoes, and hornbills make up this order.

The order Apodiformes contains two superficially different groups of birds, the swifts and the hummingbirds. The 69 species of swifts are found in most areas of the world; the 319 species of hummingbirds live only in temperate and tropical America. Another large but more diverse order is Piciformes. These 374 species include woodpeckers, piculets, jacamars, puffbirds, barbets, honey guides, and toucans. Some woodpeckers are cosmopolitan and regularly frequent bird feeders.

Tracking and Studying Birds in the Field

Ornithologists, the scientists who study birds, have been assisted by millions of people throughout the world in their studies of bird populations and their movements. One of the largest bird projects is the Christmas bird count, sponsored by the National Audubon Society. This North American bird study has been done yearly since 1900 and involves more than forty thousand people each year. Field observers are given one day each winter to count all the birds they can find in a specified area. The information compiled about numbers of birds and species distributions is published in *American Birds*.

More than a million birds in North America are captured each year, fitted with a small aluminum band that has a unique number, and released unharmed. Some are recaptured later, sometimes years later, and perhaps hundreds or thousands of miles from the place they were banded. This technique gives information about the sizes of bird populations, mortality rates, longevity, migration routes and times, sex ratios, and age distributions. Some banders study avian parasites and sequences of feather molting. Hunters and the general public also contribute valuable information when they report dead banded birds.

Sophisticated electronic equipment has been used in many avian studies. Radio transmitters have been attached to some of the larger birds, and their individual movements have been recorded. Radar has been used to monitor both the movements of individual birds and the progress of flocks. Bird songs have been recorded and converted into graphic sonograms, which can show song differences between individuals of the same species.

Many museums have large collections of preserved or stuffed birds and bird skeletons, nests, and eggs. These may be used for anatomical or biochemical studies of birds. Taxonomists use these collections, along with studies of recently collected and live birds, to recognize species and arrange them into various classification groups.

Paleontologists studying the fossils of extinct birds have classified some nine hundred species of birds that are no longer alive. Fossils have given direct evidence about the relatedness of many bird groups; however, because they usually contain only information about bone structure, they provide limited data about species and must be interpreted carefully.

Studying Birds in the Lab

As well as considering the appearance and anatomical structures of birds, ornithologists now consult many areas of biology to put together the various taxonomic groups. Fieldwork has provided enormous amounts of information about the ecology, behavior, singing, breeding habits, and biogeography (location) of birds. In the nineteenth century, Charles Darwin used the structure, function, and biogeography of the finches on the Galápagos Islands to work out the species of these birds. These studies contributed significantly to the development of his theory of evolution by natural selection.

Birds come in all shapes, colors, sizes, and habits, but with very few exceptions, the one characteristic they all share is the ability to fly. (Corbis)

Fieldwork has also helped resolve many problems that have developed in the classification of birds. In 1910, bird books listed nineteen thousand species of birds. Several thousand new kinds have been discovered since then, yet now only 8,700 species are recognized. Many studies have shown that two groups of birds that look different and were at one time considered different species are in fact able to mate and produce offspring. These two groups are then reclassified as a single species. Each original group is considered a subspecies, race, or variety, depending on how similar they are to each other. In North America, for example, the Baltimore oriole and yellow-shafted flicker are common in eastern areas, and the Bullock's oriole and red-shafted flicker are common in the west. Each type of bird looks different and can easily be recognized, so they were initially classified as four species. As towns developed in mid-America, patterns of vegetation changed, and the orioles and flickers moved with the towns until the eastern and western populations finally met. Field studies in the twentieth century showed that the two flicker types were mating and producing offspring; the two orioles were, as well. The taxonomy was adjusted to reflect this new information, and now the two flickers are considered a single species, the northern flicker. Similarly, the two orioles were combined into one species, the northern oriole.

Avian biochemistry and genetics are also areas of intensive research. Studies of the size, shape, number, and staining patterns of chromosomes have been used to show the genetic relatedness of many bird species. Just as feathers, bones, and chromosomes have been shaped by the long evolutionary history leading up to each living bird, so have molecular structures been modified over time. Bird proteins have been analyzed and compared using a variety of techniques, including spectrophotometry, electrophoresis, antibody-antigen reactions, and amino acid sequencing. Studies of avian deoxyribonucleic acid (DNA) using electrophoresis, DNA hybridization, and recombinant DNA technology have also added new insights into the evolutionary relatedness of bird species. Because DNA controls the structure of all proteins and all physical structures in a bird (or in any animal), many researchers think the comparison of DNA structure provides the best overall view of species relatedness.

Popular Ornithology

There has probably been no other area of scientific inquiry that has attracted the interest of the public as much as has the study of birds. There has undoubtedly been no other area of science where the public has made such significant contributions. From the forty thousand Christmas bird count participants to the two thousand bird banders in North America, millions of interested nonscientists around the world have collected a wealth of information about birds.

Birds are often described as environmental indicators, and their population numbers and health are monitored to get an idea of overall environmental integrity. The decline in the number of migrant warblers in North America, for example, is described by some ornithologists as an indication of environmental changes in their wintering grounds in tropical America, whereas other ornithologists believe that it reflects deterioration of their breeding grounds in North America.

Conservation projects throughout the world have used bird studies as a means of focusing on when it has become necessary to fight for the protection of a particular species, subspecies, or race of birds. Major progress has been accomplished with ospreys, peregrine falcons, bald eagles, brown pelicans, trumpeter swans, whooping cranes, kirtland's warblers, and other birds. Yet each project is time-consuming and costly and must be carefully carried out. The governmental designations "endangered species" and "threatened species" cover only very narrow, clearly defined taxonomic groups.

Birds have fascinated people—scientifically, aesthetically, and emotionally—perhaps more than any other group of animals. The vast data collected and the complex taxonomical classification of birds is something that can be passed on to generations to come. It can be hoped that an environment where these creatures can prosper will be passed on as well.

—*David Thorndill*

Bibliography

Austin, Oliver L., Jr. *Families of Birds*. Rev. ed. New York: Golden Press, 1985. This two-hundred-page pocket book is illustrated by Arthur Singer and has an index. It is found in most bookstores, and it covers all living and extinct bird orders and families. A good, concise, complete bird classification guide.

Gill, Frank B. *Ornithology*. 2d ed. New York: W. H. Freeman, 1995. An encyclopedic reference, dealing with many aspects of avian evolution, physiology, and behavior not ordinarily covered. An appendix identifies birds and their general habits. Black-and-white photos and illustrations.

Gotch, A. F. *Birds: Their Latin Names Explained*. Dorset, England: Blandford Press, 1981. With only a few black-and-white drawings and a more technical subject, this nicely indexed book is for the more serious student of birds or taxonomy. The first five chapters describe the classification system, all the animal phyla, and all the bird orders and families. The remaining pages give the Latin derivations and some interesting stories about twenty-seven bird orders and nearly two thousand species.

Hickman, Cleveland P., Larry S. Roberts, and Frances M. Hickman. *Integrated Principles of Zoology*. 11th ed. Boston: McGraw-Hill, 2001. An excellent general zoology textbook that is very clearly written. The chapter on birds gives broad coverage of many aspects of avian biology. Illustrated with photographs and diagrams; includes references and a glossary.

Margulis, Lynn, and Karlene V. Schwartz. *Five Kingdoms: An Illustrated Guide to the Phyla of Life on Earth*. 3d ed. New York: W. H. Freeman, 1999. This is a text suitable for the college or advanced high school reader, written by an eminent evolutionary biologist. She describes ninety-one phyla in the five kingdoms. Illustrated with photographs and drawings.

Pough, F. H., J. B. Heiser, and W. N. McFarland. *Vertebrate Life*. 5th ed. Upper Saddle River, N.J.: Prentice Hall, 1999. This is a fine undergraduate vertebrate biology text; it was heavily revised for this edition to reflect changes in vertebrate taxonomy. The chapters on birds present useful information on bird origins.

BIRTH

Type of animal science: Reproduction
Field of study: Reproduction science

Birth is often defined as the act of being born, via parturition, from a mammal or another vivaparous organism, after pregnancy. More broadly stated, it is the beginning of awareness in an animal.

Principal Terms

GESTATION: the term of pregnancy

HORMONE: a substance produced by one organ of a multicellular organism and carried to another organ by the blood, which helps the second organ to function

LARVA: a newly hatched form of an organism that looks very different from adults of the species and must undergo metamorphosis to the adult form

METAMORPHOSIS: the form changes in a larva that turn it into the adult form

MOTILE: able to move about spontaneously

OVIPAROUS: born from an externally incubated egg

PARTHENOGENESIS: a process whereby a female sex cell develops without fertilization, in an organism that reproduces sexually

UTERUS: the organ in which fertilized eggs develop during gestation

VIVIPAROUS: born alive after internal gestation

ZYGOTE: a fertilized egg

Animals are born in one of two ways. They may be born via parturition after an internal pregnancy (a gestation period). They may also be born from an egg that hatches externally. This includes eggs that are spawned and then fertilized externally by organisms such as fishes; those fertilized internally and laid in huge numbers to hatch on their own, as in snails and millipedes; or those laid in much smaller numbers and incubated by their parents, as in birds.

In all animals, male and female reproductive cells (gametes) unite to form a single cell, known as a zygote. The zygote then undergoes successive cellular divisions, as well as cellular differentiation, to form a new organism. In most higher animals, individuals of a species are male or female, according to the type of reproductive cells they produce. Male reproductive cells—the sperms—are motile cells, with heads containing nuclei and tails that allow them to move. Female reproductive cells—eggs or ova—are round cells many times larger than sperms. They also contain large amounts of cytoplasm located around the nucleus.

Viviparous Birth

In viviparous organisms, a fertilized egg will develop into an incompletely finished miniature or miniatures of an adult of the same species. After fertilization of an egg, the zygote enters the uterus, undergoes both cell division and differentiation, and forms an embryo within the mother. In due time parturition (birth) occurs. Most viviparous organisms are mammals. Early in gestation the implanted dividing egg and the uterine wall become interconnected by a placenta, composed of both maternal and embryonic tissue. The placenta brings oxygen and nutrients to the embryo and carries away wastes. The transfer of nutrients uses the circulatory systems of both the mother and the embryo.

At the time of birth, hormonal changes cause the mother's birth canal to enlarge, the muscles of the uterus to rhythmically contract, and the em-

Birth in Cattle

The birth of a calf, relatively representative of the births of artiodactyls, is simpler than that of primates. The first signal of readiness to calve is the passage of mucus and a bloody discharge. After this, the pregnant cow lays down on the ground. Within an hour or two, she gives birth to her calf or calves. In normal birth, each calf is delivered in either a front or a rear presentation. Most cows deliver their calves front end first (front presentation). Initially, a dark bulge, the amniotic sac (water bag), is seen in the birth canal. This is soon followed by the tips of the calf's hooves, toes down. These hooves are soft so that they do not injure the mother during the birthing process. However, they harden quickly.

A front presentation calf is born in the "diver position," with its front legs stretched out and its head between them. The legs protrude about a foot, and then the head comes out, nose first. The head is soon followed by the shoulders, and then the rest of the calf slides out. Usually, afterbirth (the placenta) comes out as well. However, it may take several hours after calving for this to happen. Within a few hours after birth, the calf is ready to nurse and grow.

bryo is expelled as a newborn. The overall process can be exemplified with the female gorilla. She menstruates monthly and can mate successfully at any time of year. Her gestation period is 9.5 months and yields one or two almost fully formed offspring. Gestation is much shorter in smaller primates and there are variations in the difficulty of parturition, related to the head-first entry of young into the world.

Some primates—including humans—must undergo major dilation of the uterine mouth (cervix) before parturition can begin. This allows the large head of the fetus to pass out of the body safely. In species such as monkeys, in which the head of the fetus is close to the size of the cervical opening, far less dilation is needed. In other placental mammals, the position of fetuses in the uterus and the fashion of birth differ.

Oviparous Birth

Many animals, including snails, insects, birds, lizards, and fish, lay eggs either before they are fertilized or before their young are completely developed. These organisms are termed oviparous. In the case of snails, most species are hermaphrodites. This means that each snail has both male and female sex organs. However, each individual snail usually mates with another snail of the same species, passing sperm to its partner and getting sperm from the partner. Fertilized eggs are then spawned into the water or laid on rocks or aquatic plants. The eggs hatch in two weeks to two months. Hatching is considered to be the time of birth of the young snails. In most cases, offspring hatch as miniature replicas of their parents.

In insects, eggs are laid in a wide variety of places. For example, grasshoppers lay eggs in the ground or on plants. When the offspring are born, they hatch as wingless grasshopper larvae, called nymphs. Over several months the nymphs undergo metamorphosis to adult locusts. In contrast, ants, wasps, and termites lay their eggs in special chambers in their nests (or colonies). Worker termites place eggs laid by a colony's queen into hatching chambers in "nurseries." Termites are born as wormlike larvae when eggs hatch. The larvae undergo metamorphosis into workers, soldiers, or reproductives (kings or queens) as a result of being fed varied amounts of hormones obtained from queens.

Birds lay eggs in nests, that are located in a wide variety of locales depending on species. Adults then incubate the eggs by sitting on them. Offspring are born when they use a specialized egg tooth to break open their egg shells. In the case of lizards, the eggs are laid after they are fertilized. However, they are not cared for by parents. Large lizards such as alligators, crocodiles, and caimans lay eggs covered with hard, calcium-containing shells like those of bird eggs—reptiles and birds are distant relatives—in holes in the ground, where they hatch into offspring that look like adults. Most fish lay fertilized eggs on plants or on the bottom of the sea, lakes, or rivers, and leave their offspring to hatch on their own. These offspring then develop into adults.

Ovoviviparous Birth

Ovoviviparous animals produce eggs in shells like those of the oviparous organisms but the eggs are hatched within the body of the mother, or by expulsion from her body. There are numerous examples of ovoviviparous organisms among animals. They include some oysters, snails, and other gastropods, as well as numerous species of sharks, and the live-bearing tropical fish such as the guppy or swordtail. The eggs of live-bearing guppies hatch internally, just before leaving the mother's body, and the young are born alive. These young fish usually leave the body of the mother head first.

In all cases, the development of the egg or eggs of ovoviviparous species begins with internal fertilization of the female of the species. Then, the zygotes formed pass through many cycles of internal cell division and differentiation. Ultimately, each egg yields a miniature of the adult organism involved. However, there is no placenta formed and the zygote becomes the complete organism in processes that depend on a yolk sac for food and energy. Often, upon birth, the newborn organism has part of its yolk sac left and can survive for one or several days without eating.

—Sanford S. Singer

Types of Shark Birth

Reproduction in sharks is very interesting. Most often it is ovoviviparous, with the eggs fertilized internally, hatching within the female, and being born as live young. Some sharks are oviparous, laying eggs externally. Often these eggs are encased in tough shells with filaments that anchor them to rocks or sea plants, while development occurs.

In still other sharks, the young develop in the uterus in a fashion very similar to that seen in mammals. In those cases, the yolk sac becomes a yolk placenta in the folds of the uterine wall. This yolk placenta brings nutrients to the embryo, as well as carrying wastes away. In such cases gestation lasts between six months and two years. In cases of live birth, the offspring of some sharks are up to three feet long, almost fully developed, and capable swimmers that eat the same prey as do the adults.

BONE AND CARTILAGE

Type of animal science: Anatomy
Fields of study: Anatomy, biochemistry, physiology

Bone is a connective tissue, much of which derives from cartilage. It forms vertebrate skeletons, which are body support networks, prevent organ damage, anchor muscles so that they can function, provide calcium to serve the body needs, and contain the sites of blood cell synthesis.

Principal Terms

ARTICULAR: pertaining to bone joints

BONE: the dense, semirigid, calcified connective tissue which is the main component of the skeletons of all adult vertebrates

CALCIFICATION: calcium deposition, mostly as calcium carbonate, into the cartilage and other bone-forming tissue, which facilitates its conversion into bone

CARTILAGE: elastic, fibrous connective tissue which is the main component of fetal vertebrate skeletons, turns mostly to bone, and remains attached to the articular bone surfaces

COLLAGEN: a fibrous protein very plentiful in bone, cartilage, and other connective tissue

CONNECTIVE TISSUE: any fibrous tissue that connects or supports body organs

OSTEOBLAST: a bone cell which makes collagen and causes calcium deposition

PERIOSTEUM: the fibrous membrane which covers all bones except at points of articulation, containing blood vessels and many connections to muscles

Bone is the hard substance that forms the supportive framework of the bodies of all of vertebrate organisms. This framework, the skeleton, is composed of hundreds of separate parts called bones. The bones support the bodies of vertebrates and protect their delicate internal organs, such as the brain, lungs, and liver, from injury. In addition, the muscles are attached to the bones, which act as levers to enable their function in actions as diverse as walking or swallowing. Furthermore, bone provides the calcium needs of the body, serves as the main repository for calcium storage, and contains the sites where the red blood cells are made.

Much of the bone in adult vertebrates derives from cartilage, elastic, fibrous connective tissue which is the main component of fetal vertebrate skeletons. Such bone, for example, that of the long bones, is called cartilage bone. Cartilage is an extracellular matrix made by body cells called chondrocytes. It is surrounded by a membrane, the periosteum, and much of its firmness and elasticity arises from plentiful fibrils of the protein collagen that it contains. These fibrils and their many interconnections provide mechanical stability and very high tensile strength, while allowing nutrients to diffuse into the chondrocytes to keep them alive. The blood vessels which surround the cartilage in the periosteum provide all of the needed nutrients and remove the cellular waste materials produced by life processes.

The cartilage-containing skeletons of newborn vertebrates become cartilage bone by ossification, a process which includes calcification, chondrocyte destruction, and replacement by bone cells, which lay down more bone. This cartilage, called hyaline cartilage, remains at the articular sites of bones. In young vertebrates, cartilage is the site for the con-

The bones of the vertebrate skull are designed to protect the brain; in fact, they do such a good job that skulls last far longer than the tissue they encase. (Digital Stock)

Physical Characteristics of Bone

To best serve their biofunctions, bones must be very hard, strong, and rigid, but remain supple enough to stay unbroken under normal conditions. These characteristics are provided by the collagen fibrils and insoluble calcium phosphate which make up the bones. The bones must also be light enough to allow vertebrates to move easily and remain erect.

Overly heavy bones are prevented by the occurrence of two general types of bone tissue. The first of these is compact bone, the portion most familiar because it makes up the hard exterior of many bones, except at their very ends. The second bone type, cancellous bone, which appears spongy, is found at the ends of long bones and inside them. It serves to lighten the bones, acting in the same fashion as the air-filled sinuses of the skull, which diminish the overall weight of the skull without weakening it. Bones are covered on their outsides by the important fibrous membrane called the periosteum, along with cartilage. Their insides are lined by an endosteum membrane, very similar to the inner layer of the periosteum.

It is also useful to think of bones in terms of woven, lamellar, and osteonic forms. These terms indicate the relative number of cells in a bone matrix region and the arrangement of collagen fibers in the region. Collagen fibers of woven bone crisscross within the bone matrix, and its bone cells are distributed randomly. In lamellar bone the collagen fibrils are more ordered and fewer bone cells are present. Osteonic bone is also well-organized. However, its cells are found in concentric rings, with narrow channels (Haversian canals) inside them. A blood vessel passes through each canal and feeds the concentric cell rings formed around it. The bone layers form from the outside in, within the internal bone cavity. This narrows its

tinued growth and calcification that produces the bone lengthening required for the attainment of adult size and stature. In addition to the cartilage bone, so-called membrane bone occurs exclusively in the top portion of the skull.

Bone is thought to have developed over a half billion years ago, as shown by its presence in the fossils of fishlike carnivores of that time period. In those creatures, it seems to have been formed into interconnected external plates covering their bodies as sheaths that strengthened and protected their bodies. The existence of bone only at the surfaces of these fossils has led many scientists to suppose that the first function of bone was protection, rather than body support. Be that as it may, bone has both functions in modern organisms. It is interesting to note that many of these early organisms lacked bone in their heads. It seems possible that this lack may have led to the development of the separate mechanisms for formation of membrane bone and cartilage bone, different means to the same end.

diameter more and more. A Haversian canal and its rings develop when cancellous bone is converted into compact bone.

Bones are either "long" or "short" bones. Most long bones are located in the arms and legs. They are divided into three parts: a shaft (the diapysis), the long central part of the bone; a flared portion at each bone end (the metaphysis); and a rounded bone end (the epiphysis). The short bones, designed for flexibility, include those in the skull, spine, hands, and feet. The centers of bones—medullary cavities—are most often filled with either red or yellow bone marrow. The yellow marrow is mostly fat. Red marrow is a network of blood vessels, connective tissue, and blood-cell-making tissue. Red blood cells (erythrocytes) are made in this red marrow. Each bone has nerves that stimulate it and blood vessels that supply nutrients and take away wastes.

Bone Composition, Development, and Remodeling

Between 66 and 70 percent of bone is an inorganic mineral composite made of calcium phosphate and calcium carbonate, which is mostly hydroxyapatite. Much of the remainder of bone is the fibrous protein collagen. This mineral and protein together are called the bone matrix. Within the bone matrix are the three types of specialized cells which ensure its formation, remodeling as is needed, and continuity throughout life. The first cell type, the osteoblast, produces the bone matrix and surrounds itself with it, synthesizing collagen and stimulating mineral deposition. The second cell type, the osteocyte, is a branched cell that becomes embedded in bone matrix, is interconnected, and acts in the control of the mineral balance of the body. Finally, the osteoclast cells destroy the bone matrix whenever it is remodeled during skeleton growth or the repair of bone breaks and bone fractures.

The stepwise conversion of cartilage into bone begins when the chondrocytes of hyaline cartilage enlarge and arrange themselves in rows. This is followed by the synthesis of collagen fibers, and mineral deposition around them. Just below the inner surface of the periosteum a vascular membrane—the perichondrium—forms and supplies the osteoblasts needed for bone formation. Simultaneously, osteoclasts excavate layers through the bone layer and set the stage for the formation of additional bone.

Membrane and Cartilage Bone

Membrane bone, such as that which makes up the upper portion of the skull, forms after cells of vertebrate embryo connective tissue gather together in the area where such bone is to form. This aggregation is followed by the development of small blood vessels in the area and the differentiation of the connective tissue cells into osteoblast cells, which make collagen, intracellular material, and cause the deposition of calcium.

In contrast, cartilage bone, in the long bones, for example, forms where cartilage was initially laid down in the vertebrate embryo. This kind of bone, also called the endochondrial bone, results via osteoblast formation from chondrocytes, followed by ossification. The differentiation between membrane bone and cartilage bone, which are indistinguishable after ossification, is made by the careful examination of appropriate tissue structures during the course of embryogenesis.

The conversion of cartilage into endochondrial bone is not complete until adulthood. At the ends of the immature cartilage bones, regions of actively growing cartilage (epiphysial plates) occur. In these regions, continued longitudinal cartilage growth followed by ossification leads to the lengthening of bones required for the development of newborn vertebrates into full-sized adults. At adulthood, the cells of the epiphysial plates stop reproducing. It is believed that imbalances between chondrocyte numbers and bone matrix material levels in articular cartilage probably play major roles in the genesis of arthritis.

All the bones in the bodies of the vertebrates change their sizes and shapes as these organisms pass through their lives. The processes involved are collectively called remodeling. An example of such change is the growth of the long bones in circumference as the limbs grow from puberty to adulthood. In the course of such bone growth the periosteum provides the osteoblasts required to deposit bone matrix around the bone exterior and to calcify it. At the same time the endosteum-derived osteoclasts often dissolve bone in the interior, thus enlarging the marrow cavity.

Remodeling in such cases occurs in response to biosignals including those caused by increases in the need for bone to bear additional weight or to anchor increased muscle mass. Conversely, inactivity and the lack of exercise can result in remodeling which produces diminished bone mass. The complex changes involved in bone remodeling are also controlled by vitamin D and hormones originating in the pituitary gland, the thyroid gland, and the parathyroid glands. Abnormalities in bone growth and remodeling are associated with a great many bone diseases, ranging from rickets to bone cancer.

BRACHIOSAURUS

Types of animal science: Classification, evolution
Fields of study: Anatomy, ecology, evolutionary science, paleontology, systematics (taxonomy)

Brachiosaurus *was a quadrupedal, herbivorous dinosaur whose role as a high browser in Late Jurassic ecosystems was similar to that of the giraffe today.*

Principal Terms

CENTRUM: the spool-shaped body of a vertebra

DIPLODOCIDS: quadrupedal, herbivorous dinosaurs whose hind limbs were longer than their forelimbs

PLEUROCOEL: chamber formed in the centrum of a vertebra to reduce its weight

STEGOSAURS: quadrupedal, herbivorous dinosaurs with vertical bony plates along their backbones

SYSTOLIC PRESSURE: the pressure in blood vessels when the ventricles of the heart contract

Brachiosaurus altithorax was described by Elmer Riggs in 1903 based on a specimen from the Late Jurassic (156 to 145 million years ago) of Colorado. However, the best skeletons are from the Tendaguru Hills of Tanzania, which, at the time the skeletons were collected, was known as German East Africa. Field work started in 1909 and continued until 1912. The dig was not a small affair. Almost $600,000 was raised to fund the dig. In 1909, 170 workers were employed, and their numbers swelled to 500 in 1911 and 1912. About 235 metric tons of fossil material was removed. No permits for further fieldwork have been issued for this area since the 1920's.

Characteristics

Brachiosaurus was a quadrupedal, herbivorous dinosaur whose forelimbs were longer than its hind limbs. This sauropod had a very long neck which it held erect and a short tail which was held out horizontally. Spoon-shaped teeth filled most of the jaws. The nostrils were positioned on a large, dome-shaped crown over the eyes. The enlarged nasal cavity may have been used to produce sounds. If not, the animal must have had a keen sense of smell. *Brachiosaurus* was between 22.5 and 25 meters (85 feet) long, 16 meters (52 feet) high, and weighed between fifty and eighty tons. The animals had a maximum speed of between twenty to thirty kilometers per hour. Unlike *Apatosaurus*, *Brachiosaurus* is a relatively rare sauropod in the western United States, hinting that it may have lived a solitary existence there rather than being part of a herd.

With its long, erect neck and long forelimbs, *Brachiosaurus* could feed on the cones and leaves of the tallest trees (conifers, cycads, and gingkoes). By feeding in the treetops, *Brachiosaurus* did not compete with other sauropods, such as *Apatosaurus*, or stegosaurs, such as *Kentrosaurus*, which fed at lower levels. To supply the brain with blood, *Brachiosaurus*'s heart would have to pump at a systolic pressure of more than 630, have had four chambers, and weighed about 400 kilograms (about 882 pounds). In comparison, humans' normal systolic pressure is somewhere between 120 and 130, with a heart that weighs about 300 grams (10.5 ounces). To help move the blood along, the artery walls may have been heavily muscularized, and a reservoir of oxygenated blood may have existed in the head for emergencies, when the animal was forced to change the level of its head rapidly.

Bibliography

Bakker, Robert T. *The Dinosaur Heresies*. New York: William Morrow, 1986. This book contains a good discussion of the ability of dinosaurs to hear as opposed to producing sounds.

Dodson, Peter. "Sauropod Paleoecology." In *The Dinosauria*, edited by David B. Weishampel, Peter Dodson, and Halszka Osmólska. Berkeley: University of California Press, 1990. The best discussion of sauropod lifestyles available.

Lucas, Spencer G. *Dinosaurs: The Textbook*. 3d ed. Boston: McGraw-Hill, 2000. This book has excellent diagrams of sauropod vertebrae that will help solve the mystery of the technical terms used in *The Dinosauria*. Also included is a comparison of the dinosaur faunas of the western United States and the Tendaguru Hills.

Brachiosaurus Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Reptilia
Subclass: Dinosauria
Order: Saurischia (lizard-hipped dinosaurs)
Suborder: Sauropoda (long-necked herbivores)
Family: Brachiosauridae (quadrupedal herbivores whose forelimbs were longer than their hind limbs)
Genus and species: Brachiosaurua altithorax, *B. atalaiensis*, *B. brancai*, and *B. nougaredi*
Note: A number of competing classification schemes exist and will probably continue to do so in the future.

Geographical location: Late Jurassic of Algeria (*B. nougaredi*), Colorado and Utah (*B. altithorax*), Portugal (*B. atalaiensis*), and Tanzania (*B. brancai*)

Habitat: In the United States, *Brachiosaurus* is a relatively rare sauropod in the dry habitats represented by the Morrison Formation; in Tanzania, *Brachiosaurus* was far more numerous in the mesic (moist) habitats characteristic of the Tendaguru Formation

Gestational period: Although no eggs have been found, *Brachiosaurus* was undoubtedly an egg layer; the frequency at which eggs were laid, the time it took for the eggs to hatch, and the reproductive life span of the adults are unknown

Life span: Based on mammalian models, sexual maturity would be reached after ten years and the life span was probably in excess of one hundred years

Special anatomy: The neural spines on the cervical vertebrae of the brachiosaurids were not V-shaped as they were in the diplodocids; instead, the neural spines on the vertebrae at the junction of the neck and back were highly elongate for attachment of the muscles that held the neck and head erect, resulting in a pronounced hump over the shoulders; the centrum of each vertebra contained several pleurocoels

BRAIN

Types of animal science: Anatomy, physiology
Fields of study: Biochemistry, cell biology, histology, neurobiology

The brain is the center of the body's information integration and storage, and the site that determines how an animal will react to changes in its environment. Both the brain and spinal cord receive information from sensory receptors and send messages to the muscles and glands, telling them how to respond to internal or external changes.

Principal Terms

BRAINSTEM: lowest or most posterior portion of the vertebrate brain, including midbrain, pons, and medulla oblongata; controls "housekeeping" functions such as breathing and heartbeat

CELL BODY: the central portion of a neuron, containing the nucleus, where most processing and integration of information occur

CEREBELLUM: second largest part of the brain, manages fine muscle control and muscle memories

CEREBRUM: largest part of most vertebrate brains, with areas that control vocalizations, vision, hearing, smell, and taste, as well as voluntary skeletal muscle movements

CORTEX: thin layer of gray matter that covers surfaces of the cerebrum and cerebellum

GANGLIA: clustered cell bodies of neurons that may form a brain-like center in lower animals

GRAY MATTER: region of the brain or spinal cord that contains cell bodies of neurons, where information processing and storage occur

WHITE MATTER: region of neural tissue that contains axons of neurons that carry electrical nerve impulses from one processing center to another

Animals are multicellular organisms that obtain their nutrients by eating or ingesting other organisms, and many have locomotor abilities. Obtaining food and avoiding being eaten are behaviors enhanced by the ability of an animal to tell what is going on in its surroundings. Using information from sensory receptors and responding to changes in the environment are generally managed by a nervous system of some sort, usually with a center where processing occurs, a brain or brainlike structure. Invertebrate nervous systems are generally very primitive and may contain only a very rudimentary brainlike structure. Some animals, however, are so structurally simple that they have no neural processing center at all.

Invertebrates with and Without Brains

Sponges (phylum Porifera) are invertebrates with no brain or nervous system of any sort, in either the sedentary adults or the free-swimming larvae. Stimuli received at the body surface produce responses (movements) directly, over the entire body, in these and related lower metazoan animals. Other primitive invertebrates such as hydra, jellyfish, corals, and sea anemones (phylum Cnidaria) have one or more nerve nets. For these radially symmetrical animals, food or danger can come from any direction in the water, and the meshlike nervous system can respond directly without a central control region. Some jellyfish also have a nerve ring that helps coordinate their movements, but no brain.

Bilaterally symmetrical invertebrates include the flatworms (phylum Platyhelminthes), roundworms (Nematodes), mollusks (Mollusca), segmented worms (Annelida), and insects and their relatives (Arthropoda). Most of these show cephalization, the presence of an anterior head containing the main processing center of the nervous system, specialized sensory receptors, and the mouth. Echinoderms (Echinodermata) such as starfish are bilaterally symmetrical as larvae, but develop radial symmetry as adults, when they lack a head. Some mollusks are not symmetrical as adults, despite the bilateral symmetry of the larvae.

Among the flatworms, some have only nerve nets like those of cnidarians, while more complex planarians, tapeworms, and flukes generally have one or more pairs of ladderlike longitudinal nerve cords with ganglia at the head. These ganglia are clusters of cell bodies of neurons, the most primitive form of a brainlike structure. Nematodes or roundworms have a nerve ring and anterior ganglia organized around the anterior digestive tract, with nerve cords extending toward the head and tail from this center. Mollusks include clams and oysters (class Bivalva), snails and slugs (Gastropoda), and octopuses and squid (Cephalopoda). These animals have nervous systems that vary from simple and relatively uncephalized nerve rings and nerve cords, to a more centralized system with at least four pairs of ganglia.

Octopuses and squid have the most complex nervous systems of the mollusks and are the most intelligent invertebrates. The relatively large cephalopod brain contains many clustered or fused ganglia that manage sensory information from complex eyes and produce motor instructions for extremely rapid muscular responses. Giant nerve fibers in squid are the largest neurons known in any animal, up to one millimeter in diameter in a single cell, and are able to conduct rapid impulses that allow lightning-fast movements. Extensive studies of these neurons' structure and function have provided scientific insights that are also applicable to human neurons. Gastropods and cephalopods may show extremely complex behaviors, such as homing, territoriality, and learning. An octopus can have as many as thirty functional brain centers, some of which are memory banks used for experiential learning.

Annelids such as earthworms and leeches have paired cerebral ganglia near the mouth, connected by a solid ventral nerve cord to smaller paired ganglia in each body segment. Giant nerve fibers in the nerve cord allow rapid responses to escape from threats using reflex actions and patterned behavior. Earthworms can be taught to travel a maze by simple associative learning, in which repeated stimuli become linked to a specific behavior pattern, but this learning requires many repetitions and disappears within a few days if not reinforced.

Arthropods include spiders, scorpions, ticks, and mites (class Arachnida), lobsters, crabs, and shrimp (Crustacea), and insects (Insecta). The nervous system in arthropods is similar to that of annelids in its segmentation, but it is much more complex, and the anterior ganglia tend to be fused into a true brain. Many arthropods have giant neurons like those of some mollusks and annelids, capable of rapid nerve impulse transmission for efficient muscle control. Insects in particular, especially ants and bees, are capable of complex learning and very intricate social behavior. Habituation allows individuals to learn to ignore repeated stimuli that do not produce harmful effects, and cockroaches and ants can learn to run mazes.

Sea urchins, sand dollars, sea stars (starfish), and sea cucumbers are echinoderms, in which the bilaterally symmetrical larvae develop a secondary radial or biradial symmetry as they mature. The resulting radial nervous system is not greatly centralized, as there is a mouth but essentially no head. The nervous system consists of a nerve ring around the mouth that is connected to radial nerves and a nerve net. Thus, behavior generally involves only localized responses to stimuli, as along one arm of a starfish.

Evolutionary Development of the Vertebrate Brain

The location of most animals' brain or brainlike organ at the anterior or superior end of the body is important, since it places the brain at the leading end of the moving animal or at its highest point. Many sensory receptors are located in the head, and information from the eyes, ears, and nose can be rapidly received and processed if the processing center is in the same region.

In vertebrates, the nervous system is much more advanced than the primitive systems of invertebrates. The vertebrate brain is an anterior enlargement of the dorsal hollow nerve cord that develops above the notochord in all chordates. This swelling of the nerve cord allows development of a large collection of neurons that receive, process, and store information, and determine what the organism's response to that information will be. The central nervous system consists of the brain at the anterior end of the nerve cord and the spinal cord behind it, encased in a skull and vertebral column of bone or cartilage. The rest of the vertebrate nervous system is called the peripheral nervous system, with nerve fibers bundled into nerves. Clusters of the cell bodies of neurons in the central nervous system are called nuclei, while the same kind of clusters in the peripheral nervous system are called ganglia.

The components of the vertebrate embryonic brain are divided into three areas or primary vesicles, known as the forebrain (prosencephalon), midbrain (mesencephalon), and hindbrain (rhombencephalon). As development occurs, the three primary vesicles form five secondary vesicles that continue to develop into the mature brain structures. The forebrain becomes subdivided into the telencephalon, which matures into the cerebrum, and the diencephalon, which contains the thalamus and hypothalamus. The midbrain does not undergo further developmental separation. The hindbrain develops into the metencephalon, which will form the pons and cerebellum, and the myelencephalon, which becomes the medulla oblongata that is connected to the spinal cord. The lower or posterior part of the brain is called the brain stem, consisting of the medulla oblongata, pons, and midbrain, which manages the most primitive functions required for life. Higher brain functions reside in the cerebrum, particularly in the outer cortex of gray matter on its surface. The cerebellum coordinates skeletal muscle or motor activities, while the diencephalon processes and sends on sensory information to the cerebrum and cerebellum, as well as being the center of autonomic or visceral motor control.

The different classes of vertebrates are grouped into subphylum Vertebrata within phylum Chordata, with the main classes including cartilaginous fish (Chondrichthyes), bony fish (Osteichthyes), amphibians (Amphibia), reptiles (Reptilia), birds (Aves), and mammals (Mammalia). The brains of fish and amphibians are relatively primitive as compared to those of other vertebrates, with the main control over body functions handled by the medulla oblongata, the oldest part of the vertebrate brain. Olfactory lobes for processing sensations of smell and perhaps also taste, located in the cerebrum, and optic lobes for vision, in the diencephalon, are large in comparison to other parts of the brain, and responses are generally reflexive.

Animals that lay eggs with shells, called amniotes and including reptiles and birds, are adapted to the rigorous requirements of life on land, and have larger, more complex brains than fish and amphibians. The amniote brain has a larger telencephalon and is able to process and store more information about the land environment, which is much more likely to vary than is a watery environment. In addition to having a larger telencephalon, the brain contains more gray matter that is closer to the brain surface in amniotes than in fish or amphibians.

Mammals and some reptiles have much or all of the surface of the cerebrum covered in gray matter, which forms a structure called the cerebral cortex. The evolutionarily newer portion of this cortex is called the neocortex, while the older part is called the paleocortex. The paleocortex is the control center for drive-related behaviors, such as activities associated with feeding (licking, chewing, swallowing), sexual behavior, and primitive emotions (anger, fear). The limbic system occupies the paleocortex, which is sometimes called the reptilian brain, because it is the highest brain area present in reptiles and governs nearly all their behaviors. The neocortex is a "higher" control area that is well developed even in primitive mammals, but it is most completely expressed and covers the entire cerebral surface in humans. In cetaceans (whales and dolphins) and primates, the neocortex is the center of higher learning, logical thinking, and storage of many memories. The activities of the neocortex can override the more primitive responses of the paleocortex under most conditions, but when the higher brain areas are inactive, as in alcoholic intoxication in humans or when removed surgically in experimental animals, the lower areas reassert themselves and take control, often causing inappropriate behaviors.

Mammalian brains have convolutions on the surface of the cerebrum and cerebellum, with the neural cortex following and covering every "hill" and "valley" of the convolutions. This provides a much greater surface area occupied by gray matter, especially in humans, the species in which the convolutions and cerebral cortex are most extensive. Below the gray matter surface is white matter, myelinated neuron fibers that carry information from one area of gray matter to another. Deep to this white matter are basal nuclei, gray matter centers that help regulate subconscious and involuntary control of body functions.

The gray matter of the cerebrum in birds is nearly all in the deep basal nuclei, which are relatively much larger than they are in mammals, and in an overlying gray area specific to birds called the hyperstriatum. The avian brain lacks a neocortex entirely, with no equivalent of the cerebral cortex present. The area of the basal nuclei called the corpus striatum is apparently the center for complex behavior patterns, while the hyperstriatum manages learning and memory.

Humans have been found to show lateralization of the brain, where one side of the cerebrum (left) controls language production and interpretation, while the other side (right) controls spatial awareness and artistic creativity. This lateralization is not generally seen in other vertebrates, but recently it has been observed in some birds, where memories of song patterns and migratory homing directions are located in gray matter areas on specific sides of the brain.

Because the vertebrate central nervous system develops from a dorsal hollow nerve cord, the anterior end of its hollow, fluid-filled central canal enlarges into four ventricles or spaces. These are the first and second or lateral ventricles of the cerebral hemispheres, the third ventricle within the diencephalon, and the fourth ventricle associated with the pons, medulla oblongata, and cerebellum. The midbrain retains a simple canal called the cerebral or mesencephalic aqueduct that connects the third and fourth ventricle spaces.

The fluid that fills the canal and ventricle spaces is cerebrospinal fluid (CSF), produced by filtration of fluids from the blood at specialized capillary beds called choroid plexuses within the ventricles. Besides filling the hollow spaces of the central nervous system, CSF also washes over the surfaces of the brain and spinal cord in an area below the arachnoid layer, one of the central nervous system's coverings or meninges. It provides protection against traumatic injury, delivers nutrients, removes wastes, and helps regulate neurochemicals for the central nervous system.

The Primate Brain

Primates, the order of animals that includes monkeys, apes, and humans, contains species that show a higher level of brain development than most other mammals. Primate brains, especially in humans, are among the largest in the animal kingdom, compared to the body size of the animal. The primate brain retains in its structure the earlier forms and functions that have developed in lower vertebrates over evolutionary time, such as the brainstem and limbic system, but higher areas give new and more complex possibilities for learning and behavior.

Because humans are upright, bipedal walkers, the human brain is at the top of the spinal cord rather than somewhat in front of it as in other primates. The human brain weighs only about three pounds, or about 2 percent of the weight of a 150 pound individual, but that is still larger relative to body size than the brains of other primates, even chimpanzees. The cerebrum makes up about 87 percent of the volume of the brain, and the cerebellum occupies most of the remaining volume. The diencephalon and brainstem in primates are relatively smaller than in most other mammals, compared to the entire brain size. The cerebral cortex in humans contains only six layers of cell bodies in the gray matter on the surface of the cerebrum. Many axons extending down from these cell bodies into the underlying white matter cross-connect the neurons that receive stimuli, process information, determine responses, and store memories. Specific areas of this cerebral cortex determine the body's voluntary muscle actions, or receive and analyze sensory information from the skin, muscles, and joints. Other cortical areas process incoming information about smell, taste, vision, and hearing, and compare those sensations to previous memories or store them as new memories.

The most "human" aspect of the brain is the prefrontal cortex of the cerebrum, where logical analysis, predictions of the results of specific actions, and social interactions take place, although even in monkeys and apes the front of the brain manages social awareness and behavior. Since the primate brains of apes and monkeys are so similar to those of humans, many studies of brain function have involved experimentation on these animals, humans' closest relatives. Other mammals such as mice, rats, cats, and dogs have also served as subjects of brain studies that can be related not only to their own specific behavior, but also to how the human brain works in its various component parts. Since neurons are very similar to each other, whether they come from sea slugs, squid, or mammals, experimentation using these animals has produced insight into how all brains and nervous systems work.

Marieb, Elaine N. *Human Anatomy and Physiology*. 5th ed. San Francisco: Benjamin/Cummings, 2001. This college text describes the structure and function of neurons in general, mainly dependent on animal studies that can be applied to humans as well. The human brain and its functions are similar in many ways to the general patterns of the mammalian brain and nervous system.

Mitchell, Lawrence G., John A. Mutchmor, and Warren D. Dolphin. *Zoology*. Menlo Park, Calif.: Benjamin/Cummings, 1988. This college text covers the nervous system in general, as well as discussing the different individual categories of animals, including their nervous system specializations and behaviors.

Restak, Richard M. *The Modular Brain*. New York: Charles Scribner's Sons, 1994. Discussion of the workings of the human brain is accompanied by descriptions of animal brain and behavior experimentation as well as observations on humans. Brain activities in cats, dogs, rats, and monkeys are examined and described.

BREEDING PROGRAMS

Types of animal science: Physiology, reproduction
Fields of study: Biochemistry, conservation biology, embryology, ethology, genetics, population biology, wildlife ecology, zoology

Breeding programs are used with domestic animals to improve their use for human needs, and are used with wild animals for conservation purposes.

Principal Terms

ACCLIMATIZATION: a process by which animals are adapted to new environmental conditions

ANIMAL HUSBANDRY: care and welfare of domestic animals

BIOTECHNOLOGY: methods used to manipulate biological processes (such as reproduction)

DOMESTICATION: a process by which animals are adapted biologically and behaviorally to a domestic (human) environment in order to tame and manipulate them for the benefit of humans

STUDBOOK: a record-keeping system that provides information on an animal's lineage

WILDNESS: characteristics that define the biological and behavioral life of a species in the wild

Keeping wild native animals began about 10,000 B.C.E. While the reasons for this remain obscured because of a lack of historical documentation, the physical evidence indicates an effort to keep animals in order to meet the population's needs. It was also more convenient to have animals nearby to avoid the dangers and difficulties of hunting. As time passed, these captive animals were bred in a manner that produced traits favorable to the people keeping these animals. This process of controlled breeding became known as domestication. Originally, this was an informal affair with little control by the caretakers. Eventually, individuals keeping animals recognized the benefits derived from captive breeding and began exercising more control over the process.

Certain native species were more compatible with the human environment and more adaptable to domestication. These species had attributes favorable to this kind of controlled situation, such as the ability to adapt to new environments, social gregariousness, a dominance hierarchy that recognized humans as an alpha species, adaptable reproductive behavior, mild temperaments, and a low tendency toward flight behavior (which allowed humans to approach them). However, these attributes were not recognized initially, so there was no conscious decision to keep only certain species. Several ancient societies maintained many species in captivity. Most species, those without the favorable attributes, remained wild, or at best were only tamed. Very few species were to become domesticated, and all of these were domesticated in the early years of human agricultural development.

Various attempts were made in Europe and the European colonies to domesticate additional species during the early 1800's, but none were successfully domesticated. The primary group of domesticated animals has remained the same throughout history: the dog, cat, goat, sheep, pig, cow, horse, camel, llama, reindeer, and elephant. Those species already domesticated have been bred over many generations to improve characteristics favored by humans, sometimes to the point that the domesticated animal no longer resembles its wild originator.

Breeding Domesticated Animals

To some extent, there were always animal breeding efforts taking place in agricultural animal herds, but for much of history they were not closely managed. This began to change in the seventeenth century, when science evolved into a reliance on observable and reproducible experimentation. That century saw improvements in livestock feeding, housing, and care, and conditions favoring the attainment of an animal's full genetic potential. Better educated and wealthy farmers were beginning to take notes and keep track of their animals, an important precursor to the breeding experiments that developed in the following century.

The eighteenth century was a time of increasing interest in agricultural improvement and experimentation. Originally, this involved breeding animals for improved adaptation to a local environment (that is, the local conditions where the farm was located). Eventually, however, this changed to breeding animals for improvements in the breed itself, without regard to its environment. Specific commercial advantages were sought, such as improved meat or milk production, or improved wool production. Eventually, as this effort at improving a breed's characteristics became widely practiced, it led to an international pedigree system, with studbooks that documented an animal's lineage.

Breed improvement and experimentation was enhanced through an exchange of information coordinated through the formation of farmers' clubs and societies. New techniques and successful experiments were publicized, and visits to breeding farms were reported upon. Journals were published that contained information previously limited to private correspondence. Monies were invested in improved breeding stock, which more widely distributed the improvements of the various breeds.

Originally these breeding efforts were conducted on the estates of wealthy farmers at their own expense. Toward the end of the eighteenth century, the governments of England and France became interested in promoting improved husbandry practices. France established the Comité d'Agriculture in 1775, and England established the Board of Agriculture in 1793. There was also an urgent need in the European colonies to adapt European domestic animals to colonial environments, or to convert colonial species to domestication. Acclimatization societies were formed for this purpose both in Europe and in the European colonies.

These developments increased significantly in the nineteenth century. In addition to practical improvements, theoretical improvements in animal husbandry were offered as the sciences of agricultural chemis-

Until the twentieth century, breeding programs concentrated on improving the quality of domesticated livestock. As the focus has turned to saving endangered species, one challenge is how to preserve the wildness of animals that will be returned to natural habitats. (Corbis)

Breeding for Wildness Rather than Domestication

Breeding domestic animals is done in order to improve characteristics that benefit humans, such as providing food and clothing. Much of animal husbandry throughout history has been devoted to the improved breeding of domestic stock for characteristics that are important to humans. Although the animal's welfare was provided for, there was no need to be concerned about characteristics that would be important to the animal.

However, when the goal is breeding wild animals, there are different breeding priorities. With wild animals, it is necessary to breed for characteristics that will favor the species, its survival, and its wildness. In fact, breeders wish to avoid what they strive for with domestic animals. This is particularly true if a species is extinct in the wild, endangered, or is to be returned to the wild to survive on its own. Even if this is not the case now, the situation may change in the future. Even species that are to remain in captivity within the foreseeable future should remain true to their wild conspecifics.

Maintaining an animal's wildness and related species characteristics through breeding is a relatively new concept. Even though studbooks are maintained for many wild species, there is no consensus on characteristics that define each species or what constitutes wildness. Unintentional domestication, or at the very least taming, may result from maintaining numerous successive generations in captivity, even though it is not intended to domesticate the animal. Thus, the problem is to overcome this domestication effect and maintain the wild characteristics of the species in those animals being cared for. This offers new challenges that have only recently been considered by those involved with wildlife conservation.

try, reproductive biology, and genetics developed. Advances in scientific knowledge aided the animal breeding efforts of farmers, and this information was better distributed once governments and universities developed agricultural departments, extension offices, and experiment stations to benefit the farmers.

Publication of *Die Organische Chemie in ihre Anwendung auf Agrikultur und Physiologie* (1840; *Organic Chemistry in Its Applications to Agriculture and Physiology*, 1840) by Justus von Liebig introduced agricultural chemistry to a wide audience and began what became known as scientific agriculture. Charles Darwin's book on evolution was published in 1859, and Gregor Mendel's work on genetics was published in 1866. Germany began a system of government-operated experiment stations in the 1870's. These combined laboratory experimentation with farm experimentation. In the United States, the U.S. Department of Agriculture was established in 1862, as were the land-grant colleges located in each of the states. Several states developed agricultural experiment stations in the late 1800's, and the federal government established a national system of experiment stations in 1887.

Implementation of federal and state programs developed in earnest during the early decades of the twentieth century. Scientific advances and a growing human population encouraged improvements in animal husbandry. Improvements in breeding techniques, improved knowledge about reproductive biology, improved veterinary care, and better housing for the animals also contributed to better animal husbandry. Eventually genetics and biotechnology began to play a major role in developing specific characteristics in each breed. After midcentury, farms decreased significantly as urban populations grew. Within this shifting demography, breeding programs gained new importance, as fewer farmers grew an ever-increasing number of domestic animals to meet the needs of a growing urban human population.

Breeding Wild Animals

Today's domestic species were once wild, but have been changed to suit human needs through the process known as domestication. Few species have been domesticated, even though attempts have been made to domesticate a wide range of species. The London Zoological Garden, the French Jardin Zoologique d'Acclimatation, and several acclimatization societies attempted to domesticate additional species in the late eighteenth century, but none were successful. The acclimatization facilities of these societies eventually closed or evolved into zoos that maintained, exhibited, and bred wild animals without changing them into tame or domestic animals.

Zoos and aquariums have always been concerned with wildlife conservation, although their effectiveness has been dependent on the era's zoological and animal husbandry knowledge, as well as the society's perceived importance of conservation. As the importance of conservation increased and the sciences related to wildlife conservation improved, zoo and aquarium conservation efforts improved. These conservation efforts included propagation programs that bred endangered species and species extinct in the wild. These propagation programs involve species studbooks, studying small populations of animals, introducing animals back into the wild, and other modern techniques.

Breeding wild animals over many generations, however, runs the risk of domesticating these animals. Of course, no such intentional domestication program has been successful. The greater risk is that the animals will become tame, will be unable to survive in the wild, and will lose their wildness. Because the breeding of wild animals is based on the animal's needs rather than human needs, propagation efforts with wild species are quite different from efforts made with domesticated animals. Nevertheless, the methods are similar.

Both wild animal breeding and domestic animal breeding require detailed studbooks in order to keep track of an animal's lineage, and the pairing of appropriate individuals is closely controlled. Many sciences provide knowledge important to the propagation programs, such as veterinary medicine, nutrition, reproductive biology, genetics, and biotechnology. Frozen tissues, artificial insemination, bioengineering, and recombinant deoxyribonucleic acid (DNA) technology play an increasingly important role in modern breeding programs.

Breeding wild animals is often more difficult than breeding domestic animals, since unusual breeding behavior is part of the reason some species are endangered. Improved knowledge about the species' social behavior and population biology needs are of assistance in the successful breeding of these difficult wild species, as is biotechnology. Frozen zoos have been established to maintain reproductive and other tissues for artificial insemination. Sometimes this artificial insemination involves the use of related surrogate species; for instance, using domestic cattle to give birth to endangered gaur. Back breeding is being attempted in order to revive extinct species; for example, breeding zebra so as to re-create the extinct quagga. As an increasing number of species become endangered and as their natural habitat continues to disappear, it is increasingly important to maintain these species through appropriate breeding programs.

BUTTERFLIES AND MOTHS

Type of animal science: Classification
Fields of study: Anatomy, entomology, evolutionary science, invertebrate biology, physiology

Approximately 17,000 species of butterflies and 153,000 species of moths have been classified in the general order Lepidoptera (insects with scaly wings). They exhibit an incredible variety of color, pattern, shape, and size, as well as the ability to adapt to almost every climate.

Principal Terms

ANTENNAE: a pair of segmented sensory appendages located above the mouth parts

BATESIAN MIMICRY: an evolutionary trend in which an edible species mimics the form of a distasteful species to avoid predation

FRENULUM: a spinelike device that connects the front and hind wings in moths

INDUSTRIAL MELANISM: the rapid rise in frequency of the melanic form in many moth species downwind of manufacturing sites, associated with the advent of industrial pollution

METAMORPHOSIS: the process through which a larval form becomes a winged adult form

PROBOSCIS: a coiled, springlike sucking tube or "tongue" used to drink nectar

Butterflies and moths are collectively the second largest order of the insect class and are found on nearly every continent. Over 170,000 species have been classified and new species continue to be identified each year. While some are known throughout the world, most lepidopteran species have more limited distributions that reflect the presence of geographic barriers (such as mountains or deserts), food plant distribution, strength of flight, and degree of tolerance to environmental factors (such as temperature). Like other animal species, butterflies and moths exhibit their greatest diversity in the tropics.

Physical Characteristics of Butterflies and Moths

Butterflies and moths exhibit an enormous diversity of physical attributes. The smallest, the Western pygmy blue, is a butterfly with a wingspan of just 1.5 centimeters; the largest, the Atlas moth, has a wingspan that can reach 30 centimeters.

Like all insects, the bodies of butterflies and moths are divided into three regions: head, thorax, and abdomen. In most species, the head has prominent, large, compound eyes and a long pair of antennae used as "feelers" mounted above. Lepidopterans also have well-developed olfactory organs, and some moths are capable of hearing. Below the eyes is a coiled proboscis used to suck nectar. The thorax of the insect has three segments, each of which bears a pair of legs, the last two of which support pairs of wings, referred to as the fore and hind wings, respectively. The wings of butterflies and moths are supported by a series of tubular struts, called veins, that form complex patterns, which are often of great taxonomic significance in distinguishing species. The abdomen is a roughly tubular structure composed of ten segments ending with external genitalia which, because they vary greatly from species to species, are also of great taxonomic significance. The entire body, with the exception of the eyes, is covered with fine hairs, some of which are flattened to form scales. On the wings these scales are arranged like the shingles on a roof, with the exposed surface having minute longitudinal ridges visible under a microscope.

Lepidopterans vary greatly with respect to wing color and pattern. Wing coloration is usually caused by pigments deposited in the scales of the wings, but in some butterflies, such as the purple emperor, the iridescent and metallic colors are due to the construction of the scales themselves. Many butterflies are highly prized for their beautiful and brilliantly colored wings, including the blue morpho, whose brightly colored blue wings are thought to play an important role in mate attraction. In other species a conspicuous pattern may serve as warning coloration. One well-known example is the monarch butterfly, which has a bold pattern of black and orange that warns potential predators that it is distasteful. In this case, the warning is accurate because monarchs feed on milkweed plants that secrete a distasteful substance. It is interesting to note that the viceroy butterfly has evolved a nearly identical wing pattern, apparently to fool potential predators into thinking it is a monarch. The latter is an example of Batesian mimicry, or the evolution of form similar to a distasteful model by an edible species. Coloration, pattern, wing size, and shape in other species may, conversely, aid the lepidopteran by rendering it inconspicuous. For example, the pale form of the peppered moth is actually a complex pattern that effectively camouflages it against lichen-covered tree trunks.

While butterflies and moths are physically quite similar to one another, there are several distinct structural features used by taxonomists to distinguish them. Butterflies have antennae that are clubbed or at least swollen at one end, whereas the antennae of most moth species are featherlike. Butterflies all lack a true frenulum, which is a device that connects and coordinates the movement of the fore and hind wings of moths during flight. In general, butterflies have slender bodies, are brightly colored, and fly during the day, whereas moths are stouter, exhibit more drab colors, and fly at night. There are, however, some brightly colored, slender moth species, such as the coppery dysphania, and some representatives of one of the butterfly families known as "skippers" have stouter bodies, are dull-colored, and may be active at night.

The Life Cycle of Butterflies and Moths

Butterflies and moths share a complex life cycle consisting of four distinct phases: egg, caterpillar

Butterflies and moths play an important role in the pollination of many plants. (Corbis) (larvae), pupa, and adult. After mating, the female lepidopteran lays eggs, sometimes singly and sometimes in clusters, on the food plant of the caterpillar or larvae. After hatching, the larvae usually feed on the plant's leaves, although in some species, such as the skippers, the larvae feed on the stems and roots of the plant. During this time the larvae grow rapidly and shed their old skin or exoskeleton four or five times before they are fully grown. Upon reaching full size, the caterpillar undergoes a dramatic transformation, called metamorphosis, into a quiescent pupa or chrysalis stage, during which the larval organ systems are dissolved and rebuilt into the structures of the adult moth or butterfly. The caterpillar begins this process by spinning a small button of silk from which it hangs head downward. While grasping the shed larval skin between the edges of its abdominal segments, the pupa fastens itself to the button of silk. In some species, such as the swallowtails, the pupa is held upright by means of a silk girdle around its middle; in other species, such as the skippers, the larvae pupate in cocoons. After a period ranging from a few weeks to years, the lepidopteran emerges from the chrysalis and expands its wings by pumping blood into them from the body cavity. When the wings have dried, the lepidopteran is ready for flight.

Several lepidopteran species undergo migration. In some species, such as the monarch butterfly, the adult migrates on a seasonal basis. Experimental releases of monarchs suggest it is unlikely that any of the adult butterflies who start the journey complete the round trip—it is thought that the journey back is completed by their offspring.

Butterfly and Moth Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Arthropoda
Subphylum: Uniramia
Class: Insecta
Subclass: Pterygota
Order: Lepidoptera (butterflies, skippers, and moths)
Suborders: Zeugloptera (mandibulate archaic moths); Aglossata (kauri moths); Heterobathmiina (valdavian archaic moths); Glossata (swallowtails, sulfurs, orangetips, coppers, hairstreaks, blues, brush-footed butterflies, milkweed butterflies, wood nymphs, satyrs, skippers, sphinx moths, giant silkworm moths, geometer moths, tiger moths, noctuid moths, tussock moths, clear-winged moths, clothes moths)

Geographical location: Every continent except Antarctica

Habitat: Mostly fields and forests, but some are found within a few hundred miles of the North Pole far above the tree line on mountains, and in deserts (in the spring or after a rainstorm)

Gestational period: In tropical climates, a lepidopteran may have four generations in a single year; in Arctic regions where the growing season is much shorter, the cycle may take as long as two years, with larvae hibernating during the cold periods

Life span: Most live from four months to one year, but species in Arctic regions may live as long as two years

Special anatomy: Six legs, three on each side of the thorax; two pairs of wings; a proboscis for sucking nectar

Beneficial and Destructive Butterflies and Moths

Butterflies and moths play essential roles in the pollination of many plant species, are important sources of food for other animals, and are highly valued for their aesthetic qualities by collectors. Larvae of the silkworm moth have been used to produce silk in China since 2640 B.C.E. Several lepidoptera, however, are pests of important agricultural crops. The larvae of the cabbage butterfly do millions of dollars of damage to the cabbage crop each year; gypsy moth larvae are notorious for defoliating trees in North America and Eurasia.

Industrial Melanism

The rapid life cycle and genetic variability of many butterfly and moth species makes them particularly useful for the study of evolution. One famous example is the classic investigations of the phenomenon of industrial melanism made by H. B. D. Kettlewell (1907-1979) in the early 1950's. Kettlewell worked with the peppered moth, a common species of moth throughout Britain and continental Europe. The moth was known to have two forms: a pale form that was very common and a dark form that was quite rare. Toward the end of the nineteenth century, this situation began to change. The first large-scale burning of coal, coke, and oil associated with the industrial revolution killed off the lichen cover of the unpolluted countryside downwind of manufacturing sites, visibly darkening the surfaces of trees. Coincident with these changes, naturalists and moth collectors alike began to notice that the previously rare dark form of this species (and others as well) was becoming more common. One way to explain this change can be stated with reference to natural selection. In unpolluted woods, the dark form is easily spotted by birds (the major predators on these moths) when it rests on pale, lichen-covered tree trunks, in contrast to the pale form, which is difficult to see. In polluted environments, the dark form is naturally camouflaged against visual predators when it rests on soot-darkened tree trunks, but the pale form is easily spotted. Kettlewell, using a series of investigations involving both experimental releases and field observations of differential bird predation, is generally credited as demonstrating that this explanation is indeed correct. It is interesting to note that since the advent of clean air legislation in Britain, the frequency of the dark form has declined once more.

CAMELS

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, developmental biology, ethology, physiology, reproduction science

Camels, the one-humped dromedary and the two-humped Bactrian, are well-adapted to the desert regions of Africa, the Middle East and Central Asia, where they are used for transport, milk, and meat. They can live without water longer than other large mammals.

Principal Terms

FERAL: domesticated animal no longer under the control of humans
HERBIVORE: animal solely dependent on plant material for its nutrition
INTERFERTILE: able to breed and produce fertile offspring
QUADRUPED: animal with four feet
RUMINATE: regurgitate and rechew ingested food

The ancestors of camels evolved in North America fifty million years ago. The oldest relatives were only twelve inches tall and lacked humps. About three million years ago, one branch migrated across a land bridge to Asia, becoming today's camels. Later, others moved to South America to become the lamoids, which include the vicuña, guanaco, llama, and alpaca. The North American camelids became extinct after the last ice age, perhaps due to climate change but more likely from overhunting by humans who were occupying the continent at that time. Dromedary camels were domesticated four thousand years ago in Arabia, while the Bactrians were independently domesticated five hundred years later in Central Asia. While primarily used for transport, they are also valued for milk, meat, hair, leather, and dung, which is dried and used for fuel. Although some wild Bactrian camels may still exist in remote regions such as China's western Xinjiang Province, most camels are domesticated or feral. Worldwide, camels are estimated at twenty million, 75 percent in North Africa (from Morocco to Somalia) and 25 percent in Asia (from Arabia to Mongolia), with twenty thousand in Europe and Australia.

Physical Characteristics of Camels

Camels, among the largest terrestrial animals at more than seven feet tall and ten feet long, are well adapted to arid regions of the world. Their long legs keep their bodies away from the hot surface of the ground. In addition, they have a thin profile when viewed from the front; this permits them to minimize absorbing solar radiation by facing the sun, which they do in the hottest periods of the year. Furthermore, they allow their body temperatures to rise up to 108 degrees Fahrenheit. They conserve water by having very efficient evaporative cooling and by producing very concentrated urine and dry, pelleted feces. They can also endure a substantial loss in body water, up to 40 percent of their body weight, with little harm or loss of appetite; they preserve the water in the blood at the expense of that in their tissues and alimentary tract. Furthermore, when rehydrating, they can consume up to fifty gallons of water without damaging their tissues or red blood cells; the latter can expand 2.4-fold without bursting. Contrary to popular myth, their humps do not provide water storage, consisting instead mostly of fat that can be used as a metabolic fuel. When camels are starved, their humps will regress or become limp.

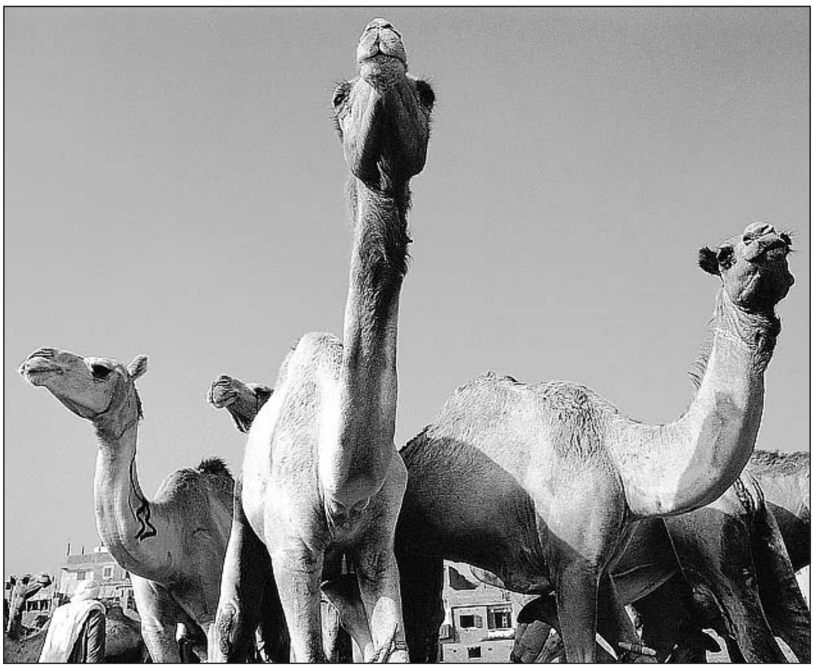
Camels are herbivores and eat a variety of plant material, grass, brush, and trees, subsisting well on browse with low nutritional value. As a result, their food preferences are complementary to those of other domesticated and wild animals. They can obtain much of their water needs from plants. With sufficient food and at moderate temperatures, they have been known to go months without drinking. They ruminate, permitting rapid ingestion of food and subsequent regurgitation and rechewing. Unlike cattle and sheep, they have three rather than four stomach compartments, although the first one, the rumen, is similarly used for microbial fermentation of plant material that would otherwise be indigestible.

Camels can carry loads of three hundred pounds and cover up to one hundred miles a day (although twenty-five to fifty is typical). They are loaded or mounted when they are in a kneeling position. They have a pacing gait, where both feet on each side move together, and their broad, padded feet keep them from sinking in sand. To deal with sandstorms, they have a third eyelid that comes up from below the eye, long eyelashes, and nostrils that they can close. Camels have very good eyesight; their eyes are protected from bright sunshine by a bony protrusion. They also have a keen sense of smell; reputedly, they can smell water a mile away.

Like their South American cousins, camels mate in a crouched position. Their pregnancies last thirteen months, resulting generally in single offspring. Females have relatively small mammary glands between their rear legs. They become sexually mature at three to four years, continue to grow until they are fifteen or older, and can live to be forty years old, although most are killed for meat before then.

Comparison of Dromedary and Bactrian Camels

The most obvious difference between the two types of camels is that dromedaries have one hump and Bactrians have two. During embryonic development, both have two humps, but one regresses before birth in dromedaries, although the vestige of that second hump is sometimes visible in front of the more prominent one. Bactrians are also shorter and hairier; these adaptations permit them to survive at the higher and colder elevations of the deserts of Central Asia. They survive at temperatures below freezing in winter and in the summer above 120 degrees Fahrenheit. They shed their hair in the spring and regrow it in the fall. Bactrians also have tougher foot-pads to deal with a more rocky terrain. Bactrians are slower animals; some dromedaries are bred as racing animals. These two types of camels are fully interfertile and, accordingly, belong to the same species. Dromedaries are much more numerous than Bactrian camels.



The camel's slender side-to-side body shape minimizes the amount of solar radiation it absorbs and helps keep the animal cool. (PhotoDisc)

Future of Camels

Camels are closely linked to the largely nomadic existence of their owners, whose lifestyle is succumbing to the demands of modern nation-states for more sedentary populations and respect for national borders, as well as the increasingly pervasive use of motor vehicles. These factors put the survival of camels at risk. However, they remain the best-adapted large animal in the most arid desert regions of the world and are not currently endangered as domestic or feral animals, although the remaining wild camels in Central Asia are under threat due to the fact that their natural habitat is China's nuclear test range. Camels could have increasing value for adventure vacations in the remote deserts of the world.

Camel Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Artiodactyla
Suborder: Tylopoda
Family: Camelidae
Genus and species: Camelus dromedarius (one-humped camel), *C. bactrianus* (two-humped camel)

Geographical location: Africa and Asia
Habitat: Deserts
Gestational period: Thirteen months
Life span: Up to forty years
Special anatomy: One hump or two humps on the back; several adaptations that permit them to conserve water

Webster, Donovan. "Journey to the Heart of the Sahara." *National Geographic* 195, no. 3 (March, 1999): 3-33. This well-photographed article reports on excursions into the central Saharan desert, describing the lives of its people and their camels.

CAMOUFLAGE

Type of animal science: Ecology
Fields of study: Ecology, ethology, evolutionary science

Both predatory and prey species use camouflage to minimize the chance that their presence will be detected. Although camouflage is often thought of as being exclusively a visual phenomenon, it must occur in all sensory modalities for it to work.

Principal Terms

APOSEMATISM: use of bright, noncamouflaged colors as a warning signal to indicate toxicity or dangerousness

COUNTERSHADING: a form of crypsis involving dark coloration on top and light coloration on the underside

CRYPTIC COLORATION: any color pattern that blends into the background

DISRUPTIVE COLORATION: use of stripes, spots, or blotches to break up the body outline and blend into a complex background

PROTECTIVE MIMICRY: use of both color and form to mimic an inanimate feature of the environment

Crypsis is the art of remaining hidden. Camouflage is usually thought of as color matching: a green aphid, for example, is likely to go unnoticed while feeding on a green leaf. Background matching, or cryptic coloration, is, indeed, the most common form of camouflage, but most crypsis involves far more than matching a single color. Very small animals such as aphids can get away with using a single camouflage color because they are much smaller than the plants on which they spend their entire lives: They only need to match one thing. Most animals, however—even most insects—are significantly larger than aphids and are likely to spend time in more than one place. Their camouflage must be more sophisticated if it is to be useful.

If a large organism is to remain undetected, it must be camouflaged with respect to an entire scene. One way to do this is with the use of disruptive coloration, that is, the use of stripes, spots, or patches of color for camouflage. Disruptive coloration can involve large color patches, as on a pinto pony, a tabby cat, or a diamond-backed rattlesnake, or may involve tiny variations of color on each scale, feather, or hair. Many brownish or grayish mammals actually have what is called agouti coloring, with three different colors appearing on each hair.

The irregular borders of multiple color patches on an animal's body help to obscure its outline against an irregular and multicolored background, just like the blotchy greens and browns on military uniforms. An animal that has a mix of browns in its fur, feathers, skin, or scales, for example, will blend into a forest or even an open desert or tundra much better than one that is a single solid color. Even the black-and-white stripes of zebras, which seem so striking, act as a form of disruptive coloration: From far away, and especially to an animal such as a lion, which does not have good color vision, the stripes of zebras help them blend into the tall, wavy grasses of the savannah.

Countershading is another form of crypsis involving differently colored patches. Countershaded animals appear dark when viewed from above and light when viewed from underneath. Animals with countershading include orca whales with their black backs and white bellies, penguins, blue jays, bullfrogs, and weasels. Countershading works and is found as camouflage in

Octopus: The Master Deceiver

Some animals such as chameleons (and anoles, which are mistakenly called chameleons) are famous for changing their color to match the background. Anoles can change from whitish to gray, brown, or green to match the sand, branches, or foliage where they rest. Some fish can go one better, creating complex disruptive color patterns to match different kinds of blotchy sand, rock, or coral backgrounds. The master of deception, however, is the octopus. No vertebrate can match the octopus in terms of the speed with which it changes color, the number of patterns it can create, or the variety of shapes and textures that it can take on.

Octopuses communicate with one another using complex and rapid changes in color, shape, and skin texture. They can also change color, shape, and texture to threaten, to bluff, or to hide from their enemies. Because they can transform themselves so quickly, octopuses are hard to follow and then hard to find again once lost from sight. They can squeeze into tiny crevices or, in a fraction of a second, turn into what looks like a piece of coral or seaweed or rotting wood—in fact, into virtually anything they might encounter in their environment.

Octopuses are also famous for another trick. When all else fails, they squirt a batch of jet-black ink into the surrounding water. By the time the ink has dissipated and the predator can see again, the octopus is long gone.

so many kinds of animals because no matter where one lives—a desert, a forest, a meadow, or an ocean—the sun shines from above. When looking up toward the sun and sky, dark things stand out and light colors blend in; when looking down toward the ground or the ocean floor, light colors stand out and dark colors blend in. Predators that are countershaded can thus approach their prey with equal stealth from either above or below; likewise, prey species that are countershaded will be equally hard to find whether a predator is searching from on high or from underneath. Countershading and other forms of disruptive coloration can occur in the same organism, so that dark spots, blotches or stripes appear on top while paler ones appear below.

Another way of remaining undetected in a complex scene is by using protective mimicry, that is, to mimic an inanimate object in both color and form. Some insects look like thorns on plant stems; others look like leaves or twigs or flowers. Some insects, frogs, and fishes look like rocks, lichens, or corals. Sea lions, sea dragons, and even eels can look like floating kelp or other forms of seaweed.

Some animals may not look much like the objects around them, but will disguise themselves by attaching pieces of plants or sand or other debris to their body. Some caterpillars use silk to tie bits of flowers and leaves to their body; others use saliva as a glue. Some crabs glue broken bits of shell and coral to their own exoskeleton. By using bits of local materials to camouflage itself, an animal can ensure that it matches the background. It can even change its disguise as it moves from one area into another.

Being transparent is another way to match whatever background happens to be present. Many marine invertebrates such as worms, jellyfish, and shrimp, are completely transparent. Complete transparency is less common among land animals, but some land invertebrates have transparent body parts, such as their wings, allowing them to break up the outline of their body and blend into whatever happens to be in the immediate background.

The Behavior and Ecology of Crypsis

Behavior is an important factor in the success or lack of success of any form of crypsis. For example, not even disruptive camouflage can hide something that is moving quickly with respect to its background. Because of this basic fact, predatory species that rely on speed or stamina to outrun, outswim, or outfly their prey generally have little use for camouflage. On the other hand, so-called sit-and-wait predators (such as boa constrictors or praying mantises), must be virtually perfectly camouflaged in order to remain undetected while their prey approach to within grabbing distance. In between are the stealth hunters that sneak up on their prey before making a final high speed attack; such animals must be camouflaged and slow moving when out of attack range, but do not have to be camouflaged or slow when at close range.

As with predators, prey species that rely on rapid escape maneuvers do not often bother with camouflage coloration, while prey species that cannot rely on efficient escape tactics must, instead, rely on not being seen in the first place. Prey species that can move quickly but not as quickly as their predators must detect their predators before their predators detect them, and then they must remain absolutely still until the danger has passed.

Some species use different strategies as they go through different stages in life. In many altricial species (species with dependent young that require extended parental care of the offspring), the eggs and/or young are camouflaged, even though the adults are not; the temporary spots on deer fawns and mountain lion cubs are examples. In other species, nesting or brooding females may be camouflaged while the adult males retain their gaudy plumage or attention-getting behaviors; the changing seasonal patterns of color and behavior of ducks and songbirds provide examples here. Some species may be toxic and gaudy during one stage of life, yet tasty and cryptic during another.

Finally, although camouflage is usually thought of as a visual phenomenon, crypsis is important in every sensory modality. If a prey animal is virtually invisible to its predators, but puts out a sound, a scent, or a vibration that makes it easy to locate, visual crypsis alone would be useless. For successful protection, prey species must be cryptic in whatever sensory modalities their predators use for hunting. Likewise, for successful hunting, predatory species must be cryptic in whatever sensory modalities their prey use to detect danger. For most species of both predator and prey, this

Zebras' stripes not only help them blend into their grassland habitat but also make it difficult for predators to pick out a single individual for attack. (Digital Stock)

Aposematism

Some prey animals use a strategy that is the opposite of crypsis: They attract attention to themselves, but advertise the fact that they might be dangerous to eat. This kind of advertising is called aposematism (or aposematic coloration or aposematic display).

A classic example of aposematism involves the monarch butterfly. The bright orange and black adults, as well as the orange, black, and white striped caterpillars, stand out against almost any background. Yet despite their obviousness, monarchs are generally left alone. As larvae, monarch caterpillars often feed on the toxic milkweed plant. Not only have they evolved an immunity to the milkweed's poison, but they take advantage of the toxin by incorporating it into their own body to act as a poison against potential predators. When birds first taste a monarch, they spit it out in disgust and learn to avoid other monarchs in the future.

Interestingly, viceroy butterflies are also distasteful and have evolved an appearance quite similar to that of the monarch. By adopting the same striking color pattern, each species is avoided after a bird first gets a taste of either one. This phenomenon, when two or more species use the same aposematic coloration, is called Müllerian mimicry. Occasionally, nontoxic prey species take advantage of the existence of an aposematic species by mimicking its warning coloration. Even though they are not toxic, these Batesian mimics are avoided by predators who have previously encountered the toxic species. For this deceit to work well, the models (the toxic species) have to outnumber the mimics (the nontoxic species) so that most predators encounter the distasteful species first.

means being camouflaged or blending into the background in several sensory modalities all at once.

Wicksten, Mary K. "Decorator Crabs." *Scientific American* 242, no. 2 (February, 1980): 146-154. As with all *Scientific American* articles, this is a nice lay summary with excellent descriptions, drawings, and photos of crabs that attach material to their shells for camouflage.

CANNIBALISM

Types of animal science: Behavior, evolution
Fields of study: Anthropology, evolutionary science, population biology, reproduction science

Cannibalism is the act or practice of consuming the bodies or parts of the bodies of a species by members of the same species. Although its practice is not universal in the animal world, there are more than 1,300 kinds of cannibal animals in existence in the world today.

Principal Terms

ECOSYSTEM: a community of organisms in relation to each other and their physical environment

ENDOCANNIBALISM: a form of human cannibalism in which members of a related group eat their own dead

EXOCANNIBALISM: a form of human cannibalism in which unrelated humans are eaten

The most persuasive reason why cannibalism takes place within a species is the need to survive. Paramount to survival is the necessity to have a diet sufficient to support development and continued existence. Competition for survival begins at birth and continues throughout the life cycle of the animal. Since most animals produce more young than can survive, it sometimes occurs that the strongest of the young feeds on the weakest. Young mantids (praying mantises), black widow spiderlings, and varieties of young salamanders, for example, often feast on their brothers and sisters as soon as they are born. In some varieties of sharks, only one or two shark pups are born from the large number of eggs that the mother shark carried during gestation; the surviving shark pups consume their brothers and sisters before birth.

Another reason for cannibalism, also related to the need to survive, is the necessity to eliminate competitors within an ecosystem. Some young tiger salamanders, when living in extremely crowded conditions, develop special structures in their mouths that enable them to eat other salamanders that are their competitors. Adult male Kodiak bears often kill and eat young cubs, especially male cubs, as a means of both supplementing their diet and eliminating future competitors. Male lions and male feral cats are also known to kill and eat the cubs of another male, thus enabling them to mate with the mother of those cubs and ensure that their own offspring will survive. Male chimpanzees are also known to engage in the practice of killing and eating infants of females that they have not impregnated.

Sometimes cannibalism is related either to the lack of enough food or to a diet deficiency. Two popular household pets, guppies and gerbils, eat their young if there is not enough food available. Female gerbils also cannibalize their own or another female's litter as a means of gaining more protein in their diet. Furthermore, livestock may be forced into cannibalism by the practice of feeding them by-products of slaughtered animals to increase their protein intake; this practice is believed to have spread bovine spongiform encephalopathy, or "mad cow disease," among cattle.

One form of cannibalism still perplexes scientists. During the mating and reproduction process, some female members of the animal kingdom kill and later consume their suitors. Black widow spiders are perhaps best known for this practice, but not all black widows eat their mates after killing them. Scientists have discovered that if the female black widow spider is not hungry, she will not consume her dead mate. The female praying mantis, however, will always devour her mate after she has killed him.

Some animals appear especially capable of consuming members of their species if there is nothing else readily available. *Tyrannosaurus rex*, the famous prehistoric predator, was apparently in that category. Scientists have discovered that the North American *T. rex* may have devoured members of its own group in order to gain a fast and easy meal. South American horned frogs apparently feed on anything, including fellow horned frogs, that moves near them.

Human Cannibalism

While factors that explain cannibalism among animals can also be applied to humans, there are several other possibilities to examine in the case of humans. Prehistoric humans engaged in cannibalism as a means of survival, and modern human cannibalism because of a natural disaster or an accident has also been recorded. There are stories of shipwrecked sailors resorting to cannibalism of their dead and even murder and cannibalism in order to survive. Perhaps two of the most famous instances of modern cannibalism forced by starvation was the 1846-1847 experience of the Donner Party in California, and the 1972 incident involving the Andes mountain crash of a plane carrying a Uruguayan soccer team. In both instances, the survivors resorted to cannibalism (but not murder) in order to withstand the peril they faced.

However, the human animal is unique in that cannibalism is also practiced as a social and religious custom not involving subsistence and survival in the normal sense. One type of human cannibalism involves a genuine reverence by relatives for their dead. Called endocannibalism, this practice is based upon the belief that eating the flesh of departed relatives shows great respect and veneration of the dead. This type was practiced among the natives of islands of the southern Pacific Ocean until it was declared illegal following World War II.

Exocannibalism has ritualistic and religious overtones as well. Native warriors of the South Pacific, popularly referred to as headhunters, ate parts of their vanquished opponents as a means of controlling them and gaining their strength. Sixteenth century South American natives mixed the eating of captured slaves with religion, making the cannibalistic ritual into a festival. Indeed, it was actions similar to these, observed by the Spanish, that gave us the word "cannibal"— Columbus incorrectly transcribed the name of the human-eating Caribs of Cuba as *Canibalis*.

CARNIVORES

Types of animal science: Anatomy, behavior, ecology, evolution
Fields of study: Anatomy, conservation biology, ecology, ethology, paleontology, wildlife ecology, zoology

Carnivores (literally, "flesh eaters") are one of the most successful orders of mammals. Most species are endangered by human persecution and habitat destruction.

Principal Terms

BODY MASS: the average weight of females of a species, expressed in kilograms
DIURNAL: active mainly during the daytime
GREGARIOUS: forming groups temporarily or permanently
NOCTURNAL: active mainly during the night
OMNIVORE: an animal that eats both plant material and animal material

Carnivores are a modern order of mammal that includes ten families: bears, cats, civets, dogs, hyenas, mongooses, pandas, red pandas, raccoons, and weasels. They first appear in the fossil record of the Eocene period, forty to fifty million years ago, and probably evolved from nocturnal, small, semiarboreal predators called miacids. Carnivores are recognizable by their teeth: enlarged canines, specialized for stabbing and holding prey, and carnassials, specialized for shearing flesh and skin. All carnivores eat other animals, which they capture in a variety of ways. Most are terrestrial, although the otters are aquatic. Carnivores are found on all continents except Antarctica. They are recent arrivals to Australia, apparently having reached this island continent along with humans ten to forty thousand years ago.

Bears, Cats, and Civets

Bears (family Ursidae) are widely distributed in Eurasia and North America, but only a few forms live in tropical areas of Asia and South America (the sloth and the sun and spectacled bears). At one time, a large predatory bear of the genus *Agriotherium* lived in Africa, but currently no wild ursids exist on this continent or in Australia. Today, the largest living ursid is the polar bear, with a body mass of 320 kilograms. Many Ursidae share with some of the Mustilidae a unique reproductive physiology, called delayed implantation, in which the fertilized egg may take many months to implant in the uterus and continue its development. This may be an adaptation to hibernation and wintertime shortages of food in temperate regions. Bears in cold climates spend much of the winter hibernating in a protected den. During this time, their heart rate and metabolism slow to conserve energy. Most bears are omnivorous, but the polar bear is a specialist hunter of seals.

Cats (family Felidae) are distributed throughout the world, from the heights of the Himalayas (the snow leopard) to the Amazon (the jaguar). The cats are among the most carnivorous of their order and the most adaptable. The earliest felids evolved in forested areas, and most retain adaptations for tree-climbing and use of cover as concealment. Millions of years ago, much larger forms of felids existed, including the extinct sabertooths whose long, bladelike upper canines were specialized for delivering killing bites to the necks of large prey, such as mammoths. Cats are a diverse family, ranging from the group-living lion (body mass 135.5 kilograms) to the solitary Geoffroy's cat (body mass 2.2 kilograms). Virtually all cats can hunt day and night, but nocturnal habits predominate. The cheetah is the only living cat that hunts exclusively by day. Often habitats will contain several species of cats, differing in size and specialized for different prey. For example, certain areas of the Amazon may contain jaguars, pumas, ocelots, and one or more forms of smaller cat, such as jaguarundi or margay.

Civets (family Viverridae) are restricted to tropical and subtropical areas in Africa and Asia. Civets retain many ancestral morphological features of the first carnivores. They are small (body mass range 1.2 to 13 kilograms), with adaptations for climbing trees and no specializations for pursuit or ambush of prey. Civets are nocturnal and, with one exception, arboreal. They eat both animals and fruits, although the fossa is almost exclusively predatory and the binturong eats almost only fruit. Viverrids are closely related to the mongooses.

Dogs, Hyenas, and Mongooses

Dogs (family Canidae) are almost as widely distributed as felids, being found from the Arctic and to the South American rainforest. However, canids evolved in open country habitats of North America and few have adapted to life in rain forests. The wolf was once the most widely distributed carnivore in the world. It evolved in east Asia and from there spread throughout Eurasia and the Arctic Circle, including migrating down into North America as far south as Mexico. Canids have reached their highest diversity in North American woodland-plains habitats (wolves, coyotes and foxes) and African savannahs (wild dogs and jackals). The dog family is diverse, but the domestic dog shows as much variation in body form (from tiny dachshunds to Great Danes) as all of the wild dog species put together. The smallest wild dog is the North African fennec (body mass 1.5 kilograms), and the largest is the wolf (body mass 31.1 kilograms). Although some canids, such as the gray fox, can climb trees to a limited extent, the dog family is highly adapted to fast running in open ground. Canids are characterized by complex social systems, often involving cooperative care of the young by older juveniles or nonreproducing adults. Dogs hunt animals by day and night, but many forms supplement their meat diet with fruit.

Hyenas (family Hyaenidae) are found mainly in Africa, with one species, the striped hyena, living in southern and western Asia. However, in the Miocene and Pliocene (two to twenty-two million years ago), the hyenas were numerous, diverse, and widespread through Africa, Eurasia, and

Predatory Behavior

Most carnivores pursue prey to obtain animal food. Four behavioral strategies for prey capture can be identified. The first and simplest is random encounter, in which the carnivore moves about its habitat and captures hidden or immobile prey. This predatory style characterizes most mongooses, civets, bears, and many mustelids. The second strategy involves following tunneling prey into their burrows. Many of the weasel group are specialized for this type of hunting, with their long, slender bodies and ability to lock their jaws on prey. The third strategy is ambush or stalking, in which predators rely on stealth to surprise prey. Any pursuit is typically a short chase that is abandoned if the prey outdistances the attacker. All cats are ambush predators. They have little stamina but can accelerate quickly. Vigilance gives early warning of attack and thus is very important for prey facing ambush predators. Finally, pursuit or coursing predators chase prey until the prey are exhausted or reach refuge. Stamina is more important than acceleration for these predators. Many canids and the spotted hyena are pursuit predators. Canids often survey fleeing prey, searching for individuals that run slowly due to age or infirmity. The coursing predators—wolves, dogs, and hyenas—commonly hunt in groups because through teamwork, the predators can run farther and faster than they could singly. The prey's best defenses are access to refuge or tireless running.

North America. Only four species of hyaenids exist today: the spotted hyena at 55.3 kilograms, the striped hyena at 35 kilograms, the brown hyena at 43.9 kilograms, and the aardwolf at 7.7 kilograms. The rise of the dog family has occurred in parallel with the decline of the hyenas. The unusual aardwolf eats termites and often digs a den in a termite mound. The other hyenas are specialized hunter-scavengers, adapted for bone-crushing with their reinforced teeth, jaws, and crania. Once considered scavengers only, field studies since the 1970's have documented the extensive hunting done by the large hyenas in Africa. All hyenas are solitary except the spotted hyena, which lives in clans. Members of clans usually disperse to hunt but also hunt in small packs, especially for large prey. Spotted hyenas are unique among carnivores because the females are larger than males and the males give the females priority of access to food and space.

Mongooses (family Herpestidae) are found only in Africa and warmer climates in Eurasia. They are closely related to viverrids but tend to be smaller (body mass range 0.5 to 1.5 kilograms), more terrestrial, and more often diurnal than the civets. Mongooses are renowned for their bravery in the face of snakes, but they generally hunt insects or small vertebrates, and may supplement their diet with fruits. Most mongooses are solitary, but Africa contains several forms of gregarious mongooses, such as meerkats, dwarf mongooses, and banded mongooses. These form long-lasting packs of up to thirty animals, using termite mounds or tunnels as dens during the night. It is believed that these mongooses have evolved highly social, gregarious habits because of the severe risk of predation by hawks, eagles, large carnivores, and snakes. The dwarf mongooses and meerkats show the most unusual social system, with one breeding male-female pair and multiple nonreproductive helpers feeding and protecting the young and the rest of the group. This system involves complex communication systems and a division of labor, including the use of sentinels to detect predators.

Carnivores' teeth are adapted for holding on to prey and shearing the meat from the bones. (Adobe)

Pandas, Raccoons, and Weasels

The giant panda is the only member of its family (Ailuropodidae), although it is considered closely related to bears. Its habitat is restricted to the Tibetan plateau. The panda bear is large (body mass 96.8 kilograms) and specialized to eat bamboo, as well as some animal foods.

The red or lesser panda has not yet been clearly related to other carnivores. Many scientists place it alone in its own

Carnivore Conservation and Human-Carnivore Conflict

Some carnivores come into conflict with humans, who destroy habitat, compete for the prey of carnivores, and hunt the carnivores themselves for meat or skins. Humans also kill carnivores to retaliate against real and perceived threats to human life and to livestock. For example, over a seventy-three year period in the twentieth century, Ugandan lions, leopards, and hyenas injured or killed 373 men, women, and children. Over the same period, thousands of lions and leopards were killed in retaliation for livestock attacks or for the trade in skins. Cheetahs and hyenas were driven extinct in Uganda by human eradication campaigns. Generally, large carnivores are subject to the most intense human persecution, but even mustelids may face trapping and lethal retaliation for raiding poultry.

Wolves present the best documented history of human-carnivore conflict. Wolves were once distributed widely throughout Eurasia and North America, until humans began raising domestic livestock. Then wolves would occasionally attack these tame, relatively defenseless prey. In turn, humans became ingenious in trapping, poisoning, and killing wolves. Wholesale decimation of wolves did not begin until the invention of firearms, but then it proceeded rapidly and without mercy. Wolves were virtually eliminated from most of the world. Now, fewer than 500,000 remain across the globe, and only a small fraction of these are legally protected.

More recently, public attitudes have changed, and respect for the wolf as a noble animal, coupled with awareness of the wolf's role in ecosystem function, have allowed the wolf to recover slightly in some countries.

family (Ailuridae), while others may group it with the raccoon family (procyonids). Its size (body mass 5.7 kilograms) and omnivorous diet is consistent with procyonids, but its distribution is not. The red panda is restricted to the Tibetan plateau, and part of its diet consists of bamboo, so it has sometimes been classified with the giant panda.

Raccoons (family Procyonidae) are found only in the Americas. This family is rather uniform in size (body mass 0.9 to 6.7 kilograms) and in diet. Virtually all of them eat a mixture of fruit, insects, and small vertebrates. Along with the familiar, widespread raccoons, there are less well-known forms in tropical regions, including the arboreal kinkajou, distinguished by a prehensile tail that permits it to hang from branch tips in order to reach fruit at the ends. Also among the tropical procyonids is the coati, which forms large groups with complex social organization. In a coati band, adult males live alone for much of the year, while adult females and young form groups of thirty or more individuals.

Weasels (family Mustelidae) are found everywhere except Australia. Scientists recognize four main subfamilies. The otters (body mass 5 to 40 kilograms) are adapted to aquatic life and eat fish and shellfish. The widely distributed badgers (body mass 0.6 to 10.9 kilograms) are adapted to digging and often specialize in eating earthworms. The true skunks of North America (body mass 0.4 to 2 kilograms) are terrestrial omnivores that have specialized anal scent glands used against predators. The weasel group (body mass 0.06 to 2.3 kilograms) includes a host of long, thin forms such as mink, ferrets, and martens. Mustelids are more numerous in temperate regions than in tropical ones, although otters are found around the world. Another tropical mustelid is the tayra, a weasel-like semiarboreal predator that may attack monkeys in the trees.

In summary, the order of carnivores is very diverse in body size, habits, social organization, geographic distribution, and basic ecology. Most members of this order are intelligent, predatory, adaptable, nocturnal, and solitary. However, among the exceptions to these general rules about carnivores are some of those species most familiar to humans: coyotes, lions, and wolves. Humans have long had a mixed view of carnivores. From the Egyptian reverence for cats and more recent romantic views of the noble wolf, positive impressions of carnivores have been countered by hatred for large predators, driven by economic concern over livestock-killing and attacks on humans.

The Serengeti of East Africa contains the greatest diversity of carnivores of any ecosystem in the world, and this book provides a guide to the ecology and conservation of this priceless treasure.

CATS

Type of animal science: Classification
Fields of study: Anatomy, paleontology, physiology, wildlife ecology

The cat family contains some thirty-six extant species, usually grouped into four genera. They are native to every continent except Australia and Antarctica.

Principal Terms

CARNASSIALS: pairs of large, cross-shearing teeth on each side of the jaw

EPIHYAL: a hyoid bone whose presence or absence determines whether a cat generally purrs or roars

HYOID BONES: series of connected bones at the base of the tongue

PAPILLAE: sharp, curved projections on the tongue

VIBRISSAE: stiff hairs, projecting as feelers from the nose and the head

Catlike animals first appeared in fossil records approximately thirty million years ago. They shared typical anatomical features with later cats: long limbs ending in feet with retractable claws and skulls featuring slicing teeth and large, pointed canines. Some genera developed especially long, curved canine teeth, called "sabers." About 10 million years ago, small cats classifiable as members of the genus *Felis* appeared, and by 3.5 million years ago examples of the genus *Panthera* emerged. They did not immediately replace saber-toothed cats, whose fossils exist in deposits containing those of modern cats. The American saber-tooth, *Smilodon fatalis*, was still active toward the end of the last glaciation; some individuals were trapped in California's Rancho La Brea tar pits as late as ten thousand years ago. An estimated four-fifths of all cat species are now extinct, often having disappeared during the same period that their favorite prey species also vanished.

Classification

Living Felidae are usually classified into four genera containing thirty-six species. In 1916, R. I. Pocock, a taxonomist at the London Zoo, established the modern feline classification system using hyoid bones as the fundamental characteristic and the epihyal structure as distinguishing the two major cat genera. He defined the genus *Panthera* as cats whose epihyal bone is replaced by a thin ligament; these animals normally vocalize by roaring rather than purring. Included in this genus are the large cats of Africa and Asia—the lion (*P. leo*), the tiger (*P. tigris*), the leopard (*P. pardus*), the snow leopard (*P. uncia*), and the American jaguar (*P. onca*).

Pocock placed cats whose epihyal develops as a normal bone within the genus *Felis*. They are able to purr continuously and usually do not roar. For the most part these animals are small cats, including the African golden cat (*F. aurata*), the ocelot (*F. pardalis*), and many varieties of the European and African wildcat (*F. sylvestris*). This genus also includes the American cougar (*F. concolor*), which few persons regard as small. The lynx and its bobcat subspecies are sometimes placed in a separate *Lynx* genus, but most authorities classify them as *F. lynx* and *F. Lynx rufus*, respectively. The domestic cat, *F. catus*, is sometimes called *F. sylvestris catus* to emphasize its probable descent from the small African wildcat.

Two large cats do not fit the usual categories and are assigned separate genera. The Asian clouded leopard, a large cat with a rigid epihyal that inhibits roaring, is classified as *Neofelis nebulosa*. The cheetah, the only cat whose claws do not fully retract, appears to be evolutionarily distant from other felines and is named *Acinonyx jubatus*.

Recent deoxyribonucleic acid (DNA) studies suggest evolutionary relationships between cat species and subspecies that challenge standard classification systems. Several new schemes have been proposed, but none has yet achieved widespread acceptance.

Feline Anatomy

Every cat, from the smallest domestic cat to the largest tiger, is physically equipped to become a successful predator—coat color, legs, claws, mouth, teeth, sight, hearing, and touch are all highly adapted for hunting and devouring prey.

Coat colors help cats blend into their environment while stalking prey. Most cats display a pattern of spots, stripes, or rosettes on a yellowish background, providing camouflage within forest or broken terrain. The lion's uniform coat color blends into the grassy plains where it usually hunts. Lion cubs and the young of other species developing uniform coat color as adults are born with patterned coats, indicating that this was the primitive coloration of all cat species.

Cat legs are often long and muscular, permitting short, high-speed bursts when attacking prey. Cat claws are usually retractable, pulling inward when running, but extending outward when catching or holding victims. Although cheetah claws do not fully retract, the cat's powerful muscles permit speeds of over sixty miles an hour in full pursuit. Claws and muscles make cats agile climbers who can scale trees when escaping enemies or hiding in ambush.

Cat teeth are adapted for seizing and cutting meat. Four elongated, pointed canine fangs grasp prey, and small, chisel-like incisors tear meat. The scissoring action of large carnassial teeth quickly slices meat from carcasses. Food tends to be swallowed in relatively unchewed chunks, then broken down in the digestive tract. Sharp-pointed, recurved papillae on the tongue help remove remnants of flesh from bones and are also used for drinking fluid and cleaning fur.

Many cats are nocturnal hunters, possessing sensory organs well adapted to low light. Their large eyes contain an extrasensitive reflective retinal layer, making cat eyes appear to glow in the dark, while pupils vary swiftly from fully open to tiny slits. Hearing is acute, and ears swivel easily to pinpoint sources of sound. Vibrissae, or whiskers, on nose and head permit cats accurately to locate obstacles and open paths, even when moving through darkness. The vibrissae also inform cats of the best position for gripping prey with their mouths.

Feline Behavior

Most cats are solitary hunters leading solitary lives, joining other adults only during mating. Kittens, however, may remain with their mother for up to two years, learning how to hunt before set-

Cat Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Family: Felidae (cats)
Genera: Felis (small cats, twenty-eight species); *Panthera* (large cats, seven species); *Acinonyx* (cheetah); *Neofelis* (clouded leopard)

Geographical location: Native to all land areas of the world except Antarctica, Australia, and some oceanic islands

Habitat: Forests and grassy plains

Gestational period: Large cats, 3 to 3.5 months; smaller cats, approximately 2 months

Life span: Potential longevity is probably fifteen years for most species; some individuals have lived over thirty years

Special anatomy: Large eyes with excellent night vision; jaws adapted to seizing and gripping prey, teeth designed for tearing and slicing flesh ting off on their own. Most cats live within habitats providing little stimulus for cooperative action. Tigers stalking prey in the jungle or snow leopards living in open country with highly dispersed prey find individual hunting most efficient. Occasionally, male cheetahs join in hunting coalitions of two to four animals, but such groupings are rare.

Both solitary and social cats, such as lions, are highly territorial—clawing trees, spraying urine, or leaving uncovered feces marking area boundaries; loud roars advertise the presence of claimants. Solitary females tend to establish ranges respected by each other. Males inhabit larger territories, usually overlapping those of two or more females, but face challenges from neighboring or interloping males.

Cats use three hunting strategies: moving slowly through their home range stalking, seizing, and killing prey; setting up ambushes near burrows or climbing trees and patiently waiting to pounce upon unsuspecting victims; and inadvertently stumbling upon prey while engaged in other activities, such as searching for water. Cats prefer to kill their quarry before eating. Small animals are bitten at the nape of the neck with canine teeth, severing spinal cords; biting the throat ruptures air passages. A lion sometimes strangles an antelope, clamping its mouth over the muzzle and suffocating its victim.

Lions live in groups called prides, consisting of up to a dozen individuals who aid each other in hunting. Females and their young compose the pride's core; usually related to each other, they raise their cubs together. Two or three related adult males dominate and defend the pride, becoming the fathers of its cubs. When male cubs mature they are generally driven off, but females

The lynx belongs to the group of cats with an epihyal bone, which allows them to purr. Roaring cats, such as lions, have a ligament in place of the epihyal bone. (Digital Stock)

Domestic Cats

Most authorities consider *Felis sylvestris lybica*, a North African wildcat, the probable ancestor of modern domestic cats. In agricultural communities whose granaries attracted rats and mice, cat remains have been found associated with human artifacts as far back as 5000 B.C.E. Actual domestication is depicted in 1600 B.C.E. Egyptian tomb paintings showing cats sheltered under their owner's chair eating fish or gnawing bones; in one case, the cat is tied to the chair leg by a ribbon. Cat lovers enjoy believing that cats voluntarily joined human settlements, but Egyptians had been taming wild animals for more than a thousand years and probably deliberately adopted and tamed a tractable species of wildcat.

Cats became important symbols of Egyptian gods. Male cats represented the sun god Ra, daily battling the serpent of darkness as a tomcat. Females signified the mother goddess Bastet, symbolizing beauty, fertility, and motherhood. In contrast, during the Middle Ages Christians associated cats with paganism and witchcraft, burning many as agents of the devil.

After Rome conquered Egypt, the cat spread across Europe, eventually arriving in the New World and various oceanic islands. Human protection permitted genetic variation and mutation in coat color that would probably have been detrimental to survival in the wild. During the nineteenth century, people began to develop these variations into purebred strains. By the late twentieth century, cats had become the most popular companion animals in Europe and America. Yet the domestic cat retains the basic anatomy and behavior of its wild ancestors. As Alan Turner noted, "Structurally, it can be seen as simply a scaled-down model of a lion or a leopard."

may become permanent members of the pride. Group hunting by females, with occasional assistance from males on a difficult kill, is an economical procedure in open terrain containing abundant large prey.

Scientists studying feral cats—domestic cats returned to the wild—found two patterns of existence. Feral cats hunting widely dispersed prey tended to be solitary, occupying separate female and male territories. Cats gathered together only at concentrated and stable food sources, such as garbage dumps and barns. In either case, a group of related females and their kittens formed the core unit; adults often aided each other raising the young. Female offspring might remain group members, but strange females were driven off. Some resident males were tolerated but faced challenges from interlopers seeking access to females. Several groups might occupy areas particularly rich in food. In all cases, resemblance to the social structure of lion prides was striking.

Adapted to widely varying environments, the Felidae remains one of the most successful animal families. A single species—the tiger—can be found ranging from the tropics to Siberia. However, the tiger and other feline relatives are increasingly endangered. Hunters seek many cats as trophies; the fur trade also values their striped and spotted skins. Big cats are particularly vulnerable, as expanding human settlements constrict the large ranges needed for successful predation. Whether large cats will survive, or join the four-fifths of Felidae species already extinct, remains for future generations to decide.

CATTLE, BUFFALO, AND BISON

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, ethology, physiology, reproduction science, wildlife ecology

Cattle and buffalo are the major domesticated oxenlike animals in the world, while bison have never been domesticated, became nearly extinct, and have made a comeback in North America.

Principal Terms

DEWLAP: loose fold of skin hanging from the throat of some cattle
HERBIVORE: animal solely dependent on plant material for its nutrition
INTERFERTILE: animals able to breed together and produce fertile offspring
QUADRUPED: animal with four feet
RUMINANT: animal with four stomach compartments that regurgitates and rechews its food
UNGULATE: animal with hoofs

Cattle, buffalo, and bison belong to the Bovidae family of oxenlike animals. Cattle include both the humpless *Bos taurus* (comprising the so-called European breeds) and the humped *Bos indicus* (known as Zebu cattle); both are of the same species in that they are fully interfertile. Buffalo, or Asiatic or water buffalo, include the river buffalo and swamp buffalo. Bison come in three varieties (interfertile and hence of the same species), namely the European wood bison, the American plains bison, and the American wood bison; while the latter two are commonly referred to as buffalo, they are actually more closely related to cattle than to the Asiatic buffalo. Cattle, Asiatic buffalo, and bison constitute three of the five genera in this family, the other two being the African buffalo (*Syncerus caffer*) and the yak (*Poephagus grunniens*), although the latter is sometimes classified in the same genus as cattle (*Bos*).

All are herbivores, dependent solely on plant material for their nutrition. Furthermore, they are ruminants, having the ability to rapidly ingest their food and to subsequently regurgitate and rechew it. The first of their four stomach compartments, the rumen, is used for microbial fermentation of plant material, some of which would not otherwise be digestible. All the animals are four-footed and have split hooves. Both male and female have horns, except for those with a genetic variation leading to polled (hornless) animals. They have a keen sense of smell, and good sight and hearing. They are herd animals and generally produce a single offspring annually; when nutritionally or metabolically stressed, they may calve every other year. They usually give birth in the spring, except for intensively managed cattle, which can do so year-round.

Cattle evolved on the plains and forests of Europe and Asia. *Bos taurus* was first domesticated in the Fertile Crescent 6000 B.C.E. and *Bos indicus* independently in south Asia, probably India, about one thousand years later. They were likely first domesticated for religious purposes, and they are still considered sacred in India. They subsequently were developed for work (such as pulling carts and riding), milk, and meat. Their hides were used for shelter and clothing. In addition, their manure is used for fertilizer and, when dried, for fuel. Currently, they are the most numerous livestock species in the world, numbering 1.3 billion, and are found in most areas of the world, except Antarctica. Depending on the breed and nutrition, mature males weigh between 1,000 and 3,000 pounds (450 to 1,350 kilograms). Worldwide, cattle produce 85 percent of the milk consumed by humans. In developed countries, cattle have been highly selected for milk or meat production, leading to specialized breeds. Holstein-Friesian is the primary dairy cattle breed, while Hereford, Angus, and Brahman are three well-known beef cattle breeds; the latter is a *Bos indicus* breed. Various crossbred and regional varieties exist. The transportation of feed grains permits cattle to be raised in areas that would otherwise not support them.

The Asiatic buffalo evolved in the forests and swamps of south and east Asia. It was also probably domesticated in two locations, the river buffalo on the Indian subcontinent 3000 B.C.E. and the swamp buffalo in east or southeast Asia about one thousand years later. Depending on the breed and nutrition, the mature male buffalo can weigh up to two thousand pounds (nine hundred kilograms). It lacks a hump and a dewlap. Like cattle, it is used for work, meat, milk, clothing, fertilizer, and fuel. While most of the world's 150 million buffalo are still found in Asia, some are around the Mediterranean (Italy and Egypt), in eastern Europe (Romania, Bulgaria, and Russia), Brazil, and Australia. In the developing world, its use as a work animal is paramount, particularly in plowing rice paddies. However, breeds of river buffalo have been selected for milk production and account for fully half of the milk production in India. Mozzarella cheese was originally made from buffalo milk in Italy, and the very best continues to be so made.

The bison evolved in the colder regions of Europe and Central Asia; it came to North America over a land bridge from Asia during the last ice age. It was never domesticated, in large measure because of its unpredictable behavior, including a tendency to stampede. The European wood bison was hunted nearly to extinction and only survives in a few small herds. After the last ice age and the demise of mammoths, the bison was the largest animal in the Western Hemisphere; the mature male weighs around two thousand pounds (nine hundred kilograms). In 1500 C.E., over forty million bison roamed the plains and woods of North America. The Plains Indi-

Cattle Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Artiodactyla
Suborder: Ruminantia
Family: Bovidae (oxenlike animals)
Genus and species: Bos primigenius, also known as *Bos taurus* or *Bos indicus* (cattle); *Bubalus bubalis* (Asiatic or water buffalo), *B. depressiicornis* (lowland anoa), *B. quarlesi* (mountain anoa), *B. mindorensis* (tamarau); *Bison bonasus* (European wood bison), *B. bison* (American bison)
Geographical location: Cattle—originally the plains of Europe and Asia, currently worldwide, except for Antarctica; buffalo—mostly south and east Asia; bison: plains and prairies of North America
Habitat: Cattle—grasslands; buffalo—tropical and subtropical forests, swamps, or grasslands; bison—temperate grasslands
Gestational period: Cattle—nine months; buffalo—ten to eleven months; bison—nine to ten months
Life span: Up to twenty-five years, depending on management
Special anatomy: Cattle—may have a hump over the shoulders and a dewlap (*B. indicus*) or neither (*B. taurus*); buffalo—a thick hide, which makes it resistant to some disease-carrying insects; few sweat glands, necessitating wallowing in water or mud in hot environments; breeds exhibit a wide variety of horns; bison—large head and a hump over the shoulders; two layers of hair, a dense undercoat and a coarser outercoat, hardy and able to withstand cold winters; a Jacobson's organ on the roof of the mouth to enhance its sense of smell

Image Not Available

ans depended on the bison for food, shelter, clothing, and fuel. With the completion of the transcontinental railroad, the American bison was decimated for meat, hide, sport, and sometimes no apparent reason. By the end of the nineteenth century, fewer than one thousand survived. However, conservation efforts by the American Bison Society were successful and today over 200,000 animals are found in hundreds of herds, including twenty-five with more than 500 animals each. The Bronx Zoo was particularly important in preserving seventy-seven animals from five founding herds, from which most American bison today are descended.

Comparison of Cattle and Buffalo

Compared to cattle, the Asiatic buffalo is big-boned, massive, and set on strong legs with large hooves. It can pull heavier loads, but is slower. It is better suited to muddy conditions because of its larger hooves and lower susceptibility to foot rot; accordingly, it is much more useful in working flooded rice paddies. On the other hand, its hooves are softer; if used extensively on hard surfaces, it must have its hooves protected by metal plates, wooden shoes, or straw pads. Perhaps surprisingly in view of its origin in the hot and humid areas of Asia, the buffalo is more susceptible to heat stress because of its limited sweat glands. It is best worked in the early morning or evening and must have access to water or mud to wallow in and dissipate heat. It is not tolerant of cold because it lacks hair and the added insulation it provides. It is relatively slow growing and, hence, is not as efficient as a producer of meat. Under similar environments and management in the Third World, buffalo and cattle produce similar amounts of milk. In the developed world, the milk production of buffalo is much lower, probably because of the greater genetic selection that has been practiced on dairy cattle. Its hide is very thick and tough; this appears to provide some protection from tick-borne diseases. The disposition of swamp buffalo, especially, is very placid, with its care often entrusted to children. However, it does have a strong hunger reflex and requires heavier fencing than cattle generally do.

Comparison of Bison with Cattle and Buffalo

Compared with cattle and the Asiatic buffalo, the bison has never been domesticated. However, it can be farmed, and around 90 percent of the animals are currently in private herds. Compared with cattle and buffalo, it is the most homogeneous in terms of color, with mature animals often a dark brown, although a few white bison do occur. While it will charge to defend itself, its preferred defense is to run; it can maintain a speed of thirty-five miles per hour (fifty-six kilometers per hour) for half an hour. Because of its hardiness, it can survive severe winters, with temperatures down to –50 degrees Fahrenheit (–45 degrees Celsius). It is easily more cold tolerant than the buffalo and even most cattle. It is susceptible to many diseases that affect cattle, specifically brucellosis, which causes abortions in cattle and undulant fever in humans. Controlling the disease in wild animals is more difficult than in cattle. Accordingly, it is important to keep bison and cattle separate unless both are known to be brucellosis-free. Bison require sturdier fencing than do cattle and probably buffalo.

CELL TYPES

Types of animal science: Anatomy, physiology
Fields of study: Anatomy, developmental biology, genetics, histology, invertebrate biology, zoology

Living cells are the basic units that make up the animal body. Cells are variable in size, shape, structural components, and function. Understanding the functions of cells provides insights into various diseases.

Principal Terms

ADENOSINE TRIPHOSPHATE (ATP): a molecule produced in the cell that provides energy for cell processes

AMINO ACID: the subunit that makes up larger molecules called proteins

CYTOPLASM: the living portion of the cell that is contained within the cell membrane

DEOXYRIBONUCLEIC ACID (DNA): the molecular structure within the chromosomes that carries genetic information

DIFFERENTIATION: the process during development in which specialized cells acquire their characteristic structures and functions

GAMETE: the sex cells of an animal; each gamete contains only one chromosome from each available pair of chromosomes found in normal body cells

GENE: the part of the chromosome that includes the DNA and is the carrier of heredity

NUCLEUS (pl. NUCLEI): a central cell structure that controls the activity of the cell because of the genetic material it contains

ORGANELLE: a subcellular structure found within the cytoplasm that has a specialized function

PROTEIN: a substance made up of amino acids; proteins are the chief building blocks of cellular structures

The cells that make up the body of an animal are the most basic units of life. Living cells use nutritional sources for energy to maintain structure as well as to maintain life processes such as growth and reproduction. Life requires structure, and cells have the minimal architectural design that enables them to retain life and to pass life on to future generations of cells. Typically, cells are joined in the animal body to form larger structures called tissues. By definition, a tissue, such as connective or muscle tissue, is an aggregate of similar cells and intercellular materials that are combined to perform a common function. An organ, such as the skin or the biceps, is frequently composed of several types of tissues.

Cell Structure

There are essential structural characteristics of animal cells that enable them to maintain life. Most fundamentally, there must be a border that limits the physical portion of the cell from its environment or surroundings. In animal cells, that border is called the cell membrane. Within the membrane lies the cytoplasm (literally, the plasm of the cell); outside the membrane is the environment from which the cell must extract its nutritional needs and into which the cell must pass the waste products that result from the numerous chemical reactions that are continually occurring inside the cell.

Structurally, the cell membrane consists of a double layer of lipid molecules. These molecules are bipolar: The head end of each molecule has an attraction, or affinity, for water molecules (it is hydrophilic), while the tail end of the molecule tends to repel water molecules (it is hydrophobic). In the formation of the membrane, these molecules are found parallel to one another and arranged in a double row. Their heads face the inside of the cell in the inner row, and their heads face their environment in the outer row. The hydrophobic tails form the interior of the membrane and provide an effective barrier that prevents the free passage of water and water-soluble substances. Interspersed among the lipid molecules, like boats in the waves of a lake, are numerous protein molecules. Some of these proteins, called transmembrane proteins, extend entirely through the lipid bilayer and have ends exposed to both the interior and exterior of the cell.

Others, called integral proteins, are found only on one side of the membrane and extend only part way into the lipid bilayer. Finally, some proteins, called peripheral proteins, are attached to the outside or inside surfaces of the membrane. Transmembrane proteins may function as channels or pores allowing specific ions or molecules to pass through them. Integral proteins may also function as transmembrane carriers in that they can bind to specific products outside the cell—such as a certain amino acid—and then flip-flop across the membrane to the inner side and release the product into the cell's interior. Peripheral proteins on the outer surface of the membrane may serve as identification markers for other cells. The membrane itself functions to maintain the integrity of the cell's cytoplasm by holding essential things inside and preventing the cell from drying out.

The cytoplasm is a general term for the viscous fluid within the cell's membrane. In the cytoplasm are numerous small, specialized structures called cell organelles. An essential structure for living cells is the nucleus, which contains genetic information in the form of DNA. DNA determines a particular cell's structure and function. Other organelles in the cytoplasm are designed for specific processes such as manufacturing energy, building structural proteins, or storing cell products prior to exporting them. Some organelles are enclosed within their own membranes, which are structurally very similar to the membrane forming the cell's outer boundary.

The Nucleus and Its Contents

The nucleus is an essential control center of the cell. It is enclosed within a unique membrane—the nuclear envelope—that has relatively large pores, through which large information-carrying molecules called ribonucleic acid (RNA) pass from the nucleus to the cytoplasm. Resident within the nucleus is a dark material called the chromatin. During cell division, the chromatin material condenses into clearly observable structures called chromosomes. When the cell divides into two, each daughter cell contains equal numbers of chromosomes from the original maternal cell. The chromatin material within the cell's nucleus is made up of two major types of material—DNA and associated proteins.

The DNA is organized into discrete packets of information called genes, which form the backbone of the chromosomes. The genes determine the characteristics of the specific cell or organism. The DNA-associated proteins regulate the gene's expression. At times, the genes may express themselves by replicating their information into chemical messengers called RNA. The RNA may diffuse out through the nuclear pores into the cytoplasm. Within the cytoplasm, RNA may bind to an organelle called the ribosome, which produces new protein molecules. Normally, the nucleus also contains one or more very dark round structures called nucleoli. The nucleoli assist in the production of the cell's ribosomes. A single nucleolus is made up of protein and RNA.

A particular cell may also contain hundreds of mitochondria, also typical organelles. The mitochondria are complex, double-membraned structures, and they are found throughout the cytoplasm of the cell. Mitochondria are the energy producers of the cell. These oval-shaped structures contain numerous enzymes that stimulate energy-producing reactions. The net sum of these reactions results in the formation of high-energy ATP molecules. These molecules diffuse throughout the cell to various other organelles and release their energy, thereby fueling most cell processes.

Lysosomes are cell organelles that are round in shape and are enclosed within a membrane; they contain many different enzymes. The enzymes function to break down, or digest, many substances into simpler substances that the cell can use. The endoplasmic reticulum (ER) consists of membrane-enclosed spaces in the cytoplasm. These complex membrane arrays are extensions of the outer cell membrane. Some of this membrane system is covered with ribosomes that function to produce protein. These parts of the ER are called rER, for rough ER or ribosomal ER. Other ER portions, that lack ribosomes, have a smooth appearance and are called smooth ER (sER). Another cellular organelle, the Golgi apparatus, appears as a bunch of flattened bags. This organelle is usually not far distant from the ER. After the rER produces a protein product, the Golgi apparatus further processes the product and packages it for cellular export.

Cell Size and Function

Animal cells have great variations in size. Among the smallest are some bacteria, which may be about 0.1 micron in diameter. (One micron equals 0.001 millimeter.) The largest known cell is the single-cell ostrich egg, which is about seventy-five millimeters in diameter—more than 750,000 times larger than the smallest bacterium. Somatic cells, the cells that make up the body structures of animals, are typically more intermediate in size. For example, the human red blood cell is about seven microns in diameter, while an intestinal epithelial cell is about thirty microns in diameter. Most animal cells are approximately the same size and typically have diameters between ten and twenty-five microns.

An essential characteristic for cell survival is the ratio of the cell's surface area to the volume of the cell, or its surface-to-volume ratio. Typically, cells with small diameters have large surface-to-volume ratios, while large cells have small surface-to-volume ratios. Many of the substances that are needed for the cell's survival, such as oxygen or nutrients, enter the cell through the surface membrane by simple diffusion. The cells that have high rates of metabolism tend to be very small and have larger surface-to-volume ratios. Alternatively, larger cells either have lower metabolic rates or have specialized shapes such as numerous membrane enfoldings to optimize diffusion of essential materials into their interiors.

In multicellular animals, cells are differentiated. Differentiated cells are those that have a specialized modification in their structure to enable them to perform a specific task. Thus, a striated muscle cell contains numerous myofibrils that shorten as the cell contracts, while a glandular cell may contain numerous secretory granules filled with products for export.

Animal cells can be classified on the basis of the number of chromosomes that they contain. Somatic cells, or body cells of an organism, are called diploid, because they contain the total number of chromosome pairs that is characteristic for that organism. For example, somatic cells in mosquitoes contain four pairs of chromosomes (or eight individual chromosomes). Each chromosome in the pair contains genetic information for the same genes that the other paired chromosome contains. Alternatively, sex cells or gamete cells—sperm and egg cells—contain a haploid number of chromosomes, which consists of a single chromosome from each of the possible pairs. Thus, a human sperm cell contains a total of twenty-three individual chromosomes, whereas a human skin cell contains a total of forty-six individual chromosomes.

Another way to classify animal cells is to consider the primary way that they use proteins. Some animal cells are primarily protein-secreting and manufacture much of their proteins for body use outside the cell that produced the protein. An example of this is the pancreatic acinar cell, which produces numerous digestive enzymes (proteins) and secretes them into the pancreatic duct for transport into the digestive tract, where the enzymes break down complex foods into simpler forms. Other animal cells are primarily protein-retaining cells in which much of the manufactured protein is retained for use by the cell itself. An example of this is the keratinocyte, the prominent cell type found in the skin. This cell produces a large amount of the protein keratin, which remains stored in the cell's cytoplasm. Because of the presence of the keratin, the skin is able to maintain its waterproofing, protective function. Without keratin, the skin would lose body water.

Cell Shapes and Types

Animal cells have a wide variety of shapes. Individual cells that are mobile within an aqueous environment tend to be spherical in shape. The neutrophil, a type of white blood cell, is an example of this. Cells that are mobile within tissues and that migrate from one area to another often have long cytoplasmic extensions. An example of this is the macrophage, which has long, changeable, armlike processes (projections) that enable it to migrate through tissue spaces and ingest bacteria that may be found there. Other migratory cells have a tail called a flagellum. Sperm cells, for example, use their flagella to propel themselves through the female reproductive tract to reach the egg.

Some cells have branching, stationary cytoplasmic processes through which information molecules move. Often, these processes form a complex network with similar cells such as the network of neuron cells in the brain. Body tissues are made of cells that have tight cell-to-cell connections between their membranes. These cells may provide a covering or form the wall of a particular structure. Protective cells, such as skin cells, are often many layers thick.

A typical animal's body is composed of about two hundred recognizable different cell types. Most of these are variations of four main categories: epithelial cells, connective cells, movement cells, and message cells.

Epithelial cells form a continuous layer over surfaces that are external or internal to the body. Skin is an external protective tissue that is made of many such layers of cells. The inner lining of the digestive tract, for the most part, consists of a single layer of epithelial cells that absorb and secrete materials. Connective cells provide the structural support of the animal body. Examples of these cells are fibrocytes, found in the dermal layer of the skin, and osteocytes, found in the matrix of bone.

Cells responsible for body movement are typified by the muscle cells. Muscle cells that are attached to bone and cause limb movement are called striated muscle cells. Muscle cells that are found in the walls of body organs such as the stomach are called smooth muscle cells; contraction of these cells causes the contents of the stomach to be mixed and stirred. Cardiac muscle cells are found in the heart, and they contract to force the movement of blood throughout the circulatory system.

Message or conveyance cells are very diverse. Branching nerve cells have long processes that carry information molecules (for example, from the spinal cord to the finger). Red blood cells carry oxygen from the lungs to the body cells. Gamete (sperm or egg) cells transfer genetic information from one organism to the next generation of organisms.

Studying Cells

Ever since the 1600's, when Antoni van Leeuwenhoek first used a simple magnifying lens system to study the structure of single-celled life forms, microscopes have been an important tool in cytology (the study of cells). Several types of microscopes are commonly used to study cells, whether alive or preserved.

Light (bright-field) microscopes with two sets of magnifying lenses are most commonly used to study animal cells today. These microscopes have magnification powers ranging from about forty to two thousand times. In their natural state, most cells are essentially colorless. In order to make microscopic viewing more effective, cells are often stained so that their structures are more readily visible. A phase-contrast microscope is a modified light microscope that can produce visible images from quite transparent objects. This type of microscope is frequently used to study unstained or living cells. Its magnification range is similar to the light microscope.

A transmission electron microscope (TEM) uses electrons instead of light rays to visualize objects. A TEM passes its electron beam through very thinly sectioned cells. The density of the stained cellular structures absorbs electrons in a differential fashion so that an image corresponding to the cell's architecture can be visualized. The TEM can magnify cellular structures from 1,000 to 250,000 times. Consequently, this type of microscopy is often used to study the small subcellular organelles.

Another popular technique used to study animal cells involves growing them in cultures outside an animal's body. This technique, called in vitro cell culture, involves obtaining a group of living cells from an animal, usually in the form of pieces of tissue. An enzyme solution is commonly used to digest the cell-to-cell connections and to produce a suspension of free individual cells. These cells are then placed in petri dishes along with a liquid medium that contains essential nutrients. Some types of animal cells, especially fibrocytes found in the connective tissues, are easily cultured with this technique. These cell cultures, if properly maintained, will grow and reproduce for generations. Experimenters can use such cell cultures to investigate how living cells function and respond to varied environmental influences.

Since cells are the basic units of life, an understanding of their function is essential in comprehending the way living organisms function. Many diseases are caused by a malfunctioning group of cells. For example, a group of cells normally undergoes an orderly sequence of growth and reproduction. At times, however, some cells become disordered and began to multiply rapidly without stopping. This may be caused by an abnormality that appears in the genetic code or by the presence of a virus that takes over the genetic controls of the cell. This situation is typical of some types of cancer.

As scientists learn more about how cells live and why cells die, they will gain valuable insights into the aging process and may thereby increase the span of life. As differentiation is better understood, scientists may be able to change mature cells or even replace them if they become damaged, destroyed, or simply worn out with age.

Chapter 5, "Cell Structure and Function: An Overview," gives a well-written, easily understood synthesis of common characteristics of all cells. Special emphasis is placed on cell organelles and cell surface specializations.

Telford, Ira R., and Charles F. Bridgman. *Introduction to Functional Histology*. 2d ed. Grand Rapids, Mich.: HarperCollins, 1995. This introductory histology text with excellent diagrams and photographs shows the relationships between individual animal cells and the tissues they form. Beginning with basic animal cell biology, the text moves to cover the major organ systems. The frequent use of line drawings to complement electron microscope photographs makes their interpretation much more apparent.

CENTIPEDES AND MILLIPEDES

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, invertebrate biology, zoology

Over twelve thousand species of the arthropods centipedes and millipedes are known. Centipedes are carnivorous, and millipedes are usually vegetarians.

Principal Terms

DIPLOSOMITE: millipede trunk segment, formed by the fusion of two body segments

MANDIBLES: jaws of insects and other arthropods

NOCTURNAL: active at night

PALP: oral sensory organs of arthropods

Centipedes and millipedes are somewhat similar organisms. Together, they make up approximately twelve thousand species of long, flattened, segmented animals, grouped among the Myriapods. A major difference between centipedes and millipedes is diet. Centipedes are carnivores, living on other animals, and millipedes are herbivores, living on dead plant matter. Millipedes have cylindrical bodies, while centipedes are wormlike.

When a centipede or millipede runs, it picks up each leg, one after the other. However, it only moves the legs on one body side at a time. The result is that legs move in rhythmic waves along the body. Millipedes are much slower than centipedes.

Physical Characteristics of Centipedes

Centipedes belong to the class Chilopoda of the phylum Arthropoda, which includes insects, myriapods, crustaceans, and spiders. Centipedes resemble worms. Their heads contain paired, jointed, sensory antennae; brains, connected to ganglia; compound eyes, simple eyes, or no eyes at all. Centipedes also have two pairs of jaws. The first pair are toothed mandibles and the second pair, the underjaws, have palps.

A centipede body is divided into between twelve and one hundred segments, each having two legs, so the name "centipede," which means "hundred-footed," is appropriate. The first pair of legs, in the segment behind the head, holds poison claws that are used to fight or kill prey. These claws are full of a venom made in the head. Each of the paired legs in all segments but the last one are shorter, of similar length, and clawed. Those in the last segment are longer than the others. A thin, tail-like cercus projects from a centipede's rear. Centipedes breathe through air tubes (tracheas) on the sides of their bodies.

The Lives of Centipedes

Centipedes are carnivores that eat worms and insects, which they poison. Nocturnal, they hide under stones, logs, or ground litter during the day. Some species bear live young, but most lay eggs. Small centipedes of temperate climates (such as the United States) are harmless to humans. Larger, tropical centipedes are much more dangerous, as exemplified by the families Scolopendridae, and Geophilidae.

The reproductive cycle of centipedes often begins in spring or fall, when a male places his semen on the ground. In the spring, a female puts the semen inside her body, immediately using it to fertilize her eggs. If the female takes in the semen in the fall, she may carry the semen for months before fertilization occurs. After fertilization, females lays their eggs, which hatch in two to four weeks. Newborns have smaller numbers of segments and legs than adults. They grow by molting. After each molt, new body segments and legs are produced. Mother centipedes tend their young until they can hunt. Centipedes mate at two to three years old and may live for six to ten years.

Centipedes Large and Small

Scutigeridae have compound eyes, long antennae, and fifteen pairs of long legs. Found in Europe and the United States is a two-inch species with a brown, striped body, the common house centipede. Lithobiidae, stone centipedes, are also short-bodied. They and scutigerids are the fastest centipedes. Stone centipedes have simple eyes, the same number of legs as scutigerids, and antennae about 35 percent the length of their bodies. Neither family delivers stings harmful to humans.

Scolopendridae have over twenty pairs of legs, short antennae, and simple eyes or none at all. These slow-moving, tropical centipedes are the largest species, reaching lengths of one foot. The fourth family, Geophilidae, known as soil centipedes, are also slow moving. They have up to 350 legs, short feelers and no eyes. They burrow in the ground. Scolopendrids and geophilids deliver bites harmful to humans.

Millipedes

Millpedes are arthropods of the class Diplopoda and occur worldwide, except for polar regions. They are 0.1 to 12 inches long. The largest American species, the four-inch, red and black *Narceus americanus*, lives in southern forests.

Millipede heads are round and hold a pair of short antennae, two simple eyes (or no eyes), and mandibles. "Millipede" means "thousand-

Image Not Available

footed" but none have over five hundred legs. The legs arise from the characteristic feature of diplopods, 9 to over 110 diplosomites. These double trunk segments form by the fusion of two body segments. Each diplosomite holds two pairs of legs, except for the legless head segments and the next three segments, each with one pair of legs. Every four-legged diplosomite contains two pairs of ganglia and two pairs of heart arteries. Millipedes grow in length and diplosomite number by molting. They live one to seven years and reproduce by laying eggs.

Millipedes are covered with thick, calcified chitin back plates. Their protective strategy, when threatened, is to curl into a ball with their head inside and excrete a smelly, toxic liquid from "stink glands." This liquid kills or repels predators. Millipedes inhabit dark, damp places and eat decaying—or in some cases live—plants. Their actions damage some crops but, more often, enrich the soil.

Centipede Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Arthropoda
Subphylum: Uniramia
Class: Chilopoda (Centipedes)
Families: Geophilidae (soil centipedes), Lithobiidae (stone centipedes), Scolopendridae (tropical centipedes), Scutigeridae (house centipedes)

Geographical location: Worldwide, in temperate, warm, or tropical regions

Habitat: Under stones, logs, leaves, other ground litter; in human habitations

Gestational period: Eggs hatch in two to four weeks

Life span: Six to ten years

Special anatomy: Sensory antennae; compound eyes; toothed jaws and underjaws; segments, each with two pairs of legs; poison claws; cercus; air tubes

CHAMELEONS

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, zoology

Chameleons, the family Chamaeleontidae, have long, sticky tongues to capture prey. Other unique characteristics include eyes that operate independently of each other, leaflike body shapes, ability to change skin color, zygodactyly, and prehensile tails.

Principal Terms

ARBOREAL: dwelling in trees
CHROMATOPHORE: a color-causing cell
COLD-BLOODED: animals whose body temperatures equal the temperature of their surroundings
PREHENSILE: able to grip things
ZYGODACTYLY: having toes pointing forward and backward in the same foot

Chameleons are a group of over one hundred lizard species living in Madagascar, Africa, Asia, and Europe. They are famous for the ability to change color, first noted in the third century B.C.E. by Aristotle. In most cases, chameleons are brown, green, or yellow. Their skins can change to almost any combination of those colors, as well as to pinks, reds, blues, and purples.

Chameleon species are mostly arboreal. They inhabit southern Spain, Crete, the Saudi Arabian peninsula, Sri Lanka, India, Madagascar, Pakistan, and most of Africa. North American color-changing lizards, particularly anoles, are wrongly called chameleons.

Physical Characteristics of Chameleons

Chameleon maximum body lengths range from one inch to three feet, depending on species. Like other reptiles, chameleons are cold-blooded, with body temperatures the same as those of their surroundings. A chameleon body is flat from side to side; it both looks smashed out of shape and has dorsal and ventral crests, which provides camouflage by making it resemble a leaf.

Chameleon eyes, placed on the sides of their heads, can rotate in a full circle, and rove separately or together. This is thought to be partly because chameleons have short necks that do not turn. It is useful for carnivorous chameleons seeking food (insects, spiders, scorpions, and mammals) and not wishing to be eaten themselves. Using independent eye motion, they may seek to eat an insect seen out of the left eye and use the right eye to check for predators that might eat them.

Arboreal chameleons have feet that grasp branches like hands. This is because their feet are zygodactyl, with toes of each foot facing in opposite directions, and can wrap around twigs and branches. This helps them to navigate safely in trees. For the optimum arboreal equilibrium, chameleons have prehensile tails to grip branches. The tails curl into snail-like spirals when not needed. Ground-dwelling chameleons lack the prehensile tails and zygodactyly.

Some chameleons have on their heads horns which, spearlike, stick out from spaces between upper lips and eyes. They are used in mating and protecting territory. The heads of most chameleons are flat on top and wide on each side, making it seem that they are wearing helmets. Chameleons move slowly and carefully on tree branches. However, their rapidly moving, body-length tongues quickly shoot out of the mouth to catch prey on sticky, mucus-rich ends, and bring it back before escape is possible.

Chameleon color changes are due to skin chromatophorea, which hold pigments and pigment-making components. To change color, chameleons send hormone signals through the blood, changing the identities and thus the colors of chromatophore pigments. Chameleon color changes indicate fear, changes in light intensity and body temperature or other environmental changes, and attempts to blend into surroundings and to attract or deter potential mates.

Life Cycle of Chameleons

Most chameleons are arboreal. Exceptions include pygmy (stump-tailed) chameleons, which are small, ground-living, and lack prehensile tails. Male chameleons are territorial. In many cases, male invaders of a territory are fought actively and the battle ends in the death of one male. In some cases, the combat is ritual, though the male who is faced down leaves.

Males and females are solitary, coming together only to mate. Most color changes indicate breeding intentions, pregnancy, or, on the part of females, disinterest. Regardless of species, chameleons mate year round. Females can lay fertilized eggs several years after mating because they store sperm and can delay their fertilization.

Image Not Available

Females lay batches of ten to sixty eggs, in some cases in burrows, in others in trees. In vivaparous species, the young, developed from eggs carried by mothers, are expelled onto tree branches. After laying eggs or depositing their young, females have no further contact with offspring.

Young chameleons break out of their eggs via egg teeth, designed for this purpose. The egg teeth later fall out, as they have no other use. Chameleons live for five to ten years, if they reach old age.

Three Representative Chameleon Species

Common chameleons (*Chamaeleo chameleon chameleon*) inhabit southern Spain, northern Africa, and the Mediterranean coast of the Middle East. Arboreal, they grow to ten-inch body lengths, with ten-inch tails and ten-inch tongues. They eat only insects, and mate in late summer. Females lay batches of twenty to thirty eggs.

Flap-necked chameleons (*Chamaeleo dilepts dilepts*) are named for skin folds near their necks and ears. They are arboreal and inhabit South Africa. They eat insects, spiders, and scorpions, and grow up to about fourteen inches long. These chameleons change color extensively, starting from a mix of brown and yellow.

Panther chameleons (*Chamaeleo pardalis*) of Madagascar are arboreal, grow to twelve inches long, and eat insects. They are aggressive and territorial, named for their ferocity, and fighting between males is to the death. Females lay thirty to fifty eggs.

Chameleons are not harmful to humans. They are actually ecologically beneficial, eating many insect pests. Chameleons are also thought desirable pets by many people. However, they are difficult to maintain in captivity.

CHAPARRAL

Types of animal science: Ecology, geography
Fields of study: Ecology, environmental science

Chaparral is the name of a major ecosystem (or biome) found in areas with moist, cool to cold winters and long, dry hot summers (Mediterranean climate).

Principal Terms

ELFIN FOREST: a stunted forest growing at high elevations in warm, moist climates

FIRE ECOLOGY: an ecosystem that depends on periodic fires to clear underbrush; the seeds of many plants in such an ecosystem require fire in order to germinate

Chaparral ecosystems with different names occur in the Mediterranean, South Africa, Chile, Australia, and Mexico. The word "chaparral" is a colloquial adaptation of the original Mexican name, *chaparro*. While the chaparral communities in other parts of the world have the same basic characteristics and very similar adaptations, this article will focus on the chaparral of California and the American Southwest.

Chaparral is an interesting and unique ecosystem. It is an elfin (stunted) forest dependent on a fire ecology, and its adaptations to a harsh and variable climate are remarkable. The chaparral's geology, latitude, altitude, and climate are all related and have played a role in its formation.

In California, the chaparral is located mainly along the central and southern coastal areas, primarily between elevations of 500 and 2,500 feet. It is also found in some areas of the Sierra Nevada foothills, one hundred miles or more inland, and in the lower elevations of some other interior mountains. The geology of most of the areas where this ecosystem occurs is believed to have started with massive upheavals from half a million to ten thousand years ago. The most common substrate was granite. Relentless disintegration resulted in rocky and sandy debris which would allow increasing amounts of plant life to grow. As the organic matter became more abundant, its debris (leaves, twigs, and decaying dead plants) became more and more mixed into the materials of the granite decomposition. This resulted in a rich, sandy loam.

Chaparral Flora

Because of the cool, moist winters and dry, hot summers, plants evolved to survive these marked changes. In most of the chaparral, there are quite extreme diurnal temperature changes, with fluctuations of fifty to sixty degrees or more. Compounding these harsh conditions are frequent strong, dry winds, often reaching forty miles per hour.

The plants that have become the residents of the chaparral are mainly shrubby, small-leaved evergreens with leathery, thick stems. Shrubs predominate, but there are also small trees, and wildflowers are in abundance in many areas. All plants are adapted to conserve water. There is little humus in the soil, which is relatively nutrient-poor. The sandy nature of the soil and the variable periods of dry and sudden rain can cause a quick run-off.

The predominant plants are between three and nine feet in height, with some trees being taller. They hug close to the ground to provide shade. The ratio of the surface area of the leaves and stems to their body mass is reduced, and they tend to have thick, heat-resistant surfaces. Some of the plants are capable of turning their leaves so the edges face the sun, which cuts down the warming effect on their surfaces. All these mechanisms greatly reduce evaporative water loss. Most of the bushes and trees also have unusually long tap roots. A three-foot plant might have a tap root that goes ten or more feet below the surface, enabling it to get more water and nutrients.

The most common plant in the chaparral is the greasewood-chamise bush (*Adenostoma fasciculatum*). Others that predominate are the christmasberry-toyon bush (*Photinia arbutifolia*), the scrub oak (*Quercus dumosa*), the yucca (*Yucca Whipplei*), and the hoary manzanita (*Arctostaphylos canescens*). The chamise is characterized by numerous small, club-shaped leaves with a waxy substance that protects them from drying. When there is a fire, the chamise burns with an intense heat and creates a very black smoke (hence the name "greasewood").

The Role of Fire

The role of fire in the maintenance and regeneration of the chaparral is of paramount importance. The hot, dry summer weather, often fanned by winds, makes the chaparral very prone to fires. Because of the high fuel content in the dense plants, with their waxy and oily components, these fires are very intense and can spread rapidly. Fire is necessary to clear excess growth and allow new seeds to germinate. Indeed, several of the key species need fire to release their seeds or they will not germinate. The amount and distribution of the canopy fuel can have a marked effect on regrowth and even spatial variation. Naturally recurring fires are usually good for germination. Unusually intense fires, often from years of fire suppression, may do harm by damaging the plants severely.

In much of the chaparral, human interference has allowed the fires to become more damaging when they occur. This creates a difficult paradox, since many people now reside in the chaparral and chaparral fires can spread very rapidly, especially with strong winds. Conversely, in some areas where fire has been controlled, the chaparral has been retreating. A good example of this is on the southern slopes of Mount Tamalpais, a mountain just north of San Francisco.

Chaparral Fauna

A wide variety of reptiles, birds, and mammals make the chaparral their home. They have developed adaptations to survive and thrive in this harsh environment. Several species of skinks, lizards, and a variety of snakes, including gopher snakes, the California king snake, and both the red diamond and western rattlesnakes are residents. There are dozens of birds, from several species of hummingbirds to the large birds: the turkey vulture, barn owl, roadrunner, and golden eagle. There are many species of rodents, including kangaroo rats, chipmunks and gophers. The variety of medium to large mammals of common interest is impressive and includes the coyote, gray fox, badger, lynx, bobcat, mountain lion, and mule deer.

Jasson-Holt, Sophie. *Unfold the Chaparral*. San Francisco: San Francisco State University Chapbook, 1996. Very well-written and excellent overview of the chaparral.

Odion, Dennis C., and Frank W. Davis. "Fire, Soil Heating, and the Formation of Vegetation Patterns in Chaparral." *Ecological Monographs* 70, no. 1 (2000): 149-169. A detailed scientific account of the role of fire in the chaparral. It would be difficult reading with no background in biology.

CHEETAHS

Type of animal science: Classification
Fields of study: Anatomy, behavior, physiology, reproduction

The fastest land mammals, cheetahs originated millions of years ago, before any of the other big cats, but are now an endangered species.

Principal Terms

GESTATION: pregnancy or the term of carrying young in the womb

HYOID: central part of the arch which joins the tongue to the skull

MUTATIONS: sudden variations of inherited characteristics

POLYESTROUS: multiple sexual heats or periods of sexual excitement

Except for rare mutations, cheetahs (whose name is the Hindi for "spotted ones") have tawny or grayish white coats covered with round or oval black spots roughly an inch in diameter, located everywhere except for the throat and abdomen. The hair on the coarse coats is slightly longer at the nape, and the tail has four to six black rings (distinctive to each cheetah) and a white tuft at the end. Cheetahs purr, yelp, and bark rather than roar, owing to the lack of an ossified hyoid.

Cheetahs have long bodies and legs and a small domed head with high set eyes, short ears, and a black line (resembling a teardrop) that runs from each eye down to the mouth. These lines aid vision by reducing solar glare. The whiskers are smaller than those of most cats, but cheetahs hunt by sight alone. Mature cheetahs weigh between 110 and 130 pounds and reach an average height of thirty-two inches at the shoulder, while their bodies extend to roughly fifty inches in length. Male cheetahs are slightly larger than females, but both sexes have small teeth and large lungs and nasal passages which produce a high volume of oxygen. One set of leg muscles is designed for walking, while another is for high-speed sprinting. Cheetah paws are round and hard, and have semiretractable claws that provide traction during sprints and help the cheetah make quick turns. By a combination of running and leaping, the cheetah can accelerate from 0 to 45 miles per hour in two seconds, and can reach recorded speeds of up to 71 miles per hour—but for no more than 300 yards.

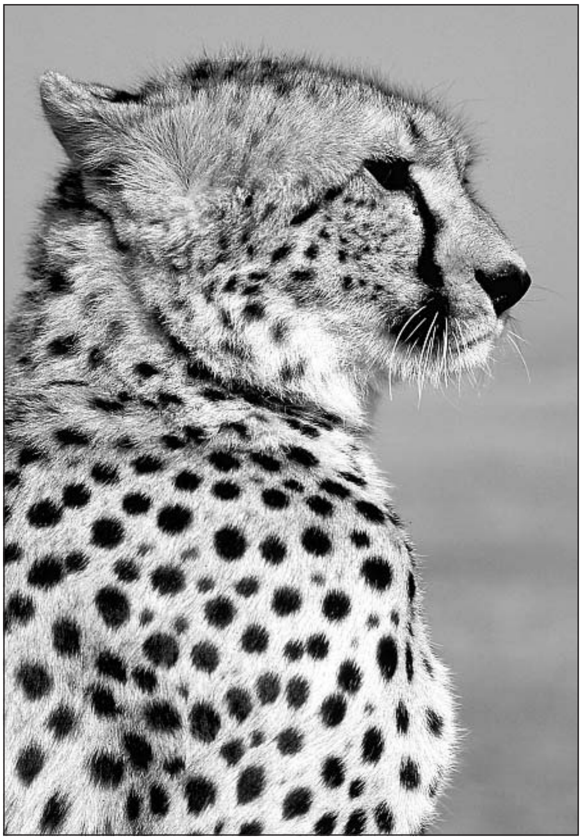
Habitat and Behavior

While about 75 percent of mammals in North America and Europe were eradicated during the Ice Age, the cheetah survived. However, the isolation of its small population created genetic problems because close relatives must mate. Cheetahs used to abound in India, but were wiped out there by the 1950's. They are not usually found in forest habitats but are mostly found in the drier parts of sub-Saharan Africa (especially Namibia and Ethiopia).

Though they are frequently observed on open, grassy plains, they also appear in bush, scrub, and woodlands. They can adapt to arid environments, having the ability to travel an average of fifty miles between drinks of water. The blood or urine of prey satisfies their thirst, as does the flesh of *tsama* melons.

Unlike lions, cheetahs hunt in early morning and late afternoon. They scan the countryside from a tree limb, the top of a termite mound, or even the roof of a safari car. Being carnivores, they feed primarily on gazelles, impalas, game birds, rabbits, and the young of warthogs, kudu, hartebeest, oryx, roan, and sable. Once they have located prey that has somehow strayed from its group, they approach stealthily to within fifty yards before sprinting. However, the sprints, though extremely swift, are brief, lasting anywhere from a few seconds to a minute. Most hunts are unsuccessful, but in successful ones, the cheetahs knock down their prey by the force of their charge or trip it, and strangle it by seizing the throat. Smaller prey are killed by a bite through the skull. A female with cubs hunts daily, whereas lone adults hunt every two to five days. Cheetahs eat quickly because they fear challenges from lions and hyenas, and they often haul their prey to high branches of trees.

Male cheetahs form coalitions to help them in hunting prey and defending territory. Unrelated males are sometimes accepted into coalitions, but lone males can secure territory only if there are no coalitions nearby. Unlike males, female cheetahs leave their natal groups, though they do occupy the same home range as their mothers. Also unlike males, they are solitary, except when they have new litters. Males and females mix to mate, but only females rear cubs. Life spans in the wild average seven years.



The black line that runs from the cheetah's eye down to its mouth serves to cut solar glare and aids the cheetah in scanning for prey. (Corbis)

Cheetah Facts

Classification:
Kingdom: Animalia
Subkingdom: Acinonychinae
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Carnivora
Family: Felidae (cats)
Genus and species: Acinonyx jubatus
Geographical location: Sub-Saharan Africa and northern Iran
Habitat: Areas with tall grass and shrubs, or areas with elevated points
Gestational period: Three months
Life span: Up to twelve years in the wild, seventeen in captivity
Special anatomy: Body is approximately four feet long; long, thin legs; a tail about half as long as the total body; a deep, narrow chest; small round skull; rounded ears set far back; large nasal passages and lungs; large heart, adrenals, and arteries; spine gives spring for back legs

Reproduction

Cheetahs reach sexual maturity in two years. Being polyestrous, females have an average reproductive cycle of twelve days, with fertility lasting from one to three days. Gestation lasts about three months, and litters usually number three to five cubs, though some have as few as one and as many as eight. Newborn cubs are about a foot long and weigh less than half a pound. They have a mantle of hair along their back which helps camouflage them in the grass, but this mantle eventually disappears.

Mothers move their cubs every few days to avoid predators. However, infant mortality rates can be as high as 90 percent, with lions being the biggest killers. Cubs are weaned at 3 to 6 months, but usually remain with their mothers between 1 and 1.5 years, while she teaches them how to hunt and kill prey.

CHICKENS, TURKEYS, PHEASANT, AND QUAIL

Type of animal science: Classification
Fields of study: Anatomy, zoology

The chicken, turkey, pheasant, and quail are related members of the family Phasianidae. Chickens are probably the most numerous bird in the world.

Principal Terms

CHICKS: baby birds from chickens, turkeys, pheasant, or quail
CLUTCH: a group of eggs in a nest
COCK: male chicken, pheasant, or quail
COCKEREL: young male chicken, pheasant, or quail
COVEY: flock of quail
EGG: a round, hard-shelled object produced by the female bird that may produce offspring, but is often used as a food product for human consumption
FLOCK: group of birds
HEN: adult female chicken, turkey, pheasant, or quail
ROOSTER: male chicken or pheasant
TOM: male turkey
WATTLE: a large, rather long, finger-type growth that hangs off the upper beak of a tom turkey

The chicken is the most widely raised of agricultural animals. It is estimated that over eight billion chickens are produced annually in the world for both meat and egg production. The chicken was domesticated over four thousand years ago in southeast Asia. The general history of domesticated fowl is not very clear. It appears that the world's chicken population was developed from at least four different wild jungle fowl. Crossbreeding allowed for the introduction of new breeds that continued to develop and change. Today's domesticated birds all come from the Asiatic birds. The wild red jungle fowl is considered to have had the most influence in chicken development. It was the most widespread of the chicken's probable ancestors, was the most calm and compact, and could be the foundation bird of the domesticated chicken.

Chickens

There are three distinct categories of domesticated chickens: meat, egg, and dual purpose. The meat-producing bird is referred to as the broiler breed, and it was developed to be a very fast-growing, quickly maturing, large-bodied bird. The purebred broiler breed chicken is usually crossbred with another breed of chicken to produce an even faster-growing bird. The broiler breed does not lay well and is seldom used as a farm flock bird for egg production.

The egg production chicken is a very lightweight bird, for it was genetically developed to produce eggs and stayed away from any kind of meat characteristics. Most of the egg production breeds come from the Mediterranean region of the world. In general, they are very quick birds, easy to scare, and excellent converters of feed into white-shelled eggs. The Leghorn breed is probably the most well known of the Mediterranean breed of chicken. The dual purpose breed of chicken was primarily developed in the United States for the American farmer or the small flock owner. In the latter part of the nineteenth century, a bird was needed that had relatively good egg production value but also was large enough so a family could use extra birds for food. Most of the American dual purpose breeds have a calm demeanor, lay a good-sized brown-shelled egg, and are easy to keep. The two most common breeds are the Plymouth Rocks and the Rhode Island Reds.

Chickens come in all different sizes and shapes. There are also enormous color and color pattern differences. Many chickens are solid colors, others are striped, splashed, dotted, tipped, or checked. In just about all cases, the rooster is more colorful than the hen. Since the hen sets on the eggs for hatching purposes, she needs to blend into the surrounding area so that a predator will have a harder time in finding her and the nest. The modern farmer, however, usually does not allow hens to set in the wild, and most chicks are now hatched in an incubator.

The chicken's comb varies in type: It may be single, or shaped like a rose, a vee, a pea, or a strawberry. The comb structure is the same for a rooster or a hen. The weight of chickens can vary also, with the rooster weighing anywhere from six to twelve pounds and the hen weighing about two pounds less, depending on the breed and age of the chicken itself. The Asiatic chicken breeds weigh the most, and the Mediterraneans the least.

The incubation period of a chicken is twenty-one days. The baby chicks are rather well-developed when hatched and can survive a day or so with little or no feed. They have a yolk-sac attached that gives them enough food until they are able to figure out how to eat and drink. Newborn chicks need a higher protein base than do older chickens. The growing chicks need between a 20 to 24 percent growth formula in order to survive and flourish.

A chicken has much in common with other birds. The bone structure is similar to that of most birds in that it is lightweight, with hollow cavities, yet strong. The muscle structure is well defined and powerful, allowing the chicken to fly, although not far. The digestive system is typical of all birds. Chickens take in food through their beaks; then it is moved to a pouch where it is stored before being passed on through the gizzard, a hard, rough muscle whose function is to crush the food with small stones that have been picked up to assist in the breaking up of the food particles. Chickens always need a new supply of stones, or grit, to help them in their dietary function. The feathers cover the bird's outer frame and serve as an insulator to keep body temperature even. Feathers constitute 4 to 10 percent of the bird's total weight, depending on the breed and age of the bird. The feathers are replaced on a regular basis, called a molt. The female molt is more dramatic than the male's.

Wild turkeys have exceptionally keen eyesight and are considerably smarter than their domesticated counterparts. (PhotoDisc)

A hen will start laying eggs when she is about six months old and will do so for about twenty weeks, when she goes through her first molt. The average laying hen will lay about 220 to 250 eggs in her first year of production. In the year following, the hen lays about half as many, and the following year, about as half as many again. Many chicken producers will get rid of the chicken after she has her first molt because egg production tends to drop off dramatically afterward.

Chicken, Turkey, Pheasant, and Quail Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Subclass: Neornithes
Order: Galliformes (chicken, turkey, and pheasant)
Suborder: Galli
Families: Megapodiidae (mound birds, two tribes); Cracidae (curassows, two tribes); Phasianidae (grouse, three tribes), with subfamilies Perdicinae (three tribes), Tragopaninae; Phasianidae, with subfamilies Meleagridinae (turkeys), Argusianinae (argus pheasant), Pavoninae (peafowl), Afropavoninae (congo peacocks), Numidinae (guinea fowl), Phasianinae (pheasant)

Geographical location: Chickens and pheasant originated in Southeast Asia from the wild jungle fowl; turkeys are strictly a North American bird that is now well received as a domestic fowl; quail are located on all continents except Antarctica

Habitat: The original habitat of chickens and pheasant was the warm region of Southeast Asia and now has spread worldwide; turkeys are an American ground bird; quail are found in forests, dryland areas, and plains

Gestational period: Eighteen to thirty-two days, depending on the species

Life span: Chickens will live about four years; pheasant live about the same length of time, but less in the wild; turkeys and quail live between three and six years

Special anatomy: Males are very colorful; females tend to be dull and drab-colored

Turkeys

The turkey is a rather large, ground-feeding bird that is native only to North America. There are two varieties. The eastern wild turkey, also called the common turkey, had a natural range that covered the southern portion of Canada to northern Mexico. The second turkey is called the ocellated turkey of southern Mexico and northern Central America. The eastern turkey had a much greater natural range, but because much of its natural cover has been destroyed over the years by human population growth, the range is now much smaller. In many cases, the eastern turkey has been wiped out of existence in numerous locales.

The domestic turkey is economically important to many regions in America. The turkey is traditionally served on Thanksgiving all across the United States. The wild turkey has a rather dark plumage, and eats nuts, bugs, and other things it finds on the forest floor. It roosts in trees during the night. The wild turkey is very wily and is alert to all danger. The wild turkey male, or tom, is rather large for a bird that can fly with ease. He weighs about twenty pounds when full grown. The female is not as large but is just as alert. She will try to hatch out ten to fifteen eggs in her clutch every year. Turkeys tend to band together after the reproduction season is over, and they stay together until the following year.

The domestic turkey does not come from the eastern variety but from the ocellated strain. The Native Americans of Mexico and Central America domesticated the bird sometime before Columbus discovered the region. Currently, there are several kinds of domesticated turkey used in agriculture, with the Giant White being the one chosen for human consumption. The domestic turkey has been bred to have huge breasts and other dominant portions. It grows rapidly but cannot reproduce by itself very easily, having become too large. Most turkey insemination is now done through artificial means.

Quail

The quail is a relatively small, very fast-flying bird that is found in the western hemisphere as well as Europe, Asia, and northern Africa. It is a ground bird that prefers to hunt for seeds, bugs, insects, and other food on the ground near cover. Quails need a high-protein source of feed because of their fast heartbeat, so they usually hunt meaty invertebrates. The quail is generally monogamous in nature. When babies arrive, both parents tend to the offspring.

There are several closely related varieties of quail in the world. All have adopted a slightly different way of living, but are recognizable by their general patterns of flight, group activity, and food-hunting tactics.

Quail belong to the Phasianidae family, which includes pheasant, turkeys, and several other fowl. The males and females are similar in color and size. Quail are nonmigratory and will establish a territory in which they want to live and stay. Quail are sportsmen's favorite bird because they are fast flyers and elusive. They serve as a challenge.

Pheasant

The pheasant also belongs to the family Phasianidae. The history of the pheasant suggests that it originated from one of several wild jungle fowl of southeast Asia at least five thousand years ago, if not more. The greatest variety is located in Asia, but there are several native species in Europe as well as in Africa. The pheasant in North America were imported as sport gamebirds. North America has no native pheasant.

The pheasant does not roam very much and prefers to keep itself in a specific territory. The bird will forage on the ground, but at night will try to sleep in trees or in some other specific cover. The pheasant male is very polygamous and will mate with as many females as he can find. He does not help in the rearing of the babies and actually serves no function other than breeding and calling out when danger is near. The male has a much different color pattern than the female. He is colorful and bright-feathered; she is dull in color. The pheasant builds her nest on the ground and needs to blend in to the surrounding area in order to elude predators that might kill her or rob her nest.

The pheasant is a strong flyer, but does have to run before taking off on most occasions. It has a long neck, very strong legs and feet, and a powerful beak that is hooked at the end. There are several species of pheasant in the world, with the most numerous being the domesticated chicken.

CHIMPANZEES

Types of animal science: Anatomy, behavior, classification
Fields of study: Anthropology, ethology, zoology

Two species of chimpanzees exist and are classified under the order Primates, an order of extreme physical variability and complexity. Chimpanzees are humans' closest relatives and exhibit significant learned behaviors.

Principal Terms

DOMINANCE HIERARCHY: ranking or status system found in some primate societies
FUSION-FISSION COMMUNITY: a society whose members are of both sexes and all ages, which can form and dissolve subgroupings
HOME RANGE: a primate's territory
KNUCKLE-WALKING: terrestrial locomotion, in which the animal walks on the knuckles of the forelimbs and soles of the hind feet
SOCIAL GROOMING: an activity maintaining social interaction, whereby debris is removed from a primate's hair

Chimpanzees are highly intelligent and emotional animals. They demonstrate many humanlike traits, such as a rudimentary culture, in their adaptive responses to environmental challenges.

Physical Characteristics of Chimpanzees

Woodland chimpanzees weigh between 73 and 132 pounds. The bonobo weighs from seventy-three to ninety-nine pounds. Females are about 10 percent smaller than males. Chimpanzees have powerful arms and shoulders and locomote through knuckle-walking, a form of quadrupedalism, although they are occasionally bipedal, and can also brachiate (swing through trees and branches). Chimpanzee forelimbs (arms) are longer than their hindlimbs. Vision is in color and highly acute. Chimpanzees have short thumbs, and their grasping ability is somewhat impaired relative to humans.

Both *Pan troglodytes* and *Pan piniscus* are promiscuous. Females of each species exhibit sexual swelling when they are receptive to mating; however, there is no consistent breeding season.

Ecology and Diet

Chimpanzees at one time inhabited a three-thousand mile belt across equatorial Africa. Today their distribution is limited, and in some regions they are extinct or disappearing.

Chimpanzee home ranges vary in size depending upon food resources and other ecological dynamics. The home range of the woodland chimpanzee can be from 2 to 215 square miles, whereas the bonobo's home range is from 7 to 19 square miles. Water availability, nesting trees, and seasonal food resources define ranges, and chimpanzees can cover several miles in a day. Adult male chimpanzees patrol their ranges to ensure the exclusiveness of a community's domain. Aggression as a result of invasion and intercommunity destruction has been documented by Jane Goodall.

Chimpanzees are omnivorous: Their diet consists of a great variety of vegetal foods, as well as insects, grubs, bird eggs, and small mammals. While leaves and fruit define much of the chimpanzee's diet, colobus monkeys, young bush bucks, and young baboons obtain supplemental protein through cooperative hunts.

Group Life and Learning

Chimpanzees of both species reside in fission-fusion communities. Membership within community subgroups can change throughout the day.

Jane Goodall

Born: April 3, 1934; London, England
Fields of study: Ethology, zoology
Contribution: Goodall, a primatologist, was the pioneer in long-term field studies of the woodland chimpanzee (*Pan troglodytes*). Her research documented previously unknown behaviors including tool manufacture, cooperative hunts, and numerous other humanlike traits.

Image Not Available

Jane Goodall was awarded a Ph.D. in ethology from Cambridge University in 1965, one of a few to not earn a bachelor's degree prior to graduate study. In 1967, she became the scientific director of the Gombe Stream Research Centre in Tanzania. In addition, she has held university teaching appointments at Stanford University, the University of Dar es Salaam, Tanzania, Tufts University, the University of Southern California, and beginning in 1996, at Cornell University as A. D. White Professor-at-Large. She holds memberships in numerous scientific organizations and has been awarded honorary degrees from many prestigious institutions, including the University of Pennsylvania in 1990, and the University of Edinburgh, Scotland, in 1997. The recipient of dozens of awards from worldwide organizations, Goodall received the Centennial Award from the National Geographic Society in Washington, D.C., in 1988 and was recognized for her scientific contributions by being made a Commander of the British Empire by Queen Elizabeth II in 1995.

Goodall demonstrated an early interest in the primates and wildlife of Africa. As a young woman she worked with famed paleontologist Louis Leakey at Olduvai Gorge in Tanzania. With Leakey's encouragement and advice she began her research in 1960 with a population of free-living chimpanzees in the Gombe National Park.

Through rigorous observations, Goodall documented numerous behaviors of *Pan troglodytes* which exploded previously held myths. Perhaps Goodall's most significant accomplishment was to demonstrate that the woodland chimpanzee possessed the capacity for rudimentary culture. Goodall's research documented that woodland chimpanzees could modify and use natural objects such as branches, twigs, and stems of grass. These tools could be employed to extend the food quest, for example in "termite fishing," intimidate other animals such as baboons, and make their daily lives easier by doing such things as using leaves as sponges to soak up drinking water.

In an early and important book, *In the Shadow of Man* (1971), Goodall described chimpanzee family and social life, basic tool-making, aggression, and predation. That chimpanzees organized themselves into distinct groups for hunting entranced a worldwide audience. Many behaviors were filmed by Goodall's first husband, Baron Hugo van Lawick, a wildlife photographer. Later contributions to the literature, particularly *The Chimpanzees of Gombe: Patterns of Behavior* (1986) and *Through a Window: Thirty Years Observing the Gombe Chimpanzees* (1990), underscored the value of long-term field studies.

Goodall's fieldwork might be characterized as a combination of patience and determined effort. By the 1980's, this effort culminated not only in an enormous amount of knowledge on woodland chimpanzee behavior but also in the establishment of the Gombe Stream Research Centre as one of the world's foremost primate research facilities.

Since the mid 1980's, Goodall has spent large amounts of time away from the Gombe Centre in worldwide lecturing and in lobbying for chimpanzee and wildlife-related issues. In addition, she has been actively involved in chimpanzee conservation and has worked to halt the illegal trade in chimpanzees.

—Rene M. Descartes

Males and females strive to attain dominance, or elevated status, which provides access to preferred food resources and desirable mates. Physical size, strength, and age influence the attainment of position within a dominance hierarchy. Hierarchies function to minimize chaos within the community. Woodland chimpanzee communities range from 20 to over 100; bonobo groups range from 50 to 120 individuals.

Social interaction is enhanced on the individual level through social grooming. Mutual grooming, or cleaning the hair carefully, is an act denoting friendship and intimacy.

Learning accounts for much of chimpanzee behavior, acquired through play and observation. Tool use, a learned behavior, has been observed frequently among woodland chimpanzees, much less so among the bonobo. Tools (sticks, rocks, branches, leaves) have been used, and in some instances modified, in order to access and extract underground termites from their nests for consumption; to intimidate other animals; to facilitate drinking; to clean the body; and to crack open nuts.

Chimpanzee behaviors associated with meat eating include begging and the subsequent sharing of the kill by the hunters. Cannibalism and infanticide among chimpanzees have also been observed.

Chimpanzees are emotional animals that require reassurance that they are part of the community. Touching and embracing among individuals are common behaviors.

—Rene M. Descartes

Chimpanzee Facts

Classification:
Kingdom: Animalia
Subkingdom: Metazoa
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Primates
Suborder: Anthropoidea
Family: Pongidae
Genus and species: Pan troglodytes (common or woodland chimpanzee), *P. piniscus* (pygmy chimpanzee or bonobo)

Geographical location: Africa; *P. troglodytes* is found from west to east Africa, from Senegal to Tanzania, including the Ivory Coast, Gabon, Sierra Leone, Congo Republic, and the Democratic Republic of the Congo; *P. piniscus* is found in the central and western regions of the Democratic Republic of the Congo

Habitat: *P. piniscus* prefers rain forests and swampy forested areas; *P. troglodytes* has been observed in diverse habitats—tropical rain forest, wooded savanna, primary and secondary forest

Gestational period: 7.5 to 8 months

Life span: Forty to fifty years

Special anatomy: Large complex brain (390 cubic centimeters average) in relation to body size

CHORDATES, LOWER

Type of animal science: Systematics (taxonomy)
Fields of study: Anatomy, evolutionary science, physiology, zoology

Lower chordates are those members of the phylum Chordata other than the vertebrates. They are small marine organisms, chiefly of interest for the light that they shed on the history of vertebrate development.

Principal Terms

CHORDATA: a phylum of organisms characterized by the presence of a notochord, a dorsal nerve cord, and gill slits

DEUTEROSTOMES: echinoderms, hemichordates, and chordates, a group linked by features of cell development including retention of the blastopore as anus

LOWER CHORDATES: a group within the Chordata that shows chordate characteristics in the larvae but is separated from vertebrates by the lack of a skeleton

NEOTENY: a process by which larval features are retained into the reproductive adult stage

NOTOCHORD: a flexible stiffening rod found in primitive chordates

PROTOSTOMES: annelids, mollusks, flatworms, and arthropods, a group linked by features of cell development including retention of the blastopore as the mouth

The phylum Chordata is chiefly of interest because it includes the human taxonomic group, the vertebrates. Yet the phylum also includes a number of lesser-known groups, termed the lower chordates. Chordates as a whole are characterized by the presence of a longitudinal cartilaginous stiffening rod (the notochord), a single tubular dorsal nerve cord, and perforations in the pharynx comparable to gill slits. The subphylum that includes humans, the Vertebrata, is further characterized by the presence of a bony skeleton that forms an internal support and protects vital structures such as the spine and brain. In land-dwelling vertebrates, gill slits are present only in the embryonic stages. The other two subphyla currently included within the Chordata and making up the lower chordates are the Urochordata, or tunicates, and the Cephalochordata, all of which are small marine organisms. In the past, an additional group, the Hemichordata (acorn worms and pterobranchs), were also considered chordates. They possess a dorsal nerve cord and gill slits but do not have a notochord; they are now placed in a separate phylum, although they are considered to be closely related to chordates. In addition, a group of fossil organisms with echinoderm affinities have been interpreted as chordates and given the name Calcichordata. Most specialists on this group (generally known as mitrates) consider them to be echinoderms, however, as their chordate affinities are based entirely on soft-part reconstructions.

Sea Squirts

The largest group of lower chordates, containing about 1,300 species, is the Urochordata. These organisms, commonly called tunicates, little resemble chordates in their adult form: Only the tadpolelike larval stage possesses distinct chordate characters. Three classes are recognized—the Ascidiacea, Thaliacea, and Larvacea—and of these the most common and typical tunicates are the ascideans, or sea squirts.

Adult sea squirts are sessile (attached to the ocean bottom) marine organisms commonly found in coastal waters worldwide. They are sack-shaped, range from a few millimeters to a few centimeters in length, and have two siphons, inhalant and exhalant, extending from the upper surface. The outer part of the body is called the tunic. This is a protective structure made of proteins and polysaccharides, which is often quite thick and may vary from a soft, delicate consistency to one that is tough and similar to cartilage. Within the tunic, much of the space is taken up by the pharynx (an expanded part of the digestive tube), which has small perforations in its wall, creating a net. Small, hairlike structures called cilia create currents that pull water in through the inhalant siphon. The water then passes through the openings in the wall of the pharynx into the atrium (the surrounding cavity), and from there it passes out through the exhalant siphon. Food particles are trapped on the pharynx wall by a mucus sheet, which moves constantly to the midline of the pharynx and then posteriorly to the gut, where digestion takes place. This is a very effective system, and it can filter out particles only one to two micrometers in diameter.

Sea squirt larvae, unlike the adults, are tadpole-shaped and mobile. They are generally very small and are mobile for only a few hours before settling and becoming sessile adults. The tail of the larva has a notochord, which acts in much the same way as the vertebral column of vertebrates. As it is flexible but of a fixed length, it will not shorten when muscles on either side contract; it thus makes them antagonistic, bending the tail from side to side. Above the notochord is a dorsal nerve cord that swells anteriorly into a light detector and an organ sensitive to tilting. The larvae tend to swim down and away from light—behavior that takes them to sites such as overhanging rock faces that are suitable adult habitats.

Thaliacea, Larvacea, and Cephalochordata

The Thaliacea and Larvacea are both planktonic (that is, they float near the surface of the ocean). The Thaliacea, or salps, are colonial forms that may reach two meters in length. Their inhalant and exhalant siphons are at opposite ends of the body, and water is pumped through by rhythmic muscular contractions. This class has no tadpole-like larvae, but instead develops directly into the adult form. The Larvacea do develop from larvae, but they retain the tail as a permanent organ. Water is filtered through a mucus sheet in the pharynx as in other tunicates, but in this group the entire animal is surrounded by a delicate gelatinous "house" that is probably homologous to the sea squirt's tunic. The house has mesh at the inhalant and exhalant openings that helps to concentrate food particles; this concentrate is then passed through the mucus sheet, and food particles are trapped. The house is continually shed and replaced, probably to counteract clogging of the filters, and may not last more than a few hours.

The subphylum Cephalochordata includes only about twenty species of two genera of organisms that are often referred to as amphioxus. These are small, fusiform, and rather fishlike organisms up to seven centimeters long that live in sandy and shelly bottoms in shallow coastal waters. They burrow head down in coarse sediments and can filter-feed even when buried by filtering the water that penetrates between grains.

In cephalochordates, the notochord extends almost to the snout. This is further forward than in fishes, and it may aid in burrowing by stiffening the snout. The swimming muscles are arranged in myomeres (muscle segments) down the body and are similar to those found in fish, though simpler in shape. A hollow dorsal nerve cord runs above the notochord and is enclosed in a tube of collagen fibers that enclose the cord in a way similar to the vertebrae in fish. There is no anterior swelling of the nerve cord that might be comparable to the brain in vertebrates. The nerve cord, however, sends a ventral motor nerve and a dorsal sensory nerve to each myomere, an arrangement identical to that found in vertebrates. As it is in the urochordates, the pharynx is pierced by numerous slits, and food particles are trapped by a mucus sheet that moves across them and back to the gut. The blood system is more complex, however, and is similar in general arrangement to that of fish, although there is no heart; blood is propelled by pulsations of some of the vessels.

Hints About Vertebrate Origins

The cephalochordates and urochordates are particularly interesting for what they suggest about vertebrate origins. Although in the past it has been suggested that vertebrates evolved from various invertebrate groups such as annelids (segmented worms) or cephalopods (squid and octopuses), it is now recognized that fundamental patterns of development distinguish chordates and echinoderms from mollusks and advanced segmented invertebrates. These differences involve the way in which cells divide and the relative potential of the cells.

In mollusks and annelids, spiral cleavage results in cells that are nested between one another in successive rows. They are also determinate—that is, the fate of each cell is predetermined, so that the removal of one results in the developmental failure of part of the organism. In chordates and echinoderms, however, the cells are directly above one another in layers (radial cleavage), and if a cell is removed, adjacent cells will compensate for its loss (indeterminate cleavage). In both groups, cells initially form a ball, termed the blastula, and cells at one end grow in to form a second layer of tissue, the endoderm, which forms the lining of the gut. The external layer, or ectoderm, forms the outer surface of the body. In the mollusk-annelid group, the opening in the blastula (the blastopore) is retained as the mouth, while in the echinoderms and chordates it becomes the anus.

Despite the fact that this information points to a close relationship between echinoderms and chordates, there are too many differences for them to make convincing vertebrate ancestors. The larvae are similar to those of lower chordates, but the adults are quite different. The same can be said for hemichordates, although they are probably more closely related to chordates than echinoderms are. Adult urochordates are also too specialized to be suitable candidates for the vertebrate ancestor, and the same can be said of cephalochordates, although amphioxus does show many vertebrate-like features. It is currently accepted that the echinoderms, hemichordates, and lower chordates must have diverged from vertebrate ancestors no later than the lower Cambrian period (about 550 million years ago). This is substantiated by the presence of a fossil cephalochordate in the Burgess shale, which is middle Cambrian in age.

It has been suggested that the lower chordates show how the vertebrate ancestor may have arisen by a process of neoteny or pedogenesis, in which larval characteristics may be retained in the adult. Sexual development is accelerated, and the development of other organ systems is arrested, so that the nonreproductive larvae of the ancestor become the reproductive adults of the descendant. In this case, a notochord and tail muscles are found in sea squirt larvae but not in the adults; however, they are retained in the Larvacea. Further retention of larval features could have given rise to cephalochordates and, by a further step, to vertebrates.

Studying Chordates

Lower chordates, small marine organisms, are often difficult to study because of their size and delicacy. The gelatinous covering of the Larvacea, for example, is so easily damaged as to be almost impossible to observe. Many modern techniques, however, have been developed to aid in the study of organisms such as these. Cinematography is used in studies of movement, and high-speed photography is particularly useful; the film can then be shown at a much slower speed to enable detailed analyses of complex movements. Electromyography can also be used to trace muscular action, as it follows the electrical changes that take place in muscles when they are active. The lower chordates are all filter feeders, and it is possible to carry out experiments that show how effective they are at removing small particles from the water. Sea squirts can be placed in a dish containing a suspension of colloidal graphite, and their filtering ability can be seen as a function of the rate at which the water clears. In addition, the size of particles can be varied to show how efficient the filtering apparatus is; this has shown that sea squirts can remove particles as small as one to two micrometers in diameter, although the diatoms on which they normally feed are closer to two hundred micrometers in diameter.

Fossil lower chordates are extremely rare; however, a probable cephalochordate, *Pikaia*, is known from the Burgess shale of British Columbia, which is dated as middle Cambrian (530 million years ago). The Burgess shale contains a variety of soft-bodied organisms preserved as films of carbon on the bedding surfaces. Study is difficult because the material is compressed and because it is the same color (black) as the rock that contains it. Specimens can be prepared by picking rock away with needles. Details can then be studied by observing the specimens under low-angle light, which picks out differences in reflectivity of the rock surfaces and carbon films, or by immersing specimens in water or alcohol, which also enhances differences between the fossil and the surrounding rock.

These techniques make it possible to determine which characters are important in determining relationships within the lower chordates. Studies on relationships rely heavily on a methodology called phylogenetic systematics, or cladistics. In this taxonomic method (taxonomy is the study of interrelationships), only advanced characters shared between species (termed synapomorphies) are used to develop a picture of relationship. These relationships are expressed as branching diagrams termed cladograms (*klados* is Greek for "branch"), hence the name cladistics. Studies using this technique have advanced understanding of the relationship between lower chordates and the vertebrates. The picture is by no means clear, however, and much still waits to be done.

Understanding the Route of Evolution

The lower chordates are of particular interest for the light that they shed on the way in which the group to which humans belong, the vertebrates, may have developed and when this may have occurred. Vertebrates differ from lower chordates in possessing both an internal skeleton and a brain; however, there is only limited fossil record of the earliest members of the group. The earliest known vertebrates are fish that are found in rocks of the Ordovician period (450 million years ago) in Australia, South America, and North America. These animals had an external bony armor, but knowledge of both their external appearance and their internal anatomy is restricted by poor fossil preservation. It is clear, however, that these animals were already relatively advanced and, hence, that a fairly long period of vertebrate development is not represented in the fossil record. As the lower chordates are the nearest relatives of the vertebrates, they can provide some information on how this development may have taken place.

It has been suggested that the process of neoteny, or pedogenesis, might explain the development of vertebrates. In this process, development of adult characters is retarded, and the organism reaches sexual maturity while still in the larval stage. This process may already have operated in the lower chordates, as the urochordates show chordate characters in the tadpolelike larval stage only, whereas the more advanced cephalochordates retain the chordate characters in the fishlike adult stage. It is fairly easy to see, therefore, how a continuation of this process could lead, by fairly small morphological changes, to organisms similar to the larvae of modern lampreys, jawless fish that represent the most primitive modern vertebrates.

It is clear, however, that vertebrates did not evolve directly from cephalochordate ancestors. Although the modern cephalochordate amphioxus shows many features that one would expect to find in a vertebrate ancestor, it also has a number of basic differences that are inconsistent with a position on the direct evolutionary lineage of the vertebrates. In particular, the presence of a notochord extending to the anterior end of the rostrum and the lack of a clearly differentiated head make cephalochordates unlikely ancestors of organisms with large brains. It seems more likely, therefore, that both vertebrates and cephalochordates represent divergent lineages from a common ancestor, probably of urochordate type. The presence of the fossil cephalochordate *Pikaia* in rocks of Middle Cambrian age (530 million years ago) indicates that the division had already taken place then and that the first vertebrates must have been present some time in the early Cambrian period.

Bibliography

Alexander, R. McNeill. *The Chordates*. 2d ed. New York: Cambridge University Press, 1981. A general review of the entire phylum, covering both fossil and modern representatives. The second chapter deals entirely with lower chordates, providing a very useful review of their anatomy and relationships. Suitable for high school and college students.

Barrington, E. J. W. *The Biology of the Hemichordata and Protochordata*. Edinburgh, Scotland: Oliver and Boyd, 1965. Although this is not a recent text, the study of these organisms has not moved fast enough to make it obsolete. There is a particularly good section on life habits and development. Suitable for college students.

Hayward, P. J., and J. S. Ryland, eds. *The Marine Fauna of the British Isles and North-West Europe*. Vol. 2 in *Molluscs to Chordates*. Oxford, England: Clarendon Press, 1990. Primarily an identification manual, systematizing the inshore fauna of the British Isles and North Sea. Each species is illustrated and given a brief description. An excellent reference list is supplied for each phylum or major taxon. Indexes of taxonomic and technical terms.

Hochachka, P. W., and T. P. Mommsen, eds. *Molecular Biology Frontiers*. New York: Elsevier, 1993. Covers the molecular biology and physiology of fishes. Individual articles are written by experts in the field. Includes references and index.

Kardong, Kenneth V. *Vertebrates: Comparative Anatomy, Function, and Evolution*. 2d ed. Boston: McGraw-Hill, 1998. An accurate, up-to-date reference work with hundreds of figures, as well as box essays on interesting related stories. Presents vertebrate morphology as a central intersection for ideas about structure, function, development, and evolution.

Margulis, Lynn, and Karlene V. Schwartz. *Five Kingdoms*. 3d ed. New York: W. H. Freeman, 1999. This text covers all known phyla, devoting only two or three pages to each; it therefore provides only an overview. It has sections on hemichordates and chordates and is very valuable in placing them in context. Suitable for the general reader and the college student.

Pough, F. H., J. B. Heiser, and W. N. McFarland. *Vertebrate Life*. 5th ed. Upper Saddle River, N.J.: Prentice Hall, 1999. An excellent text, particularly in its use of cladistic taxonomy throughout. Deals with lower chordates in discussion of vertebrate ancestry in chapter 2. Suitable for college students.

Wolff, Ronald G. *Functional Chordate Anatomy*. Lexington, Mass.: D. C. Heath, 1991. A college-level textbook. Each chapter covers development, basic structure, comparative survey of structure and function, and phylogenetic analysis of vertebrate trends. Extensive references and further reading lists.

Young, John Z. *The Life of Vertebrates*. 3d ed. New York: Oxford University Press, 1981. A revised version of a classic text. The cephalochordates are dealt with as part of chordate classification. Also covers the hemichordates and tunicates as part of a discussion of the origin of chordates from filter-feeding organisms. Suitable for college students.

CIRCULATORY SYSTEMS OF INVERTEBRATES

Type of animal science: Anatomy
Fields of study: Evolutionary science, histology, invertebrate biology, systematics (taxonomy)

Any circulatory system provides transport for materials required by cells that cannot be supplied quickly or efficiently enough by diffusion. Invertebrates possess a great variety of circulatory systems. Some are closed systems; some are open systems.

Principal Terms

BLOOD: the fluid connective tissue within blood vessels that carries raw materials to cells and carries products and wastes from them

CLOSED CIRCULATION: a circulatory pattern in which blood is always contained within blood vessels

DIFFUSION: the process whereby a substance moves from an area of greater concentration to one of lesser concentration, as through a cell membrane

HEMOLYMPH: the transport fluid of organisms with open circulation systems in which there is no clear distinction between blood and intercellular tissue fluid

LACUNAE: small spaces among tissue cells through which hemolymph flows in open circulatory systems

OPEN CIRCULATION: a circulatory pattern in which the blood is not always contained within blood vessels

SINUSES: larger spaces, thought to represent through channels, for hemolymph in open circulatory systems, sometimes bound by membranes

TRACHEAL SYSTEM: the respiratory system of insects and other terrestrial invertebrates; it consists of numerous air-filled tubes with branches extending into tiny channels in direct contact with body cells

Circulatory systems are necessary when the process of diffusion no longer provides an organism with sufficient gas, nutrients, and waste exchange with its environment. Some invertebrate groups, such as sponges, coelenterates, and flatworms, have such thin body walls that diffusion can meet all their needs. For most invertebrates, however, the distance from the organism's surface to the cells in the interior is too great for diffusion to support their metabolic requirements. A circulatory system is composed of three parts: the pump, the fluid that is pumped, and the vessels in which the fluid is transported. As in the design of invertebrate body plans, there is great diversity in the design of invertebrate circulatory systems.

The Components of the Circulatory System

The pump may be a simple tube lined by muscle fibers. Alternate contraction and relaxation of these muscles produces a peristaltic wave that pushes the blood along. The pump may be a heart: a localizable, discrete organ whose muscle layers are the primary generators of the power that propels blood through the blood vessels. The heart can be a simple muscular enlargement, or it can be complex and multichambered, depending on the evolutionary history and the needs of the organism. Some organisms may have more than one heart.

If the pumped fluid remains within the blood vessels, it is usually called blood. If it leaves the blood vessels to enter cavities surrounded by tissue cells with which it exchanges materials, it is called hemolymph. In the cavities (called lacunae if small and sinuses if large and lined with a membrane) blood mingles with intercellular fluid. Whatever it is called, the fluid is composed of water, solutes (such as salts, sugars, and other nutrients), and, in some cases, cells and formed elements. The blood may also contain a respiratory pigment that helps deliver oxygen to the cells.

Fluid Transport Systems

Blood vessels may extend only a short distance from the heart or may provide a continuous path for the transport of blood. If the blood vessels are incomplete and blood is pumped from arteries into body spaces—sinuses and lacunae—it is an open circulatory system. If the blood vessels are continuous and the blood never leaves these circulatory channels, it is a closed circulatory system. These are generalized terms for convenience; there are actually many intermediate cases. Some open systems have membrane-lined sinuses and lacunae, and exchange takes place by diffusion just as it does in the tiniest vessels of closed systems. Blood vessels are categorized according to their function. Arteries carry blood away from the heart; veins carry blood back to the heart. Closed circulatory systems have tiny tubules, called capillaries, connecting small arteries to small veins. The exchange of materials between the tissue cells and the blood takes place only in the capillaries.

A few generalities based on physical principles indicate the rules guiding fluid transport. Organisms relying on diffusion alone to circulate nutrients and eliminate wastes are limited to certain shapes and sizes: They are often only two cell layers thick. Organisms using bulk transport of fluid, on the other hand, may be as complex and as differently shaped as plants and animals are.

A fluid transport system is any system in which internal fluid movement reduces diffusion distances—either between points within an organ or between a point within an organism and the external environment. While diffusion is always used for short-distance transport, bulk flow augments diffusion for any long-distance transport. Bulk flow requires a pump and a fluid that must come into intimate contact with tissues and the environment for efficient transfer. Either the tissue layers must be thin (as in open circulatory systems) or the vessels must have a small radius (as in a closed circulatory system). The circulatory fluid should spend the majority of its time in the transfer regions (sinuses and lacunae or capillaries) and not in transit.

Such transport systems use both large and small vessels. Large vessels move fluid from one exchange site to another, and small vessels allow diffusion at the exchange sites. The total cross-sectional area of the small vessels must exceed that of the large vessels so that the flow rate in small vessels will be less than the velocity in large vessels. High-speed pumps in large vessels are preferable to low-speed pumps in the small vessels. This means that accessory hearts are only used when the "cost" of operation is not a major factor or when the pump serves some additional functional role—as when active cephalopod mollusks, such as squid and octopods, use accessory hearts to ensure adequate blood flow through their gills.

Closed and Open Circulatory Systems

Circulatory systems are traditionally divided into two categories. Closed systems are those in which the blood is always contained within distinct vessels and is physically separated from the organism's intercellular fluids. They are usually characteristic of organisms with high metabolic demands. High volumes and high pressures can be maintained in the closed vessels to aid transport and diffusion. Annelids, cephalopod mollusks, and vertebrates usually have closed circulatory systems.

Open systems are those which possess large, usually ill-defined, cavities (sinuses if bound by an endothelial layer, lacunae if not) and in which the blood is not physically separated from the intercellular fluids. Arthropods and noncephalopod mollusks have open systems.

Open circulatory systems are not always sluggish, low-pressure arrangements. Some spiders generate sufficient pressure in their open systems to use hydraulic pressure as a substitute for extensor muscles in their legs. In addition, capillaries often exist in open systems, particularly in areas such as the excretory organs and the cerebral ganglion. The major sinus in the foot of gastropod and bivalve mollusks is not a large, open cavity but a network of channels in a spongy tissue that function as capillaries. The lack of return vessels in these systems is usually a result of the fact that fluid simply has nowhere to go other than in the direction of low pressure: back to the heart. These volume constraints are sufficient to develop pressure, although this system is incompatible with high pressure and flow rates.

In the two major groups with open circulatory systems, arthropods and noncephalopod mollusks, the circulatory sinuses play an additional role: In bivalve and gastropod mollusks, the hemocoel (main body cavity) functions as a hydrostatic skeleton in locomotion and burrowing. In aquatic arthropods, it serves the same function during molting, when arthropods lose the support of the exoskeleton. In insects, the tracheal system has assumed the respiratory function, and the blood merely delivers nutrients and removes wastes. In large flying insects, the circulatory systems may also have the primary responsibility of removing heat to maintain thoracic temperatures.

Pressure Patterns in Heart Action

To function effectively, the circulatory system must have a regular pattern of pressure increases that will push the blood along through the vessels. The heartbeats that accomplish this may be initiated and maintained by nerves, or they may be self-generated. If nerves initiate the contraction of the heartbeat, the heart is called neurogenic, meaning that nerve impulses generate the depolarization that results in the contraction of the heart's muscle cells. In these hearts, the heart muscle will not contract without a nerve impulse. Some species with neurogenic hearts are crustacea, horseshoe crabs, some spiders, and scorpions.

Heart muscles that continue to beat even when nervous connections are severed are called myogenic, meaning that the heart muscle contracts without external stimuli. Under these circumstances, the contraction of the muscles may occur at a different rate from that imposed by the nervous system when active. Myogenic hearts are found in mollusks and many insects.

All heart action must be modulated to respond to external and internal conditions, so even myogenic hearts usually receive some innervation. Modulation occurs through the mediation of nerves, hormones, or intrinsic controls in the heart. In the lobster, for example, nerves are crucial to maintaining the best rhythm and amplitude, but neurohormones released from a pericardial organ influence the heart action. Stretching the heart muscle, an intrinsic control, will also increase the vigor and rate of contraction.

In many cases, the structure of the heart and its suspensory ligaments contributes to the functioning of the circulatory system. Values at the openings (ostia) to the heart prevent backflow when the heart contracts. This pulls at the ligaments. Their elasticity pulls back the walls of the heart, creating low pressure that enables the heart to fill on relaxation. In effect, the heart sucks blood from veins to refill itself for the next contraction.

In many species, the contraction of body parts contributes to the circulation of blood. Arthropods have a rigid exoskeleton; contraction in one part pushes the blood into another segment. In American lobsters, a quick flexion of the abdomen (an important locomotor movement) raises pressure in the abdomen and increases the rate of blood flow to the thorax and into the heart region.

All flow depends upon pressure differences, regardless of whether the circulatory system is open or closed, and there are two kinds of pressure. Background pressure is the pressure that prevails everywhere in the animal. Since pressure differences are responsible for flow, these pressure differences are imposed on the background pressure. If the body changes posture and increases background pressure, the blood pressure must similarly increase in order to maintain flows at the same level they were before the postural change. The blood-pressure gradient and the resistance to flow in the system affect blood flow.

The low resistance in open circulatory systems probably permits relatively high rates of blood flow with relatively low pressure. The high blood-flow rate compensates for the low oxygen-carrying capacity of the blood.

Open and closed systems differ; neither is necessarily superior. The inherent weakness of the open circulatory system is that the peripheral blood flow cannot be as well controlled as that of closed circulatory systems. Yet the large sinuses are often subdivided, thereby providing discrete channels of flow, and the peripheral blood flow may be more regular than previously thought. Closed circulatory systems have a flow that is easily controlled. Flow through particular regions can be managed by using muscles to close off certain channels. Cardiac output can be distributed to meet tissue demands. In open systems, this is not possible after the blood leaves the major vessels, although muscle contractions and accessory hearts may influence peripheral flow. Whatever their patterns, the circulatory systems of invertebrates are adequately matched to their needs; they have enabled these creatures to survive and proliferate for millions of years.

Studying Invertebrate Circulation

Methods used to study invertebrate circulatory systems are varied. One basic problem is that 95 percent of all animal species are invertebrates, and many of these creatures are not known and have never been studied. The larger, more common organisms that are easiest to study have been subjected to experimentation. Many invertebrates are difficult to maintain in the laboratory, but techniques to maintain them in good health are being developed and improved. Without these culture techniques, experimenters must use recently caught subjects whose condition is doubtful.

Most knowledge of invertebrate circulatory systems is anatomical. Even a common animal must be described so that a physiologist can apply appropriate techniques to study the functioning of the heart, vessels, and blood. Descriptions are usually derived from dissection and from microscopic study. These painstaking methods have been used on known species for centuries. Larger invertebrates, such as lobsters, crabs, clams, squid, and octopods, have been studied by techniques similar to those used in vertebrate circulation physiology. A heart can be exposed and either attached to a lever that can record its contractions or attached to an electronic force transducer, which can measure the strength of contraction.

The heart is large enough to be punctured for blood samples, and hemolymph can be withdrawn from the larger sinuses. These blood samples can be analyzed for the presence and activity of cells, respiratory pigments, nutrients, and wastes, using ordinary biochemical techniques. The development of microanalytic techniques in biochemistry allows the sampling of body fluids from small insects, worms, and rare organisms that might be damaged by taking larger samples.

In addition, force transducers can be placed along blood vessels and in hemocoels to determine the pressure exerted during flow. Electronic devices can monitor the flow rate by detecting cells or the passage of a dye or magnetic substance. Radioactive tracers can be injected and their path followed. All these less invasive techniques allow the animals to survive longer and to deliver data that can be more reliably interpreted because they are from a healthy subject. The use of fewer organisms in research and the survival of rare creatures are important both to the environment and to the development of a full understanding of these complex systems.

Advantages of Closed Versus Open Systems

Invertebrate circulatory systems occur in two plans, closed or open, and both styles of circulation have benefits for their users. Although open circulatory systems are usually thought to be sluggish and inefficient, they are not necessarily so. Active animals such as crustaceans and insects have open circulatory systems and metabolic rates (oxygen and nutrient demands) that equal those of the most active invertebrates, squid and octopods, which have closed circulatory systems.

Nemertean worms (Rhynchocoela) are a small group of inconspicuous and inconsequential worms that have an interesting circulatory system. These worms may reach thirty meters in length (although they are only a few millimeters wide), but they have a simple blood system. There may be two or three blood vessels, with connections between them, running the length of the body. The vessels have a layer of muscle in the walls. Contraction of these muscles and the main body muscles move blood—in any direction—along the vessels.

Annelids (wormlike animals) also have a closed circulatory system. The major blood vessel has pulsatile regions, often called hearts, which drive the blood forward. The pattern of blood vessels, including capillaries, is repeated in each segment of the animal, although most segments do not have "hearts." Accessory hearts occur in different segments, and the overall pattern of circulation varies greatly among species (and even within a single individual's many segments).

Arthropods and most mollusks have open circulatory systems; these invertebrates have a well-developed central heart. The heart pumps blood through an extensive arterial network, which may end in capillaries. The blood eventually leaves the blood vessels and enters lacunae. Diffusion of materials takes place in the capillaries or in the lacunae. Sinuses collect the blood for return to the heart. In these organisms, the blood follows an ill-defined path. Contractions of the body musculature affect the speed and volume of blood flow in any region.

The crustacean arthropods are a group having inactive members, which lack a heart and blood vessels entirely, and active members, which have a high level of circulatory system organization. The inactive members pump their body fluid through sinuses and lacunae using the pressure developed by muscle contraction. Decapod crustaceans, the familiar crabs, have a heart whose contraction drives blood into well-defined arteries; the return of blood to the heart from the veins occurs because of the elastic recoil of the ligaments suspending the heart in the pericardial cavity. Part of the beauty of this pattern is that only veins from the gills enter the pericardial cavity. Therefore, only oxygenated blood enters the heart and is pumped into the body. Thus, although there may be body spaces in which flow is indeterminate, the important blood flows are well controlled and can meet the needs of complex and active organisms.

CIRCULATORY SYSTEMS OF VERTEBRATES

Type of animal science: Physiology
Fields of study: Anatomy, histology, zoology

Vertebrates' circulatory systems consist of a closed system of blood vessels with a centrally placed heart, which receives oxygen-poor blood from the body and pumps it to the organs of respiration, where it is oxygenated and returned to the body's tissues. It is here that the oxygen and nutrients are unloaded and carbon dioxide and excretory products are picked up.

Principal Terms

AORTA: the major arterial trunk, into which the left ventricle of the heart pumps its blood for transport to the body

ARTERY: a blood channel with thick muscular walls which transports blood from the heart to various parts of the body

ATRIA: the two chambers of the heart, which receive venous blood from the body (via the right atrium) or oxygenated blood from the lungs (left atrium)

CAPILLARIES: the very fine vessels in various tissues, which connect arterioles with venules; it is here that the exchange between blood and the extracellular fluid takes place

CARDIAC OUTPUT: the amount of blood ejected by the left ventricle into the aorta per minute

DIASTOLE: relaxation (filling with blood) of the heart chambers

PACEMAKER: a specialized group of cardiac muscle cells in the right atrium which initiates the heartbeat; also called the sinoatrial node

SYSTOLE: contraction (emptying of blood) of the heart chambers

VALVES: specialized, thickened groups of muscle cells in the heart chambers, major arterial trunks, arterioles, and veins which prevent backflow of blood

Cells, the units of the animal body, need a constant supply of blood. Blood effects the transport of important materials needed for metabolic, synthetic, and degradative activities, supplying energy and materials necessary for growth, repair of worn-out components of cells, reproductive activity, and other functions of the body. Among the many products that blood transports through a system of closed channels are oxygen, nutrients, metabolic wastes, heat, and hormones. The circulatory system links all tissues with one another and with the external environment to and from which many of these materials are transported.

Basically, the circulatory system of vertebrates consists of two parallel systems of blood vessels: One, the arterial system, actively transports blood and its constituents from a central pumping station, the heart; the other, the venous system, more or less passively brings the blood back to the heart. The two systems branch again and again until they ramify all tissues. In the extracellular space of tissues, the finest branches of each system, called arterioles and venules, are connected by means of a network of fine capillaries that allow the movement of blood in one direction, from arterial into the venous system, in which the valves prevent any backflow of blood. A head of pressure, generated in the heart, pumps the blood in this direction, facilitating the transport of substances as well as their movement and filtration out of the capillary membranes and into the extracellular fluid.

Circulatory Systems of Fish, Amphibians, and Reptiles

The simplest level of organization of the circulatory system of vertebrates is seen in fishes. The heart in fishes consists of two chambers, an atrium (auricle) and a ventricle. The oxygen-poor, carbon-dioxide-rich blood returning from the body via a system of veins is first received by an enlarged vein, the sinus venosus, prior to entering the atrium. The atrium empties its blood into the thick-walled, muscular ventricle, which then pumps it into an enlarged artery, the conus arteriosus. The blood then passes through a major arterial trunk, the ventral aorta, going directly to the gills. The arteries in gills branch profusely and are connected via capillaries with other arteries. In the capillary bed, the blood becomes oxygenated and provides nutrients to the tissue. The oxygenated blood then flows to the head and the rest of the body, and from there returns to the heart through the venous system.

In preparation for their journey to land, ancient aquatic vertebrates had to evolve lungs for aerial breathing and had to evolve a complementary circulatory system. As demands for oxygen for a terrestrial existence increased, greater blood pressure and a new way of oxygenating blood were in order. The atrium became divided into two, the right one receiving the deoxygenated blood returning from the body and the left one receiving the oxygenated blood from the lungs (which replaced gills). The deoxygenated blood, entering the right part of the single ventricle, is pumped into the pulmonary artery, all the way to the lungs. The left part of the ventricle, receiving oxygenated blood from the left atrium, pumps it into the body. This three-chambered heart is present in amphibians and most reptiles. The oxygenated and deoxygenated bloods mix partially in the ventricle. In some amphibians, flaps and partial valves tend to prevent such mixing. Reptiles have a partition between the right and left parts of the ventricle, which is complete in alligators, crocodiles, and turtles.

Circulatory Systems of Birds and Mammals

Later reptiles, birds, and mammals developed four-chambered hearts. This complete division of the heart into two separate right and left pumps enables birds and mammals to achieve high speeds. One pumping circuit, the pulmonary, receives blood from the body and pumps it to the lungs; the other pumping circuit, the systemic, receives oxygen-rich blood from the lungs and pumps it into the systemic circulation. Valves within the heart prevent the blood from flowing through it in the opposite direction.

The contractile tissue of the heart consists of muscle cells that receive sympathetic and parasympathetic nerve impulses. The vertebrate heart is myogenic; that is, all of its muscle cells and fibers possess an inherent capacity to contract (electrically depolarize) rhythmically; however, all these fibers are under the control of a group of specialized heart muscle cells which have a lower threshold for depolarization than other heart muscle cells: the pacemaker. In fish, amphibians, and reptiles, the pacemaker is located in the wall of the sinus venosus (the first heart chamber before the atrium). In higher vertebrates, which lack a sinus venosus, the pacemaker is found in the wall of the atrium and is called the sinoatrial node. The wave of electrical depolarization initiated here is conducted through the atrioventricular node via a special group of fibers called the Bundle of His, which branch out into the ventricular muscle. The depolarization enters and traverses the atrioventricular node only relatively slowly but spreads down the atrioventricular bundle and its branches much more rapidly than it could travel through ordinary ventricular muscle. This regulates the sequence of contraction of the heart chambers: The atria contract first and the ventricles later, each group of muscles contracting approximately in unison.

Since the pulmonary (right) circuit is much shorter than the systemic circuit, it contains less blood volume and offers less frictional resistance to blood flow; also, the right ventricle has muscular walls that are less thick than those of the left ventricle, which has to pump large volumes of blood to the entire body via the systemic circuit. After the two ventricles are completely filled (a condition referred to as diastole), they contract simultaneously (called systole). During systole, the maximum arterial pressure is generated; during diastole (just before systole), arterial pressure decreases to a minimum. The pulmonary side of the heart contains the funnel-shaped valve between the atrium and the ventricle known as the atrioventricular valve, the right one having three flaps, or cusps (and hence named the tricuspid valve), and the left one (the bicuspid or mitral valve) having two. The free edges of these cusps hang down into the ventricular cavities and are anchored by tendonlike cords of connective tissue called chordae tendinae, each of which is attached to the ventricular wall by a lump called a papillary muscle. The pulmonary artery and the aorta originate at the base of the right and left ventricles, respectively, each having a semilunar valve at its origin. Each of these valves opens in the direction of the blood flow and prevents the backflow of blood. The ventricular contraction and the resulting turbulence in the blood produce the long, low-pitched "lub" sound that can be detected with a stethoscope. The sudden closure of the semilunar valves is similarly perceived to emit a relatively short, high-pitched "dup" sound.

Blood Volume and Blood Vessels

The volume of blood that is pumped by the heart each minute is called the minute-volume, whereby the heart beats (contractions) per minute (cardiac stroke rate) eject a typical quantity of blood per beat. This rate is altered by the body's activity and by the volume of blood returning to the heart from the veins each minute. If the venous blood volume is adequate, then increase in stroke rate can increase minute-volume. The increased stroke rate, however, involves a decrease in the ventricular filling time, and as a result, the ventricles do not fill completely. Thus, the stroke volume is decreased; at rapid heart rates, even the minute-volume may be decreased, so that it offsets the stroke rate. During systole, the ventricles do not empty completely. A small residual volume of blood remains in them. An increased venous return may cause more complete filling and emptying of the ventricles, thus increasing the cardiac output without changing the stroke rate.

The vessels at various points in the circulatory path differ anatomically and functionally. The great arteries have thick walls heavily lined with smooth muscle and contractile tissue to enable them to transport blood under pressure from the heart to peripheral tissues. The arteries become smaller and thinner-walled as they branch out toward the periphery. The systemic arteries deliver blood to the microcirculatory beds of the tissues and organs. These "capillary beds" consist of microscopic arterioles, capillaries, and venules. The contraction (vasoconstriction) and relaxation (vasodilation) of the smooth muscles in the terminal branches of the arteries play an important role in regulating blood flow in the capillary bed. Control of the arteriole muscles is mediated by sympathetic neurotransmitters, hormones, and local effects. From the arterioles, the blood enters the capillaries, minute vessels whose walls consist of a single layer of cells, facilitating transfer of oxygen and nutrients to the tissues and the loading of metabolic waste and carbon dioxide, all via the extracellular fluid. Their density depends on the need of the particular tissue for nutrients and oxygen. The capillaries drain into small, thin-walled but muscular vessels called venules, whence the blood begins its return to the heart through the veins. The veins have elastic walls but are without muscles. The venous vasculature serves as a reservoir, storing about 60 percent of the blood.

Studying Vertebrate Circulation

Circulatory systems of vertebrates have been studied since ancient times through dissection and observation of animal and human cadavers: The heart can be cut open to examine its chambers and their structures, and the body wall can be cut open from the ventral side to expose the circulatory organs. Preserved, dissected animals, including fish, amphibians, reptiles, and mammals, are available from suppliers for students of anatomy who wish to conduct their own dissections. The venous systems of these animals are dyed blue and the arterial systems are dyed red. Plastic models of the circulatory system can be purchased for classroom use.

Scientists are also interested in microcirculation, or circulation at the capillary level. One can fasten a live frog on a frog board and observe the capillaries in the frog's foot web under a microscope. The movement of the red blood cells into the capillary is observed; it is slow and intermittent. The blood flow is regulated by the central nervous system (the vasomotor center in the medulla), as well as by local conditions (such as levels of carbon dioxide, acidity, histamine, temperature, and inflammation). One can then immerse the foot in hot or cold water and observe the resulting change in blood flow. Histamine can be applied to cause vasodilation, which can be controlled by epinephrine. Drops of dilute hydrochloric acid can be applied to the foot to cause vasodilation and inflammation. Thus, it is clear from the foregoing discussion that the heart and circulatory system are of vital importance to the health of an animal.

CLAMS AND OYSTERS

Types of animal science: Anatomy, classification, ecology
Fields of study: Anatomy, ecology, marine biology, zoology

The category of clam is confusing, because there are some organisms found in freshwater or marine environments that are termed clams and some that are termed mussels. In sea water, fourteen marine organisms called clams are commercially valuable. Chief among these are the Atlantic surf clam and the ocean quahog. Scientists recognize twelve living genera of oysters but, as more studies are made by classification experts, the actual number may be slightly more or slightly fewer. In the United States, four species are commercially important, with the eastern oyster, Crassostrea virginica, *leading the list.*

Principal Terms

ESTUARY: a bay where seawater is diluted by freshwater from a river or land runoff

NACRE: shiny, pearly lining of some seashells; mother of pearl

PLANKTON: floating or weakly swimming plants and animals, usually very small in size

SALINITY: a measure of the quantity of dissolved salts in seawater

SESSILE: a type of existence in which organisms are permanently attached and incapable of moving

TIDE: periodic rise and fall of sea level influenced by gravitational attraction of the Sun, Moon, and Earth

Clams and oysters have long been of value to humans as food, while their shells have been valued as ornamentation. Paleolithic shell middens, some twenty-five feet high and seventy feet in base diameter, consist almost entirely of the discarded shells of clams and oysters. Oysters were especially prized because they lay on the surface of the estuary bottom and were easily gathered. Clams, buried a few inches deep, required some effort to gather. To prepare the shellfish for food, they were often simply placed on a fire and roasted in the shell. The fleshy contents were removed, eaten as they were, or cooked in a stew with some vegetables.

Physical Characteristics of Clams and Oysters

There are more than fifteen thousand different species of clams worldwide. They range in size from the *Condylocardia*, about 0.004 inches long, to the giant clam (*Tridacna gigas*) of the southwest Pacific Ocean, which grows up to nearly five feet long and weighs about 550 pounds.

Classified as bivalves, the animals have two shells that protect the soft body parts. In clams, two syphons, one incurrent and one excurrent, draw in and discharge seawater. The water supplies the shellfish with oxygen as well as plankton and other organic matter for food. A muscular projection (the foot) enables the clam to burrow into the sandy bottom. The valves are held together by two adductor muscles that slowly contract and relax to pump water into the shell. When the shellfish senses danger, the adductor muscles contract, closing the valves tightly and effectively sealing the soft body parts from a potential predator.

Oysters vary in shape depending on the type of bottom on which they lie. The shells usually are elongated with a rough surface. They do not have siphons. Instead, seawater, containing food organisms, is drawn into the body by a pumping action of the valves. Oysters do not have a foot and are sessile.

Clam Facts

Classification:
Kingdom: Animalia
Phylum: Mollusca
Class: Bivalva, with ten orders, fifty-seven families
Geographical location: Worldwide
Habitat: The bottom of all marine waters, from coastal subtidal to great depths of the sea
Gestational period: Larval stage varies according to species but generally lasts around one month
Life span: For the edible clam (quahog), harvest occurs in three to five years; some researchers estimate a life span of up to three hundred years for this species, if it is not eaten
Special anatomy: Shape of the shell varies only slightly and is generally roundish; lips of the *Tridacna* shell are wavy; some species have a powerful tongue or foot that enables the clam to dig quickly into the sandy bottom to escape predators

The Life Cycle of Clams and Oysters

In clams and oysters, the sexes are separate and spawning is triggered by favorable water temperature. The eggs and sperm, several hundred thousand to several million each, are broadcast into the water through the excurrent siphon. Of the millions of eggs, only a very few reach adulthood; many fail to be fertilized, some are eaten by small fishes and other predators, some succumb to molds and bacteria, and some adults are eaten by eels, sea stars, and whelks. Each year, more than 112 million pounds of clams and nearly 26 million pounds of oysters are taken for human food.

Shellfish that grow in polluted waters may ingest disease organisms which accumulate in their tissues. These can cause disease in humans. Some toxic plankton may cause illnesses, such as paralytic shellfish poisoning in humans who eat the clams or oysters uncooked (“on the half-shell”). Commercially canned shellfish are cooked under pressure and are safe to eat. The incidence of human illness from eating toxic clams is very low. One species of clam, the teredo, or shipworm, burrows into wood and leaves it honeycombed.

Pearls

Most clams and oysters produce pearls but not all are of gem quality. The pearl is made of the same material as the lining of the shell. It is deposited around some irritant such as a grain of sand. The giant clam produces pearls as large as golf balls.

CLAWS, NAILS, AND HOOVES

Type of animal science: Anatomy
Fields of study: Anatomy, marine biology, ornithology, zoology

Claws, nails, and hooves are widespread among animals, including vertebrate herbivores and predators, as well as invertebrates such as crabs and lobsters. The functions of these growths include defense, obtaining food, and safe locomotion.

Principal Terms

CHITIN: a transparent, horny substance of invertebrate exoskeletons

CRUSTACEANS: lobsters, shrimps, crabs, and barnacles

EPIDERMIS: the outer, protective layer of the skins of vertebrates

KERATIN: a tough fibrous substance found in hair, claws, nails, and hooves

MATRIX: the skin beneath a nail, involved in its growth

UNGULATE: a hoofed mammal

VASCULAR PAPILLA: a protuberance having a blood supply

Claws, nails, and hooves are very often special growths of the outer skin (epidermis) of warm-blooded, vertebrate animals. Nails are considered to be claws whenever they are thicker, longer, harder, and sharper than those of humans. Nails and claws contain large amounts of keratin, the hard substance present in the skin and nails of human fingers and toes. The skin below a nail or claw, from which it grows, is called the matrix. If a nail, claw, or hoof part is torn off, it grows again, as long as the matrix has not been overly damaged. Nails and claws occur on the digits of fore limbs and hind limbs of vertebrates.

Nails and claws are made of dead skin cells, very rich in the fibrous substance keratin. Each nail or claw consists of a root, concealed within a fold of skin at its base; a body, the exposed part attached to the skin surface; and an anterior edge overlapping the end of the digit to which it is attached. In clawed animals such as badgers, moles, rodents, wolves, and cats this edge can become quite long. The matrix, the skin below the root and body of a nail or claw, is thick and covered with highly vascular papillae. The matrix color is sometimes seen through transparent horny tissue, in humans and in some other species with relatively thin nail bodies or claws. A nail or claw grows forward by a combination of continual growth of new cells both at the root and under its body.

The body of the nail or claw in the predatory and burrowing animals is much thicker than in humans. Unlike human nails, the claws of burrowing animals do not have to be trimmed; they are worn down by use. The claws of cats, from house cats to lions and tigers are retractable. This allows these animals to walk easily without wearing their claws down and to unsheathe them for the serious business of capturing and killing prey. Predatory animals, especially cats, that have retractable claws must hone them down from time to time. Cats use scratching posts—whether fallen tree limbs found in the wild or specially made carpet-covered posts provided by hopeful pet owners—for this purpose, as well as to sharpen the claws.

Ungulate Hooves

A hoof is a thick, hard growth at the front of a foot of a horse or other mammal in the order Ungulata (the hoofed mammals). The ungulates include elephants, pigs, horses, and many horned animals, such as deer and cattle. A hoof, really a "hoof-nail," is also made of keratin and it arises from the outer skin layer, or epidermis. A hoof differs physically from a nail or claw in that it is blunt and encases a toe or foot. Hooves are thought to have developed from animal toes, and ungulates are divided into those with even and odd numbers of toes. For example, a horse hoof developed from one toe. It almost completely circles the bottom of the foot. Zebras and donkeys are also animals whose hooves are single toes, not divided (or cleft). Even-toed ungulates have two or four toes. Usually, the two middle toes are developed into a cleft (divided) hoof. This vertebrate group includes deer, antelope, sheep, goats, cattle, pigs, and hippopotamuses. Hooves adhere to the earth well and give animals that have them a firm footing for pulling, running, walking on slippery or icy ground, and climbing mountains.

Lizard and Bird Claws

Lizards, reptiles in the order Squamata, which also includes snakes and crocodiles, are the largest extant group of reptiles, with about three thousand species. All have dry scaly skin, clawed feet, and external ear openings. In many cases, lizard claws are used for traction on slick surfaces, or in climbing trees. They are also used by large carnivorous and omnivorous species to pick apart or tear apart food.

Most land birds have clawed feet, which help them to perch in trees. The claws are thought to have derived partly from the evolution of birds from ancient lizards. The most extensive claws seen in the birds are the talons of birds of prey (the raptors). Raptors include the night-hunting owls and the day-hunting hawks, eagles, falcons, and vultures. All are meat eaters, although the meat devoured by the small species is insects. All of the raptors have powerful bills, and all but vultures

Hooves are adaptations of the nails on two or three of an animal's toes; they help protect the foot on rough or rocky terrain. (PhotoDisc)

Ungulates: The Class of Hoofed Animals

Ungulates, the hoofed mammals, belong to the subphylum Vertebrata. Their name comes from *ungula*, Latin for "hoof." Ungulates with an odd number of toes belong to the order Perissodactyla, including horses (one-toed) and rhinoceroses (three-toed). Even-toed ungulates belong to the order Artiodactyla, including pigs (four-toed) and camels, giraffes, antelope, deer, cattle, sheep, and goats (all two-toed).

The other ungulate orders contain elephants and hyraxes. Ungulates vary in size extremes, from the seven-ton male African elephant to rabbit-sized antelope. Ungulates are herbivores and the only mammals that possess horns or antlers. In every case, the toes of an ungulate hoof are the correct size and right number to make the animal sure-footed, whether on mountain trails, in the desert, or in icy and snowy conditions. Ungulates are widely dispersed around the world, occurring on all continents except Australia. They can live for up to twenty-five years.

have grasping toes tipped with large, curved, sharp talons. It is believed that the weak talons of vultures are part of the reason why they eat carrion, not live prey. That is, they cannot strike live prey like the other raptors or carry it off in strong claws.

Invertebrate Claws

Among invertebrates, insects, scorpions, and crustaceans are examples of organisms that possess claws. Examples are praying mantises and beetles, among the insects; scorpions, among the arthropods; and lobsters and crabs, among the crustaceans. In all cases, the claws are restricted to the first two legs of these invertebrates. Also, unlike those of vertebrates, the claws are not keratin-containing epidermis outgrowths. They are portions of the chitinous invertebrate exoskeletons, and therefore part of their shells.

Crustacean claws are huge, compared to animal claws. Most often, both claws are of somewhat similar size and used to capture prey. However, some crustaceans, such as hermit and fiddler crabs, have claws where one is much larger than the other. In those cases, the larger of the claws is usually used in protection and/or mating.

Lobsters have two huge, body-length claws used to grasp prey, and to dig burrows in which they live. In "true lobster" species, the claws are especially huge. One claw is heavier than the other and has blunt teeth to crush prey. The other is somewhat smaller and has sharp teeth to tear up prey. Not all lobsters have the heavy claw on the same side. They are "right clawed" or "left clawed." During the day, a lobster stays in its burrow awaiting prey. At night it comes out to seek food, catching it and tearing it up into eating-sized chunks with its claws. Lobsters grow by shedding their shells (molting). When they do this, their claws are soft. They cannot use them well for hunting until the new shells harden. At those times, they mostly eat carrion.

Crabs, related to lobsters, are also clawed decapods. Like other cephalopods, the crab body is sheathed in tough chitin. A crab has five pairs of walking legs, and two front legs which hold claws for feeding and defense. Male hermit and fiddler crabs have one claw that is huge compared to the other. The oversized claw in hermit crabs is used defensively, to close off the mollusk cell it uses as its abode to protect its soft, vulnerable body. Fiddler crabs also have one oversized huge claw; they use it in mating and combat.

Claws, nails and hooves are very important to animals. They are weapons used for protection and to secure food, appendages that impress potential mates, and locomotor appendages that assure safe, optimized movement around habitats. It is interesting that in organisms as far apart, evolutionarily, as lobsters and ungulates, claws and hooves are made of similar, tough insoluble materials, chitin and keratin, respectively.

CLEAVAGE, GASTRULATION, AND NEURULATION

Type of animal science: Reproduction
Fields of study: Anatomy, cell biology, invertebrate biology, physiology, reproduction, zoology

A single-celled zygote goes through the processes of cleavage, gastrulation, and neurulation to become a many-celled embryo. By learning about normal development, scientists are finding ways to prevent abnormal development.

Principal Terms

ARCHENTERON: the primitive gut cavity formed by the invagination of the blastula; the cavity of the gastrula

BLASTULA: an early stage of an embryo which is shaped like a hollow ball in some animals and a small, flattened disc in others; contains a cavity called the blastocoel

CLEAVAGE: the process by which the fertilized egg undergoes a series of rapid cell divisions which result in the formation of a blastula

GASTRULATION: the transformation of a blastula into a three-layered embryo, the gastrula; initiated by invagination

GERM LAYERS: the embryonic layers of cells which develop in the gastrula: ectoderm, mesoderm, and endoderm

INVAGINATION: the turning of an external layer into the interior of the same structure; formation of archenteron

MORULA: a solid ball or mass of cells resulting from early cleavage divisions of the zygote

NEURULATION: the process by which the embryo develops a central nervous system

NOTOCHORD: a fibrous rod in an embryo which gives support; a structure that will later be surrounded by vertebrae

ZYGOTE: the fertilized egg; the first cell of a new organism

A fertilized egg divides into many smaller cells, which then undergo rearrangement and differentiation to form the embryo of a new individual. The division of the one-celled zygote into smaller and smaller cells is called cleavage. The cellular rearrangement is known as gastrulation, and the proliferation and movement of cells into position to form the beginnings of the central nervous system is termed neurulation. The significance of these events lies in the fact that a single cell with genetic information from two parents is transformed into a multicellular structure with three germ layers that will give rise to all the organs and systems of the body.

Cleavage

After fertilization, the resultant zygote undergoes many rapid cell divisions. The cleavage process results in smaller and smaller cells, called blastomeres. The cell divisions are by mitosis, which produces identical chromosomes in each new cell. When between sixteen and thirty-two cells have been formed, the structure is called a morula, from the Latin for “mulberry,” which it resembles.

The morula stage is short-lived because, as soon as it is formed, processes are initiated that bring it to the next stage, known as the blastula. A cavity begins to form in the center of the morula as water flows in and pushes out the cells. The new cavity is called the blastocoel and the embryonic stage the blastula. Cleavage continues until the blastula consists of hundreds of cells but is still no larger than the original zygote. The blastula is the terminal cleavage structure. The egg, much larger than an average cell, has been fertilized and subdivided into hundreds of normal-sized cells. The blastomeres all appear to be similar to one another, but studies have shown that the individual cells are already destined for the tissues they will become.

The principles of cleavage are the same in all vertebrate groups, but the mechanics differ according to the amount of yolk in the egg. Eggs with large amounts of yolk undergo only partial cleavage, because the yolk retards the cytoplasmic division. In birds, reptiles, and many fishes, the yolk is so dense that the cytoplasm and nucleus are crowded into a small cap or disk on one side of the cell. The cleavage divisions all occur in this small area, resulting in a flattened blastula atop the large inert yolk.

Eggs with but a moderate amount of yolk, such as amphibian eggs, are able to cleave completely. Because division proceeds more slowly through the part of the cell where yolk has accumulated, the cleavage is uneven. The cells are formed more slowly on the yolky side and are larger and fewer in number. The blastocoel is smaller and displaced to the side, with less yolk. The side with smaller blastomeres will develop into the embryo and is called the animal hemisphere. The side containing larger amounts of yolk is called the vegetal hemisphere and will provide nutrients for the embryo.

Eggs with very little yolk undergo total and equal cleavage divisions. The blastula has a large, centrally located blastocoel, and blastomeres are uniform in size. Starfish and the primitive chordate amphioxus undergo this kind of cleavage. They are often used to demonstrate the successive cleavage stages which are more easily seen in the absence of yolk. Though mammalian eggs do not have large amounts of yolk, their development is similar to that of birds. The outer layer of cells of the morula develop into a membrane, called the trophoblast, that surrounds the embryo. The embryo forms from cells in the inner region known as the inner cell mass. A large, fluid-filled blastocoel forms within the trophoblast, giving rise to the term "blastocyst" for the mammalian blastula. The inner cell mass develops atop the blastocoel as the bird embryo on the yolk.

Gastrulation

Gastrulation is the next process in embryonic development and consists of a series of cell migrations that result in cellular rearrangement. The final gastrula will have three embryonic germ layers destined to give rise to all body structures and systems.

The first step in gastrulation is an indenting or invagination in the blastula at a spot known as the dorsal lip. Cells begin to move over the lip and drop into the interior, forming the lining of a new cavity, the archenteron, or primitive gut. Continued inward movement of cells forms a middle layer between outer cells and inner ones which have dropped in through the opening, or blastopore. The three embryonic germ layers have now been formed, and they are called ectoderm, mesoderm, and endoderm.

In animals with little egg yolk, such as the starfish, gastrulation begins when a few cells lose their adhesiveness and drop into the blastocoel. That causes a dent or depression in that area. Cells move in and deepen the depression, forming the archenteron. As the archenteron expands, the inner blastocoel shrinks and is finally obliterated. This process may be visualized as punching in the side of a hollow rubber ball with one's finger. The hole the finger makes is the blastopore; the new cavity formed by the hand represents the archenteron; and the original space inside the ball represents the blastocoel. The indentation forms two cell layers, and a third one is formed as cells continue to move in and take position between the inner and outer layers.

The outer ectoderm is destined to become epidermis and nerve tissue. The inner endoderm will form digestive glands and the lining of the digestive and respiratory systems. The middle germ layer, the mesoderm, will give rise to bone, muscle, connective tissue, and the cardiovascular and urinary systems. Additional mesoderm forms a rodlike structure known as the notochord, which lies in the roof of the archenteron. The notochord is a distinctive characteristic of chordates and gives embryonic support. The mesoderm lateral to the notochord will segregate into paired masses known as somites, each with prospective skin, bone, and nerve segments.

Gastrulation in blastulas with moderate quantities of yolk, such as amphibians have, proceeds similarly, but the archenteron is displaced toward the animal hemisphere and is filled with yolk cells. The early stages are similar to those in starfish.

Gastrulation in birds and mammals is initiated in a manner different from that in starfish and amphibians, because of the discoidal configuration of the blastula. Both groups have incomplete cleavage with embryonic development on a disk-like area on one side of the egg. The upper cells of the disk separate from the lower ones, forming two layers, the epiblast and the hypoblast. After the two layers are formed, a thickening occurs in one quadrant of the blastula and soon becomes noticeable as a distinct streak, the primitive streak. The streak becomes grooved, and cells from either side begin to migrate to the groove and sink down through it. The cells then move into position between the epiblast and hypoblast. The three embryonic germ layers have been formed.

The primitive groove in the gastrula is considered homologous to the blastopore in the starfish and amphibians. After the germ layers have been established, cells continue to move in to the new cavity, the archenteron, and form a mesodermal notochord in the roof of the archenteron.

Neurulation

Neurulation is the final stage of early embryonic development. Studies have shown that the notochord induces the neurulation process to begin. Cells just above the notochord are induced to proliferate and thicken, forming a neural plate. After the neural plate is formed, a buckling occurs in it, forming a depression known as the neural groove. Modern microscope techniques have revealed microfilaments and microtubules lying beneath the surface of the plate. Contraction of the microfilaments and elongation of microtubules appear to cause cell buckling and folding of the plate. The neural groove deepens at its cephalic end, and folds on either side continue to grow higher until they actually touch each other, forming an enclosed tube, the neural tube. At the same time that the neural tube is forming, the head is growing forward and tissue is folding beneath it so it projects forward free from the surface. Brain differentiation begins with the enlargement of the anterior end of the neural tube. The undilated caudal portion will give rise to the spinal cord. The brain forms several constrictions, so that three bulges appear. These will become the three embryonic brain divisions: the forebrain, the midbrain, and the hindbrain.

Upon completion of the three brain divisions, the embryo undergoes forward flexion of the forebrain and a lateral torsion so that the embryo comes to life with its left side on the yolk. A final caudal flexion causes the embryo to take its typical C-shaped configuration.

Extraembryonic membranes form from tissue outside the embryo to provide oxygen, nutrients, and waste storage. In birds, an outer chorion and amnion fuse to form a membrane with a large blood supply which provides for the exchange of oxygen and carbon dioxide between the embryo and the atmosphere. The allantois is a membranous sac to contain waste secretions.

In mammals, the outer chorion becomes extensively vascularized on one side and interconnects with the uterus to form the placenta. Nutrient and waste exchange between mother and baby take place in the placenta. The amnion forms a fluid-filled sac that lies closely around the embryo and cushions it. The allantois is not needed for waste storage and is not well developed.

Embryology

Humans have always been intrigued by the processes of gestation and birth. Aristotle questioned whether the embryo unfolds from a preformed condition and then enlarges to adult proportions or progressively differentiates from simple to complex form. Not until the eighteenth century were actual observations made of a developing embryo. The chick egg was the first to be studied, because of its large size. Early studies were descriptive, as each stage of the embryo was observed and carefully described. It was found that development does proceed from simple form to forms increasingly complex.

In the late nineteenth century, great interest developed in evolutionary theory, and comparative embryology became the focal point of studies. Clues were sought for possible evolutionary relationships between organisms. The theory emerged that embryonic stages reflect the evolutionary past of an organism.

The twentieth century has seen the explosion of experimental embryology and multiplication of knowledge. Cleavage of the large fertilized egg was first observed in the eighteenth century, but not until the late twentieth century did the mechanics begin to be understood. With improved microscope techniques, a ring of microfilaments can be seen just below the egg cell surface. These protein filaments have contractile qualities, and it was thought perhaps they lined up around the equator to contract and squeeze the cell in two. To test this hypothesis, a drug which causes microfilament subunits to break down was added to the cell culture. It was found that cell division was inhibited, suggesting that microfilaments are involved in the division process. Removal of astral rays also hindered cleavage. Each new discovery answers some questions and raises more.

Embryologists have questioned how blastomeres all formed from the same cell could differentiate into many kinds of cells and tissues. Some of the earliest experiments in embryology involved separating the first two daughter cells to demonstrate that each could form two complete individuals. How and when cells differentiate continues to be a challenge to researchers. The substance in cells which predisposes them to differentiate between one another is still not understood.

It has been discovered that each part of the embryo surface is already divided into prospective organ areas by the blastula stage. Fate maps have been constructed by marking certain areas on the blastula with vital stains and observing the structures into which they develop.

Since the early days of experimental embryology, researchers have performed all kinds of operations on embryos, marking areas and observing their movement, transplanting cells from one area to another, exchanging cell nuclei and removing portions. These experiments have led to many discoveries and better understanding of the complicated developmental process. When one considers the multitude of complex events that must take place in the development of a new individual from a single cell, it might seem impossible that the entire developmental process could occur without a slip.

Malformation usually begins during early development. Deformities may arise from inherited mistakes in the genetic code or from the harmful influence of external factors such as radiation, poor nutrition, or infection. Studies of cell migration in the embryo have led to ideas for procedures to inhibit tumor cell migration. Knowledge of normal cell development is helping to find ways to prevent abnormal cell development.

Bibliography

Horder, T. J., J. A. Witkowski, and C. C. Wylie, eds. *A History of Embryology*. Cambridge, England: Cambridge University Press, 1986. A sourcebook that covers the history of embryology from 1818, when the first human abnormalities were described, until the 1943 production of radioisotopes at Oak Ridge, which are used in marking and tracing development. Describes the contributions of scientists from around the world, with interesting sidelights. Includes an extensive bibliography on all aspects of embryology.

Johnson, Leland G., and Rebecca L. Johnson. *Essentials of Biology*. Dubuque, Iowa: Wm. C. Brown, 1986. An introductory-level college text, well illustrated and including outlines, major concepts, key terms, essays, summaries, questions, suggested readings, and a glossary. The chapter on reproduction and development gives a concise summary of embryonic development in each vertebrate group and has an informative essay on animal cloning.

Mathews, Willis W. *Atlas of Descriptive Embryology*. 5th ed. Upper Saddle River, N.J.: Prentice Hall, 1998. A paperback manual intended for laboratory work in an intermediate college course. The manual includes a complete series of large photomicrographs of developmental stages. A different form of development is noted in eggs with differing amounts of yolk. A complete series of cross sections is shown for sea-urchin, amphioxus, frog, chick, and pig embryos. Cross sections include an illustration of a whole mount showing the exact location of each section, helping to integrate the three-dimensional aspect of the embryo. The complete series is helpful for laboratory identification of microscopic embryology sections. A thorough glossary is included.

Oppenheimer, Steven B., and George Lefevre, Jr. *Introduction to Embryonic Development*. 3d ed. Boston: Allyn & Bacon, 1989. An intermediate-level college text which gives extensive coverage to the embryological stages in primitive chordate and vertebrate classes. Molecular and cellular aspects of development are emphasized, and the discussion of molecular genetics is informative. Extensive coverage of the topics of cleavage, gastrulation, and neurulation. Illustrated, glossary, references.

Starr, Cecie, and Ralph Taggart. *Biology: The Unity and Diversity of Life*. 9th ed. Pacific Grove, Calif.: Brooks/Cole, 2001. An introductory-level college text that uses the principles of evolution and energy flow as a conceptual framework for each chapter. Clear writing style and color illustrations on every page make this an attractive and informative text. Gives a concise overview of the early embryological stages and describes experiments that have led to the understanding of mechanisms of development.

CLINES, HYBRID ZONES, AND INTROGRESSION

Type of animal science: Evolution
Fields of study: Ecology, genetics, systematics (taxonomy), zoology

A cline is a genetic variation in the characteristics of populations of the same species that results from a variation in the geographical area that it occupies. Hybrid zones are areas where there are populations of a species composed of individuals with characteristics of one or more species that have interbred. Introgression is speciation that occurs when the genes of one species are incorporated into the gene pool of another as the result of successful hybridization.

Principal Terms

CLINE: a gradual, continuous variation from one population of a species to the next that is related to differences in geography

DEME: a local unit of the population of any one species

GENE: the unit of molecular information, a portion of a deoxyribonucleic acid (DNA) molecule that codes for some product, such as a protein, that governs inherited traits

GENE FLOW: the movement of genes from one part of a population to another part, or from one population to another, via gametes

GENE POOL: the sum total of all the genes of all the individuals in a population

HYBRID: the offspring of a mating between genetically differing individuals

INTROGRESSION: the assimilation of the genes of one species into the gene pool of another by successful hybridization

POPULATION: the members of a species that live in the same geographical area

SPECIES: a group of similar organisms whose members can reproduce with one another to produce fertile offspring

Gene flow among populations tends to increase the similarity of characters among all the demes (local populations) of a species. Natural selection has the opposite effect: It tends to make every deme uniquely specialized for its specific habitat. Clines are one possible result of these two opposing forces; a cline is a phenomenon in which a genetic variation occurs that is caused by a difference in geographical habitat. Each species is continuously adjusting its gene pool to ensure that the species survives in the face of an environment that is continuously changing.

Comparing the characteristics of the demes of a single species usually will reveal that they are not identical. The greater the distance between the demes, the greater the differences between them will be. The grass frogs in Wisconsin differ from the grass frogs in Texas more than they differ from those in Michigan. On the average, the song sparrows of Alaska are heavier and have darker coloration than those in California. These phenomena, in which a single character shows a gradient of change across a geographical area, are called clines.

North-South Clines

Many birds and mammals exhibit north-south clines in average body size and weight, being larger and heavier in the colder climate farther north and smaller and lighter in warmer climates to the south. In the same way, many mammalian species show north-south clines in the sizes of body extremities such as tails and ears, these parts being smaller in northern demes and larger in southern demes. Increase in average body size with increasing cold is such a common observation that it has been codified as Bergmann's rule. The tendency toward shorter and smaller extremities in colder climates and longer and larger ones in warmer climates is known as Allen's rule. The trend toward lighter colors in southern climates and darker shades in northern climates has been designated Gloger's rule. The zebra, for example, shows a cline in the amount of striping on the legs. The northernmost races are fully leg-striped, and the striping diminishes toward the southern latitudes of Africa; this appears to be an example of Gloger's rule. Another example of a cline, which does not fit any of the biogeographical rules mentioned, is the number of eggs laid per reproductive effort (the clutch size) by the European robin: This number is larger in northern Europe than it is for the same species in northern Africa. Other birds, such as the crossbill and raven, which have wide distribution in the Holarctic realm, show a clutch-size cline that reveals a larger clutch size in lower latitudes. The manifestation of such clines in clutch size is a consequence of the interplay of two different reproductive strategies that may give a species a competitive advantage in a given environment. The stability of the environment is what elicits the appropriate strategy.

In unstable environments, such as those in the temperate zone, where there may occur sudden variations in weather and extremes between seasons, a species needs to reproduce rapidly and build its numbers quickly to take advantage of the favorable warm seasons to ensure survival of the species during the harsh, unfavorable conditions of winter. This strategy is known as r strategy (r stands for the rate of increase). In the tropics, the climate is more equable throughout the year. The environment, however, can only support a limited number of individuals throughout the year. This number is called the carrying capacity. When carrying capacity is reached, competition for resources increases, and the reproductive effort is reduced to maintain the population at the carrying capacity. This is called K strategy, with K standing for carrying capacity.

In birds, clutch size tends to be inversely proportional to the climatic stability of the habitat: In temperate climates, more energy is directed to increase the reproductive rate. In the tropics, the carrying capacity is more important, resulting in a reduced reproductive rate. In the apparent contradiction of the crossbills and ravens, it may be the harshness of the habitat at higher latitudes that limits the resources available for successfully fledging a larger number of young.

Grass Frog Clines

The cline exhibited by the common grass frog is one of the best known of all the examples of this phenomenon. It has the greatest range, occupies the widest array of habitats, and possesses the greatest amount of morphological variability of any frog species. This variability and adaptation are not haphazard. The species includes a number of temperature-adapted demes, varying from north to south. These adaptations involve the departmental processes from egg to larva. The northernmost demes have larger eggs that develop faster at lower temperatures than those of the southernmost demes. These physiological differences are so marked that matings between individuals from the extreme ends of the cline result in abnormal larvae or offspring that are inviable (cannot survive) even at a temperature that is average for the cline region. Leopard frogs from Vermont can interbreed readily with ones from New Jersey. Those in New Jersey can hybridize readily with those in the Carolinas, and those in turn with those in Georgia. Yet hybrids of Vermont demes and Florida demes are usually abnormal and inviable. Thus, it appears that the Vermont gene pool has been selected for a rate of development that corresponds to a lower environmental temperature. The gene pool of the Florida race has a rate of development that is slower at a higher average temperature. The mixture of the genetic makeup of the northern and southern races is so discordant that it fails to regulate characteristic rates of development at any sublethal temperature, so the resulting embryo dies before it becomes a tadpole.

There are two primary reasons why characters within a species may show clinal variation. First, if gene flow occurs between nearby demes of a population, the gene pools of demes that are close to one another will share more alleles than the gene pools of populations that are far apart. Second, environmental factors, such as annual climate, vary along gradients that can be defined longitudinally, latitudinally, or altitudinally. Because these environmental components act as selective pressures, the phenotypic characters that are best adapted to such pressures will also vary in a gradient.

Hybridization

Hybridization is the process whereby individuals of different species produce offspring. A hybrid zone is an area occupied by interbreeding species. Partial species can and do develop on the way to becoming new species as products of hybridization. Natural hybridization and gene flow can take place between biological species no matter how sterile most of the hybrid offspring may be. As long as the mechanisms that prevent free exchange of genes between populations can be penetrated, there is the potential for a new species to develop. Because the parental species has a tendency to be replaced by the hybrid types if natural selection favors them, hybridization can be a threat to the integrity of the parental species as a distinct entity.

Hybridization between different species leads to various and unpredictable results. Any time that hybridization occurs, the isolation mechanisms of populations are overcome, forming bridging populations. Such connecting demes of hybrid origin fall into one of two general categories: hybrid swarms or introgressive demes. The formation of these types of demes reverses the process of speciation and changes the formerly distinct species into a complex mixture of highly variable individuals that are the products of the segregation and independent assortment of traits. This is the primary advantage of sexual reproduction: to produce variation in the population that is acted upon by natural selection over time. It cannot be overemphasized that hybrid swarms and introgressive demes are highly variable.

The environmental conditions that contour animal communities have endured for a very long time. In long-lived communities, every available niche has been filled by well-adapted species. When populations with new adaptive characteristics occur, there is no niche for them to occupy, so they usually die out. In contrast, when such communities are disturbed, the parity among their component species is upset, which gives new variants an opportunity to become established.

Hybrid swarms can be observed in nature by the careful investigator. The hybrid swarm forms in a disturbed habitat, where hybrid individuals backcross with the parental types to form a third population, which result from the migration of the genes of one population into the other. Such a population is designated an introgressive population. The progeny of such populations resembles the parent species, but the variations are in the direction of one parental species or the other. If introgression is extensive enough, it may eradicate the morphological and ecological distinctions of the parental types. The parental types become rarer and rarer, until they are no longer the representatives of the species.

There appear to be three reasons that first-generation hybrids occurring naturally are more likely to form offspring by backcrossing to one of the parental species than by mating with each other. Primarily, the hybrids are always rarer than the parents. Second, the parental individuals are so much more fertile than the hybrids that many more parental gametes are available than hybrid ones. Finally, backcross progeny, since they contain primarily parentally derived genes, are more likely to be well adapted to the habitat in which they originated than are the purely hybrid individuals.

Introgression

Thus, the most likely result of hybridization is backcrossing to one of the parental species. Genotypes containing the most parental genes usually have the selective advantage, and the fact that they contain a few chromosomal segments from another species gives them unique characteristics that may also be advantageous. This sequence of events—hybridization, backcrossing, and stabilization of backcross types—is known as introgression. Hybrid swarms are interesting phenomena, but they are unlikely to be of evolutionary significance except through introgression.

There are many examples of introgression among plants, but examples of introgression in animals are not common. Those that have been demonstrated are usually associated with the domestication of livestock. In the Himalayan region of Asia, there exists a relative of cattle, the yak, which is also domesticated. Many of the herds of cattle found along the western edge of the Himalayas, in central Asia, contain characteristics that clearly are derived from the gene pool of the yak. Many of these characteristics are manifested as adaptations to the harsh climatic conditions in this region.

In western Canada, there has been a modest introgression of the genes of the American bison into the gene pool of strains of range cattle. The bisonlike characters incorporated into beef cattle created a new breed called the beefalo, which exhibits such characteristics as greater body musculature, lower fat content of the flesh, and great efficiency in the utilization of range forage. A beefalo steer is ready for market in only eight months, while the same live weight is not obtained in the standard beef breed until eighteen months.

These examples serve to illustrate the concept that, as an evolutionary force, introgression is rather insignificant in natural biomes. It is almost always in the wake of human activity or the activities of their domesticated animals that the process of introgression can and does result in new combinations of gene pools from different species.

This landmark publication contains one of the earliest definitive descriptions of the genetic mechanism that underlies the formation of clines in animals. It concerns the variations found in the leopard frog.

CLONING OF EXTINCT OR ENDANGERED SPECIES

Type of animal science: Scientific methods
Fields of study: Biochemistry, cell biology, conservation biology, developmental biology, embryology, genetics, reproduction science

Cloning involves the insertion of deoxyribonucleic acid (DNA) from a body cell into an egg cell from which the nucleus has been removed. This method may permit the reproduction of endangered or recently extinct species if the fertilized egg is then implanted into the uterus of a closely related, but nonendangered species. It provides a novel but controversial way of rescuing species headed for extinction.

Principal Terms

BIODIVERSITY: variety of plants, animals, and habitats, and the interactions among these species

BIOTECHNOLOGY: the use of the tools of recombinant DNA technology to study or modify biological systems

CLONING: the reproduction of an individual that is genetically identical to its parent

EXTINCTION: the dying off of all individuals of a species

GENE POOL: the collection of genes or genetic information in a population of individuals

NUCLEAR TRANSFER: the insertion of genetic material from a donor cell to a recipient cell; in reproductive technologies the recipient cell is an egg cell from which the nucleus has been removed

The threat of extinction to endangered animal species is of great concern to conservation biologists as well as to animal lovers everywhere. Extinction is the dying off of all members of a species. It occurs naturally as a process termed background extinction, part of evolution in response to global climatic changes and dynamic relationships within ecosystems that result in interspecies competition. Conservation biologists have noted that ever since the 1600's, the rate of animal species extinction has increased significantly, primarily due to the rapid growth of the human population and the resulting destruction of animal habitats. The global extinction rate is about twenty thousand species per year; moreover, conservation biologists have theorized that the planet is in the midst of the greatest period of animal extinction since the dinosaurs disappeared, sixty-five million years ago. Such wide-scale extinctions may have profound effects on ecosystem survival, as they culminate in the irretrievable loss of thousands of species of plants and animals, some of which have never even been identified. Some of the more recent extinctions of note include the great auk and the passenger pigeon, both of which disappeared in the nineteenth and early twentieth centuries. Other species, such as the California condor, are on the verge of extinction. Mammals are not exempt from this list; of particular concern are the 20 percent of the world's primates that may be lost to extinction in the next ten to twenty years. Due to recent advances in reproductive biotechnology, however, it has become apparent that the rise and decline of a species may no longer be determined solely by the forces of natural selection and the survival of the fittest, as proclaimed by the great evolutionary biologist Charles Darwin. Rather, the tools of recombinant DNA technology may afford humans a role in preventing the extinction of endangered species. On this rapidly evolving planet, where human civilization increasingly encroaches upon the domain of the natural world, the possibility of preserving endangered wildlife species by biotechnology approaches may be the last remaining hope for treasured animal species whose numbers had dwindled sharply by the end of the twentieth century.

Cloning Technology

The basic scientific procedure that has made this hope possible is a cloning technology termed nuclear transfer. This method involves the insertion of a body cell from an endangered animal into an egg cell obtained from a closely related species. First, the nucleus which contains the genetic material is removed from the egg cell, and then the body cell obtained from the endangered animal is inserted by a microinjection technique using a fine needle. An electric pulse then fuses the inserted body cell with the egg cell cytoplasm, the nucleus enters the egg cell cytoplasm, and cell division begins. Amazingly, the genetic material of a fully differentiated or mature body cell (such as a skin cell) becomes genetically reprogrammed once fused to the egg cell to generate all the cells that will ultimately make up the tissues and organ systems of the fetus. Because the donor body cell and egg cell originate from two different species, the procedure is termed interspecies nuclear transfer. This concept is critical to cloning endangered species, since often it is impossible to harvest egg cells from the threatened species and a related but thriving species must serve as the egg donor. Once the nuclear transfer has been accomplished, the embryonic cells are implanted into the uterus of a surrogate mother, also from a related species. The result is that an animal of one species participates in the reproduction of a cloned animal of a different species.

Image Not Available

Endangered Species on the Cloning List

The world's first successful cloning of an animal belonging to an endangered species by interspecies nuclear transfer was carried out by researchers at Advanced Cell Technology (ACT), in Worcester, Massachusetts, who cloned a baby gaur, an oxlike animal found in India, Indochina, and Southeast Asia. Using skin cells from the gaur as a source of genetic material, internuclear transfer by microinjection of an egg cell obtained from a cow and subsequent implantation into the uterus of a cow serving as a surrogate mother resulted in the birth of a cloned ox named Noah on January 8, 2001. Unfortunately, the cloned animal died just two days later from a common dysentery infection,

Cloning Extinct Animals

An intriguing question involves the cloning of animals that are extinct. In order to accomplish this feat, one must have access to preserved frozen animal cells as a source for the genetic material to be cloned. In 1999, a preserved frozen woolly mammoth was discovered in Siberia, giving rise to the hope that this great creature might one day live again. However, the animal's body had been subject to repeated cycles of freezing and thawing over many years, disrupting the structure of its genetic material so that it is unsuitable for interspecies nuclear transfer. Scientists at the Australian Museum have attempted to clone the Tasmanian tiger, which became extinct in the 1930's. The source of animal tissue in this case is a tiger that was preserved in alcohol in 1866; however, DNA analysis has shown that there was extensive damage to the genetic material of this specimen, making successful cloning unlikely. In Spain, the recently extinct bucardo, a mountain goat, has been the subject of cloning experiments. Scientists at the Agricultural Research Service in Zaragoza prepared frozen tissue from the last surviving animal of this species of mountain goat, which had been relegated to extinction due to loss of its natural habitat and poaching. In 1999, successful interspecies transfer of embryos of the bucardo using a domestic goat as a surrogate mother raised hopes that the bucardo might be cloned using this same surrogate species.

apparently unrelated to the cloning procedure or gestation in a different species. In November, 1999, the first successful transplantation of a frozen embryo from an African wildcat, an endangered animal species, into a surrogate mother of another species, the common housecat, was carried out by Betsy Dresser and colleagues of the Audubon Center for Research of Endangered Species (ACRES). Other interspecies embryo transfer successes include a mouflon sheep born to a domestic sheep, a red deer born to a white-tailed deer, and a bongo antelope born to a common African antelope called an eland.

Endangered species that could benefit from the new interspecies cloning technologies include the cheetah, which is close to extinction due to the loss of its natural habitat, and the panda, which has already been the subject of assisted reproductive technologies in captivity. In August, 1999, Hua Mei was born at the San Diego Zoo following successful artificial insemination. Research efforts on interspecies embryo transfer involving pandas have been largely focused on American black bears as egg donors and surrogate mothers. The first donor panda cells used in these experiments were frozen cells obtained from the late Hsing Hsing and Ling Ling.

Future Challenges

A broader question involves the potential role of cloning in maintaining species and genetic diversity. It has been argued that the selective cloning of individual members of a species will lead to a reduction in genetic diversity due to a streamlined gene pool. This may ultimately affect the survival and adaptability of a species. Moreover, cloning does not impact directly the conditions that led to the loss of species fitness, which are reflected in reproduction and survival rates. In many instances, species become endangered due to a loss of habitat; thus, survival of the species may require long-term existence in captivity. In certain cases, attempts have been made to return animals bred in captivity to their natural habitat; however, it is not clear that these efforts will be successful in general. The reproductive technologies and long-term effects of captivity may have serious consequences on the survival of the species once reintroduced to the wild. Some successes have been noted in this area; for example, the American peregrine falcon has been reintroduced into the wild in eastern North America, where it had become extinct.

Another problem associated with interspecies nuclear transfer and assisted reproductive technologies in general is their high cost and low success rate. It has been estimated that the success rate of same species nuclear transfer in cows is between 1 and 2 percent. The success rate for interspecies nuclear transfer is considerably less. For example, attempts by scientists at ACT at interspecies nuclear transfer involving the gaur required almost seven hundred cow eggs, about eighty of which developed as suitable donors for transplantation. About forty of these were implanted into cows, which resulted in eight pregnancies and ultimately one live birth.

Despite these concerns, zoological parks around America have collected sperm and eggs from many types of animals in the form of "frozen zoos," which may serve as genetic repositories for producing animals of the future. In addition, the San Diego Zoo's Center for Reproduction of Endangered Species and ACRES have sponsored animal tissue banks which could be the future source of cloned animals to safeguard species from extinction.

The death of a species by extinction engenders a sense of profound loss as it brings to a close a chapter of evolutionary and biological history. It may also disrupt the delicate balance of life, as species interdependence is a fundamental component of ecological systems. As efforts to save individual species from permanent extinction by the cloning of selected members are applauded, it is important to reflect upon the conditions and circumstances which have contributed to their loss.

Type of animal science: Classification
Field of study: Entomology

There are more than 3,700 species of cockroaches, also called roaches. They are among the oldest insects, having a fossil record that dates back about 340 million years.

Principal Terms

NOCTURNAL: active at night
VESTIGIAL: an organ that is no longer biologically useful

Cockroaches are one of the oldest and most primitive of insects. They flourished during the Carboniferous period of the earth's history, 350 to 320 million years ago, which has been nicknamed "The Age of Cockroaches" by paleontologists. The fossil evidence uncovered indicates that during this time, cockroaches made up about 40 percent of the world's insect population. Cockroaches from 340 million years ago looked much like roaches living today.

Cockroaches have a flattened, oval body, long, slender antennae, and a shiny black or brown exoskeleton. Most species also have wings that are held flat over the back. The exoskeleton, or shell, is made of chitin, which is about as thick as a human hair. The chitin covers the roach's entire body, even its eyes. Cockroaches range from about 0.5 to 2 inches in length, with the largest being found in the tropics. They have grasshopper-like mouth parts for chewing and feed on plants or animal matter, including dead insects and bedbugs or even cardboard, paper, books, glue, and other manufactured products. They are nocturnal insects and are rarely active or visible during the day. They live and hide in warm, damp, dark places, coming out at night to hunt for food.

The cockroach has three life stages: egg, nymph, and adult. Cockroach eggs are deposited in groups in a leathery case or capsule, the ootheca. There may be from thirty to forty-eight eggs in the capsules of some species, while others have only ten to twenty-eight. The newly hatched nymphs have no wings and shed their skins (molt) several times before becoming winged adults. Indoor roaches generally have several generations of young per year, but outdoor species may require a full year to develop from egg to adult.

Cockroach Classification

The German cockroach, *Blatella germanica*, also called the "water bug" in some places, is found throughout the world. It is commonly carried home in paper grocery bags and boxes (where it hides because it loves the taste of glue) and also likes to live around water pipes. Though it has only a 150-day life span, one adult female can produce as many as eight egg capsules, each filled with up to forty eggs. Thus, a female can produce more than 3,200 young in its lifetime. According to a bulletin from the U.S. Food and Drug Administration, one female could be the source of over ten million females in a single year, and over ten billion females in 1.5 years, assuming that all the babies survived and reproduced and food supplies were adequate.

The German roach is relatively small in size, about one-half inch long, compared to some of its Asian relatives. The Asiatic (or oriental) cockroach, *Blatta orientalis*, can be up to two inches in length and is considered one of the dirtiest household pests. It is oval in shape, with a shiny black exoskeleton. Males have short wings and can fly, unlike females, who have only vestigial wings. This species is found throughout the world, having been carried almost everywhere by ships, trucks, railroad cars, and airplanes.

The American cockroach, *Periplaneta americana*, is found in most warm climates throughout the world. It prefers to live indoors and is found in basements and furnace rooms. It has a life span of about 1.5 years and lays about sixteen eggs every forty-five days. It originally came from Central and South American rain forests. The American roach has a set of wings that enable it to fly long distances.

The American and German species are cannibals. Young nymphs eat their own kind if there is not enough food available. Mothers frequently eat their own egg capsules if food shortages develop. However, roaches can survive for more than a month without water or food. This feature has consequences for the food industry—for instance, roaches accidentally sealed in shipping crates can survive fairly comfortably even if shipped long distances with extremely limited resources.

Cockroaches are found in the desert as well as the forest. Desert roaches, *Arenivaga investigata*, burrow under the sand during the hottest part of the day, coming out to feed only at night. They can absorb water merely by sticking out their tongues. The brown-hooded wood cockroach, *Cryptocercus punctulatus*, lives in decaying logs in the forest along the Atlantic coast. Only three other species of this genus survive, one in China, one in Russia, and one in the western United States, because the forest habitat in which it thrives is disappearing. The common wood cockroach, *Parcolblatta pennsylvanica*, on the other hand, is found in abun-

Cockroach Facts

Classification:
Kingdom: Animalia
Subkingdom: Eumetazoa
Phylum: Mandibulata
Subphylum: Arthropoda
Class: Insecta
Subclass: Exopterygota
Order: Dictyoptera
Suborder: Blatteria
Families: Blattidae, Blaberidae, Blattellidae, Polyphagidae, Cryptocercidae
Species: Over 3,700 species, about forty considered household pests

Geographical location: Every continent except Antarctica

Habitat: Land (forests, deserts, and grasslands)

Gestational period: Varies greatly, but typically forty to sixty days

Life span: Five months to 1.5 years, depending on species

Special anatomy: Oval body, brown or black; two pairs of wings in males; females usually wingless; eggs carried in an egg case (ootheca) dance under logs and stones in northern forests. This species eats wood, which it digests with the help of bacteria living in its stomach, and is not considered a household pest.

Cockroach Control

Closing spaces and cracks around pipes, doorframes, and baseboards can prevent cockroach infestations. Paper bags and cardboard boxes should be inspected for roaches when they are brought into the home. Store food in containers with tight fitting lids. Pet food should be served by placing the bowl in a second, shallow bowl filled with soapy water. Roaches cannot swim across this barrier. Leaking water attracts roaches, so plumbing leaks should be fixed quickly. Sink and bathtub drains without stoppers are also inviting homes for roaches. Garbage cans should have lids and be emptied frequently. Cool temperatures can also kill roaches; few survive temperatures below freezing.

COEVOLUTION

Type of animal science: Evolution
Field of study: Ecology

Numerous stable and surprisingly complex relationships between various apparently unrelated organisms, such as plants and animals, have evolved over long periods of time. All these relationships, whether beneficial or harmful to one or more of the participants, represent adaptive interactions that can be used to understand ecological patterns and processes.

Principal Terms

ANTAGONISM: any type of interactive, interdependent relationship between two or more organisms that is destructive to one of the participants

COEVOLUTION: the interactive evolution of two or more species that results in a mutualistic or antagonistic relationship

COMMENSALISM: a type of coevolved relationship between different species that live intimately with one another without injury to any participant

PARASITISM: a type of coevolved relationship between different species in which one species exploits the other to its physical detriment

PHYTOPHAGOUS: animals, also referred to as herbivorous, that feed on plants

RECIPROCAL RELATIONSHIP: any type of coevolved, highly interdependent relationship between two or more species

SELECTIVE PRESSURE: evolutionary factors that favor or disfavor the genetic inheritance of various characteristics of a species

SYMBIOSIS: a type of coevolved relationship between two species in which both participants benefit; a type of mutualism

Coevolution is an extremely important and widespread phenomenon in the world of living things; it is a biological factor that is global in influence. When two or more different species experience a relationship in which any of the participating species' evolution directly affects the evolution of the other members, coevolution is taking place. This interactive type of evolution is characterized by the fact that the participant life-forms are acting as a strong selective pressure upon one another over a period of time.

The assumption of the interdependence of all organisms is today such a commonplace and fundamental concept that it is surprising that the phenomenon of coevolution has not always enjoyed a more prominent position in evolutionary thinking. Many scientists seem to have considered sets of coevolved organisms as relatively unimportant phenomena, almost on the level of biological "curiosities." The consensus appears to have been that while numerous examples of coevolution existed in both plant and animal kingdoms, on the whole it was of relatively minor importance in comparison with other evolutionary phenomena, such as competition. This opinion has begun to change as researchers increasingly recognize the intrinsic and ubiquitous role that coevolution has played, and continues to play, in the evolution of life at all levels throughout earth history.

Gaia

Organisms do not evolve in a biological vacuum. All organisms exist in, and have evolved within, the framework of one of a great number of delicately balanced and self-tuning biological systems or living communities termed ecosystems. Indeed, the entire planet can be regarded as one huge, incredibly complex ecosystem in which all the lesser ecosystems fit together and work together harmoniously. This planetary ecosystem has been called "Gaia" by some biologists, in reference to the ancient Greek earth goddess. In some respects, Gaia can be conceived of as actually one giant, worldwide organism. All the living communities in this huge ecosystem are products of coevolution. This phenomenon has been in effect over the vast expanses of geologic time and continues today. The only period in history when coevolution was probably not operating was at the dawn of life, billions of years ago, when the very first species of organisms appeared and had not yet established interactive communities. The importance of coevolution as a factor affecting life cannot be overstated.

Some biologists use the term coevolution in a more restricted sense to describe coevolved relationships that have developed between plants and animals, particularly between plants and animals that are herbivores or pollinators. The coevolution between plants and animals is one of the aspects of the field that has traditionally received the most attention, so this aspect of coevolution provides a useful departure point in describing the phenomenon.

Coevolutionary Warfare

The coevolution of plants and animals, whether animals are considered strictly in their plant-eating role or also as pollinators, is abundantly represented in every terrestrial ecosystem throughout the world where flora has established itself. Moreover, the overall history of some of the multitude of present and past plant and animal relationships is displayed (although fragmentally) in the fossil record found in the earth's crust. The most elemental relationship between plants and animals is that of plants as food source. This relationship has an extremely long history, beginning with the evolution of microscopic, unicellular plants that were the earth's first autotrophs (organisms that can produce their own food from basic ingredients derived from the environment). In conjunction with the appearance of autotrophs, microscopic, unicellular heterotrophs (organisms such as animals, which must derive food from organic sources such as autotrophs) evolved to exploit the simple plants. This ancient and basic relationship has resulted in uncounted numbers of plant and animal species evolving and coevolving over billions of years of earth's history.

As both plants and animals became multicellular and more complex, more elaborate defense mechanisms evolved among plants, as did more elaborate feeding apparatuses and behavior among animals. This biological "arms race" grew ever more intense as groups of plants and animals eventually adapted to the more rigorous demands of a terrestrial existence, leaving the marine environment behind. New ecosystems developed that culminated in the world's first swamps, jungles, and forests. The plant-animal arms race engendered increasingly more sophisticated strategies of botanical defense and animal offense, and this coevolved interrelationship has continued unabated. This coevolutionary "warfare" between plants and animals has expressed itself partly through the evolution of botanical structures and chemicals that attempt either to discourage or to prevent the attentions of herbivores. These include the development of spines, barbs, thorns, bristles, and hooks on plant leaf, stem, and trunk surfaces. Cacti, holly, and rose bushes illustrate this form of plant strategy.

Another type of deterrence evolved in the form of chemical compounds that can cause a wide spectrum of negative animal response. These compounds range in effect from producing a sensation of mild distaste, such as bitterness, to more extreme effects, such as actual poisoning of herbivore metabolisms. Plants that contain organic compounds such as tannin are examples of the chemical defensive strategy. Tannins produce several negative results in animals, including partially inactivating digestive juices and creating cumulative toxic effects that have been correlated with cancer. Plants containing tannin include trees, such as members of the oak group, and shrubs, such as those that produce the teas used as human beverages. Other plants have developed more lethal poisons that act more rapidly. Plants have also developed other strategies, such as possession of a high silica content (as found in grasses), that act to wear down the teeth of plant eaters. Animals have counteradapted to these plant defensive innovations by evolving a higher degree of resistance to plant toxins or by developing more efficient and tougher teeth with features such as harder enamel surfaces, or the capacity of grinding with batteries of teeth.

Coevolutionary Alliances

Not all coevolution is characterized by having an adversarial nature; mutually beneficial relationships are also very common. Sometime during the latter part of the Mesozoic era, angiosperms, the flowering plants, evolved and replaced most of the previously dominant land plants, such as the gymnosperms and the ferns. New species of herbivores evolved to exploit these new food sources. At some point, probably during the Cretaceous period of the late Mesozoic, animals became unintentional aids in the angiosperm pollination process. As this coevolution proceeded, the first animal pollinators became more and more indispensable as partners to the plants. Eventually, highly coevolved plants and animals developed relationships of extreme interdependence exemplified by the honeybees and their coevolved flowers. This angiosperm-insect relationship is thought to have arisen in the Mesozoic era by way of beetle predation, possibly on early, magnolia-like angiosperms. The fossil record gives some support to this theory. Whatever the exact route along which plant-animal pollination partnerships coevolved, the end result was a number of plant and animal species that gained mutual benefit from the new type of relationship. Such relationships are in general termed mutualisms.

Eventually some of these plant-animal mutualisms became so intertwined that one or both participants reached a point at which they could not exist without the aid of the other. These obligatory mutualisms ultimately involved other types of animal partners besides insects. Vertebrate partners such as birds, reptiles, and mammals also became involved in mutualisms with plants. Contemporary ecosystems, such as the United States' southwestern desert, include mutualisms between aerial mammals, such as bats, and plants, such as the agave and the saguaro cactus. The bats involved are nectar drinkers and pollen eaters. They have evolved specialized feeding structures such as erectile tongues similar to those found among moths and other insects with similar lifestyles. In turn, the plants involved with the pollinating bats have evolved either reciprocal morphologies or behavior patterns to accommodate their warm-blooded visitors. For example, angiosperms coevolutionarily involved with bats have developed such specializations as bat-attractive scents, flower structures that minimize the chance of injury to bats, and petal openings timed to the nocturnal activity of bats.

Symbioses, Commensalisms, and Parasitisms

Coevolved relationships are not restricted to beneficial or nonbeneficial relationships between plants and animals. They also include an immense number of relationships between animals and other animals, and even between plants and other plants. Among these various types of coevolved situations can be found subcategories such as symbioses, commensalisms, and parasitisms. The first two involve relationships beneficial to varying degrees that feature interactions of increasing physical intimacy between or among two or more species. Parasitism involves an intimate relationship produced through coevolution in which one participant, the host, experiences serious harm or even death through exploitation by the parasite. Predation is probably the most obvious form of coevolution among higher animals such as vertebrates. Modern carnivores such as the canines and felines and their prey are a dramatic example of coevolution at work. Animal hunters over time responded to the improved defenses of their prey by evolving better senses, such as stereoscopic, three-dimensional vision, hearing with expanded range of frequency response, and more effective body structures, such as multifunctional teeth. Such teeth are termed heterodont and represent a great improvement over the simple dental array of the more primitive vertebrates, such as fish and amphibians.

Beginning with the more advanced reptiles appearing in the late stages of the Paleozoic era, teeth began to differentiate into specialized components—incisors, canines, premolars, and molars—that enhanced food acquisition and improved mastication. This, in turn, improved digestion and allowed quicker energy acquisition from food. This evolutionary advantage has reached a zenith of adaptive success among the mammals. Mammalian predators evolved fangs and efficient claws, sometimes retractable, to minimize injury and wear. Along with improved hunting senses and better dentition came increased speed from the evolution of improvements in pelvic and limb arrangements. In response to this process, vertebrate herbivores also became generally swifter or better defended, more alert, attained higher metabolic rates, and were thus better able to elude or defend against predation. Advanced predators placed an intense selective pressure on their prey herbivores, spurring ever more efficient and acutely tuned responses among the herbivore populations. Herbivores evolved either as swift forms, such as deer, or became efficiently defended, walking fortresses, such as porcupines or armadillos. Because of the pervasive effect of coevolution, the overall relationship between predator and prey has been a reciprocal one in which all participants affect one another in an interactive manner.

Unraveling the Intricacies of Coevolution

Field research and laboratory research are pursued concurrently in the effort to unravel the intricacies of the subject of coevolution. Field research involves actual observation in nature of animals and plants, their behavior, and, especially, their interaction with other species. Special attention is given to useful clues that can be employed to establish evolutionary relationships, either presently existing or previously in effect. For example, cooperative behavior between or among several different species of animal or plant is often indicative of an established, coevolutionary relationship. If this behavior is consistent over time and can also be traced or inferred through the agency of the fossil record, more useful data are acquired concerning a possible, evolved, reciprocal relationship. Of particular importance is the confirmation of specialized physical structures that are unique to the members of the observed relationship. Examples are the specialized feeding apparatuses of pollinating animals and the specialized, accommodating flower structures of their angiosperm partners. Such physical structures are strong evidence for the handiwork of the coevolutionary process. Direct human observation is preferable in ascertaining coevolutionary behavior; however, this is not always possible because of the rapidity of the animals involved, their habitat, their extremely small size, their preference for nocturnal activity, or their determined avoidance of humans. Consequently, electronic and mechanical aids are sometimes indispensable. These include remote-controlled still and video cameras, microscopic or telephoto lenses, infrared or ultraviolet lighting units, sonar or radar sensors, trip wires and other mechanical triggering devices, and sound recording equipment with high-gain or long-range microphones.

Laboratory research in the field of coevolution involves investigations heavily reliant on modern, sophisticated laboratory equipment and techniques. High-powered conventional, optical microscopes are employed to determine tissue and cellular structures. Scanning electron microscopes (SEMs) are employed for study of extremely small unicellular animals or plants such as planktonic organisms or extremely small organic structures. In addition to these tools of laboratory specimen observation, there are the analytical equipment and techniques used to determine the genetic codes and blood protein complexes of animals and plants to establish the degree of relatedness or divergence between various species.

Maintaining Balances

Coevolutionary studies are increasingly important in the biological sciences. One of the aims is to determine the degree of interdependence between various species, whether the relationship is between animals and plants, animals and other animals, or plants and other plants. A key factor to be determined in all these coevolved relationships is that of the nature and degree of balance attained. Although most of the biological world is forever in a state of flux, some categorical, coevolved relationships have been of long duration and can be reasonably assessed as having been in existence for tens of millions of years, such as that of flowering plants and vertebrate and invertebrate pollinators, or even hundreds of millions of years, such as the oceanic, planktonic food chain.

The degree to which these large-scale, coevolved relationships, involving entire planetary ecologies, continue to enjoy their former degree of health and well-being is of the utmost importance to human society. The present depth of understanding of the biological sciences clearly indicates the interrelatedness of all nature. Many angles of study agree that the global life system is experiencing great stress from human intervention: industrialization, urbanization, and overpopulation. It becomes increasingly urgent to know with the utmost precision all facets of the way the global life system operates, and has operated with general stability, over geological expanses of time. Every detail that contributes to this knowledge—every coevolved relationship, no matter how seemingly insignificant—adds to the total effect. This information can be used as an important resource to help maintain the stability of the entire system for ourselves and future generations.

Bibliography

Bakker, Robert T. *The Dinosaur Heresies*. New York: William Morrow, 1986. An interesting book by one of the most fascinating and controversial writers on the subject of evolution. Although the emphasis of the book is on dinosaur evolution, the author's specialty, it also includes a number of good discussions of the coevolved interrelationships between predators and their prey. A wonderful thought-provoking book for all reading audiences. Numerous detailed and beautiful line drawings.

Barth, Friedrich G. *Insects and Flowers: The Biology of a Partnership*. Translated by M. A. Biederman-Thorson. Princeton, N.J.: Princeton University Press, 1991. An introduction to the coevolution of insects and flowers, written by a zoologist. Focuses on the mechanisms of plant-animal relationships and the sensory capabilities of insects. Bibliography and index.

Chaloner, William G., Peter R. Crane, and Else Marie Friis, eds. *The Origins of Angiosperms and Their Biological Consequences*. New York: Cambridge University Press, 1987. A series of essays by professional researchers on the subject of flowering plant evolution with an emphasis on the deduced history of the angiosperms and their coevolved animal partners as recorded in the geologic record. Suitable for the college level.

Clayton, Dale H., and Janice Moore, eds. *Host-Parasite Evolution: General Principles and Avian Models*. New York: Oxford University Press, 1997. A collection of essays that seeks to reinforce the interaction between theory and practice in the field of natural history. Aimed at avian ecologists and evolutionists. Glossary. Appendices cover how to collect and identify microparasites, helminths and protozoa, and arthropods; species names; organizations that identify parasites; and the immune system.

Gould, Stephen Jay. *The Panda's Thumb*. 1980. Reprint. New York: W. W. Norton, 1992. Each chapter of this book is a brilliant reflection on diverse aspects of organic evolution in essay form; the book is suitable for anyone interested in evolution. Chapter 27, "Nature's Odd Couples," focuses on a conspicuous example of a possible coevolution—an inferred mutualistic relationship between the extinct dodo bird and a large tree (*Calvaria major*) that is found on the island of Mauritius. Gould presents the evidence objectively, both for and against the dodo's possible role in facilitating the tree's germination. The chapter is a good example of the kind of investigations and speculations in which evolutionary biologists engage.

Grant, Susan. *Beauty and the Beast: The Coevolution of Plants and Animals*. New York: Charles Scribner's Sons, 1984. This is one of the best books devoted solely to the subject of coevolution written for a general audience. The book is easy and fun to read, and full of information that rests solidly on the most recent scientific research and thinking. Each of the ten chapters is devoted to a major subtopic within the phenomenon of coevolution, such as specific animal and plant symbioses or antagonisms.

Lawton, J. H., Richard Southwood, and D. R. Strong. *Insects on Plants*. Cambridge, Mass.: Harvard University Press, 1984. Gives detailed examples from the scientific literature of coevolved relationships between various insects and plants. An authoritative and dependable source of hard scientific information on the topic, the book tends to the abstract side of theorizing and biological modeling. Readers with a solid foundation in biology or scientific analysis will find this book of greatest use.

Powell, Jerry A. *Biological Interrelationships of Moths and "Yucca Schottii."* Berkeley: University of California Press, 1984. A short but detailed source explaining the pollination relationship between two species of desert moth and their coevolved partner, a particular genus of the yucca plant of the southwestern United States. Extremely detailed scientific documentation is used to describe the known aspects of the interrelationship between the moths and the plant. Appropriate for serious botany, entomology, and evolutionary biology students at the advanced high school or college level or as a general reference.

Rothstein, S. I., and S. R. Robinson, eds. *Parasitic Birds and Their Hosts: Studies in Coevolution*. New York: Oxford University Press, 1998. A collection of essays by an international roster of scholars. Focuses on field studies of cuckoos and cowbirds, and their relationships with their hosts. The two sections of the books address conspecific brood parasitism and prevailing models of host-parasite coevolution.

Thompson, John N. *The Coevolutionary Process*. Chicago: University of Chicago Press, 1994. A cross-disciplinary view of coevolution by a researcher of plant-animal interactions. Proposes that coevolution is a result of processes occurring at multiple geographic scales, or what Thompson calls the "geographic mosaic theory of coevolution." Utilizes field observation and experiment, comparative studies, ecological genetics, and phylogenetic reconstruction.

COLD-BLOODED ANIMALS

Types of animal science: Anatomy, behavior, physiology
Fields of study: Anatomy, environmental science, physiology, zoology

Cold-blooded animals, which include all invertebrate animals, as well as fish, amphibians, and reptiles, maintain body temperature by exposure to environmental sources of heat and cold, rather than by the internal feedback mechanisms utilized by warm-blooded animals.

Principal Terms

CORE TEMPERATURE: internal body temperature around the heart, brain, and spinal cord

ECTOTHERM: an animal that depends on environmental heat sources, usually solar radiation, to maintain body temperature

HOMEOTHERM: an animal that maintains a constant, steady body temperature

METABOLIC RATE: the rate (expressed as calories per minute) at which an animal produces and consumes energy

METABOLISM: the conversion of carbohydrates, proteins, or fats into chemical energy that can be used to accomplish work and generate heat

POIKILOTHERM: an animal that has a changing body temperature

Cold-blooded animals include all the invertebrate animals. Insects, spiders, other "bugs," worms, and all animal sea life except fish are examples of invertebrates. Of the five classes of vertebrate animals, fish, amphibians, and reptiles are cold-blooded. Only birds and mammals are warm-blooded. The proper scientific term for cold-blooded animals is poikilotherms (or ectotherms), while the scientific term for warm-blooded animals is homeotherms (or endotherms).

The best way to understand and appreciate cold-blooded animals and how they adapt is to compare them with warm-blooded animals. While a few of the cold-blooded animals have some rudimentary abilities to achieve temperature control internally, only birds and mammals are truly homeothermic.

Both birds and mammals maintain quite high core (internal) body temperatures with a very narrow range of variability. Mammals maintain a temperature of about 37 degrees Celsius with only about one degree of variation. Birds' temperatures are about two degrees higher. Homeotherms control their high and constant temperatures with an elaborate system of neural and chemical feedback systems. Most homeotherms have highly developed systems of insulation (feathers, fur, or fat).

Mechanisms of Ectothermic Temperature Control

Poikilotherms have little or none of the internal mechanisms of the homeotherms and they usually have poor insulation or surfaces that enhance heat transfer. They maintain their temperature control primarily by external exposure to the environment. They have a much lower basal metabolism and most species maintain a much lower temperature range than homeotherms.

Some cold-blooded animals live in very constant environments and maintain their temperature range with little or no adjustment. For sea life and other organisms that live in the ocean or very large bodies of freshwater, this is especially true. The entire surface of the organism is in contact with water, which conducts heat at least five times as fast as air. Fish can easily adjust their thermal

Since they cannot generate their own body heat, cold-blooded animals such as this lizard often lie on rocks in the direct sun to warm themselves. (Corbis)

environment in lakes and estuaries by changing their depth, since water temperatures can vary greatly below the surface. Some fish have internal mechanisms to become somewhat dormant with extreme seasonal changes in lakes whose surfaces freeze during the winter.

Amphibians and reptiles have more complicated mechanisms and use more adaptations than fish. Amphibians and reptiles can operate within a much wider core body temperature range than mammals or birds. This is especially true of some amphibians. Some salamanders' body temperatures range from –2 degrees Celsius to 36 degrees Celsius (mean 27). The range of external temperatures that some amphibians can tolerate, at least for varying lengths of time, varies from 28 degrees Celsius (below freezing) to 38 degrees Celsius (about 100 degrees Fahrenheit).

Both amphibians and reptiles maintain their body temperatures primarily by changing their locations to gain or lose heat from the sun, shade, or substrate. Some species achieve control by moving in and out of the water. This is an especially effective method since water conducts heat so rapidly. Many of these animals change body positions to increase or decrease exposure to the sun or to decrease surface area to gain or lose heat more rapidly. Reptiles have scaly and often thin skins, while amphibians have moist secretory skins, both of which are very effective for heat transfer. A very interesting internal adaption that is present in some amphibians and reptiles is the ability to change the color of their skins. A darker skin color will absorb heat and lighter will reflect the heat.

Reptiles

Reptiles are the most interesting of the poikilotherms for several reasons. Lizards and snakes are very adept at changing their locations frequently to maintain temperature control. They may be in holes or in the shade, hidden in the grass, or among rocks and vegetation, quietly conserving energy and waiting for prey. They will bask in the sun or lay on warm surfaces in the evening as needed. Some lizards will actively generate heat by doing multiple push-ups.

Reptiles have a wider body temperature range than homeotherms, but usually not nearly as wide as amphibians. The crocodile is one of the more advanced reptiles. One species was found to have a mean body temperature of 25 degrees Celsius with a maximum range of six degrees above or below the mean. Being so large, the surface area to body ratio is not very great compared to smaller reptiles, and the surface exchange of heat takes much longer. Crocodiles sometimes spend long periods in the water and will be at their lower temperature range. Then they will lay for hours in the sun on warm sand or dirt. They have learned to use the water to cool down, and they may submerge or be partially in and out of the water. On hot days, they will open their huge jaws, not to pant like fur-bearing animals, but to expose the very large surface area of the mucous membranes in their mouths, which creates an effective evaporative cooling effect. When crocodiles or alligators have had their jaws tied shut for transport by their captors, many have died from overheating. They do have some ability to slow or speed up their metabolic rate. In severe drought conditions they will burrow into deep wet mud and sand and change their metabolic rate enough to survive.

Bibliography

Dudley, Karen. *Alligators and Crocodiles*. New York: Raintree/Steck Vaughn, 1998. An overview of these reptiles, written for children in the nine- to twelve-year-old range.

Ganong, W. F. *Review of Medical Physiology*. 19th ed. Stamford, Conn.: Appleton and Lange, 1999. This is a good reference for the physiology of temperature regulation and metabolic homeostasis. Aimed at those with a background in biology.

Hine, Robert. *The Facts on File Dictionary of Biology*. 3d ed. New York: Facts on File, 1999. Offers very concise, clear, and up-to-date definitions and brief descriptions of the physiologic and classification terms applicable to cold-blooded animals.

Rahn, Joan E. *Keeping Warm, Keeping Cool*. New York: Atheneum, 1983. Offers clear, interesting explanations of thermoregulation with some elementary physics and physiology that are made understandable to a general audience, including advanced juveniles.

Stebbins, Robert C., and Nathan W. Cohen. *A Natural History of Amphibians*. Princeton, N.J.: Princeton University Press, 1995. This is a scholarly overview of amphibians, but most of the text does not require a biological background for an educated adult to follow. The chapter on temperature is comprehensive and very interesting.

COMMUNICATION

Type of animal science: Ethology
Fields of study: Evolutionary science, invertebrate biology, systematics (taxonomy), zoology

In animal communication, information is exchanged through signals. Such signals are vital for survival, finding mates, and rearing young.

Principal Terms

DISCRETE SIGNALS: signals that are always given in the same way and indicate only the presence or absence of a particular condition or state

DISPLAY: a term used to indicate social signals, particularly visual signals

PHEROMONE: a chemical substance used in communication within a species

PRIMER PHEROMONE: a chemical substance that affects behavior by altering physiology and is therefore not rapid in its effects

RELEASER: a standard signal that elicits a standard response

TROPHALLAXIS: food exchange between organisms, particularly in social insects

A simple definition of animal communication is the transmission of information between animals by means of signals. Developing a more precise definition is difficult because of the broad array of behaviors that are considered messages or signals and the variety of contexts in which these behaviors may occur. Animal signals can be chemical, visual, auditory, tactile, or electrical. The primary means of communication used within a species will depend upon its sensory capacities and its ecology.

Pheromones

Of the modes of communication available, chemical signals, or pheromones, are assumed to have been the earliest signals used by animals. Transmission of chemical signals is not affected by darkness or by obstacles. One special advantage is that the sender of a chemical message can leave the message behind when it moves. The persistence of the signal may also be a disadvantage when it interferes with transmission of newer information. Another disadvantage is that the transmission is relatively slow.

The speed at which a chemical message affects the recipient varies. Some messages have an immediate effect on the behavior of recipients. Alarm and sex-attractant pheromones of many insects, aggregation pheromones in cockroaches, or trail substances in ants are examples. Other chemical messages, primers, affect recipients more slowly, through changes in their physiology. Examples of primers include pheromones that control social structure in hive insects such as termites. Reproductive members of the colony secrete a substance that inhibits the development of reproductive capacity in other hive members. The chemicals important for controlling the hive are spread through grooming and food sharing (trophallaxis). Chemical communication is important not only among social and semisocial insects but also among animals, both vertebrate and invertebrate. Particularly common is the use of a pheromone to indicate that an animal is sexually receptive.

Visual Signals

Visual communication holds forth the advantage of immediate transmission. A visual signal or display is also able to encode a large amount of information, including the location of the sender. Postures and movements of parts of an animal's body are typical elements of visual communication. Color and timing are additional means of providing information. Some visual signals are discrete; that is, the signal shows no significant variation from performance to performance. Other displays are graded so that the information content of the signal can be varied. An example of a graded display is found in many of the threat or aggressive postures of birds. Threat postures of the chaffinch vary between low-intensity and high-intensity postures. The elevation of the crest varies in ways that indicate the bird's relative readiness for combat. The song spreads of red-winged blackbirds and cowbirds show variation in intensity. In red-winged blackbirds, the red epaulets, or shoulder patches, are exposed to heighten the effect of the display. Discrete and graded signals may be used together to increase the information provided by the signal. In zebras, ears back indicates a threat and ears up indicates greeting. The intensity of either message is shown by the degree to which the mouth is held open. A widely open mouth indicates a heightened greeting or threat.

Visual displays depend upon the presence of light or the production of light. The ability to produce light, bioluminescence, is found most frequently in aquatic organisms, but its use in communication is probably best documented in fireflies, beetles belonging to the family Lampyridae. Firefly males advertise their presence by producing flashes of light in a species-specific pattern. Females respond with simple flashes, precisely timed, to indicate that they belong to the appropriate species. This communication system is used to advantage by females in a few predatory species of the genus *Photuris*. After females of predatory species have mated with males of their own species, they attract males of other species by mimicking the responses of the appropriate females. The males that are tricked are promptly eaten. The luminescence of fireflies does not attract a wide variety of nocturnal predators, because their bodies contain a chemical that makes them unpalatable.

Visual displays are limited in the distance over which they can be used and are easily blocked by obstacles. Visual communication is important in primates, birds, and some insects, but can be dispensed with by many species that do not have the necessary sensory capacities.

Auditory Communication

The limitation of visual communication is frequently offset by the coupling of visual displays with other modes of communication. Visual displays can be coupled with auditory communication, for example. There are many advantages to using sound: It can be used in the dark, and it can go around obstacles and provide directional information. Because pitch, volume, and temporal patterns of sound can be varied, extremely complex messages can be communicated. The auditory communication of many bird species has been studied intensively. Bird vocalizations are usually classified into two groups, calls and songs. Calls are usually brief sounds, whereas songs are longer, more complex, and often more suited to transmission over distances.

The call repertoire of a species serves a broad array of functions. Many young birds use both a visual signal, gaping, and calling in their food begging. Individuals that call more may receive more food. Begging calls and postures may also be used by females in some species to solicit food from mates. One call type that has been intensively studied is the alarm call. Alarm calls of many species are similar, and response is frequently interspecific (that is, interpretable by more than one species). Alarm calls are likely to be difficult to locate, a definite advantage to the individual giving the call. Calls used to gather individuals for mobbing predators are also similar in different species. Unlike alarm calls, mobbing calls provide good directional information, so that recruitment to the mobbing effort can be rapid.

Call repertoires serve birds in a great variety of contexts important for survival of the individual. Song, on the other hand, most often serves a reproductive function, that of helping a male hold a territory and attract a mate. Songs are species-

Karl von Frisch

Born: November 20, 1886; Vienna, Austria
Died: June 12, 1982; Munich, West Germany
Fields of study: Biology, ethology, zoology
Contribution: Frisch, founder of the science of ethology (animal behavior), was awarded a Nobel Prize in Physiology or Medicine in 1973 for his studies of sensory discrimination and communication in bees.

Karl von Frisch enrolled at the University of Vienna as a medical student in 1905. Although he excelled in the study of anatomy and physiology, he realized he had no interest in clinical medicine. In 1907, he transferred to the Zoological Institute in Munich. After studying zoology with Richard von Hertwig and experimental biology with Hans Przibaum in Vienna, Frisch studied marine biology at the Biological Institute for Marine Research in Trieste, Italy. He was awarded the Ph.D. in 1910 for his thesis on light and color perception in minnows. These studies led to experiments on color discrimination in bees. While serving as assistant to Richard Hertwig at the Zoological Institute at the University of Munich, he earned his University Teaching Certificate in Zoology and Comparative Anatomy. By 1914, Frisch had proved that food stimuli could be used to train bees to respond to different colors. His research was interrupted by World War I, during which he worked in a Vienna hospital.

Frisch returned to Munich as an assistant professor in 1919 and carried out research on the ability of bees to distinguish specific scents. Working from premises based on Darwinian theory, Frisch thought that there must be an evolutionary link between sensory discrimination in bees and the scents and colors found in flowers. While analyzing the ability of bees to distinguish between different scents, Frisch noted that when a bee discovered a new food source it was able to summon other bees to the exact location. His observations revealed that bees communicate information about food by means of a "round dance." He subsequently discovered that the round dance was used to direct bees to a source of sugar water, but a more vigorous "waggle dance" provided information about a source of flower pollen. According to Frisch, in the language of the bees the round dance was performed when a bee discovered a food source that was close to the hive. The waggle dance provided information about more distant food sources.

After accepting appointments at the University of Rostock (1921-23) and the University of Breslau (1923-25), Frisch returned to Munich as director of the Zoological Institute. Here he helped establish a new research facility for the study of insects. In addition to his continuing ethological research on the behavior of bees, he carried out pioneering investigations on the hearing abilities of fish. Frisch established that bees use the sun as a compass and that they possess an internal clock. His research had practical implications for apiculture (beekeeping) and plant pollination. Frisch retired in 1958, but continued his research and writing and served as director emeritus of the Zoological Institute of the University of Munich. Having deciphered what he called the Rosetta Stone of honeybee communication, Frisch published several books that made his work accessible to general readers. These books include *Aus dem Leben der Bienen* (1927; *The Dancing Bees: An Account of the Life and Senses of the Honeybee*, 1955), *Du und das Leben* (1936; *Man and the Living World*, 1963), *Erinnerungen eines Biologen* (1957; *A Biologist Remembers*, 1964), *Bees: Their Vision, Chemical Senses, and Language* (1950), and *Tiere als Baumeister* (1974; *Animal Architecture*, 1974). In 1973, at the age of eighty-six, Frisch shared the Nobel Prize with Konrad Lorenz and Nikolaas Tinbergen.

—*Lois N. Magner*

specific, like the distinctive markings of a species. In some cases, songs are more distinctive than physical appearance. The chiffchaff and willow warbler were not recognized as separate species until an English naturalist named Gilbert White discovered, by examining their distinctive songs, that they are separate. The North American wood and hermit thrushes can also be distinguished more readily by song than by appearance. Bird song can communicate not only the species of the individual singing but also information about motivational state. Most singing is done by males

Karl von Frisch founded the science of ethology as the result of his study in the communicative dances of honeybees. (Nobel Foundation)

during the breeding season. In many species, only the male sings. In some species, females sing as well. Their songs may be similar to the songs of the males of their species or they may be distinctive. If the songs are similar to those of the males, the female may sing songs infrequently and with less volume. In some instances, the female song serves to notify her mate of her location. An interesting phenomenon found in some species is duetting, in which the male and female develop a duet. Mates may sing in alternate and perfectly timed phrases, as is done by the African boubou shrike, *Laniarius aethiopicus*. An individual shrike can recall its mate by singing the entire song alone.

Individuals in some bird species have a single song, and individuals of other species have repertoires of songs. Average repertoire size of the individual is characteristic of a species. Whether songs in repertoires are shared with neighbors or unique to the individual is also characteristic of a species. Sharing songs with neighbors permits song matching in countersinging. Cardinals and tufted titmice are species that frequently match songs in countersinging. Possible uses for matching are facilitating the recognition of intruders and indicating which neighbor has the attention of a singer. Some species of birds have dialects. The species-specific songs of one geographic region can be differentiated from the song of another geographic region. The development of dialects may be useful in maintaining local adaptations within a species, provided that females select mates of the same dialect as their fathers.

Although auditory signals of birds have received a disproportionate share of attention in the study of animal communication, auditory communication is used by a broad spectrum of animals. Crickets have species-specific songs to attract females and courtship songs to encourage an approaching female. The ears of most insects can hear only one pitch, so the temporal pattern of sound pulses is the feature by which a species can be identified. Vervet monkeys use three different alarm calls, depending upon the kind of threat present; they respond to the calls appropriately by looking up, looking down, or climbing a tree, depending upon the kind of call given.

Tactile and Electrical Communication

Tactile communication differs significantly from other forms of communication in that it cannot occur over a distance. This form of communication is important in many insects, equipped as they are with antennae rich in receptors. Shortly after a termite molts, for example, it strokes the end of the abdomen of another individual with its antennae and mouthparts. The individual receiving this signal responds by extruding a fluid from its hindgut. Tactile signals are frequently used in eliciting trophallaxis (food sharing) in social insects. Tactile signals are also important in the copulatory activity of a number of vertebrates.

Additional channels of communication available in animals are electrical and surface vibration. Many modes of communication are used in combination with other modes. The channels used will depend in part on the sensory equipment of the species, its ecology, and the particular context. Most messages will be important either for the survival of the individual or the group or for the individual's ability to transmit its genes to the next generation.

Communication Studies

Early study in animal communication depended primarily on careful observation of animals. This technique has been supplemented by a number of tools. The motion-picture or videotape camera permits the observer to analyze visual displays more completely. The tape recorder is a particularly versatile tool; acoustical communication can be recorded and the result used in playback experiments, in which the ethologist plays the recording in the field in order to test hypotheses about communication. Playbacks have helped scientists determine that some species of birds can discriminate between songs of neighbors and songs of strangers. Taped songs have been cut and spliced in various sequences to find out which features of a song's structure are important in species recognition.

The development of song in some species has been studied by means of isolation experiments. Birds that have been hatched and reared in the laboratory have been isolated from their species-specific song to determine whether the song needs to be learned. Some isolates are exposed to tutors (either tape recordings or living birds) at various intervals to examine the possibility of critical periods for song learning.

Sound spectrographs make it possible to produce pictures of calls and songs. Spectrographs represent song frequency on one axis and time on the other. These graphs have revealed the intricate structures of many auditory communication signals.

Information about sensory reception and about neural control of signals is an important research area. Some information in this area has come from ingenious but simple experiments. Bees have been trained to respond to color clues in association with a sugar source to determine which colors they are able to discriminate. Important knowledge in sensory research comes from determining the specific stimuli that will elicit a response in specific neurons. By using microelectrodes placed in or near the neuron, scientists can detect the presence of a response. Another technique used to determine the function of a presumed sense organ is to block or remove either the organ or the neural connections to the organ. One of the earliest experiments of this type was done in 1793 by Lazzaro Spallanzani. He found that flying bats could not avoid obstacles when their ears were tightly plugged but that the bats were able to avoid obstacles when they were blinded. In 1938, the use of an ultrasonic recorder made it possible for Donald Griffin to discover the bat's use of ultrasonic sound.

Synthetic pheromones can be produced that have the same effects on behavior as natural pheromones. Scientists can also determine at what dilution a pheromone will still evoke response. Hence, the sophisticated tools of chemistry have important applications in ethology.

Talking to Animals

Animal communication provides a fascinating frontier for exploration. Some of the knowledge acquired has had practical applications as well. Pheromones have been used to bait traps for insect pests. In some cases, this technique is used directly as a control measure; in other instances, the traps are used to estimate population size, and other control measures are used when pest populations are high. A key advantage of pheromone use is its specificity.

Recognizing the communication signals of pets and domestic animals is often useful in their care. Knowledge of releasers, standard signals that receive standard responses from animals, is important for survival in some contexts. Knowing which signals are perceived by animals as threats allows humans to avoid triggering an attack. This knowledge also allows control of animals in less destructive ways. Recordings of alarm signals of birds are used to disperse flocks that are creating problems.

Knowledge of a species' communication repertoire is critical in the training of animals for useful work or for entertainment. Also, knowledge of their sensory capacities makes it possible for appropriate signals to be selected—particularly important as it applies to human nonverbal communication. Knowing which signals of our nonverbal communication repertoire are characteristic of the whole species is both useful and interesting.

Bibliography

De Waal, Frans. *Chimpanzee Politics: Power and Sex Among Apes*. New York: Harper & Row, 1982. A well-illustrated account of a group of chimpanzees using their communication skills with adroitness in the politics of their social group. Enjoyable reading for high school, college, and general audiences. Bibliography and index.

Goodall, Jane. *In the Shadow of Man*. Rev. ed. Boston: Houghton Mifflin, 2000. Goodall's classic, well-illustrated account of the beginnings of her long-term study of chimpanzees in their natural habitat. Chimpanzee communication is described in the context of its use in the social group. Informative and enjoyable, with a good index of forms of communication.

Gould, James L. *Ethology*. New York: W. W. Norton, 1982. A very readable textbook. Places animal communication in the context of the species' social behavior and ecology. Chapters end with summaries and lists of additional readings. There is no glossary, but terms are adequately defined in the text and can be traced through the index.

Grier, James W. *Biology of Animal Behavior*. 2d ed. St. Louis: Times Mirror/Mosby, 1992. Chapters on communication modes, mechanisms, and ecological considerations, and sensory worlds provide useful information on animal communication. Well illustrated and clearly presented, with end-of-chapter summaries and lists of additional readings. There is no glossary, but terms are well defined in the text and can be located by means of a good index.

Hart, Stephen. *The Language of Animals*. New York: H. Holt, 1996. A high school textbook written in narrative form. Each chapter describes the communication of an animal group, such as cephalopods, spiders, fish, frogs, and birds. Black-and-white illustrations. Index. List of further readings. Includes a foreword by Frans B. M. de Waal.

Hauser, Marc D. *The Evolution of Communication*. Cambridge, Mass.: MIT Press, 1996. A thorough comparative and cross-disciplinary study aimed at informed general readers and scholars venturing outside their own fields. Covers well-studied domains such as mating calls, echolocation, alarm calls, and primate social communication, with detailed coverage of key experimental results and theoretical frameworks. Extensive bibliography.

Peters, Roger. *Mammalian Communication: A Behavioral Analysis of Meaning*. Monterey, Calif.: Brooks/Cole, 1980. A readable book covering a variety of mammalian species. Communication is treated in the context of the biology and ecology of the species. Excellent drawings (although the quality of a few of the photographs could be improved). There is no glossary, but there is a useful reference list at the end of the text. Written at the college level but suitable for the high school student as well.

Roitblat, Herbert L., Louis M. Herman, and Paul E. Nachtigall, eds. *Language and Communication: Comparative Perspectives*. Hillsdale, N.J.: Lawrence Erlbaum, 1993. A collection of essays on animal communication. Includes essays on communication in dolphins, gray parrots, primates, and interspecies communication. Bibliography and indexes.

Wilson, Edward O. *Insect Societies*. Cambridge, Mass.: Harvard University Press, 1971. A classic, thorough, and well-written account of the behavior of social insects. Describes the communication of alarm and assembly; recruitment; and recognition, food exchange, and grooming. A bibliography, glossary, and index assist the reader. Clear and understandable to the interested nonscientist.

COMMUNITIES

Type of animal science: Ecology
Fields of study: Conservation biology, ecology, population biology, wildlife ecology, zoology

Each ecological community has a characteristic structure and function that determines its ability to withstand and recover from disturbance. Since so many of the disturbances experienced by communities are caused by human activities, ecologists seek to understand why some communities are susceptible and why some disturbances cause irreversible damage.

Principal Terms

ECOSYSTEM: a community together with its physical environment

FOOD CHAIN: a pathway through which energy travels in a community

FOOD WEB: the interconnections among all food chains in a community

FREQUENCY-DEPENDENT PREDATION: predation on whichever species is most common in a community

GLOBAL EXTINCTION: the loss of all members of a species

KEYSTONE SPECIES: a species that determines the structure of a community, usually by predation on its dominant competitor

LOCAL EXTINCTION: the loss of one or more populations of a species, but with at least one population of the species remaining

RESILIENCE STABILITY: stability exhibited by a community that changes its structure when disturbed but returns to its original structure when the disturbance ends

RESISTANCE STABILITY: stability exhibited by a community that absorbs the effects of a disturbance until it can no longer do so; then, it typically shifts permanently to an alternate structure

TROPHIC LEVEL: a single link in a food chain; all species that obtain energy in the same way are said to be at the same trophic level

An ecological community is the assemblage of species found in a given time and place. The populations that form a community interact through the processes of competition, predation, parasitism, and mutualism. The structure and function of communities are determined by the nature and strength of the population interactions within it, but these interactions are affected by the environment in which a community exists. An ecological community together with its physical environment is called an ecosystem. No ecological system can be studied apart from its physical environment; the structure and function of every community are determined in part by its interactions with its environment.

The species constituting a community occupy different functional roles. The most common way to characterize a community functionally is by describing the flow of energy through it. Correspondingly, communities usually contain three groups of species: those that obtain energy through photosynthesis (called producers), those that obtain energy by consuming other organisms (consumers), and those that decompose dead organisms (decomposers). The pathway through which energy travels from producer through one or more consumers and finally to decomposer is called a food chain. Each link in a food chain is called a trophic level. Interconnected food chains in a community constitute a food web. Food webs have no analogy in populations.

Very few communities are so simple that they can be readily described by a food web. Most communities are compartmentalized: A given set of producers tends to be consumed by a limited number of consumers, which in turn are preyed upon by only a few predators, and so on. Alternatively, consumers may obtain energy by specializing on one part of their prey (for example, some birds may eat only seeds of plants) but utilize a wide range of prey species. Compartmentalization is an important feature of community structure; it influences the formation, organization, and persistence of a community.

Dominant and Keystone Species

Some species, called dominant species, can exert powerful control over the abundance of other species because of the dominant species' large size, extended life span, or ability to monopolize energy or other resources. Communities are named according to their dominant species: for example, oak-hickory forest, redwood forest, sagebrush desert, and tallgrass prairie. Some species, called keystone species, have a disproportionately large effect on community structure by preventing dominant species from monopolizing the community. Keystone species usually exert their effects through predation, while dominant species are good competitors (that is, better at obtaining and holding resources than other species).

The species that make up a community are seldom distributed uniformly across the landscape; rather, some degree of patchiness is characteristic of virtually all species. There has been conflicting evidence as to the nature of this patchiness. As one moves across an environmental gradient (for example, from wet to dry conditions or from low to high elevations), there is a corresponding change in species observed and in the type of community present. Some studies have suggested that changes in species composition usually occur along relatively sharp boundaries and that these boundaries mark the boundaries between adjacent communities. Other studies have indicated that species tend to respond individually to environmental gradients and that community boundaries are not sharply defined; rather, most communities broadly intergrade into one another.

The Nature of Community

These conflicting results have fueled a continuing debate as to the underlying nature of the community. Some communities seem to behave in a coordinated manner; for example, if a prairie is consumed by fire, it regenerates in a predictable sequence, ultimately returning to the same structure and composition it had before the fire. This coordinated response is to be expected if the species in a community have evolved together with one another. In this case, the community behaves analogously to an organism, maintaining its structure and function in the face of environmental disturbances and fluctuations (as long as the disturbances and fluctuations are not too extreme). The existence of relatively sharp boundaries between adjacent communities supports this explanation of the nature of the community.

In other communities, it appears that the response to environmental fluctuation or disturbance is determined by the evolved adaptations of the species available. There is no coordinated community response, but rather a coincidental assembly of community structure over time. Some sets of species interact together so strongly that they enter a community together, but there is no evidence of an evolved community tendency to resist or accommodate environmental change. Data support this explanation of the community as an entity formed primarily of species that happen to share similar environmental requirements.

Mechanisms of Community Structure

Disagreement as to the underlying nature of communities usually reflects disagreement as to the relative importance of the underlying mechanisms that determine community structure. Interspecific competition has long been invoked as the primary agent structuring communities. Competition is certainly important in some communities, but there is insufficient evidence to indicate how widespread and important it is in determining community structure. Much of the difficulty occurs because ecologists must infer the existence of past competition from present patterns in communities. It appears that competition has been important in many vertebrate communities and in communities dominated by sessile organisms, such as plants; it does not appear to have been important in structuring communities of plant-eating insects. Furthermore, the effects of competition typically affect individuals that use identical resources, so that only a small percentage of species in a community may be experiencing significant competition at any time.

The effects of predation on community structure depend on the nature of the predation. Keystone species usually exert their influence by selectively preying on species that are competitively dominant. Predators that do not specialize on one or a few species may also have a major effect on community structure, if they attack prey in proportion to their abundance; this frequency-dependent predation prevents any prey species from achieving dominance. If a predator is too efficient, it can drive its prey to extinction, which may cause a selective predator to become extinct as well. Predation appears to be most important in determining community structure in environments that are predictable or unchanging.

Natural Disturbances

A variable or unpredictable environment influences the structure of a community. No environment is completely uniform; longer-term or seasonal environmental fluctuations affect community structure by limiting opportunities for colonization, by causing direct mortality, and by hindering or exacerbating the effects of competition and predation. Furthermore, all communities experience at least occasional disturbance: unpredictable, seemingly random environmental changes that may be quite severe. It is useful in this regard to distinguish between disasters and catastrophes. A disaster is an event that occurs so frequently in the life of a population that adaptation is possible; for example, fire occurs so often in tallgrass prairies that most of the plant species have become fire-adapted—they have become efficient at acquiring nutrients left in the ash and at sprouting or germinating quickly following a fire. In comparison, a catastrophe is so intense, widespread, or infrequent that a population cannot adapt to it; the eruption of Mount St. Helens in 1980, for example, was so violent and so unpredictable that the species affected could not evolve adequate responses to it.

Natural disturbances occur at a variety of scales. Small-scale disturbances may simply create small openings in a community that are filled in by other species suited to thrive in such spaces. Large disturbances are qualitatively different from small disturbances, in that large portions of a community may be destroyed, including some of the ability to recover from the disturbance. Early ecologists almost always saw disturbances as destructive and disruptive for communities. Under this assumption, most mathematical models portrayed communities as generally being in some stable state, at equilibrium; if a disturbance occurred, the community inevitably returned to the same (or some alternative) equilibrium. It later became clear, however, that natural disturbance is a part of almost all natural communities. Ecologists now recognize that few communities exhibit a stable equilibrium; instead, communities are dynamic, always responding to the last disturbance, always adjusting to the most recent environmental fluctuation.

The Long-Term Dynamics of Communities

The evidence suggests that three conclusions can be drawn with regard to the long-term dynamics of communities. First, it can no longer be assumed that communities remain at equilibrium until changed by outside forces. Disturbances are so common, they occur at so many different scales and frequencies, and they so readily affect the processes of competition and predation that the community must be viewed as an entity that is constantly changing as its constituent species readjust to disturbance and to one another.

Second, communities exhibit several types of stability in the face of disturbance. A community may absorb disturbance without markedly changing, until it reaches a threshold and suddenly and rapidly shifts to a new state, called resistance stability. Alternatively, a community may change easily when disturbed but quickly return to its former state; this characteristic is called resilience stability. Resilience stability may occur over a wide range of conditions and scales of disturbance; such a system is said to be dynamically robust. On the other hand, a community that exhibits resilience only within a narrow range of conditions is said to be dynamically fragile.

Finally, there is no simple way to predict the stability of a community. At the end of the 1970's, it appeared that complex communities were generally more stable than simple communities. It appeared that stability was conferred by more intricate food webs, by more structural complexity, and by higher species diversity. On the basis of numerous field studies and theoretical models, ecologists now conclude that no such relationship exists. Both very complex communities, such as tropical rain forests, and very simple communities, such as Arctic tundra, may be very fragile when disturbed.

Complex Systems

Most communities consist of thousands of species, and their complexity makes them very difficult to study. Most community ecologists specialize in taxonomically restricted subsets of communities (such as plant communities, bird communities, insect communities, or moss communities) or in functionally restricted subsets of communities (such as soil communities, tree-hole communities, pond communities, or detrivore communities).

The type of community under investigation and the questions of interest determine the appropriate methods of study. The central questions in most community studies are how many species are present and what is the abundance of each. The answers to these questions can be estimated using mark-recapture methods or any other enumeration method.

Often the aim is to compare communities (or to compare the same community at different times). A specialized parameter called similarity is used to compare and classify communities; more than two dozen measures of similarity are available. Measures of similarity are typically subjected to cluster analysis, a set of techniques that groups communities on the basis of their similarity.

Many multivariate techniques are used to search for patterns in community data. Direct gradient analysis is the simplest of these techniques; it is used to study the distribution of species along an environmental gradient. Ordination includes several methods for collapsing community data for many species in many communities along several environmental gradients onto a single graph that summarizes their relationships and patterns.

Patterns of Community Responses to Disturbance

At the most basic level, destruction of a community eliminates the species comprising the community. If the community is restricted in its extent, and if its constituent species are found nowhere else, those species become extinct. If the community covers a large area or is found in several areas, local extinction of species may occur without causing global extinction.

Destruction of a community can cause unexpected changes in environmental conditions that were modified by the intact community. Even partial destruction of an extensive community can eliminate species. For example, the checkerboard pattern of clear-cutting in Douglas fir forests of the Pacific Northwest threatens the survival of the northern spotted owl, the marbled murrelet, Vaux's swift, and the red tree vole, even though fragments of the community remain. Many fragments are simply too small to support these species. A Douglas fir forest is regenerated following cutting, but this young, even-aged stand is so different from an old, mixed-age forest that it functions as a different type of community.

Altering the population of one species can affect others in a community. The black-footed ferret was once found widely throughout central North America as a predator of prairie dogs. As prairie dogs were poisoned, drowned, and shot throughout their range, the number of black-footed ferrets also declined. As of 1989, fewer than one hundred black-footed ferrets were in a captive breeding program in Wyoming in a final attempt to preserve the species.

Introducing a new species into a community can severely alter the interactions in the community. The introduction of the European rabbit into Australia led to a population explosion of rabbits, excessive predation on vegetation, and resulting declines in many native marsupials.

Finally, it appears that many communities exhibit stability thresholds; if a community is disturbed beyond its threshold, its structure is permanently changed. For example, acid deposition in lakes is initially buffered by natural processes. As acid deposition exceeds the buffering capacity of a lake, it causes insoluble aluminum in the lake bottom to become soluble, and this soluble aluminum kills aquatic organisms directly or by making them more susceptible to disease. The lesson is clear: It is far easier to disrupt or destroy natural systems (even accidentally) than it is to restore or reconstruct them.

Bormann, Frank H., and Gene E. Likens. "Catastrophic Disturbance and the Steady State in Northern Hardwood Forests." *American Scientist* 67 (1979): 660-669. This article is based on nearly twenty years of work on the Hubbard Brook Forest in New Hampshire. It summarizes clearly and authoritatively the dominant understanding of disturbance and stability in natural communities. A good starting point for further investigation in this area.

Goldammer, J. G., ed. *Tropical Forests in Transition: Ecology of Natural and Anthropogenic Disturbance Processes*. Boston: Birkhäuser Verlag, 1992. A collection of multidisciplinary essays on disturbance ecology, originally presented at a conference in Freiburg, Germany. Covers paleoecology, the impact of human populations, and models of the tropical forest's future in a changing environment.

Krebs, Charles J. *Ecological Methodology*. 2d ed. Menlo Park, Calif.: Benjamin/Cummings, 1999. This book provides an excellent presentation of the most widely used methods in ecology. It is a college-level text, most suitable for those who have had some previous instruction in ecology, as well as a good facility with algebra.

_______. *Ecology: The Experimental Analysis of Distribution and Abundance*. 4th ed. Menlo Park, Calif.: Benjamin/Cummings, 1994. One of the most widely used college-level texts, this book is written with excellent clarity and scope. Chapter 25 provides concise, complete coverage of community organization.

Pickett, S. T. A., and P. S. White, eds. *The Ecology of Natural Disturbance and Patch Dynamics*. Orlando, Fla.: Academic Press, 1985. Provocative and wide-ranging, this book is a gold mine of information and examples illustrating current hypotheses about the many kinds of natural disturbance and the ways in which communities respond. The entire book is readily accessible to the general reader. An excellent overview of the topic. The bibliography is very complete through 1984.

Pielou, E. C. *The Interpretation of Ecological Data: A Primer on Classification and Ordination*. New York: John Wiley & Sons, 1984. The definitive book for those interested in cluster analysis and ordination, and in the classification of communities. Although it is an introductory textbook, the reader with a knowledge of matrix algebra and previous instruction would benefit most.

COMPETITION

Type of animal science: Ecology
Fields of study: Evolutionary science, zoology

Competition is the conflict between different organisms for control of food, natural resources, territories, mates, and other aspects of survival. Competition can occur between individuals of the same species or between individuals of different species. In either case, it is natural selection for the fittest organisms and species; therefore, it is a major driving force in evolution.

Principal Terms

EVOLUTION: gradual changes in organisms over time, caused by mutation and selected by the environment, resulting in better adapted organisms and new species

HABITAT: the type of environment in which a particular organism prefers to live, based upon various physical and chemical conditions

NATURAL SELECTION: the ability of an organism or species to survive, compete, and reproduce in its habitat; success is dictated by the alleles (traits) that it possesses

NICHE: an organism's role in its habitat environment

PREDATION: a situation in which one animal species hunts and eats another species (examples: lynx versus hare; cheetah versus gazelle)

TERRITORIALITY: a phenomenon in animal behavior whereby individual organisms occupy and defend an area from other individuals of the same or different species

THREAT DISPLAY: a territorial behavior exhibited by animals during defense of a territory, such as charging, showing bright colors, and exaggerating body size

Competition is the struggle between individuals of different species (interspecific competition) or between individuals of the same species (intraspecific competition) for food, territories, and mates in order to survive. It is a major driving force in evolution, the process by which living organisms change over time, with better-adapted species surviving and less well-adapted species dying. Evolution begins with mutation, changes in the nucleotide sequence of a gene or genes, resulting in the production of slightly altered genes called alleles which encode slightly different proteins. These altered proteins are the expressed traits of an organism and may give the organism an advantage over its competitors. The organism outcompetes its rivals in the environment, and hence the environment favors the better-adapted, fitter organism, a process called natural selection. A mutation may help an organism in one environment but may hurt the same organism in a different environment (for example, an albino squirrel may flourish in snowy regions but may not do as well in warm regions). Mutations can be caused by chemicals called mutagens or by ionizing radiation such as ultraviolet light, X rays, and gamma radiation.

The Struggle to Survive

The science of ecology can best be defined as the experimental analysis of the distribution and abundance of organisms. Natural selection influences the distribution and abundance of organisms from place to place. The possible selecting factors include physical factors (temperature and light, for example), chemical factors such as water and salt, and species interactions. Any of these factors can influence the survivability of organisms in any particular environment. According to ecologist Charles Krebs, species interactions include four principal types: mutualism, which is the living together of two species that benefit each other (for example, humans and their pets); commensalism, which is the living together of two species that results in a distinct benefit (or number of benefits) to one species while the other remains unhurt (commensalism is shown in the relationship of birds and trees); predation, which is the hunting, killing, and eating of one species by another (examples: cats and mice; dogs and deer); and competition, which is defined as an active struggle for survival among all the species in a given environment.

This struggle involves the acquisition of various resources: food, territory, and mates. Food is an obvious target of competition. All organisms must have energy in order to conduct the cellular chemical reactions (such as respiration) that keep them alive. Photoautotrophic organisms (plants, phytoplankton, photobacteria) obtain this energy by converting sunlight, carbon dioxide, and water into sugar, a process called photosynthesis. Photoautotrophs, also called producers, compete for light and water. For example, oak and hickory trees grow taller than most pines, thereby shading out smaller species and eventually dominating a forest. All other organisms—animals, zooplankton, and fungi—are heterotrophs; they must consume other organisms to obtain energy. Heterotrophs include herbivores, carnivores, omnivores, and saprotrophs. Herbivores (plant eaters such as rabbits and cattle) obtain the sugar manufactured by plants. Carnivores (meat eaters such as cats and dogs) eat other heterotrophs in order to get the sugar that these heterotrophs received from other organisms. Omnivores, such as humans, eat plants and animals for the same reason. Saprotrophs (such as fungi and bacteria) decompose dead organisms for the same reason. Life on earth functions by intricately complex food chains in which organisms consume other organisms in order to obtain energy. Each human being is composed of molecules that were once part of other living organisms, even other humans. Ultimately, the earth's energy comes from the sun.

Competition Between and Within Species

Territoriality is equally important for two reasons: An organism needs a place to live, and this place must contain adequate food and water reserves. A strong, well-adapted organism will fight and drive away weaker individuals of the same or different species in order to maintain exclusive rights to an area containing a large food and water supply. Species that are less well-adapted will be relegated to areas where food and water are scarce. The stronger species will have more food and will tend to produce more offspring, since they will easily attract mates. Being stronger or more adapted does not necessarily mean being physically stronger. A physically strong organism can be overwhelmed easily by numerous weak individuals. In general, adaptability is defined by an organism's ability to prosper in a hostile environment and leave many viable offspring.

Within a species, males attempt to attract females to their territory, or vice versa, by courtship dances and displays, often including bright colors such as red and blue and exaggerated body size. Mating displays are very similar to the threat displays used to drive away competitors, although there is no hostility involved. Generally, females are attracted to dominant males having the best, not necessarily the largest, territories.

Competition for food and territory is interspecific and intraspecific. Competition for mates is intraspecific. In an environment, the place where an organism lives (such as a eucalyptus tree or in rotting logs) is referred to as its habitat. Simultaneously, each species has its own unique niche, or occupation, in the environment (such as decomposer or carnivore). More than one species can occupy a habitat if they have different ecological niches. When two or more different species occupy the same habitat and niche, competition arises. One species will outcompete and dominate, while the losing competitors may become reduced in numbers and may be driven away from the habitat.

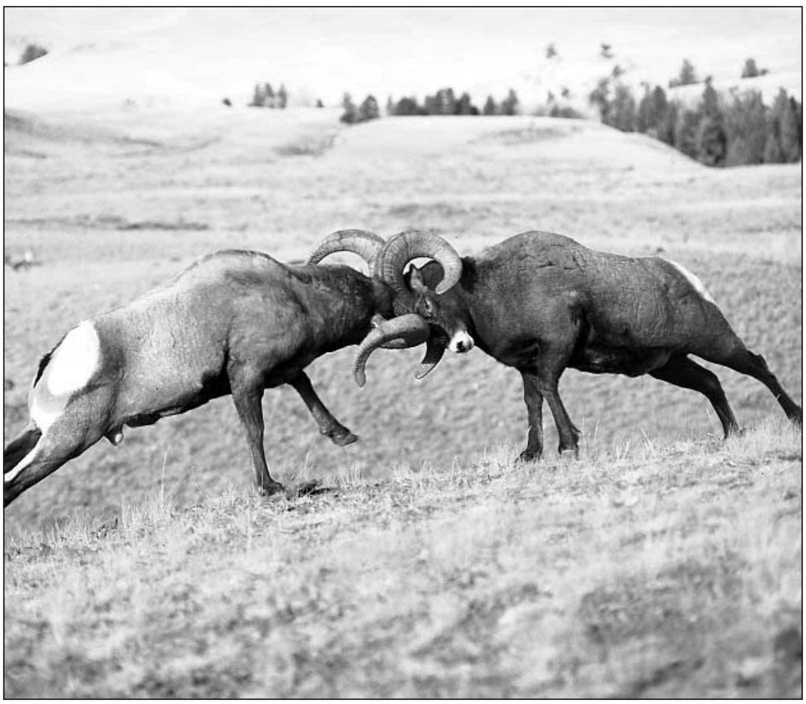
Pecking Orders

In vertebrate organisms, intraspecific competition occurs between males as a group and between females as a group. Rarely is there male-versus-female competition, except in species having high social bonding—primates, for example. Competition begins when individuals are young. During play fighting, individuals nip or peck at each other while exhibiting threat displays. Dominant individuals exert their authority, while weaker individuals submit. The net result is a very ordered ranking of individuals from top to bottom, called a dominance hierarchy or pecking order. The top individual can threaten and force into submission any individual below it. The number two individual can threaten anyone except number one, and so on. The lowest-ranked individual can threaten no one and must submit to everyone. The lowest individual will have the least food, worst territory, and fewest (if any) mates. The number one individual will have the most food, best territory, and most mates. The pecking order changes over time because of continued group competition that is shown by challenges, aging, and accidents.

Pecking orders are evident in hens. A very dominant individual will peck other hens many times but will rarely be pecked. A less dominant individual will peck less but be pecked more. A correct ranking can be obtained easily by counting the pecking rate for each hen.

In The Netherlands, male black grouse contend with one another in an area called a "lek," which may be occupied by as many as twenty males. The males establish their territories by pecking, wing-beating, and threat displays. The most dominant males occupy small territories (several hundred meters) at the center of the lek, where the food supply is greatest. Less dominant males occupy larger territories with less food reserves to the exterior of the lek. Established territories are maintained at measurable distances by crowing and flutter-jumping, with the home territory owner nearly always winning. Females, which nest in an adjoining meadow, are attracted to dominant males in the heavily contested small central territories.

A baboon troop can range in size from ten to two hundred members, but usually averages about forty. Larger, dominant males and their many female mates move centrally within the troop. Less dominant males, with fewer females, lie toward the outside of the troop. Weak individuals at the troop periphery are more susceptible to predator attacks. Dominant males exert their au-



Animals compete for territory, social status, food, and access to mates. Although the competition may be violent and painful, as when these rams butt heads at high speeds, animals rarely compete to the death. (Corbis) thority by threat displays, such as the baring of the teeth or charging; weaker males submit by presenting their hindquarters. Conflicts are usually peacefully resolved.

Female lions maintain an organized pride with a single ruling male. Young males are expelled and wander alone in the wilderness. Upon reaching adulthood, males attempt to take over a pride in order to gain access to females. If a male is successful in capturing a pride and expelling his rival, he will often kill the cubs of the pride, simultaneously eliminating his rival's descendants and stimulating the females to enter estrus for mating.

Competition Within Niches

Interspecific competition occurs between different species over food and water reserves and territories. Two or more species occupying the same niche and habitat will struggle for the available resources until either one species dominates and the others are excluded from the habitat or the different species evolve into separate niches by targeting different food reserves, thus enabling all to survive in the same habitat. Numerous interspecific studies have been conducted, including crossbills, warblers, blackbirds, and insects, to mention a few.

Crossbills are small birds that live in Europe and Asia. Three crossbill species inhabit similar habitats and nearly similar niches. Each species has evolved a slightly modified beak, however, for retrieving and eating seeds from three different cone-bearing (coniferous) trees. The white-winged crossbill has a slender beak for feeding from small larch cones, the common crossbill has a thicker beak for feeding from larger spruce cones, and the parrot crossbill appropriately has a very thick beak for feeding from pine cones. The evolution of different niches has enabled these three competitors to survive.

Another example of this phenomenon is shown by five species of warblers that inhabit the coniferous forests of the American northeast. The myrtle warbler eats insects from all parts of trees up to seven meters high. The bay-breasted warbler eats insects from tree trunks six to twelve meters above the ground. The black-throated green, blackburnian, and Cape May warblers all feed near the treetops, according to elaborate studies by Robert H. MacArthur. The coexistence of five different species is probably the result of the warblers occupying different parts of the trees, with some warblers developing different feeding habits so that all survive.

G. H. Orians and G. Collier studied competitive exclusion between redwing and tricolored blackbirds. Introduction of tricolored blackbirds into redwing territories results in heavy redwing aggression, although the tricolored blackbirds nearly always prevail.

Two species of African ants, *Anoplolepis longipes* and *Oecophylla longinoda*, fight aggressively for territorial space. M. J. Way found that *Anoplolepis* prevails in sandy environments, whereas *Oecophylla* dominates in areas having thick vegetation.

Interspecific competition therefore results in the evolution of new traits and niches and the exclusion of certain species. Mathematical models of competition are based upon the work of A. J. Lotka and V. Volterra. The Lotka-Volterra equations attempt to measure competition between species for food and territory based upon the population size of each species, the density of each species within the defined area, the rate of population increase of each species, and time.

Observing Competiton

Studies of competition between individuals of the same or different species generally follow one basic method: observation. Interactions between organisms are observed and carefully measured to determine if the situation is competition, predation, parasitism, or mutualism. More detailed analyses of environmental chemical and physical conditions are used to determine the existence of additional influences. Observations of competition between organisms involve direct visual contact in the wild, mark-recapture experiments, transplant experiments, measurements of population sizes in given areas, and competition experiments in artificial environments.

Direct visual contact involves the scientist entering the field, finding a neutral, nonthreatening position, and watching and recording the actions of the subject organisms. The observer must be familiar with the habits of the subject organism and must be keen to detect subtle cues such as facial gestures, vocalizations, colors, and patterns of movement from individual to individual. Useful instruments include binoculars, telescopes, cameras, and sound recorders. The observer must be capable of tracking individuals over long distances so that territorial boundaries and all relevant actions are recorded. The observer may have to endure long periods of time in the field under uncomfortable conditions.

Mark-recapture experiments involve the capture of many organisms, tagging them, releasing them into an area, and then recapturing them (both tagged and untagged) at a later time. Repeated collections (recaptures) over time can give the experimenter an estimate of how well the species is faring in a particular environment. This technique is used in conjunction with other experiments, including transplants and population size measurements.

In transplant experiments, individuals of a given species are marked and released into a specific environmental situation, such as a new habitat or another species' territory. The objective of the experiment is to see how well the introduced species fares in the new situation, as well as the responses of the various species which normally inhabit the area. The tricolored blackbird takeover of redwing blackbird territories is a prime example. Another example is the red wolf, a species that was extinct in the wild until several dozen captive wolves were released at the Alligator River Wildlife Refuge in eastern North Carolina. Their survival is uncertain. Accidental transplants have had disastrous results for certain species; for example, the African honeybee poses a threat to the honey industry in Latin America and the southern United States because it is aggressive and produces poorly.

Measurements of population sizes rely upon the point-quarter technique, in which numerous rectangular areas of equal size are marked in the field. The number of organisms of each species in the habitat is counted for a given area; an averaging of all areas is then made to obtain a relatively accurate measure of each population's size. In combination with mark-recapture experiments, population measurements can provide information for birthrates, death rates, immigration, and emigration over time for a given habitat.

Laboratory experiments involve confrontations between different species or individuals of the same species within an artificial environment. For example, male mouse (*Mus musculus*) territoriality can be studied by introducing an intruder into another male's home territory. Generally, the winner of the confrontation is the individual that nips its opponent more times. Usually, home court advantage prevails; the intruder is driven away. Similar studies have been performed with other mammalian, reptile, fish, insect, and bird species.

Interactions between different species are subtle and intricate. Seeing how organisms associate enables scientists to understand evolution and to model various environments. Competition is a major driving force in evolution. The stronger species outcompete weaker species for the available ecological niches. Mutations in organisms create new traits and, therefore, new organisms (more species), which are selected by the environment for adaptability.

All environments consist of a complex array of species, each dependent on the others for survival. The area in which they live is their habitat. Each species' contribution to the habitat is that species' niche. More than one species in a given habitat causes competition. Two species will struggle for available territory and food resources until either one species drives the other away or they adapt to each other and evolve different feeding habits and living arrangements. Competition can be interspecific (between individuals of different species) or intraspecific (between individuals of the same species). The environment benefits because the most adapted species survive, whereas weaker species are excluded.

Andrewartha, H. G. *Introduction to the Study of Animal Populations*. Chicago: University of Chicago Press, 1967. From one of the great animal ecologists, this classic textbook is a tremendous source of information for practical animal behavior research. The book concisely covers all aspects of ecology, including competition. Part 2, "Practical Course," is a valuable guide for conducting precise experiments.

Arthur, Wallace. *The Niche in Competition and Evolution*. New York: John Wiley & Sons, 1987. Discusses the population dynamics of competition and considers its evolutionary consequences and its role as an agent of community structure. Gives an exposition of basic niche theory in population and evolutionary ecology. Aimed at all ecologists from upper-level undergraduates upward, as well as all readers interested in ecology. References, author and subject indexes.

Hartl, Daniel L. *Principles of Population Genetics*. 3d ed. Sunderland, Mass.: Sinauer Associates, 1997. Hartl's work, aimed at graduate-level biologists, is a detailed mathematical approach to species interactions and evolution. The book approaches the study of populations from a genetic and statistical viewpoint and provides numerous examples and references.

Keddy, Paul A. *Competition*. New York: Chapman and Hall, 1989. Aimed at college-level students with strong backgrounds in general ecology. Looks at the usefulness of the idea of competition in interpreting data, and lucidly covers current controversies over the use of competition in explaining communities.

Krebs, Charles J. *Ecology: The Experimental Analysis of Distribution and Abundance*. 4th ed. Menlo Park, Calif.: Benjamin/Cummings, 1994. This advanced textbook is a wonderfully comprehensive survey of ecology, with many references. Numerous experiments are cited, with a thorough but understandable discussion of mathematical modeling in ecology.

Lorenz, Konrad. *On Aggression*. New York: Harcourt, Brace & World, 1963. This book by the 1973 Nobel laureate in physiology or medicine is a readable survey of animal interactions, especially that of competition and its aggressive nature. Lorenz discusses major theories with great clarity and wit and provides examples of applications to human and animal behavior.

Raven, Peter H., and George B. Johnson. *Biology*. 4th ed. Boston: McGraw-Hill, 1996. A beautifully illustrated, clearly written, well-diagrammed introductory biology textbook for undergraduate biology majors. The chapter on population dynamics is a clear presentation of species interactions, such as competition, containing numerous examples.

Wilson, Edward O. *Sociobiology: The New Synthesis*. Cambridge, Mass.: Belknap Press of Harvard University Press, 1975. Wilson's work is a major contribution to animal behavior research in terms of its unique approach and enlightening theories concerning species interactions. It is well written, illustrated, and referenced.

CONVERGENT AND DIVERGENT EVOLUTION

Type of animal science: Evolution
Fields of study: Ecology, invertebrate biology, zoology

The phenomena of convergent and divergent evolution have produced a number of good examples of natural selection at work. Thus, they provide results which can be studied in detail of interactions between environment and species which solidly validate aspects of basic evolutionary theory. Examples abound in the earth's fossil record as well as in a number of living species.

Principal Terms

ADAPTIVE RADIATION: the successful invasion by a species into a number of previously unavailable ecological niches

ANALOGUE: an individual structure shared by two or more species that is of only superficial similarity; thus, it is not indicative of a common ancestor

CLADE: a type of grouping of living or extinct species along lines of shared, unique structures, or homologues, indicative of a common ancestor; helpful in establishing evolutionary relationships

CONVERGENCE: the evolution of a similar morphology by unrelated or only distantly related species caused by both having adapted to similar lifestyles in similar environments

DIVERGENCE: the evolution of increasing morphological differences between an ancestral species and offshoot species caused by differing adaptive pressures

ENVIRONMENTAL CONSTRAINTS (PRESSURES): the physical demands placed upon any species by its surroudings that ultimately determine the success or failure of its adaptations and consequently its success as a species

HOMOLOGUE: an individual structure shared by two or more different species that is indicative of a common ancestor

Biological species have been defined as populations of organisms that are capable of successfully interbreeding (producing fertile offspring) only with other members of the same species. Members of any species possess unique sets of biological characteristics, termed "characters." These characters are physical expressions of a genetic code unique to members of that species. The code represents an extremely complex and thorough set of instructions for equipping an individual organism with the body and the behavioral knowledge it requires for success in the particular environment to which its species has adapted.

Thus, because of natural selection acting upon many past generations of that species, living members are fine-tuned to a specific ecological niche, or econiche, of the greater ecosystem of which the species is a member. When conditions within the ecosystem change (a general climatic change, for example) or when other scenarios occur, such as when a smaller subpopulation of the species migrates into new, ecologically different territory or becomes isolated in some way, selective pressure is brought to bear upon members of the group or subgroup. Random mutation is a mechanism by which selective pressure is thought to be brought about. Such mutations are changes in the genetic code that occur spontaneously in some individuals within the species in an ongoing manner. Most random mutations are insignificant phenomena with regard to the species as a whole, because most have either a neutral or negative survival value: Either they do not help the individual possessing them to survive or they are counteradaptive to an extreme degree and prove fatal. Consequently, mutations in general are not usually transmitted beyond the generation in which they occur or beyond the affected member or members. In certain scenarios, however, mutations that have a positive survival value can spread throughout the population. This is believed to be especially true when a smaller, isolated subgroup of the population is dealing with a changed or new environmental situation. Such processes are thought, for example, to have been instrumental in the evolution of groups of closely related but now morphologically distinct species found in isolated, mid-ocean island groups. These adaptive radiations of species that are monophyletic and thus share a relatively recent common ancestor are good examples of the process of evolutionary divergence at work.

The Case of the Galápagos Finches

In one of the best-known cases, studies have traced the presumed paths of divergence among a set of island bird species. This particular radiation produced a number of new species possessing novel adaptive morphologies evolved to exploit new econiches. This is the classic example of Darwin's finches. Darwin's finches are a group of closely related birds, numbering about fourteen species, found on the various islands of the Galápagos Archipelago, which straddles the equator. The islands are remote from any large body of land that would typically harbor similar birds: South America lies about 960 kilometers to the east across an unbroken stretch of the Pacific Ocean. In 1835, Charles Darwin, author of the highly influential work on organic evolution, *On the Origin of Species* (1859), visited the islands while employed as a naturalist on a British scientific voyage. His studies of the flora and fauna of these islands provided him with many observations that directly influenced his later writings.

Darwin's studies of the Galápagos finches convinced him, and generations of subsequent scientists, that the finches are a clear example of divergent evolution in operation. The scenario he deduced is that probably only one ancestral species arrived from South America by ocean currents or winds, established itself, and began to exploit the numerous, as yet unoccupied, econiches that the volcanic islands provided. In the relative ecological vacuum that the original finch species found among the islands, adaptive radiation occurred, resulting in the present, diverse species. The species of Darwin's finches found today on the islands exhibit a great variety of beak types, many of which are atypical of finch-type birds in general but rather are typical of birds found among totally different avian family classifications. Typical finches are noted for beaks adapted for the crushing of seeds—the diet of the usual members of the finch family, such as the familiar North American cardinal. Among the dozen or so Galápagos finches can be found a wide assortment of beaks adapted for obtaining or processing a much greater variety of diets. Darwin's finches include species with beaks and behaviors adapted for diets of insects, seeds, cacti, and other vegetal matter. The adaptive radiation in the case of the Galápagos finches was relatively easy to work out because of the obvious environmental factors involved (the islands' remoteness and general barrenness) and the unusual variety of adaptations that the finches had made. Establishing the details of evolutionary divergence in other living ecosystems can be confusing because the numbers and types of econiches and interacting species are often far more numerous and diverse—for example, the lush and intricate ecosystem of a large, tropical rain forest such as the Amazon.

Tracing the Fossil Record

Myriad examples of evolutionary divergence exist between both living plant and animal species throughout existing ecosystems in the modern world. The fossil record, however, also can be studied, to examine the phenomenon between extinct animal groups. This record of past life-forms preserved in the crustal rocks of the earth provides numerous examples of diverging species as organisms adapted to changing general conditions or spread into novel environments. An ex-

An example of convergent evolution is the way that sharks (left), which are fish, and dolphins (right), which are mammals, have evolved similar body shapes to adapt to their marine ecological niches. (Digital Stock)

ample is the many species of ceratopsian dinosaurs found in the latter part of the Cretaceous period of the Mesozoic era of the earth's history. Although the earlier ancestral forms appear to be bipedal and possess no significant armor, the later radiation of ceratopsians is well known by way of such impressive animals as *Triceratops*, a typical ceratopsian: a heavy, quadrapedal herbivore with a large, horned and beaked skull with a defensive, bony frill. Many variations on the basic late ceratopsian body architecture evolved through divergence. Varieties included such forms as *Pentaceratops*, *Torosaurus*, *Styracosaurus*, *Chasmosaurus*, and *Centrosaurus*, among many others. In all these later animals, the basic morphology regarding body, tail, and limbs remained the same. All forms also retained the typical massive, beaked head. What diverged were such morphological features as number and length of facial horns and length and degree of ornamentation of the frill. One of the important things that study of such fossil forms shows is that such past examples of evolutionary divergence eloquently underscore the continuity of the evolutionary process through time down to the present living world. This continuity further reinforces the validity of basic evolutionary theory in general.

Evolutionary Convergence

A related phenomenon concerning adaptive evolution is the phenomenon of evolutionary convergence. This process can be described briefly as the evolution of similar body structures in two or more species that are only quite distantly related; they therefore come to resemble each other, sometimes to a startling degree of at least outward sameness. These sets of similar-looking but polyphyletic species frequently even display similar behavioral characteristics. All similarities found in convergence cases are believed to be attributable to the fact that the various species involved have adapted to a similar econiche within a similar ecosystem. Because in nature, form follows function and the morphology of an animal or plant is the product of environmental pressures that continuously favor the better-adapted organism, it is easy to understand how convergence can take place. Like divergence, the evidence for convergence can be traced not only among the many participants in contemporary biospace but also over the course of vast stretches of past time.

One of the classic examples of convergence is a threefold example that, conveniently, not only includes representatives from three different classes of vertebrates but also spans many millions of years of time and includes an extinct group. This is the textbook example that compares and contrasts the morphology of sharks, a type of cartilaginous fish; ichthyosaurs, an extinct type of marine reptile; and dolphins, marine mammals like whales. All three groups possess numerous member species, both fossil and alive (except for ichthyosaurs), which resemble each other in body plan and lifestyle. All three groups include species which lead (or led) an open ocean, fish-eating existence. Consequently, the forms of their bodies came to follow the functions dictated by their environment—sometimes termed their environmental constraints. All three groups' general body plan began to approach a hydrodynamic ideal for a water-living animal: a streamlined fusiform, or spindle shape, efficient in passing through an aqueous medium. Besides this feature, pelagic, or open ocean-living, sharks, ichthyosaurs, and dolphins all evolved a dorsal fin to act as a vertical stabilizer for water travel. In addition, each group evolved a propulsive tail and a pectoral fin necessary for the demands of constant swimming and steering in water. Even more remarkable in this comprehensive example, dolphins' and ichthyosaurs' ancestors were both originally land-dwelling vertebrates that returned to the marine environment. This case presents an inclusive and persuasive argument for the reality of the phenomenon of convergent evolution.

As with the use of both living and extinct examples in the discussion of divergent evolution, the existence of fossil as well as contemporary species that display convergent morphology is convincing evidence for the process of adaptive evolution. Again, a continuity across vast stretches of time exists that connects evolutionary phenomena in a continuum.

Observation, Comparison, and Classification

Research in the field of adaptive evolution, especially the phenomena of divergence and convergence of species, began centuries ago with the simple process of recognizing relationships in the surrounding environment between living plants and animals. The search for a unifying order to tie the complex web of animal and plant life together in some meaningful manner was for a long time a part of natural science. The modern theory of organic evolution fulfills this goal admirably in many respects. The methods used to illuminate the intricacies of evolution still encompass the type of keen, analytical observation of phenomena and reflection on their causes and effects that characterized Darwin's studies on the voyage of HMS *Beagle*. Observation, collection of specimens for comparison, classification of specimens according to a meaningful scheme, and, finally, an attempt to sort out the processes involved in a way that agrees with the dictates of strict logic are hallmarks of the scientific method at work.

Researchers investigating evolutionary divergence and convergence have powerful aids in the form of increasingly sophisticated technology. The main focus of their work is the correct interpretation of the path that various lineages took over time to arrive at known, living forms or extinct forms. In the case of living forms, technology originally developed in the field of medicine has been pressed into service to help establish relationships. For example, detailed analyses of various body tissues and fluids have been employed. Blood types have been traced with varying degrees of success, as have various proteins. Powerful optical microscopes are employed to analyze various tissue types and their structures. Since the invention of scanning electron microscopes, these more powerful instruments have further aided in probing the compositions and textures of animal and plant tissues to determine affinities among various species. In addition to these methods, very sophisticated laboratory techniques are now used to unravel and analyze deoxyribonucleic acid (DNA) strands and to try to determine the actual genetic encoding possessed by a particular organism. All these methods help establish more clearly the picture of biological relationships in regard to ancestries.

This physiological approach is obviously of limited utility with regard to fossil species. Except for such instances as the various ice age animals that were frozen in such environments as the tundra, extinct life-forms cannot be analyzed by medical means, as the original tissue has been transformed or destroyed by geological processes. In the case of most fossil forms, hard body parts such as bones and teeth (for vertebrates) and exoskeletons (in the case of invertebrates) must be analyzed in a more structural way to determine possible evolutionary relationships.

The clarification of the paths that various animal and plant lineages took during the process of their evolution further confirms the validity of basic organic evolutionary theory such as natural selection and adaptation. Study of divergent and convergent species is part of the ongoing study of living organisms that make up the functional ecosystems of which humankind is also a part. Learning more about these ecosystems and the parts that all the member species play within them is extremely important in the light of the contemporary world picture of pollution, overpopulation, and industrialization. The increased insight into how ecosystems operate from the species interaction approach is one of the positive by-products that studies of divergent and convergent evolution among species provide.

Carroll, Robert L. *Vertebrate Paleontology and Evolution*. New York: W. H. Freeman, 1988. A thorough treatment of the complex subject of vertebrate evolution. Each vertebrate order is covered by a chapter profusely illustrated with excellent anatomical drawings, which discusses at length the order's biological characteristics, adaptations, and occurrence in the fossil record. There are also chapters that clearly explain evolutionary concepts in an understandable way. Convergence and divergence are treated within the greater context of biological evolutionary phenomena.

Cvancara, Alan M. *Sleuthing Fossils: The Art of Investigating Past Life*. New York: John Wiley & Sons, 1990. Intended as a portable reference book aimed primarily at amateur fossil collectors and nonprofessional enthusiasts, this "how to" book also is designed as an authoritative introduction to the subject of the total fossil record of the earth and its implications for the subject of organic evolution. Good black-and-white photographs enhance the text, along with some graphs and drawings. Little science background is assumed, except for a very basic high school level.

Orians, Gordon H., and Otto T. Solbrig, eds. *Convergent Evolution in Warm Deserts*. Stroudsburg, Pa.: Dowden, Hutchinson & Ross, 1977. A series of summaries of a large-scale, comparative study undertaken by more than twenty different scientists from both South and North America. The study aimed at determining the degree of actual convergence attained by the flora and fauna in two geographically remote deserts: the Sonoran in the American Southwest and the Monte in Argentina. The deserts analyzed were chosen because of their similar topographies, soils, and climatic conditions. Photographs, drawings, diagrams, and charts help make this book an exceptionally useful reference on the subject.

Paul, Gregory S. *Predatory Dinosaurs of the World*. New York: Simon & Schuster, 1988. A meticulously thorough book that covers almost every conceivable aspect of theropod, or flesh-eating, dinosaurs. Evolutionary convergence and divergence among the theropods is adroitly explained.

Ridley, Mark. *Evolution*. 2d ed. Boston: Blackwell Scientific, 1996. A college-level textbook in evolutionary biology. Explains the theory of evolution in four sections: evolutionary genetics, adaptation and natural selection, evolution and diversity, and paleobiology and macroevolution. Includes a Windows/Mac-compatible CD-ROM with extensive supplementary material, including interviews with evolutionary biologists, animations explaining difficult concepts, interactive experiments and timeline, and a mini encyclopedia of terms with video clips, animation, photographs, and diagrams.

Savage, R. J. G. *Mammal Evolution: An Illustrated Guide*. New York: Facts on File, 1986. Presents mammalian evolution in a colorful, highly illustrative manner, with frequent use of lifelike reconstructions of extinct forms going about their hypothesized daily lives. Skeletal and dental diagrams are also frequently used to explain the evolutionary adaptations and innovations of various groups. The authoritative text succeeds in clarifying the various concepts and points of evolutionary theory covered, among which are convergence and divergence. A clearly written reference work for scientifically inclined high school and college students.

Strickberger, Monroe W. *Evolution*. 3d ed. Sudbury, Mass.: Jones and Bartlett, 2000. Introductory textbook for college students. Traces current ideas about how, why, and where the world and its organisms changed throughout history. Broadly covers all evolutionary topics in the fields of anthropology, biochemistry, comparative anatomy, molecular biology, population, ecology, and population genetics.

COPULATION

Type of animal science: Reproduction
Fields of study: Anatomy, developmental biology, embryology, reproduction science

Copulation, also called coitus or sexual intercourse, is the process by which sperm are placed directly into the female reproductive system by the male reproductive system, thus assuring that sperm and ova are in close contact for fertilization. It is also a critical adaptation for land-based reproduction, since on land, unlike in the water, sperm released into the environment cannot swim to ova that have also been released. The behaviors leading up to copulation are also important in assuring that gametes of the same species meet for fertilization.

Principal Terms

AMPLEXUS: a form of pseudocopulation seen in amphibians, where the male mounts and grasps the female so that their cloacae are aligned, and eggs and sperm are released into the water in close proximity and at the same time

CLOACA: a common opening for the reproductive, urinary, and digestive systems

HEAT: that part of the estral cycle when the female is receptive to male copulatory behavior

SEMEN: fluid produced by the male reproductive system that contains the sperm

Animals have many diverse strategies to ensure that eggs and sperm are in close enough proximity for fertilization to take place. One widespread process that is seen in many different phyla is copulation. Copulation is seen in many aquatic phyla and is the rule in terrestrial phyla. In most forms of copulation, the male reproductive system has an intromittent organ, often called a penis, which deposits sperm into the female reproductive system. Once there, sperm can travel the short distance to the eggs.

In some organisms, pseudocopulation is seen. In hermaphroditic oligochaetes, such as earthworms (*Lumbricus terrestris*), two worms align in opposite directions so that their genital pores are applied to the openings of the seminal receptacles of their partners. Semen released by the genital pores flows into the seminal receptacles where it is stored. Fertilization, however, is actually external. The worms build cocoons where they lay their eggs and then deposit the stored sperm. Amphibian amplexus is also a form of pseudocopulation. Here, the male frog clasps the female in such a way that their cloacae are in close proximity. Sperm are not deposited in the female's cloaca, however. Instead, both sperm and eggs are released into the aquatic environment for external fertilization.

Copulatory Organs

True copulation takes many forms. In several invertebrates, such as a few flatworms (some Acoela, Rhabdocoela, and Polycladida) and the bedbugs (Cimicidae), hypodermic injection is sometimes seen. In this form of copulation, the female has no external gonopore and the intromittent organ punctures the epidermis and deposits sperm in the underlying body tissue. This sperm must then migrate through the intercellular spaces to the female reproductive organs for fertilization of the eggs to occur. In most organisms, however, the male does not have to pierce the female's epidermis, but instead deposits sperm in an already-present opening of the female's reproductive system.

In birds and some reptiles (such as the tuatara, *Sphenodon punctatus*), the male does not have a true intromittent organ. Instead, the male must manipulate the female during mounting so that their cloacae are pressed against each other. During this "cloacal kiss," the male ejaculates sperm into the female's cloaca. In some bird species, a false penis is present in the male. These organs are not connected to the ducts of the male reproductive system and thus do not serve as intromittent organs. There is speculation that they may provide a necessary stimulation to the female during copulation.

In some fish, fins are modified for semen delivery. In guppies and their allies (Poeciliidae), gonopodia, modified anal fins, are used for insemination. Each gonopodium is a hollow, tube-like structure formed from the paired anal fins of the male. When mating, the male inserts his gonopodium directly into the female's gonopore. Usually, not all the sperm are used to fertilize this batch of eggs, and the rest is stored in the oviduct walls for future fertilizations. Other fish (such as the Coodeidae) have the anal fins modified into andropodia, which are cup-shaped structures that direct the flow of semen into the female without the andropodia actually entering the female's gonopore. Sharks (Elasmobranchii) have modified pelvic fins called claspers, which the male directs into the female's cloaca for insemination. Each shark has two claspers and, depending on species, either the one closer to the female or both are inserted for copulation.

Males of mammals, some reptiles, and many arthropods also have intromittent organs that deposit sperm directly into the female reproductive tract. In these copulations, by either female behavior or male manipulation, the opening of the female reproductive tract must be exposed. In many organisms, the male mounts a squatting or otherwise stationary female. Male snakes and lizards (Squamata) have two intromittent organs called hemipenes. Males and females line up side by side and the male uses the hemipenis closer to the female to inseminate her. Many arthropods often go through intricate body contortions to bring the male's penis in proper position for mating. This may be the common rear-mounting pattern, but can also be face-to-face or tail-to-tail. In many animal species, insertion of the penis is followed by one or more thrusting movements that lead to ejaculation.

Copulatory Behaviors

Among animals, both the lengths of time per copulation and the frequencies of copulation vary widely. When a female lion comes into heat, the male will remain near her, copulating up to one hundred times a day for periods up to ten days. Each copulation, however, lasts for just a few seconds. Other animals may copulate only once, but the copulation may be prolonged. Canid females do not usually remain stationary for mating. To remedy this, once the male mounts, his penis becomes further engorged and this effectively locks him to the female long enough to ejaculate even if she tries to get away. Other animals have hooks and barbs on their penises that may also help to lock them to a female for prolonged copulation. In some animals, prolonged copulation can last sev-

Echidna Mating

The female echidna, or spiny anteater (*Tachyglossus aculeata*), an Australian monotreme mammal, makes it rather difficult for the male to access her cloaca. As a female comes into heat, she is followed closely by one or more males that will try to mate with her. When she is ready to mate, she lies flat on the ground on her abdomen, often grabbing a tree or other support with her forelegs. This directs her cloaca toward the ground, certainly not exposed toward the male. If there are no other males present, the single enterprising male must dig a ditch on one side of the female. When it is deep enough, he can descend into the ditch, turn on his back and insert his tail beneath the female's tail. This positions his penis to enter her cloaca and deposit semen. When more than one male is present, they dig a semicircular rut on both sides of the female's tail, in which rut the males jostle for position until one finally maneuvers his tail under the female's. If all goes well the female lays a single small egg a few weeks later that she incubates in an abdominal pouch until hatching.

eral hours. This may be a mechanism to prevent other males from fertilizing the same female. Females can also play a role in prolonging copulation. In some water mites (*Arrenerus* sp.), the female gonopore can be opened or closed by means of chitinous plates. The smaller male inserts his intromittent organ into the female's gonopore, which then closes, trapping the male. Although sperm transfer is thought to occur in the first few minutes, the female may swim off dragging the male with her for several hours.

Copulation can be dangerous to males. In the domestic honeybee (*Apis mellifera*), a swarm of drones pursue the unmated queen. In-air copulation occurs as a drone inserts his endophallus into the queen's sting chamber. After ejaculation, a small part of the drone's phallus remains inside the queen and the drone falls to the ground and soon dies. Several more drones mate and die until the queen's spermatheca is filled. Male spiders have to be very careful when copulating. If a male does not leave the female's web immediately after depositing his sperm, the female may envenomate and then eat him. The female praying mantis (*Stagmomantis carolina*) have also been known to begin feeding on the heads of males with which they are copulating. Luckily, the headless male can continue to deposit sperm.

CORAL

Types of animal science: Anatomy, classification
Fields of study: Anatomy, invertebrate biology, marine biology

Coral refers to a large group of marine invertebrates, class Anthozoa, in the phylum Coelenterata. Anthozoa form reefs, gorgeous coral bushes, and precious coral.

Principal Terms

BUDDING: development of asexually produced protuberances that become complete organisms

EXOSKELETON: an external skeleton

HORN: hard, smooth, keratinous material forming an external covering

LIMESTONE: the insoluble calcium-containing substance, calcium carbonate

PLANKTON: microscopic plants and animals that float in huge numbers in oceans

RADIAL SYMMETRY: symmetry around a central axis

Coral refers to a large group of marine invertebrates, class Anthozoa, in the phylum Coelenterata. Anthozoa form reefs, gorgeous coral bushes, and precious coral, used for jewelry. The individual organisms involved are coral polyps. They have protective calcium carbonate (limestone) or horn skeletons.

Stony corals of the order Scleractinia, also called true corals, form reefs. The reefs are limestone formations in oceans, made by billions of polyps. The polyps have saclike shapes, with a mouth at the upper end, surrounded by tentacles. Coral polyps form reefs from calcium taken from ocean water and deposited around their bodies.

Besides reef-building corals, their relatives, gorgonians, have skeletons of flexible, horny material. Gorgonians make coral bushes and lacy-looking coral fans. These formations are covered with live polyps, which are yellow, pink, purple, brown, and even black. Wherever they occur, such as in West Indian waters, the forms produced look like parts of underwater gardens.

Precious coral is used to make jewelry. It is produced by polyps closely related to gorgonians. This hard coral polishes into beautiful red, rose, or pink material that can be made into jewelry beads. Most precious coral grows as small "bushes" in the Sea of Japan and the Mediterranean.

Physical Characteristics of Coral Polyps

There are two colonial anthazoan subclasses, differing in radial symmetry. The first, Octocorallia, is composed of eight-tentacled animals. Included are gorgonians and red precious coral. Members of the second subclass, Hexacorallia, have six tentacles (or multiples of six tentacles). Hexacorallia include true corals (Scleractinia).

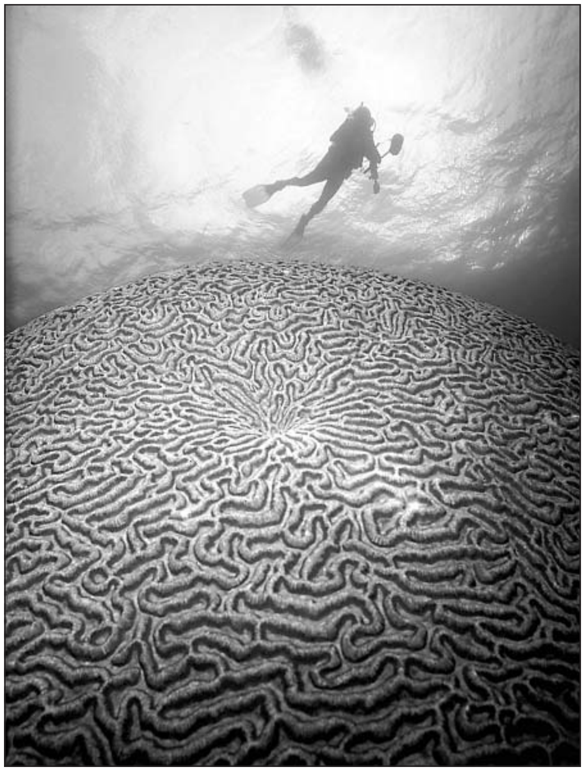
Most scleractinians are colonial. Their polyps have diameters of about 0.1 inches and are interconnected. The shapes of coral colonies, such as branched forms, depend on the coral species. Colonial corals can grow in deep waters, but reef-building corals occur only in warm, shallow ocean regions. The true corals secrete calcium carbonate from the bottom of each polyp, forming skeleton cups in which each polyp is anchored and into which it withdraws for safety. In an oral apparatus atop the stalk is an opening with tentacles and cilia. It serves as both mouth and anus. At night, the tentacles catch plankton and carry them to the mouth. Stinging cells on the tentacles paralyze prey.

Life Cycles of Coral Polyps

Each coral colony grows by asexual polyp budding. Live polyps build on limestone or horn deposits of past generations. In this way, they make new reefs or other coral masses. The polyps remain associated in colonies. The combined limestone- or horn-forming activity of a colony yields huge masses of coral. They may be dome-shaped or towering and branched.

Live polyps cover the outside of each mass and create its gorgeous colors, ranging among tans, browns, oranges, yellows, pinks, purples, and greens. When reef coral is removed from the ocean, the polyps die and wash off, leaving behind white skeletons. These corals build foundations for tropical atolls and barrier reefs.

Reef corals must live at depths where light penetrates, because symbiont algae (zooxanthellae) that live in their tissues require sun light for photosynthesis, and polyps cannot exist without the algae. The algae produce most of the carbon compounds that polyps use to make energy and protoplasm. The plankton caught by polyps provides the algae with nitrogen, phosphorus, and other nutrients otherwise unavailable. The coral's dependence on the algae varies with coral species and habitat.



This hard coral is composed of the fused, calcified exoskeletons of thousands of individual corals. (Digital Stock)

Coral Facts

Classification:
Kingdom: Animalia
Phylum: Coelenterata
Class: Anthozoa
Subclass: Hexacorallia (six-tentacled or six-tentacle multiples), Octocorallia (eight-tentacled)
Orders: Include Gorgonia (bush or fan corals), Scleractinia (true corals, Hexacorallia)
Geographical location: Mediterranean, Sea of Japan; east coast of the Americas from Brazil, through the West Indies, and along Florida coast; the Bahamas and Bermuda; South Pacific islands; East Indies; Indian Ocean; around Australia
Habitat: Marine, warm to tropical waters
Gestational period: None; reproduction uses asexual budding of indeterminate duration
Life span: Coral colonies can live indefinitely as living polyps grow on the skeletons of dead ones
Special anatomy: Tentacles, exoskeletons

Coral Reefs and Atolls

Coral reefs, elevated parts of shallow ocean floors, form by accumulation of calcium-containing exoskeletons of scleractinian polyps. The tropical reefs extend to 30 degrees north and south of the equator. They form only in shallow waters, at temperatures of 65 degrees Fahrenheit or warmer.

The three reef types are fringing reefs, barrier reefs, and atolls. Fringing reefs extend from the shore, with no body of water between reef and land. Barrier reefs are farther offshore, follow shorelines, and are separated from them by lagoons. They form barriers between the shore and the open ocean. Atolls are coral islands that have narrow, horse-shoe reefs and shallow lagoons. Many South Pacific islands are atolls.

Reefs are especially abundant on the east coast of the Americas from Brazil to the West Indies, along Florida's coast, and through the Bahamas and Bermuda. Very beautiful reefs occur in the South Pacific islands, the East Indies, and near Madagascar. The most magnificent coral reef is the Great Barrier Reef of Australia, over 1,200 miles long.

Polyps that build reefs have diameters from 0.05 inches to 1 foot. Constant battering by the ocean breaks up the reefs. The pieces accumulate over time, and eventually reach above the ocean surface. Soil deposited by ocean water lodges on them, and seeds wash up and become vegetation. Then the pile of coral debris becomes a coral island or atoll.

COURTSHIP

Type of animal science: Behavior
Fields of study: Ethology, invertebrate biology, zoology

Courtship is a set of behaviors that function to bring males and females of the same species together for the purpose of mating and reproduction. Courtship usually is quite similar among individuals within a species but is usually quite distinctive among individuals of different species. The behavior increases the likelihood that males and females are brought together at a time when mating is most likely to be successful.

Principal Terms

ARACHNID: a class of arthropods with jointed legs and hard external skeleton that includes mites, scorpions, spiders, and ticks

ESTRUS: the period during a female's sexual cycle when she is sexually receptive

LEK: a territory used by certain animals for mating

MONOGAMY: a mating system in which one male pairs with one female

PHEROMONE: a chemical produced by one animal that influences another animal of the same species

POLYGAMY: a mating system is which an individual of one sex pairs with several of another sex

Courtship is the ritualistic behavior animals carry out preceding mating. The courtship process allows the male and the female of the species to attract each other and choose a mate for reproduction. This behavior varies greatly among the species. Courtship rituals for mating can be as simple as sign stimuli, such as the emission of pheromones by certain female moths, to the complex dance of the stickleback or the bowerbird.

In nature, most animals are solitary except when courting and rearing their young. For each animal the signals used to communicate with and attract a mate must be clear and unambiguous. This is to avoid any confusion in identifying the sex and species of an animal's potential mate, as the ultimate goal of nature is to encourage reproduction and survival of all species.

The procreation process in most multicellular plants and animals involves a complex form of sexual reproduction. Here unique and differentiated male and female reproductive cells called gametes unite to form a single cell known as the zygote. The zygote undergoes successive divisions to form a new multicellular organism where half the genes in the zygote come from one parent and half from the other, creating a singularly different living creature.

The sexual reproduction process requires a pair of distinct partners of opposite sexes to mate, hence the need for courtship, so that animals can find and attract prospective mates for producing offspring. It is the sexual interest of the opposite sexes that leads to mating; therefore, copulation in most animals is preceded by a period of courtship. The mating of most lower animals is governed by endocrine secretions specific to certain seasons. In female mammals, receptivity to mating is called estrus, which is operative only for short periods during the year. Cows have several such periods of estrus during the year; dogs have one or two.

As courtship is always a precursor to mating, which leads to the proliferation of the species, it is often intermixed with both greeting and aggression. Often the aggression is directed toward a rival that might wander into marked territory. What is fascinating is that quite often it is difficult to distinguish between greeting and aggression. There are many different types of courtship be-

Pseudoscorpions: Unusual Courtship in Invertebrates

Pseudoscorpions are arthropods in the order of Pseudoscorpinadea. These are a group of small arachnids, such as spiders, mites, and ticks, that look like scorpions but do not have the scorpion's tail and sting. Even though the sexes in these creatures look very similar, they have complex courtship displays. The male in some of these species will drop a sperm bundle or spermatophore, which is often in the shape of a stalk, onto the ground. The female is attracted to this either by some chemical in the deposit or by a strand of silk left by the male. The female situates herself on top of the spermatophore and admits it into her own body through her genital opening. There are other species where the male steers the female to the spermatophore and helps her to position herself above it. He does this by grabbing her pedipalps. These are small appendages that resemble pincers with poison glands at their tips. The male pushes and vibrates against her to help in the reception of the sperm into her body. After the successful transmission of the sperm into her body, the female is ready to produce eggs. At this point, the female in several species of spiders will devour the male simply for nourishment. Although this is quite a common practice in spiders, the black widow is renowned for it, hence the name. This carnivorous mating behavior is not uncommon in nature. The female praying mantis, which is not an arachnid, does the same with its mate.

havior, including shoaling, nest building, mouth or pouch brooding, parasitic mates, carnivorous mates, marking territory, pair bonding, domination, female dominance, bower building and gift offerings, communal display, exotic pirouettes, group breeding, monotremes, odor marking, color signals, sounds, and migration.

Fish Courtship

The male stickleback, a fish similar to the minnow, orchestrates its mating by changing its color. During breeding season the underside of the male turns bright red. The bright red not only attracts females but also instigates attacks from other males. In fact, studies have shown that during this time, just about any red object can provoke male stickleback aggression. The female's response to the red signal of the male stickleback is to advance in a posture that clearly exhibits her swollen, egg-filled underbelly. This stimulates the male to carry out a zigzag dance that in turn seduces the female into following him to the tunnel-like nest he has built. The male waits until the female struggles into the nest and immediately touches her tail with his nose and starts quivering. The vibration causes the female to release her eggs so that the male stickleback can externally fertilize them. If for some reason the male is unsuccessful in executing the last part of this intricately choreographed dance, the female will not lay her eggs. However, it is extremely interesting to note that vibrating the female with some arbitrary object, which she may even realize is not a male stickleback, works just as well to induce the release of the eggs, although, as the male did not complete the last step of the courtship ritual, he does not fertilize the eggs, but rather eats them.

Amphibian and Reptile Courtship

Amphibians have varied and interesting courtship rituals. Generally the tailless amphibians breed communally. Amphibians such as frogs or toads will use sound to attract their mates, whereas male newts use odor to attract the females. The American tree frog (*Hyla crucifer*) sings in trios. Only the males have vocal sacs that can make sounds; the females are silent. The sounds of the males among the different species are distinctly different and versatile. The notes are delivered in different speeds and frequencies. The female has her own features of recognition. The way a female frog advertises her sex and readiness for mating is that she develops a series of granulations on her thighs, which is clearly visible to a male frog. During courtship many amphibians use their heads in different ways to rub their partners. For most frogs, the male climbing onto the female's back and aiding in the discharge of her eggs accomplishes mating. The male in turn releases his sperm after being excited by the female's movements.

In reptiles, even though the courtship behavior is not very complex, bobbing, circling, and marking of territory is noticed. Snakes such as the crotalids, including vipers and rattlesnakes, have a mutual dancelike ritual for courtship. As the snakes circle each other, they rear up facing one another and intertwine together for copulation. Most snakes of the Crotalidea family give birth to living young from eggs that hatched inside the mother's body. The colubrids, such as the boomslangs and kingsnakes, and elapids, such as the cobras, have a nuptial procedure where the male rubs his lower jaw along the back of the female in an attempt to stimulate her. It is conjectured that perhaps this behavior also stimulates him and all the other males in the matrix group. A male snake copulates by throwing coils round the female and bringing their cloacas into juxtaposition. However, sometimes they simply lie close without the retaining coils. They may use a branch or similar object to maintain a grip to hold them close together. Even though most snakes are more aggressive during mating season, few males fight among themselves. Other than among the elapids there does not seem to be much competition among the males.

This is contrary to what is noticed in crocodiles and alligators. In these reptiles, the breeding season for the males is a loud and contentious time. They will battle and resist any potential competitor with ritual gaping, lunging, and hissing. Yet the courtship behavior is serene. The male marks his territory using a secretion from his musk glands. This not only warns off unwelcome male rivals, it also attracts females. Male crocodiles and alligators confidently bellow their love calls to make their presence and location known to the females. Once a female gets paired with a male, they swim together. They progressively increase their speed and the male rubs his throat against the female's snout to mark her with his odor, and vocalizes without encumbrance before he copulates with her. The male leaves to find his own area after mating. The female goes on to build a nest above flood level using mud and vegetational debris. She covers her eggs with mud and decaying vegetation so that the sun's heat will incubate her eggs. She guards her eggs until they are hatched. She may aid the young ones to get to the water's edge by carrying them in her mouth. It has been observed that some female alligators may even stay with their young for a year or more. A female alligator is quite protective of her young and responds quickly to the sharp croaks of a young one in distress.

Bird Courtship

Birds in general have engaging and quite elaborate courtship rituals. Usually birds do not stay with the same mate all year round or from year to year. Sometimes the same pair may be together for several years, but nonetheless the pair bond, that is, the relationship of the couple, must be renewed or reinforced at the onset of each breeding season. Birds use auditory, visual, or both kinds of display in order to conclude their courtship ritual. Peacocks use intricate visual displays that involve specialized plumes. In the barbets and wrens, duetting is used for courtship and attracting the mate. The male and the female alternate their calls in such exact synchronization that it seems as though the sound is coming from one bird. This is an example of an auditory display. Some birds, such as ducks, follow an extremely stereotyped movement pattern. However, both birds must respond with the correct display or the sequence is broken. There are certain birds where a pair bond does not exist at all. The male birds gather together and display against each other, contending for the right to mate with the maximum number of females possible. This type of a gathering of males is called a lek. The bird of paradise is well known for this particular type of courtship behavior. Other examples would be manakins, sandpipers, and grouse.

The different types of bowerbirds are renowned for their extraordinary courtship behavior. These birds are commonly found in New Guinea and Australia. It is believed that the bowerbirds are close relatives of the birds of paradise of this area. For the most part, the males and females live apart from each other during the course of the year. Only during mating season do the males gather together and compete for females. Each male bird creates a clearing on the forest floor that becomes his "playing field." This is where he tries to entice and lure the females. The bird will arrange rocks, shells, colorful fruits and berries, flowers, and inanimate articles such as pieces of glass or other interesting manmade items. In some species, the males will construct different types of forms and structures. Some of these birds erect what look like upright poles of sticks around a tree trunk that are embellished with colorful flowers, mushrooms, lichens, and other objects.

The Australian male satin bowerbird is a silky blue-black bird that is approximately 20 centimeters (about 7.8 inches) long, with bright blue eyes. The male bird builds a stick mat. He then places two walls of vertical sticks down the middle. These walls may reach a height of thirty-eight centimeters (sixteen inches). The bird then mixes his own saliva with a blue or green fruit juice to form a "paint." He uses a tree bark to paint the bower, and tries to attract the grayish-green female into the bedecked bower to mate. This is one of the few known instances of birds using tools.

Another species known as the gardener or Vogelkop bowerbird makes a tentlike structure that resembles a teepee. The bird is only about 25 centimeters (10 inches) long, but the teepee can be as extensive as 1.6 meters (63 inches) across. This little teepee comes complete with a low entranceway overlooking a "garden," consisting of brightly colored flowers and objects that are diligently replenished as soon as they fade. There are about nineteen species of bowerbirds and they all have similarly elaborate courtship displays.

Mammal Courtship

Mammals have evolved to have the most sophisticated sexual apparatus of all animals, yet in general mammals do not spend as much time in courtship as birds do. Mammals also have the most highly evolved manner of parenting. Therefore, the relationships between mates are diverse. Lower mammals, such as some rodents, practice promiscuous polygamy without any particular selection process by the female. The females are left to rear the young on their own. In bears, both the male and female are promiscuous. There are others where the male appears to have a harem. The California sea lion may have up to forty females, the Pribilof seal from forty-five to a hundred. Many deer and antelope have harems, too. Even the sedate koala may monopolize several females. These are also examples of dominance. Dominance can also extend toward other males, so that the dominant male can have all the females to himself.

Monogamy is rarer in mammals. A few canines are monogamous, but only for a particular season. Some monkeys and apes, not including chimpanzees, follow this rule. Foxes may be monogamous, and the American beaver is one rare mammal that practices monogamy for life. Even in the higher mammals, including humans, monogamy causes a decline in sexual interest for the partner and eventually sexual relations may cease if there is no stimulus of novelty. There is also the other extreme, where the animals are solitary and only meet for copulation, such as the titi monkey.

Most mammals tend to be complacent in their efforts at enticement, and rely on simpler stimuli such as secretions, color changes, and odors. For mammals, arctic foxes have an elaborate and rather graceful courtship dance. They rear up on their hind legs and face each other as though they are playing. The elephant has a most gentle approach to courtship. The female is attracted to the male by the strong scent of the two glands near his ears, which start to secrete during rut. Once the male and female have found each other, they caress one another with their trunks and intertwine these sensitive organs. They express their affection and confidence by placing the tips of their trunks in each other's mouths.

In some species, the female takes the initiative for mating. A small number of primates will do so. When the female is ready she entices the male to attend to her. The female hedgehog will lift her tail up and lay all her spines down to solicit the male for mating.

Odor marking is very common in placental mammals. Most male mammals, even the pack animals, will mark out their territory by odor glands, urine, or feces. Some will mark the female as a sign of ownership. There are others that display color, signaling a potential partner of the opposite sex of its interest in mating. The female gelada baboon, which mostly spends her time sitting, develops a red patch on her chest similar to the one in her genitals, so that both markings can be easily observed by other baboons.

In many different animals, migration is required as part of the courtship and breeding process. Migratory rituals exist in just about all types of animals: fish, birds, and mammals. Some fish, such as the salmon or sturgeon, will travel thousands of miles in order to return to their ancestral waters to spawn. The urge is so strong that the fish will die trying to reach this place rather than give up.

Ultimately, nature's most primordial instinct is to continue the species. Every living organism feels the irrepressible compulsion to perpetuate its genes. This necessitates sexual selection, Darwin's other type of natural selection. The consequence is sexual dimorphism, including different size, color, and traits in the sexes. There are two types of sexual selection: intrasexual selection, where males contend among themselves through contests and displays for the favor of a female; and epigamic selection, where the females accept males with certain characteristics. The male may monopolize the females by practicing polygamy and thereby effecting a much more intense sexual selection for procreation purposes. Courtship behavior is about sexual selection, which eventually leads to the proliferation of the species.

—Donald J. Nash

CRABS AND LOBSTERS

Types of animal science: Anatomy, classification
Fields of study: Anatomy, invertebrate biology, marine biology

Crabs and lobsters are joint-legged crustaceans of the phylum Arthropoda. Phylum characteristics include a chitinous exoskeleton, jointed appendages, a ventral nervous system, and a dorsal brain.

Principal Terms

ABDOMEN: posterior portion of a crustacean

CEPHALOTHORAX: combined head and thorax

CHELICERAE: also called pincers, claws, or chelipeds, these are the enlarged first and sometimes second pairs of walking legs, which are used for feeding, defense, or sexual recognition

DECAPODS: animals with ten appendages (from Greek *deca*, "ten," plus *poda*, "foot or leg")

THORACIC: related to the middle section of the body of arthropods, which are generally subdivided into a head, thorax, and abdomen; both thorax and abdomen may have several segments

Crabs and lobsters are joint-legged animals that belong to the phylum Arthropoda. This diverse phylum of animals also includes the insects, spiders, ticks, mites, millipedes and centipedes. Phylum characteristics include a chitinous exoskeleton, jointed appendages, a ventral nervous system, and a dorsal brain. Both crabs and lobsters are crustaceans, which are placed in the class Malacostraca along with the shrimp. Crabs differ from lobsters in having a broad upper shell or carapace and an abdomen that is shorter and either tapered or tucked forward beneath the carapace.

Because they have five pairs of legs, crabs and lobsters belong to the order Decapoda. The first one or two pairs of legs are typically enlarged and modified as chelicera, which are variously used for feeding or defense. In some decapods they may also have a sexual function. The remaining three or four pairs of legs are used for walking, or, in some species, swimming or climbing.

Crabs

There are two kinds of crabs. The irregular-tailed crabs, or Anomurans, include the hermit, porcelain, and mole crabs. Some have a small, tapered abdomen, and others, especially the hermit crabs, have a somewhat coiled abdomen that is tucked into a discarded snail shell. The true crabs, or Brachyurans (short-tailed crabs), have a greatly reduced abdomen that is tucked forward beneath the carapace.

Contrary to popular belief, crabs do not always scuttle sideways; they can walk forward or backward with equal facility. A few of the fast moving crabs seem to use two pairs of legs when running. The blue crab (*Callinectes sapidus*) family, which also includes the familiar lady crab (*Ovalipes ocellatus*) have a paddlelike last pair of appendages and are fast and agile swimmers.

Crabs vary greatly in size and shape. The smallest are pea crabs, which measure only a few millimeters across the carapace, while the legs of a Japanese spider crab can span up to four meters. The differences in size and shape have allowed crabs to colonize a wide range of habitats. Most of the 4,500 species of true crabs are marine, inhabiting the rocky intertidal zone or burrowing in sand and mud. Some species are benthic and others invade freshwater, especially in the tropics. Still others are terrestrial or semiterrestrial, often ranging far away from water, although they generally prefer moist places. A tree-dwelling tropical species feeds on coconuts.

Ecologically, almost all crabs function as scavengers, feeding on dead or dying animals or organic debris of any kind. Many species are also active predators, capable of killing small fish and breaking open the shells of different mollusks. Porcelain crabs, for example, have one of their mouthparts equipped with long, feathery setae that are swept through the water. They catch small particles and transfer them to other parts of the mouth, where they are eaten. Organic matter is dismembered by the pincers and conveyed to the mouth by a series of appendages called maxillipeds and maxillae. A pair of comblike mandibles guard the mouth and chop the food into tiny pieces, which are then swallowed. A short esophagus leads to a gastric mill analogous to the gizzard of other animals, where food is ground up.

Crab Reproduction

Reproductive behaviors vary, but during courtship males may use various chemical, visual, or acoustic signals including pheromones, waving chelipeds back and forth, or drumming at the entrance to the female's burrow. Other males build pyramid-shaped mounds to attract females. Following courtship the male transfers sperm to her in a packet called a spermatophore. The eggs are attached to the female's abdominal appendages and form an egg mass between the abdomen and the thorax. The abdomen is therefore out of place and hangs downward when the female is carrying eggs. The eggs are usually brightly colored with carotenoid pigments, and can be red, yellow, blue, brown, or green. They range in size and number between species, but a large marine crab can lay up to a million eggs at a time. The tiny larvae are called zoea and are very common summer components of marine plankton. It takes one or two

Crab and Lobster Facts

Classification:
Kingdom: Animalia
Phylum: Arthropoda
Subphylum: Crustacea
Class: Malacostraca
Order: Decapoda
Families: Homaridae or Nephropsidae (true lobsters), Palinuridae (spiny lobsters or sea crayfish), Scyllaridae (slipper, Spanish, or shovel lobsters), Polychelidae (deep-sea lobsters); Brachyryncha (true crabs), Anomura (irregular-tailed crabs)
Geographical location: All the earth's oceans, except at the poles
Habitat: Mostly marine, although some crab species live much of their lives on land near salt water
Gestational period: Lobsters, eggs hatch in one year
Life span: Lobsters, up to fifty years
Special anatomy: Segmented exoskeleton; large claws on front pair of legs (one often larger than the other); eyes on the ends of stalks

more molts before the crablike form is evident. Many of the semiterrestrial and freshwater species develop directly into miniature crabs.

Lobsters

Millions of American lobsters (*Homarus americanus*) are harvested for food each year, making them possibly the most commercially important of all crustaceans. Lobsters differ from crabs in having an extended thorax. Most are large: up to sixty centimeters in length and twenty-two kilograms in weight. The first pair of walking legs is modified into large claws or chelipeds. The European lobster (*Homarus gammarus*) is similar in shape but somewhat smaller. Lobsters walk forward using their walking legs, but when threatened swim rapidly backward using their broad tail segment or telson.

Ecologically, lobsters are creatures of rocky subtidal zones that rarely extend activities shoreward. Eggs are laid in late summer, generally July and August of every other year, and are glued to the female's abdominal appendages. They hatch in about a year and the young remain attached for some time before drifting free and becoming part of the plankton.

The spiny and slippery lobsters of the tropics and pantropics are not closely related to the American lobster. Some reach the size of American lobsters, but lack pincers. Spiny lobsters are noted for their mass migrations during fall, in which up to fifty individuals march together, heads-to-tails, in long queues. Females are capable of producing four million eggs during the spring reproductive season. The transparent juveniles attach to jellyfish and undergo a series of molts for about a year, gradually transforming into a five-centimeter lobster. Lobsters actively forage for live prey, including worms, mollusks, crabs, and small fishes, as well as organic debris.

Crustaceans as Food

Crabs are food for a variety of other animals, including fish and larger invertebrates. To protect themselves, some species carefully place sea anemones on their carapace, while others, such as the decorator crab, glue pieces of shell all over their carapace. Still other species, such as the pea crab, take refuge inside oysters and other shellfish, while boring crabs dig burrows into mud substrates or soft limestone rocks.

Both crabs and lobsters are important food for humans as well. Crabs are caught in traps or by crab dredges. The most highly prized are soft-shelled crabs, which are really the ordinary species of crabs that are caught just after molting and before they have had time to secrete a new shell. Both American and European lobsters are the centers of a fisheries industry measured in the billions of dollars annually. They are caught in baited lobster pots. Coastal pollution and over-fishing coupled with an apparent die-off of the American lobster population in the Northeast has spawned millions of federal dollars in research to determine causes and provide restoration protocols. With the demise of the American lobster population, most of the frozen lobster tails shipped to market are the spiny or slippery lobsters, which are caught in tropical and subtropical waters of the world.

CRANES

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, physiology, population biology, wildlife ecology

Cranes are among the oldest of living bird groups, dating back sixty million years. Their interesting appearance, majestic flight, and unusual behavior characteristics have made them the subject of reverence and folklore around the world.

Principal Terms

FLYWAY: an established route that migratory birds take between their wintering and nesting grounds
MOLTING: the process whereby a bird loses its feathers and replaces them with new ones
OMNIVORE: an animal that feeds on both plants and animals
PREENING: a bird's act of grooming itself by cleaning and straightening its feathers
WETLAND: habitats that have an abundance of shallow waters, such as marshes and salt flats

Cranes are large wading birds that live in open wetland and meadow habitats. There are fifteen species of cranes in the world. North America is home to two species, the sandhill and the whooping crane. Sandhills are the most numerous of all cranes, and whoopers the least. Cranes are omnivores, though food preferences vary among species. As opportunistic feeders, they dine on numerous animal foods, such as fish, crustaceans, worms, insects, and small animals, and many plant foods, including berries, acorns, grains, and seeds.

Physical Characteristics of Cranes

Cranes vary in size from 2.5 to 6 feet tall, and weigh from five to twenty-five pounds. Their wingspan can measure up to 7.5 feet. Males and females look alike, though the male is usually larger. Plumage ranges from pure white to gray to brown. Many cranes have a red, featherless patch of skin on the head. Crowned cranes also have a golden ornamental tuft.

Cranes have long, slender legs and unwebbed feet, features that allow them to wade in shallow water and walk through mud. Their three large toes and a tiny back toe keep them from sinking. Cranes have long necks, and the length of the trachea correlates to the volume and resonance of vocalization among species. They also have pointed, powerful bills, which they use for obtaining food by fishing, digging, or foraging. They are also used for defense.

Crane Behavior

Most cranes are migratory, spending spring and summer in northern locations and wintering in more southerly habitats. A few species stay in the same location year round. The same flyway is always used. Unlike other birds, cranes learn the flyway through visual memorization rather than by instinct. Flock size varies from a single family to between fifty and one hundred birds. Cranes fly with their necks stretched out and their legs extended out straight behind them, distinguishing them from other large wading birds. They glide on thermal air currents to conserve energy. They are quite vocal during takeoff and landing.

Mating occurs in the spring, when the birds reach their northern nesting grounds. Cranes do not reproduce until they are about four years old. They mate for life and tenaciously nest in the same location from year to year. Nests are mounds of plant material, usually built in shallow water. Most species lay two eggs, and male and female share incubation. Generally only one chick survives to adulthood. The fledgling period lasts from two to five months, during which time the chick grows its feathers and the adults molt. Brooding parents are very protective. The young bird returns to the wintering grounds with its parents, but separates the following spring after migration.

Cranes have a distinctive, buglelike call and can be heard from up to three miles away. The most notable of the crane's vocal repertoire is the unison call between male and female, performed when mating or when defending their territory. It consists of a series of responsive, coordinated calls of differing length and pitch while the two birds stand in an erect, stylized position.

Cranes engage in many colorful behaviors, such as preening, defense posturing, stretching, feather ruffling, and head scratching. They are famous for their spectacular dance. One bird will lower its head and flap its wings, then leap upward with stiff legs, throwing its head upward. Another bird will respond with similar movements, and this may continue for several minutes. Although its function is not fully understood, it seems to correlate with a state of excitement. Dancing is exhibited throughout the year, often between bonded pairs, but also singly and in large groups.

Conservation

Changes to wetland habitats caused by building, farming, leisure pursuits, and pollution have threatened many crane species. The diminishing number of suitable habitats has interfered with their migration patterns and nesting habits. In 2000, the Siberian, Japanese, and whooping crane were listed as endangered by the International Union for Conservation of Nature and Natural Resources. Six additional species are considered vulnerable.

Around the world, efforts are being made to protect wetland ecosystems and reestablish dwindling species. In North America, biologists have been attempting to establish new migratory and nonmigratory flocks of whooping cranes. In the 1990's, a program was launched to establish new migration routes by imprinting chicks to follow an ultralight aircraft.

CROCODILES

Types of animal science: Anatomy, behavior, classification, ecology, evolution, geography, physiology, reproduction

Fields of study: Anatomy, conservation biology, ecology, herpetology, paleontology, physiology, reproduction science, systematics (taxonomy), zoology

The Crocodilia, comprising twenty-three endangered species, are the last surviving reptilian group of the subclass Archosauria, which also includes the extinct dinosaurs, pterosaurs, and the stem group Thecodontia. Crocodilians are the closest living relatives of birds, and most species are highly endangered due to hunting and habitat destruction.

Principal Terms

BISERIAL DERMAL ARMOR: bony plates running along side of the vertebral column

EUSUCHIA: the living Crocodilia

MEOSUCHIA: the first aquatic crocodilians of the Mesozoic

PROTOSUCHIA: the first crocodilians of the Triassic

SECONDARY PALATE: the palate forming a shelf in the mouth that places the internal nares far back in the throat

Classically, the order Crocodilia is divided into six suborders: Protosuchia, Archaeosuchia, Mesosuchia, Thalattosuchia, Sebecosuchia, and the Eusuchia. Today, Crocodilia are familiar inhabitants of rivers, swamps, and lakes, distributed in the tropical and subtropical regions of North and South America, the Caribbean, Africa, Asia, and Australia. However, crocodilians did not begin their evolution as amphibious reptiles. The earliest recognizable crocodilians arose in the Upper Triassic and appear to have been terrestrial in nature. Protosuchians are small, averaging below two meters in length. They have terminal nostrils, a single row of dermal armor on either side of the vertebral column, and elongated carpal bones and hindlimbs. They show other classic morphological features of crocodilians in that the pubic bone does not contribute to the formation of the hip socket as in all other reptiles. Before apparently giving rise to the Mesosuchia, the first amphibious crocodilians, the protosuchids, gave rise to another side group, the Notosuchia. The Mesosuchia appear to be the ancestors of the living Eusuchia. The Thalattosuchia are Mesozoic marine crocodilians, most of which have longirostrine (having long, thin jaws) mandibles adapted for fish eating. Some Thalattosuchia, the geosaurs, apparently were well adapted to the marine environment, having reevolved a tail fin for aquatic locomotion.

The living Crocodilia are all placed within the suborder Eusuchia. They are divided into three families, the Gavailidae, Alligatoridae, and Crocodylidae, the latter with its two subfamilies, the Crocodylinae, and the Tomistominae. The gharials or gavials of Nepal and India comprise the family Gavialidae. They are longirostrine crocodilians specialized for fish eating. They attain large size, growing to nearly nine meters. Their limbs are reduced more than in most crocodilians and they are unable to climb over obstacles of more than a half meter high. The Crocodylidae are divided into alligatorines, which include the American and Chinese alligator and the caimans, and the Crocodylinae, which include members of the genus *Crocodilus*, *Osteolaemis*, and *Tomistoma*. The placement of the fourth mandibular tooth in crocodilians has often been cited as the difference between these families, in that in alligatorines the

Crocodile Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Craniata
Class: Reptilia
Subclass: Archosauria
Order: Crocodyla
Suborder: Eusuchia
Families: Alligatoridae (alligators and caimans, four genera, seven species), Crocodilidae (crocodiles, three genera, fourteen species), Gavialidae (garials, two genera, two species)

Geographical location: Every continent except Antarctica and Europe

Habitat: Variable depending on species; freshwater lakes, rivers, streams and swamps, estuaries, and oceans

Gestational period: Approximately three months

Life span: Up to seventy years

Special anatomy: Quadrupedal; biserial dermal armor consisting of two rows of osteoderms running on either side of the vertebral column; secondary palate with fleshy valve; ear flap; verticalized braincase; elongated carpals; pubic bone is excluded from the acetabulum; extensive air sinus systems extending from the Eustachian tubes to the middle-ear cavity and skull bones

fourth mandibular tooth resides in a socket in the upper jaw when the mouth is closed. Within the crocodiles this tooth fits in a groove in the upper jaw and thus is visible when the jaw is closed. The longirostrine crocodilians, such as gharials, tomistomines, and *Crocodilus johnstoni*, have longirostrine jaws and have interdigitating teeth. Thus, the tooth character is equivocal in these taxa. Another method of dividing the living forms into the subfamilies has to do with salt tolerance. With one exception alligatorines are salt intolerant. Crocodiles are often found in brackish waters and some, such as *Crocodilus porosus*, have been found hundreds of miles off the coast of Australia. Unlike alligatorines, crocodiles have well-developed salt glands in the tongue. Gharials, although not marine, have salt glands in the tongue as well as an orbital salt gland. This trait may indicate an oceanic origin for gharials.

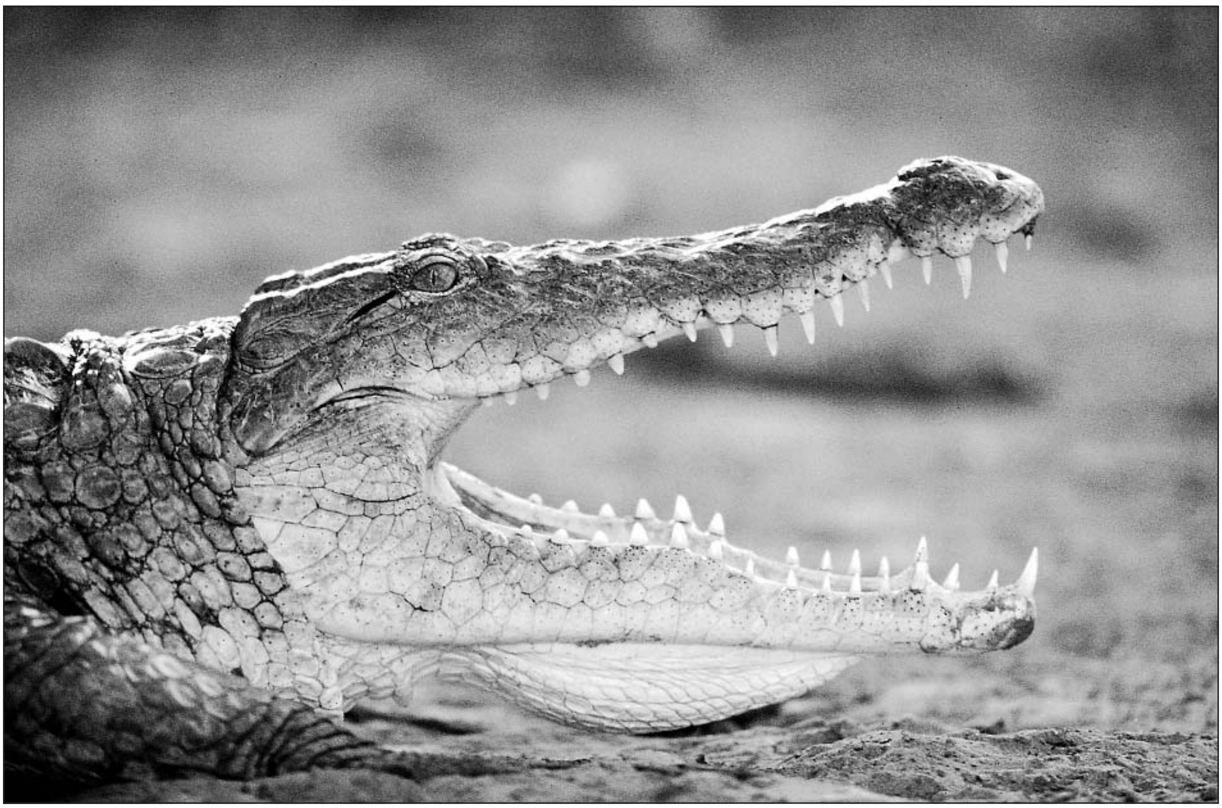
Aquatic Adaptations

Eusuchians are better adapted to the aquatic environment than their mesosuchian ancestors. The secondary palate is well developed, extending the internal nostrils back to the pharynx. The external nostrils face dorsally so the crocodiles can stay hidden in the water. Here a fleshy valve separates off the mouth from the pharynx and the internal nostril openings. Eusuchians also have an earflap or *Ohr Klappe* that closes off the external ear from the water during dives. The Eusuchia have enhanced the dermal armor and have a biserial or double row of osteoderms running on either side of the vertebral column. This dermal armor was once thought to be evolved for protection but this system is tied to back muscles that aid the crocodilians in bending the vertebral column for locomotion. Dermal armor was widespread in early archosaurs but is best-developed in eusuchian crocodilians. All crocodilians have a strong bite. Although crocodilians have jaw adductor muscles in the temporal region of the skull, the largest jaw adductor originates on the palate. Except for fish-eating species that have sharp, curved, conical teeth, most crocodilians have more squat-shaped teeth in the rear of the jaw for crushing. Crocodilians will often position turtles in the posterior region of the jaw in order to crush the shells of those they cannot swallow whole.

Crocodiles as Social Organisms

Crocodilians have complex mating rituals with both male and female mating displays. Both sexes engage in bellowing behavior, although male bellowing is of a deeper tone, as well as head splashing to announce their presence to potential mates. Moreover, males will create subaudible vibrations in the water above their backs, vibrating the water so that it "dances" above the animal's back, as a sexual display. Males may use bellowing to define territories during the mating season. Males will fight over territory and may not tolerate the presence of other sexually mature males in their territory during the breeding season. Females may approach males and by a series of rubbing moves indicate their intention to mate. Musk glands located under the lower jaws are used as a sexual perfume to arouse the male. The male also has musk glands that are used in response to the female scent. Mating occurs in the water, with the male on top of the female. Males have a copulatory organ, a grooved penis that is inserted into the cloaca of the female.

Many crocodilians, such as the American alligator and saltwater crocodile (*Crocodylus porosus*), build aboveground nests using foliage, while others, such as gharials, may dig nests in the sand. Temperature-dependent sex determination occurs in crocodilians. Low nest temperatures, below 30 degrees Celsius, produce females, whereas higher temperatures, above 33 degrees Celsius, produce males. Intermediate temperatures may produce males or females depending upon species. Thus, both sexes are found in a nest, since the temperature at the top of nest may differ from the temperature at the bottom. While egg numbers vary, many crocodilians lay forty eggs or more. In populations studied, only 2 percent of the hatchlings survived to maturity. When hatching occurs, crocodilians use an egg tooth to break the eggshell. Hatchlings inside the nest will bark or grunt to signal to the mother, who may defend the nest and may be nearby to come and help dig out the hatchlings. Female crocodiles may defend the hatchlings from predators that include other crocodiles. In some species, she will carry the hatchlings to the river in her mouth.



Crocodiles are the last surviving relatives of the dinosaurs. (Digital Stock)

The Gharial

The Indian crocodile, the gharial, is perhaps the most unusual living crocodile. It has an extreme longirostrine condition, where the elongated jaws are markedly set off from the skull. Below its skin, the gharial is different from all other crocodiles in the back and hindlimb muscles and the skull construction. It is worth noting that crocodiles as well as most other archosaurian reptiles have a verticalized floor of the braincase. Thus, in most crocodilians, the floor of the braincase is high and narrow. This feature of the braincase comes about only after the crocodile hatches. The function of this feature is to extend the space for the size of the jaw adductor muscles, thus increasing the crocodile's biting power. The gharial braincase is quite elongated and not high. They make up for some of this lost space for the jaw adductor muscles by elongating the back of the jaw and thus increasing the size of the pterygoideus muscle that helps close the jaws. The point of these differences in morphology as compared to other crocodilians suggests that gharials may represent a different lineage of crocodilians, apart from the Alligatoridae-Crocodylidae clade.

Diet and Locomotion

Diet is dependent upon the stage of life and the adult size. When crocodiles are juveniles they may eat insects, arachnids, small frogs, and snakes. Adults may eat snails, fish, turtles, small mammals, and birds. The larger species, such as *Crocodylus niloticus*, may take large prey such as wildebeest. Crocodiles may hunt cooperatively in bringing down large prey that a single individual cannot handle alone. Others species, such as caimans, may chase fish into the paths of waiting members of the population, or may herd fish to the shore for easy capture. Crocodilians are quite adept at stealthy behavior. They remain submerged and will slowly approach prey until they can leap or lunge to grab the prey in their viselike jaws. It is not the teeth that kill a prey but rather the crushing power of the jaws. If the prey is too large to kill outright, crocodiles will usually drown the prey animal and then tear it apart by rolling movements of the body. In this way two or more crocodiles can cooperate by holding on to the same prey animal and tearing it apart by combined rolling actions.

Aquatic locomotion is accomplished by undulations of the tail. There is a double row of elongated scutes running down the length of tail that may aid in swimming. The limbs are normally held against the body during swimming. Crocodiles show versatility in their terrestrial locomotion. Crocodiles are mainly quadrupedal in stance and gait; the limbs can be held at about 70 degrees under the body. Some of the smaller species, such as *Crocodylus johnstoni*, can gallop, while the saltwater crocodile, *C. porosus*, has been observed to run bipedally. All crocodilians are capable of leaping to capture prey. They appear to be fond of belly sliding as a means of locomotion over short distances, especially in entering the water.

Physiology and Size

Crocodilians are cold-blooded animals and must thermoregulate by means of evaporative cooling, using the mouth, and basking and shade usage behaviors. Crocodilians, like most reptiles, lack sweat glands. Despite the fact that crocodilians essentially have a four-chambered heart, there remains a small opening between the ventricles persisting as the foramen of Panizza at the base of the systemic and pulmonary trunks. Nonetheless, the crocodile heart is too small for the body to maintain a high metabolic rate. The stroke volume of the heart and the heart versus body mass ratio determines whether the animal may maintain high activity levels. Crocodiles have a metabolic rate that is about 4 percent that of an adult human. However, small crocodilians have higher metabolic rates than do larger species.

Crocodilians come in all sizes. Some of the caimans are small species, such as *Paleosuchus*, which may reach little more than five feet in length. However, other caimans, such as *Melanosuchus*, the black caiman, may reach up to twenty feet. Crocodiles also vary in length. The dwarf crocodiles of Africa, *Osteolaemis tetraspis*, may reach over six feet in length. The largest crocodilians are crocodiles. *Crocodylus niloticus* may reach over twenty-one feet in length, and specimens of *Crocodylus porosus* have been known to reach lengths of nearly thirty feet. Despite their size, some species of crocodilians, such as the gharials that are over twenty feet in length, are relatively harmless to humans because they are specialized for fish catching and cannot open their mouths very wide.

CRUSTACEANS

Types of animal science: Anatomy, classification, ecology, reproduction
Fields of study: Anatomy, ecology, invertebrate biology, marine biology, zoology

The twenty-five thousand species of crustaceans make up the class Crustacea. They are mainly aquatic arthropod animals which have jaws and two pairs of antennae. Examples are crabs, lobsters, and shrimp. Crustaceans are food for humans and whales and have useful ecological functions.

Principal Terms

CARAPACE: a hard, chitinous outer covering, such as a crustacean shell or insect exoskeleton

CEPHALOTHORAX: the anterior (front) section of a crustacean, consisting of a fused head and thorax

CHITIN: a semitransparent, hard, horny substance forming much of crustacean shells and insect exoskeletons

DECAPOD: any crustacean having five pairs of locomotor appendages (legs)

DORSAL: at the hind (posterior) end of a living organism

HERMAPHRODITE: an organism having both male and female reproductive systems

MOLTING: shedding part of or all of a crustacean carapace (shell)

The majority of animals in the oceans are crustaceans. The name indicates their class, Crustacea, which consists of aquatic arthropods having jaws and two pairs of antennae, such as crabs, lobsters, and shrimps. Crustaceans are among the most successful of animals, dominating the oceans as the insects dominate the land. They also live in freshwater, and some even live in moist land habitats. Most crustaceans are small, but they can differ widely in body form, size, and habits. The twenty-five thousand crustacean species include lobsters up to two feet long and giant spider crabs with leg spans of over ten feet.

Physical Characteristics of Crustaceans

All crustaceans are covered by hard chitin coats (carapaces) acting as external skeletons (or exoskeletons), which grow as backward extensions of their heads. Carapace texture varies from bone-like to tough and leathery. The hardness of the covering depends on the amount of calcium salts in the chitin. The exoskeleton acts like armor, to protect the animal. Crustacean bodies are made up of several segments and divided into sections. Each section usually has one pair of jointed legs.

Crustacean heads are fused with several segments just behind them, forming the cephalothorax. This is followed by the abdomen. The head holds two pairs of sensory organs, jaws (mandibles), and antennae. Behind the mandibles are two other pairs of mouth parts, the maxillae. These limbs, which evolved under and in front of the mouth, are used to hold, tear, and taste food. Antennae provide the sense of touch. Each crustacean head also holds a pair of compound eyes, an unpaired eye, or both. Each eye is on a movable stalk and can be turned in any direction.

The cephalothorax also holds limbs used in locomotion and others used as gills in respiration. Special legs under the body are used for walking. Large legs called pincers or claws are used to catch fish, crack mollusks, dig burrows, and fight. Slow-swimming legs under the tail can be used to hold eggs. The legs at the end of the tail are flattened into a fan-shaped fin, also used in swimming.

The main body cavity is a blood circulatory system, pumped by a dorsally located heart. The crustacean intestine is a straight tube containing

Crabs and lobsters must periodically shed their hard exoskeletons in order to accommodate growth. (Adobe)

glands that secrete digestive fluid and absorb food. All crustaceans also have at least rudimentary brains, composed of ganglia near sense organs and below the intestine.

Shrimp, Lobsters, and Crabs

Shrimp make up two thousand crustacean species. Structurally similar to lobsters and crayfish but flattened laterally, they are green or brown. They range from insect size to ten inches long, inhabiting salt water and freshwater (mostly on shallow ocean floors) and eat smaller animals and plants. Some species, krill, live deep in the oceans and are eaten by whales. Shrimps have eight pairs of appendages; the first three are used for eating and the rear five are for walking. The shrimp abdomen also contains five pairs of swimming legs and a fanlike tail.

Lobsters are marine decapods, with five pairs of thoracic locomotor appendages. They belong to the crustacean suborder Reptantia and are related to freshwater crayfishes. Their narrow, dark green bodies are up to two feet long and weigh two to fifteen pounds. In each lobster, two large, body-length claws stretch forward to grasp prey, and a fan-shaped tail is used for propulsion. The three true lobster species are very important foods in North America and Europe. American and European lobsters (*Homarus americanus* and *Homarus vulgaris*) have enlarged claws. Norway lobsters (*Nephrops norvegicus*) have longer, thinner claws. In these true lobsters, one claw is heavy and has blunt teeth to crush prey. The other is smaller and has sharp teeth to tear prey up. Not all lobsters have the heavy claw on the same side. They are "right clawed" or "left clawed."

The lobster head has two pairs of antennae and its eyes are compound, on the ends of mobile stalks. A female lobster lays 5,000 to 160,000 eggs every two years, and carries them under her tail

Crustacean Cuisine

The terms “shrimp,” “lobster,” and “crab” are catchalls that do not definitively classify decapod crustacean groups. Rather, they are popular or slangy terms. “Shrimp” somewhat arbitrarily indicates smaller crustaceans. In the same vein, “lobster” generically indicates large crustaceans, and “crayfish” indicates freshwater lobsters. For example, the suborder Reptantia consists of crawling forms, including elongated species called lobsters and shorter ones called crabs. True lobsters are classified together with crayfish.

Many crustaceans provide food for humans. The well-muscled abdomens of shrimps provide shrimp meat. The tails and claws of lobsters are luxury food items, as are crab claws and legs. Millions of pounds of crabs, shrimps, and lobsters are eaten every year. This has led to an increasing scarcity of the most prized crustaceans. For example, at one time a hundred million lobsters were caught per year, some weighing fifteen pounds or more. This sort of fishing has made larger lobsters rare, and the average lobster sold now weighs two pounds or less.

Lobsters might have died out completely from overfishing, but laws were passed to protect them, and young lobsters were raised in areas where lobster fishing was forbidden. Most crustaceans have very sweet-tasting flesh, even though their diet includes dead, decaying matter. Because of their eating habits, they help keep the ocean and its beaches clean. Other crustaceans are eaten by fish that humans use as food.

for up to eleven months, until the young hatch. The young, initially 0.3 inches long, drift and swim for a month before settling on the bottom, at 1 inch long. Survivors of the next few months on the dangerous ocean bottom dig shallow burrows beneath rocks, or inhabit crevices in the ocean bed. During the day, a lobster stays inside its burrow waiting for prey. At night it comes out to search for dead or live food. Lobsters grow by molting and may live up to fifteen years. All are primarily scavengers.

American lobsters occur only off eastern North America, from Labrador to North Carolina. Most live on the ocean bottom, at depths of ten to one hundred feet. Caught in baited lobster pots, they average lengths of ten inches and weigh up to five pounds. Norway lobsters are most abundant near France and Spain. European lobsters are caught off Great Britain, France, Italy, Norway, and Portugal. Rock lobsters, lacking the enlarged claws of the true lobsters, are found off South Africa, Australia, New Zealand, Japan, Brazil, the United States, Mexico, and the Bahamas.

Crabs, related to lobsters and shrimp, can move sideways, burrow, and swim. They are decapods, whose smallest members, tiny pea crabs, consist of females which live in the shells of live oysters and males who live in the outside world and visit them to mate. The giant spider crabs of Japan are the largest crabs, often ten feet in circumference (including legs). Many kinds of crabs are used as human food. For example, the blue crab is the common food crab in eastern America. Two important groups, 1,500 species of Anomura (hermit crabs) and 4,500 species of Brachyura (true crabs), have similar body shapes, with small abdomens and large, broad anterior bodies, though hermit crabs have fewer walking legs. Seen most as ocean-bottom dwellers, crabs also inhabit freshwater, and some live on land.

The crab body is covered by a chitin carapace. The small abdomen under the body is most often a brood pouch. A crab has five pairs of walking legs, two sense antennae, and front legs which are pincers (claws) for feeding and defense. Crabs also have complex nervous systems, with keen compound eyes and the ability to smell and taste food. They enjoy complex mating rituals and communicate by pincer waving. Crabs often mate just after a female molts, when its shell is soft. Eggs are kept in the brood pouch and may pass through two larval stages: the initial form, zoea, does not resemble adults; the later form, megalops, does. Each time a crab molts after birth, it increases in size. Crabs may live for three to twelve years.

There are many different crab species. Some interesting crabs are the lobsterlike anomurans, called squat lobsters; sand crabs, which burrow into sand and filter suspended matter from the water; large spider crabs with long legs and slender bodies; swimming crabs (blue crabs) with paddlelike legs; and fiddler crabs, whose males each have a huge claw that they use in mating and combat. There are even land crabs, omnivores found in the tropics, that release larvae into oceans.

Life Cycle of Crustaceans

Crustaceans reproduce via eggs, which usually hatch underwater. Some crustaceans, such as lobsters, carry their eggs and young on the hairs of swimming legs. The eggs of different crustaceans hatch at different stages of development. Young lobsters and crayfish look like their parents; young crabs do not. After hatching, young crustaceans grow until their shells become too tight. Then the crustacean sheds its old shell for a larger new one. The process of changing shells (molting) takes place several times during growth. The new shell is formed inside the old one, and is soft and wrinkled until exposed to the environment. When a lobster molts, its shell splits along the back and the lobster leaves through the opening. Sometimes molting accidents will occur. For example, a leg or a feeler often breaks off in the process of leaving the old shell. When the animal molts again, it grows a replacement limb. The new limb is small at first, but becomes full-sized after several molts.

Some crustaceans, such as barnacles, are hermaphrodites. All barnacles live in oceans. Their larvae are free-swimming, but adults attach to foreign objects, such as ship bottoms, wharf piles, rocks, and whales. There are five orders of barnacles. Four are parasites of shellfish. The fifth order includes stalked barnacles, originally found in warm waters. However, because barnacles attach to ships, they are found worldwide.

DEATH AND DYING

Types of animal science: Behavior, development, ecology, physiology
Fields of study: Cell biology, ethology, genetics, marine biology, population biology, physiology, wildlife ecology, zoology

Animals die from old age, disease, their encounters with predators, starvation, human use, human-made disasters, and pollution created by industrial and agricultural chemicals. Some nonhuman animals appear to have a concept of dying.

Principal Terms

CETACEANS: plant-eating marine mammals, such as whales, dolphins, and porpoises
MARINE MAMMALS: part of the class of mammals that adapted to life in the sea
MYOCARDITUS: inflammation of the heart muscle
PERSISTENT ORGANIC POLLUTANTS (POPs): chemicals that remain in the environment for a very long time and can be found at long distances from where they are used or released; they are nearly all of human origin
PINNIPEDS: flipper-footed marine mammals, such as sea lions, fur seals, true seals, walruses
SIRENIANS: plant-eating dugongs and manatees

The life span of all species in the animal kingdom depends upon genetic composition, environmental conditions, and the amount of energy expended throughout their lifetime. The natural life span varies from one species to another. Insects generally have the shortest lives; the adult mayfly lives only a few hours, the fruit fly lives from thirty to forty days. At the other extreme, a giant tortoise may live up to 177 years and the quahog clam can live up to 220 years. Human life expectancy has increased substantially since the beginning of the twentieth century. In 1998, it ranged from seventy-five to eighty years in the United States, Canada, Western Europe and Australia, to fifty-five years in most African countries.

Environmental conditions affecting the genetically determined life span and hastening death include the number and ferocity of predators, viral, bacterial and fungal disease, poisons and pollutants, changing climate, and the rise of carbon dioxide in the air. Humans have contributed to the annihilation of many species and placed others close to extinction by either deliberately or accidentally destroying animal habitats and by overhunting wildlife. In 1973, the United States Congress passed the Endangered Species Act, to protect endangered animals and their habitats. The Environmental Protection Agency (EPA) monitors the fate of endangered species. If pesticide use adversely affects the habitat of an endangered species, the EPA can prohibit it.

Pollutants

Maritime oil spills, which kill huge numbers of marine life and birds, affect wildlife species differently. Birds especially are sensitive internally and externally to the effects of crude oil and its refined products. If they become coated with oil and their feathers collapse and mat, the insulating properties of their feathers and down change, making them vulnerable to hypothermia. They become vulnerable to predators and can suffer from dehydration, drowning, and starvation.

Cetaceans, sirenians, and pinnipeds, who depend on air and have amphibious habits, are all susceptible to the effects of oil spills. Like birds, they can suffer from hypothermia. Due to ingesting the oil during grooming and feeding, they suffer from organ dysfunction, congested airways, damaged lungs, gastrointestinal ulceration and hemorrhaging, and eye and skin lesions. Sea turtles are particularly vulnerable during their breeding season, as their nesting sites are on beaches and their eggs may become contaminated by the oil. Newly hatched turtles would have to move over the oiled beach to the water. Among the most deadly oil spills was the wreck in Alaska of the supertanker *Exxon Valdez*, in March 1989, which resulted in more than thirty thousand sea birds dying.

Persistent organic pollutants (POPs) have been related to many behavioral problems in birds, marine mammals, and fish, as well as in humans. Studies of humans exposed through food to POPs show a possible relationship to disruptions of the immune system. This finding has been used to explain why more seals and whales are dying and getting stranded. High levels of cancers in fish have been attributed to another class of potential POPs. Environment Canada reported that when POP levels were reduced, population declines in some birds reversed.

Viral and Bacterial Disease

Nonhuman animals, like humans, are vulnerable to viruses. Livestock contract highly contagious and serious diseases. Among the more commonly known are foot and mouth disease, which affects hoofed animals; scrapie, which affects sheep; and bovine spongiform encephalopathy (BSE), known also as mad cow disease, which occurs in cattle. BSE appears to jump species; humans who contract BSE can develop Creutzfeldt-Jacob disease, a fatal brain disorder. Pigs contract swine fever. Capripox occurs in sheep. In Africa, Rift Valley fever kills livestock and humans. Poultry can contract avian influenza and Newcastle disease, both of which spread rapidly, killing more than 90 percent of infected birds. Because rabies is fatal in animals and humans, many countries require a quarantine period for animals entering the country. In wildlife, trapping has been used to prevent the spread of rabies. However, usually the healthier animals are caught in traps and not the sick, who are less active, are symptomatic, and debilitated, and who are more likely to deviate from their normal behavior.

Organized Animal Fighting, Animal Farming, and Sport Hunting

Humans are voracious predators of other species, killing nonhuman animals for food, clothing, sport, scientific experimentation, and financial gain. Many animals meet their death through organized fighting: bull fighting in Spain and Mexico, and cock fighting in the United States and several Asian cultures, which usually results in the death of one or both roosters. Dog fighting, although banned in most of the United States, is still held clandestinely.

Animal agriculture is the largest food industry in the United States. Animals reared for slaughter are frequently housed in crowded conditions in large buildings, which are ideal for disease. Under natural conditions, chickens can live for as long as fifteen to twenty years. In a modern egg factory hens live about a year and a half. Each year in the United States, about two-thirds of the eighty million pigs raised for slaughter live their lives in a confinement system, as do about half of the ten million milking cows and heifers raised. When birds are debeaked and calves and pigs weaned prematurely, they can die from the shock. Slaughtering is sometimes undertaken without safeguards in place to prevent unnecessary pain.

About 7 percent of the United States' population legally hunt animals. Sport hunting of polar bears in areas of Canada eventually led to such a substantial loss of bears that the local government banned hunting in 2002. In 2001, the government of British Columbia placed a moratorium on the hunting of grizzly bears. The whale population initially decreased because of hunting. The blue whale, which once numbered 200,000, was estimated to be 10,000 in 2001. Marine mammals also become accidentally entangled in fishing nets and

Foot and Mouth Disease

Foot and mouth disease (FMD—also known as hoof and mouth disease), an acute viral disease, is one of the most contagious animal diseases, affecting ungulates: cattle, sheep, pigs, and goats, wild and domestic cloven hoofed animals, elephants, hedgehogs and rats. It causes fever, followed by the development of blisters and sores on the feet and in the mouth. Pigs and sheep may suddenly become lame. There is a high mortality rate in young animals due to myocarditis.

The virus thrives in moist conditions, is airborne and endemic in parts of Asia, Africa, the Middle East, and North America. Transmission occurs directly or indirectly from contact with an infected animal, contaminated foodstuffs, or from a human who has attended an infected animal. It may be picked up on contaminated roads by the wheels of vehicles. Until they are disinfected, vehicles and implements from places where infected animals may have been present are sources of infection.

Prevention and control involves protecting disease-free zones with border animal movement control and surveillance, slaughtering infected, recovered, and FMD-susceptible contact animals, disinfecting premises, cars, clothes, and implements, destroying cadavers, litter, and susceptible animal products in the infected area, and introducing quarantine measures. After two initial vaccinations, one month apart, of an inactivated virus vaccine, immunity is provided for six months, depending on the antigenic relationship between the vaccine and outbreak strains.

An outbreak in 2001 in Great Britain was vastly different from a previous outbreak in 1967 due to the speed and geographical scale of the spread of the infection and the species involved. The outbreak necessitated slaughtering thousands of cattle. Despite the strenuous measures employed, the disease spread from Britain to parts of Europe and Ireland. Experts agreed the outbreak was unprecedented internationally.

collide with boats. Dolphins died at a considerable rate due to tuna fishing methods until U.S. legislation prohibited the method and the number caught in nets was reduced dramatically. Manatees, who move slowly and sometimes sleep near the surface of the water, are particularly vulnerable to being fatally hit by motor boats.

Scientific Experimentation

Using animals in scientific experiments has been widely sanctioned throughout the world for testing consumer products, disease prevention and/or progression techniques, the effects of noxious agents, and psychological theories of behavior. An animal rights movement developed in the late 1970's and early 1980's to protest this use of animals, who not only died during and following the experimental procedures but were also subjected to extreme pain and injury. Industrial manufacturers and scientists were urged to find alternate methods of safety testing and conducting experiments. The Johns Hopkins Center for Alternatives to Animal Testing was founded in 1981, while In Defense of Animals (http://www.idausa.org) grew out of challenges to the University of California's research. It grew into one of the foremost animal advocacy organizations in the United States. The ethical question raised by animal rights groups is whether nonhuman animals should be treated as independent sentient beings and not as a means to human ends.

Beyond the ethical issues raised by philosophers, such as Tom Regan and Peter Singer, are the questions concerning the emotional life of animals and whether animals experience grief and have a concept of death. Marc Hauser, an animal-cognition researcher, maintains that animals, lacking a capacity for empathy, sympathy, shame, guilt, and loyalty, are without self-awareness or an awareness of what another of their species experiences, and therefore are incapable of having a deep understanding of death.

Researcher Cynthia Moss, at the Amboseli Elephant Research Project in southern Kenya, takes a different view. From her field observations, she maintains that elephants have a concept of death. They recognize one of their own carcasses or skeletons, always react to the body of a dead elephant, and have been seen putting dirt on a dead elephant's body and covering it with branches and palm fronds. Healthy elephant mothers whose young calves have died look lethargic for many days afterward, trailing behind their family. Wild animals and birds, as well as animals in captivity and animal pets, have been seen reacting to the loss of a mate or companion that can be interpreted as mourning behavior and grief.

DEEP-SEA ANIMALS

Types of animal science: Anatomy, ecology
Fields of study: Ecology, marine biology

The great depths of the sea, below about 150 feet, had always been considered azoic (without animal life). Oceanographic research has shown the ocean supports a large number and diversity of animals in all areas, from the surface to the bottom of the deepest parts, nearly six miles down.

Principal Terms

BIOLUMINESCENCE: production of visible light by living organisms
DEEP SEA: water depths below six hundred feet, also below penetration of light
GULPER: a fish that captures and ingests its prey in one swallow
PLANKTON: marine organisms, usually small, that are free-floating
SUBMERSIBLE: a vessel, like a submarine, that can operate with or without occupants

Early in the nineteenth century, an English naturalist, Edward Forbes, theorized that there was an azoic or lifeless environment in the ocean deeper than about two thousand feet. However, as technology advanced, broken submarine cables recovered from depths greater than five thousand feet were found to be teeming with living organisms, many of which were new to science. In the 1950's and later, collections from deep-water zones, made both with collecting devices and through explorations by scientists aboard submersibles, revealed fishes, snails, and other animals in the deepest part of the world ocean, the Mariana Trench in the southwest Pacific Ocean. This trench, at 6.8 miles deep, with crushing pressure, near-freezing temperature, and complete absence of light, supports life.

Deep-Sea Exploration

Scientists exploring in submersibles such as *Trieste* and *Alvin* watched in wonder as bizarre-looking fishes swam past the viewing ports. Many of the fishes were brightly colored—red and orange—and most of them featured light organs on their skin, glowing or flashing a bioluminescent light in the otherwise total darkness. Some of the fishes were equipped with body parts which resembled fishing rods and lures.

The advent of submersibles offered the promise that someday soon, scientists might actually see one of the mythical sea monsters. This was not to be. Most of the strange-looking fishes were in many cases only a few inches long.

Gulpers and Anglers

In the lightless depths of the sea there is no primary production of food from plants as there is in the surface waters. Thus, the deep-sea fishes depend for food on whatever may descend from surface waters. A dead whale drifting down is a bonanza of nutrition to the organisms below. However, many of the deep-water fishes are unable to handle such large matter and are reduced to eating each other: their own kind or even a larger neighbor. The gulpers are remarkably adapted to the necessity of seizing and swallowing whatever comes along. The gulper, or pelican eel, has a huge mouth, jaws that open fantastically wide, and a belly that can contain a fish larger than itself. Some gulpers are about two feet long but one remarkable species reaches a length of six feet. Most of its length consists of a long, whiplike tail,

Hydrothermal vents in the ocean floor create temporary ecosystems that attract animal life, such as these tubeworms, during the relatively short life of the vent. (OAR/National Undersea Research Program)

with the mouth making up the rest of the body. The feeding action of the gulpers has been described as not swallowing their prey, but instead drawing themselves over it like a snake consuming a mouse.

Many deep-sea fishes are anglers; that is, they are fishes that fish. Most of them bear a long, flexible appendage dangling from the top of the head. A light organ at the tip of the rod is dangled provocatively. Any fish that comes closer to investigate the glowing, wormlike bait is rapidly taken in to the angler's mouth and swallowed. Most anglers are jet black with enormous heads and mouths. The mouth is fitted with long, sharp, curved teeth that effectively trap the prey.

A bizarre variation of the angler is the bottom-dwelling, deep-sea fish that has a lighted appendage hanging from the roof of its mouth. It rests on the bottom, mouth agape, with the glowing "worm" wiggling in the dark. Any fish that is attracted into the angler's maw by an apparent bit of live food is quickly swallowed with little effort on the angler's part.

Sea Monsters

Most scientists discount stories of sea monsters in the sense of serpentine animals that resemble the mythical dragon. None has ever been seen or examined by a reputable biologist. There are, however, denizens of the sea that are monstrous. Except for the whales (which are mammals, not fish), the three largest fishes are sharks. The megamouth shark (only discovered in 1976) is up to seventeen feet long. The basking shark reaches a length of forty feet. The giant of all fishes is the whale shark, reaching lengths of more than fifty feet. All three species are docile and feed on tiny plankton near the surface at night, but each day descend into the dark depths. Probably the source of most sea-monster stories is the giant squid. Related to the six- to eight-inch squid eaten as calimari or used as fishing bait, the giant squid truly lives up to its name. It grows to a length of sixty feet, has eyes the size of automobile hubcaps, and bears eight arms. It feeds on fishes and any other marine creature it can capture in its natural domain, three thousand feet down. It frequently is attacked and eaten by sperm whales. The squid is not a fish, but is a member of the same group of sea organisms that includes oysters and clams.

DEER

Type of animal science: Classification
Fields of study: Anatomy, zoology

Deer are hoofed, artiodactyl mammals of the family Cervidae, having bony antlers, which are shed and regenerated annually.

Principal Terms

ANTLER: temporary horn made of solid bone, grown and shed each year

ARTIODACTYL: herbivorous, hoofed mammal that walks on two toes of each foot

FRONTAL BONE: bone comprising the forehead; important in forming the top (roof) of the orbital and nasal cavities

PEDICLE: small bone from which an antler grows

RUMINANT: hoofed animal, with a stomach divided into four parts; it chews a cud of regurgitated, partly digested food

SOLITARY: animal that lives alone

Deer are hoofed, artiodactyl mammals of family Cervidae. They have bony, branching antlers, which are shed and regrown annually. The family contains sixteen genera and approximately forty species, and inhabits the Americas, Europe, Asia, and North Africa. Deer live in woods, prairies, swamps, mountains, and tundra. Common species are the white-tailed and mule deer in the United States; wapiti in the United States, Canada, Europe, and Asia; moose in North America and Europe; reindeer in Russia, Finland, and Alaska; and caribou in northern North America.

The four deer subfamilies are the Cervinae (true deer), Moschinae (musk deer), Muntiacinae (muntjacs), and Odocoileinae (hollow-toothed deer). They are hunted worldwide for their meat, hides, and antlers. Deer meat (venison) tastes beeflike. Tanned deerhide makes soft leather. Reindeer, which are domesticated in Scandinavia and Russia, are sources of meat, leather, and milk, and serve as draft animals.

Physical Characteristics of Deer

Deer have gray, brown, red, or yellow upper bodies with lighter colored bellies. Their stiff fur is smooth looking in the summer and longer and shaggier in cold weather. Deer shed fur in spring and fall, a process called molting. They range in size from seven feet at the shoulder and a ton in weight for moose, to one foot at the shoulder and a weight of around twenty pounds for the tiny pudu. All deer have lithe, compact bodies, short tails, large, narrow ears, long, slender legs, and paired hooves on each foot. Their eyes are large, placed on the sides of the head, and yield a wide visual range. Deer also have keen senses of smell and hearing. They run quite quickly to escape danger.

Males of most species have antlers, as do female reindeer and caribou. Antlers are solid bone growths arising from the frontal bone. In moose, the largest deer, they reach widths of six feet and weigh nearly fifty pounds. Antlers are shed and regrown each year, arising from pedicles on the frontal bone. The pedicles and the growing antlers are covered with soft skin called velvet. Antlers grow rapidly. When the antlers have reached their maximum growth, bone deposition at the antler's base cuts off the velvet's blood supply. This makes the velvet dry up, and the itchiness of the dry velvet leads the deer to rub it off. The shape and complexity of branched antlers is species dependent. Antler shedding in late fall is due to bone resorption at the antler bases. This annoys deer and they rub their antlers against trees, weakening them and causing them to come off. Antlers are important protection for individual deer and their family groups. Males use antlers to fight other males and to protect their herds from predators. The protective function may explain why, most often, it is the males who have horns. Horns of females are much smaller than those of males of a species.

Deer are herbivorous, and their lower molars have ridges which enable them to grind vegetable foods. They are ruminants (cud chewers) and have four-chambered stomachs. Nearly all deer have facial glands in front of each eye. These make strongly scented musk, which is used to mark their territories.

Deer Life

Deer are solitary or live in small to large groups. Often males and females are solitary except when mating. Deer are polygamous, with males collecting harems and battling others for them. Deer can be gregarious at special times, when they live in herds ranging from extended families to thousands. In warm climates deer breed at any time, while in cold climates they breed from autumn to winter. Their gestation periods are between five and eleven months, depending on species. One or two young are born and are at first hidden, camouflaged by dappled body markings. Young deer mate at five to six years old.

All deer eat twigs, leaves, bark, buds of bushes and saplings, and grasses or other plants. They are diurnal (active during daylight), and feed most at twilight. They are also ruminants, who chew and swallow food several times. Rumination helps deer get all nutrients and vitamins they can from their food.

In many countries, especially the United States, deer have few natural predators. Many of

Deer are herbivores, eating grasses and the tender buds, shoots, bark, and twigs of trees. The boundary between forest and field offers them the widest range of food choices. (PhotoDisc)

Deer Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Artiodactyla
Family: Cervidae (deer)
Subfamilies: Cervinae (true deer), Moschinae (musk deer), Muntiacinae (muntjacs), Odocoileinae (hollow-toothed deer)
Geographical location: The Americas, Europe, Asia, and North Africa
Habitat: Forests, grasslands, deserts, tundra, swamps, mountains
Gestational period: Five to ten months
Life span: Eight to twenty years, depending on species
Special anatomy: Antlers, ruminant stomach

their predators, such as wolves and mountain lions, have been driven to endangerment or extinction as a result of their perceived threat to livestock, and the deer have benefited by this. If they become too plentiful, deer overbrowse and die of starvation during winter. This is managed through adjusting the hunting season, based on population estimates made by the U.S. Fish and Wildlife Service. Deer are one of the few wild animals that still provide a real contribution to the diet of humans in some parts of the United States, where some families rely on a deer or two in the freezer to provide their meat throughout the winter.

Deerskin is also used for shoes, boots, and gloves, and antlers are made into buttons and other decorative items. Scandinavian and Russian Lapps and North Asian nomads use reindeer for food, clothing, and transportation. Caribou, a reindeer variant, are equally important to North America's Inuit. Deer were brought to New Zealand from Europe, and are currently raised on deer farms. Most commercial venison used in the United States is imported from New Zealand.

DEFENSE MECHANISMS

Types of animal science: Behavior, ecology, evolution
Fields of study: Biochemistry, ecology, entomology, ethology, invertebrate biology, marine biology

All organisms represent a potential resource for their predators. Several have evolved ingenious ways to prevent themselves from becoming their predator's next meal.

Principal Terms

APOSEMATIC COLORATION: brightly colored warning coloration that toxic species use to advertise their distastefulness to would-be predators

AUTOTOMY: the self-induced release of a body part

MIMICRY: a type of defense in which an organism gains protection from predators by looking like a dangerous or distasteful species

PREDATION: broadly defined, any interaction in which one organism consumes another living organism, including herbivory (predation on plants), parasitism (predation by small organisms), and familiar predation (where one animal kills and eats another animal)

SECONDARY METABOLITE: a biochemical that is not involved in basic metabolism, often of unique chemical structure and capable of serving a defensive role for the organism

SEQUESTER: to store a material derived from elsewhere. In defenses, some predators sequester defensive properties from their prey to defend themselves from their own predators

SYMBIOSIS: "living together"; a term that describes the association between two species in which one species typically lives in or on the other species. Parasitism is a common type.

All organisms are composed of fixed carbon, biomolecules, and mineral nutrients, and therefore represent energy and nutrient resources for consumers. To be successful in life, animals must avoid, tolerate, or defend themselves against natural enemies such as predators, parasites, and competitors. The term "defense" can be attributed to any trait that reduces the likelihood that an organism, or part of an organism, will be consumed by a predator. There are several categories of defenses that have evolved in animals, including structural defenses, chemical defenses, associational defenses, behavioral defenses, autotomy, and nutritional defenses. Animals often possess more than one type of defense, thereby having backup plans in case the first line of defense fails. The number of defenses devised by organisms is a reflection of the strong selective pressure exerted by predators.

Structural Defenses: Being Hard and Sharp

Structures that defend animals can act as external shields: sharp spines located externally or internally, skeletal materials that make tissues too hard to bite easily, or weaponry such as horns, teeth, and claws. External structures that protect vulnerable soft tissues include the chitonous exoskeleton of crustaceans, the calcareous shells of corals, mollusks, and barnacles, the tests (skeletal plates) of echinoderms, the tough tunic of ascidians, and the hard plates of armadillos. The pretty shells that tourists collect along beaches were once used to protect a soft, delicate animal that lived inside the shell. Hard, protective shells remain after the animal dies and can be used by other animals for pro-

Sequestration

The production of chemical defenses is often assumed to be expensive because it requires resources that might otherwise have been used for growth and reproduction. One way for a species to avoid such cost is to sequester compounds produced by its prey.

Sequestration was first discovered in the monarch butterfly. Monarch caterpillars feed on milkweeds and sequester the plant's cardenolides. Milkweeds produce toxic cardenolides that deter most vertebrate herbivores, but monarchs have evolved the ability to tolerate and sequester these compounds. When blue jays were fed monarchs, the birds soon regurgitated and learned to associate this unpleasant response with eating monarchs. To help advertise their chemical nastiness and perhaps to increase the learning response of birds, monarchs evolved aposematic coloration. Other species of butterflies, such as the viceroy and the queen butterflies, mimic monarchs, affording them protection from predators that have already learned to avoid orange and black butterflies.

Nudibranchs are a class of sea slugs that lack the protective shell that most of their gastropod relatives possess. Because they lack the physical defense of a shell, they must protect themselves from other mechanisms, and have ingenious ways of doing so. Most nudibranchs do not produce their own defenses. Rather, they sequester the defenses of their prey. For example, aeolid nudibranchs are famous for sequestering functional nematocysts from their cnidarian prey. They transfer nondischarged nematocysts from their gut to their skin, thereby protecting themselves from predators such as fish. Nudibranchs also sequester secondary metabolites from their invertebrate prey, which effectively protect them from predatory fishes.

tection. For example, small fishes will retreat into empty conch shells when they feel threatened by predators, and hermit crabs live inside empty snail shells to protect their soft, vulnerable abdomens.

Some animals cover their bodies with sharp structures that puncture predators that try to bite them. The porcupine is a good example of a mammal that uses this defensive strategy. Porcupines are covered with tens of thousands of long, pointed spines, or quills, growing from their back and sides. The quills have needle-sharp ends containing hundreds of barbs that make the quills difficult to remove. Sea urchins are also covered with long, sharp spines that deter would-be predators. Urchins can move their spines, and will direct them toward anything that comes in contact with them, such as a predator. While porcupines and urchins are covered with multiple spines, stingrays defend themselves from enemies by inflicting a wound with a single barbed spine. The wound is extremely painful, giving these rays their common name.

Predators have sharp claws and teeth that help them grasp, subdue, and consume their prey. These same structures, used offensively in hunting, can also be used to protect themselves from their own predators. Small predators such as badgers, raccoons, and foxes can fend off larger predators such as wolves and mountain lions with their weaponry. Rather than risk injury, the larger predators will avoid a fight with the smaller predator and seek a less risky meal, such as a rabbit or mouse.

Chemical Defenses: Poor Taste, Bad Smell, or Toxic Chemicals

Both plants and animals defend themselves by using compounds that are distasteful, toxic, or otherwise repulsive to consumers. Most defensive compounds are secondary metabolites of unique structures, but can also include more generic compounds such as sulfuric acid or calcium carbonate. Secondary metabolites get their name because they are not involved in basic metabolic pathways such as respiration or photosynthesis (that is, primary metabolic reactions), not because they are of secondary importance. Indeed, many organisms probably could not survive in their natural envi-

This badger bares his sharp and powerful teeth to ward off a threatening presence. (Digital Stock)

ronment without the protection of their secondary metabolites.

Stink bugs get their names because of the smelly secondary metabolites they release from pores located on the sides of their thorax. These smelly compounds repel predators, and may even indicate toxicity to the predator. These insects are common garden pests that are usually controlled with chemical pesticides. However, it appears that the eggs of stink bugs are not defended against roly-poly pill bugs, which can control stink bug numbers (and hence, garden damage) by preying on eggs.

Bombardier beetles take chemical defenses a step further, erupting a boiling hot spray of chemicals in the direction of a predator. To accomplish this, the bombardier beetle has a pair of glands that open at the tip of its abdomen. Each gland has two compartments, one that contains a solution of hydroquinone and hydrogen peroxide, and the other that contains a mixture of enzymes. When threatened by a predator, the bombardier beetle squeezes the hydroquinone and hydrogen peroxide mixture into the enzyme compartment, where an exothermic reaction that produces quinone takes place. The large amount of heat generated brings the quinone mixture to its boiling point, and it is forcefully emitted as a vapor toward the threat. An average bombardier beetle can produce about twenty loud discharges of repulsive, hot chemicals in quick succession.

Chemical defenses are common among small, slow animals such as insects, sponges, cnidarians, and sea slugs, which might be limited in their ability to flee from predators. However, chemical defenses are rather rare among large, fast animals. One of the few mammals that uses chemical defenses is the black-and-white-striped skunk. Most people are familiar with the smelly chemical brew emitted from these animals, as it is distinctly detectable along roads when skunks get hit by cars, and can be detected up to a mile from the location where a skunk sprays. These mammals hold their smelly musk in glands located below their tail, and squirt the liquid through ducts that protrude from the anus. When threatened by a predator, the skunk raises its tail and directs its rear end toward the predator. A predator that has had prior experience with a skunk might retreat from this display, but if the predator is persistent at harassing the skunk, the striped mammal will deliver a spray of smelly chemicals that usually sends the predator running. The musk also causes intense pain and temporary blindness if it gets in the eyes of the predator.

Associational Defenses: The Guard Dog Approach

Associational defenses occur when a species gains protection from a natural enemy by associating with a protective species, such as when humans gain protection from enemies by keeping a guard dog on their property. Types of protection provided to the defended species through this coevolution can be structural, chemical, or aggressive.

Small animals can avoid predators by using a defended species as habitat. For example, small fishes defend themselves by associating with sea urchins, gaining protection by hiding among the sharp spines. Some species of shrimp inhabit the cavities and canals of sponges. Sponges are known to be chemically and structurally defended against most predators, with the exception of angel fishes and parrot fishes. Finally, much of the diverse coral reef fauna seeks protection among the cracks and the crevices in the reef. Reefs, slowly built by coral animals, are the largest structures ever made by living organisms, and serve a protective role for thousands of species that inhabit reefs.

Associational defenses can also be chemically mediated. For example, bacteria that grow symbiotically on shrimp eggs produce secondary metabolites that protect the egg from a parasitic fungus. The numerous examples of sequestration of chemical defenses can be categorized as associational defenses, as they involve associating with chemically defended prey.

An organism might even be defended by protective species that aggressively attack would-be predators, especially if the protected species is a resource for the aggressive defender. For example, humans are protected by guard dogs because dogs view people as a resource that provides them with food, water, and shelter. Stop feeding the dog, and it is likely to look elsewhere for somebody to protect. There are several nonhuman examples of aggressive defensive associations, especially among ants. Aphids are insects that feed on the sugary phloem stream of plants. In the process of feeding and processing phloem, the aphids secrete large amounts of honeydew, which the ants harvest and consume; that is, aphids provide ants with a resource. Ants tend to aphids in the same way that dairy farmers tend to their cows. The ants carry aphids to prime feeding locations, defend aphids from predators, and periodically "milk" the aphids of their honeydew by stroking them with their antennae.

Defensive Behaviors: Advertising and Trickery
Being chemically defended does not protect an animal from being accidentally eaten. Therefore, chemically defended animals often advertise the fact that they are nasty to avoid such accidents. This advertisement is often in the form of outlandish colors and patterns that flaunt the animal's distastefulness to predators. Using bright warning patterns is called aposematic coloration.

One problem with aposematic coloration is the training of predators: Bright coloration is only useful if the predator understands the warning. Otherwise, the coloration simply makes the animal a conspicuous prey item. An interesting way that different species with aposematic coloration share the cost of training naïve predators is through mimicry. A predator that eats an individual of species A (assume species A is bright red with blue stripes) and vomits shortly thereafter may learn to avoid things that are red with blue stripes, though at the cost of that first individual's life. This educated predator will now avoid other members of species A, and any other organism that looks like species A (the mimic), whether the mimic is toxic or not. If the mimic is toxic, the system is termed Müllerian mimicry. If the mimic is a palatable species that looks like a toxic model, the system is termed Batesian mimicry.

Mimicry is common within groups of closely related organisms (for example, snakes, butterflies, and bees) which are already similar in appearance. However, mimicry can also occur even when the model and mimic are distantly related. For example, there are caterpillars that mimic the head of a snake, moths that mimic the eyes of a cat, and beetles, moths, and flies that mimic stinging bees and wasps.

Autotomy: Throw the Predator a Bone
Sometimes, despite the best defenses, a predator will get hold of a prey. If this happens, some animals are able to sacrifice a portion of their body to the predator, with the hope that the remaining parts will survive, and perhaps even regrow the lost parts. This ability to lose a body part intentionally is called autotomy.

Many lower animals, such as sponges, cnidarians, and worms, have great regeneration abilities, and can regrow body parts well. In fact, these animals can even use regeneration as a form of asexual reproduction: Break the animal into four parts, and the parts will generate four complete individuals.

Sea cucumbers, in addition to being chemically defended, are able to eviscerate (autotomy of intestines) when harassed by a predator. These are not fast animals, so this action does not allow them to escape, but it might satisfy (or disgust) the predator enough to make it lose interest in the sea cucumber. Losing a large portion of its digestive tract interferes with feeding, but the sea cucumber can regenerate those parts of the gut that were eviscerated, restoring itself to original function. Sea cucumbers also play an important role in a defensive association with the pearlfish. When the pearlfish feels threatened, it locates the anus of a sea cucumber, then backs into its intestine, where it hides until the danger has passed.

The regenerative ability of higher animals is generally less than that of lower animals. However, autotomy does occur even in some vertebrates. Lizards are well known for their ability to release the tips of their tails when grabbed by a predator. The predator is distracted, and perhaps satisfied, by the wiggling piece of flesh, and in the meantime, the remainder of the lizard scampers off to safety. Geckos release skin instead of tails. The part of the skin that is grabbed by the predator is released, enabling the gecko to break free and escape.

Nutritional Defenses: Not Worth the Effort

Some animals, such as corals, jellyfish, anemones, and gorgonians (phylum Cnidaria), possess a type of combined structural and chemical defense in the form of specialized stinging cells called nematocysts. When nematocysts are stimulated, they rapidly discharge a barb that punctures the skin of a predator, often releasing toxic chemicals at the same time. The stinging sensation that people get when they swim into a jellyfish is caused by nematocysts. Some of these jellyfish stings are so potent that they can result in death.

Not only do many predators avoid jellyfish because they posses nematocysts, but predators may avoid jellyfish because they are jellylike, being composed of more than 95 percent water. It takes time and effort for predators to locate, handle, ingest, and digest prey. If the prey item is basically a bag of seawater (as jellyfish are), then predators might not bother eating these nutrient-deficient animals. Thus, these animals are "nutritionally" defended. Nutritional defenses are also used by plants, but they are generally not an avail-

Acacia-Ant Mutualism

Acacia ants are found throughout Central America and only inhabit the hollow thorns of acacia trees. The ants harvest and feed on nectar from extrafloral nectaries and special leaf tips, called Beltian bodies, produced by the acacia trees. In a sense, these ants are herbivores of acacia trees. However, in return for the shelter and food provided by the tree, the ants defend the tree from other herbivores and competitors. When an herbivore begins feeding on the acacia tree, the ants release an alarm order that signals the colony to attack the herbivore with painful bites and stings. The busy ants also remove competing vegetation that comes in contact with the tree or that grows near the trunk of the tree. The weeding activity of the ants results in a circle of cleared ground surrounding the acacia tree that also protects the tree from the damaging effects of fire. This mutualistic relation is obligate, meaning that each species is absolutely dependent on the other: The tree cannot survive without the ants and vice versa. Other species take advantage of the acacia-ant mutualism: Some birds preferentially nest in acacia trees, presumedly because the ants deter egg predators as well as herbivores. How the birds avoid attack by the ants is not well understood.

able strategy for animals other than jellyfish, as most animal tissue is relatively nutritious.

DEMOGRAPHICS

Type of animal science: Ecology
Fields of study: Environmental science, population biology, zoology

Demography is the study of the numbers of organisms born in a population within a certain time period, the rate at which they survive to various ages, and the number of offspring that they produce. Many different patterns of birth, survival, and reproduction are found among organisms in nature.

Principal Terms

COHORT: a group of organisms of the same species, and usually of the same population, that are born at about the same time

FECUNDITY: the number of offspring produced by an individual

LIFE TABLE: a chart that summarizes the survivorship and reproduction of a cohort throughout its life span

MORTALITY RATE: the number of organisms in a population that die during a given time interval

NATALITY RATE: the number of individuals that are born into a population during a given time interval

POPULATION: a group of individuals of the same species that live in the same location at the same time

SURVIVORSHIP: the pattern of survival exhibited by a cohort throughout its life span

No animal lives forever. Instead, each individual has a generalized life history that begins with fertilization and then goes through embryonic development, a juvenile stage, a period in which it produces offspring, and finally death. There are many variations on this general theme. Still, the life of each organism has two constants: a beginning and an end. Many biologists are fascinated by the births and deaths of individuals in a population and seek to understand the processes that govern the production of new individuals and the deaths of those already present. The branch of biology that deals with such phenomena is called demography.

The word "demography" is derived from Greek; *demos* means "population." For many centuries, demography was applied almost exclusively to humans as a way of keeping written records of new births, marriages, deaths, and other socially relevant information. During the first half of the twentieth century, biologists gradually began to census populations of naturally occurring organisms to understand their ecology more fully. Biologists initially focused on vertebrate animals, particularly game animals and fish. Beginning in the 1960's and 1970's, invertebrate animals, plants, and microbes also became subjects of demographic studies. Studies clearly show that different species of organisms vary greatly in their demographic properties. Often, there is a clear relationship between those demographic properties and the habitat in which these organisms live.

Demographic Parameters

When conducting demographic studies, a demographer must gather certain types of basic information about the population. The first is the number of new organisms that appear in a given amount of time. There are two ways that an organism can enter a population: by being born into it or by immigrating from elsewhere. Demographers generally ignore immigration and concentrate instead on newborns. The number of new individuals born into a population during a specific time interval is termed the natality rate. The natality rate is often based on the number of individuals already in the population. For example, if ten newborns enter a population of a thousand individuals during a given time period, the natality rate is 0.010. A specific time interval must be expressed (days, months, years) for the natality rate to have any meaning.

A second demographic parameter is the mortality rate, which is simply the rate at which individuals are lost from the population by death. Losses that result from emigration to a different population are ignored by most demographers. Like the natality rate, the mortality rate is based on the number of individuals in the population, and it reflects losses during a certain time period. If calculated properly, the natality and mortality rates are directly comparable, and one can subtract the latter from the former to provide an index of the change in population size over time. The population increases whenever natality exceeds mortality and decreases when the reverse is true. The absolute value of the difference denotes the rate of population growth or decline.

When studying mortality, demographers determine the age at which organisms die. Theoretically, each species has a natural life span that no individuals can surpass, even under the most ideal conditions. Normally, however, few organisms reach their natural life span, because conditions are far from ideal in nature. Juveniles, young adults, and old adults can all die. When trying to understand the dynamics of a population, it makes a large difference whether the individuals are dying mainly as adults or mainly as juveniles.

Patterns of Survival

Looking at it another way, demographers want to know the pattern of survival for a given population. This can best be determined by identifying a cohort, which is defined as a group of individuals that are born at about the same time. That cohort is then followed over time, and the number of survivors is counted at set time intervals. The census stops after the last member of the cohort dies. The pattern of survival exhibited by the whole cohort is called its survivorship. Ecologists have examined the survivorship patterns of a wide array of species, including vertebrate animals, invertebrates, plants, fungi, algae, and even microscopic organisms. They have also investigated organisms from a variety of habitats, including oceans, deserts, rain forests, mountain peaks, meadows, and ponds. Survivorship patterns vary tremendously.

Some species have a survivorship pattern in which the young and middle-aged individuals have a high rate of survival, but old individuals die in large numbers. Several species of organisms that live in nature, such as mountain sheep and rotifers (tiny aquatic invertebrates), exhibit this survivorship pattern. At the other extreme, many species exhibit a survivorship pattern in which mortality is heaviest among the young. Those few individuals that are fortunate enough to survive the period of heavy mortality then enjoy a high probability of surviving until the end of their natural life span. Examples of species that have this pattern include marine invertebrates such as sponges and clams, most species of fish, and parasitic worms. An intermediate pattern is also observed, in which the probability of dying stays relatively constant as the cohort gets older. American robins, gray squirrels, and hydras all display this pattern.

These survivorship patterns are usually depicted on a graph that has the age of individuals in the cohort on the x axis and the number of survivors on the y axis. Each of the three survivorship patterns gives a different curve when the number of survivors is plotted as a function of age. In the first pattern (high survival among juveniles), the curve is horizontal at first but then swings downward at the right of the graph. In the second pattern (low survival among juveniles), the curve drops at the left of the graph but then levels out to form a horizontal line. That curve resembles a backward letter J. The third survivorship pattern (constant mortality throughout the life of the cohort) gives a straight line that runs from the upper-left corner of the graph to the lower right (this is best seen when the y axis is expressed as the logarithm of the number of survivors).

In the first half of the twentieth century, demographers Raymond Pearl and Edward S. Deevey labeled each survivorship pattern: Type I is high survival among juveniles, type II is constant mortality through the life of the cohort, and type III is low survival among juveniles. That terminology became well entrenched in the biological literature by the 1950's. Few species exhibit a pure type I, II, or III pattern, however; instead, survivorship varies so that the pattern may be one type at one part of the cohort's existence and another type later on. Perhaps the most common survivorship pattern, especially among vertebrates, is composed of a type III pattern for juveniles and young adults followed by a type I pattern for older adults. This pattern can be explained biologically. Most species tend to suffer heavy juvenile mortality because of predation, starvation, cannibalism, or the inability to cope with a stressful environment. Juveniles that survive this hazardous period then become strong adults that enjoy relatively low mortality. As time passes, the adults reach old age and ultimately fall victim to disease, predation, and organ-system failure, thus causing a second downward plunge in the survivorship curve.

Patterns of Reproduction

Demographers are not interested only in measuring the survivorship of cohorts. They also want to understand the patterns of reproduction, especially among females. Different species show widely varying patterns of reproduction. For example, some species, such as octopuses and certain salmon, reproduce only once in their life and then die soon afterward. Others, such as humans and most birds, reproduce several or many times in their life. Species that reproduce only once accumulate energy throughout their life and essentially put all of it into producing young. Reproduction essentially exhausts them to death. Conversely, those that reproduce several times devote only a small amount of their energy into each reproductive event.

Species also vary in their fecundity, which is the number of offspring that an individual makes when it reproduces. Large mammals have low fecundity, because they produce only one or two progeny at a time. Birds, reptiles, and small mammals have higher fecundity because they typically produce a clutch or litter of several offspring. Fish, frogs, and parasitic worms have very high fecundity, producing hundreds or thousands of offspring.

A species' pattern of reproduction is often related to its survivorship. For example, a species with low fecundity or one that reproduces only once tends to have type I or type II survivorship. Conversely, a species that produces huge numbers of offspring generally shows type III survivorship. Many biologists are fascinated by this interrelationship between survivorship and reproduction. Beginning in the 1950's, some demographers proposed mathematically based explanations as to how the interrelationship might have evolved as well as the ecological conditions in which various life histories would be expected. For example, some demographers predicted that species with low fecundity and type I survival should be found in undisturbed, densely populated areas (such as a tropical rain forest). In contrast, species with high fecundity and type III survival should prevail in places that are either uncrowded or highly disturbed (such as an abandoned farm field). Ecologists have conducted field studies of both plants and animals to determine whether the patterns that actually occur in nature fit the theoretical predictions. In some cases the predictions were upheld, but in others they were found to be wrong and had to be modified.

Age Structures and Sex Ratios

Another feature of a population is its age structure, which is simply the number of individuals of each age. Some populations have an age structure characterized by many juveniles and only a few adults. Two situations could account for such a pattern. First, the population could be rapidly expanding, with the adults successfully reproducing many progeny that are enjoying high survival.

Second, the population could be producing many offspring that have type III survival. In this second case, the size of the population can remain constant or even decline. Other populations have a different age structure, in which the number of juveniles only slightly exceeds the number of adults. Those populations tend to remain relatively constant over time. Still other populations have an age structure in which there are relatively few juveniles and many adults. Those populations are probably declining or are about to decline because the adults are not successfully reproducing.

Since most animals are unisexual, an important demographic characteristic of a population is its sex ratio, defined as the ratio of males to females. While the ratio for birds and mammals tends to be 1:1 at conception (the fertilization of an egg), it tends to be weighted toward males at birth, because female embryos are slightly less viable. After birth, the sex ratio for mammals tends to favor females, because young males suffer higher mortality. The posthatching ratio in birds tends to remain skewed toward males, because females devote considerable energy to producing young and suffer higher mortality. As a result, male birds must compete with one another for the opportunity to mate with the scarcer females.

The Age-Specific Approach

To understand the demography of a particular species, one must collect information about its survivorship and reproduction. The best survivorship data are obtained when a demographer follows a group of newly born organisms (this being a cohort) over time, periodically counting the survivors until the last one dies. Although that sounds relatively straightforward, many factors complicate the collection of survivorship data; demographers must be willing to adjust their methods to fit the particular species and environmental conditions.

First, a demographer must decide how many newborns should be included in the cohort. Survivorship is usually based on one thousand newborns, but few studies follow that exact number. Instead, demographers follow a certain number of newborns and multiply or divide their data so that the cohort is expressed as one thousand newborns. For example, one may choose to follow five hundred newborns; the number of survivors is then multiplied by two. Demographers generally consider cohorts composed of fewer than one hundred newborns to be too small. Second, methods of determining survivorship are much more different for highly motile organisms, such as mammals and birds, than for more sedentary ones, such as bivalves (oysters and clams). To determine survivorship of a sedentary species, demographers often find some newborns during an initial visit to a site and then periodically revisit that site to count the number of survivors. Highly motile animals are much more difficult to census because they do not stay in one place waiting to be counted. Vertebrates and large invertebrates can be tagged, and individuals can be followed by subsequently recapturing them. Some biologists use small radio transmitters to follow highly active species. The demography of small invertebrates such as insects is best determined when there is only one generation per year and members of the population are all of the same age-class. For such species, demographers merely count the number present at periodic intervals.

Third, the frequency of the census periods varies from species to species. Short-lived species, such as insects, must be censused every week or two. Longer-lived species need be counted only once a year. Fourth, the definition of a "newborn" may be troublesome, especially for species with complex life cycles. Demographic studies usually begin with the birth of an infant. Some would argue, however, that the fetus should be included in the analysis because the starting point is really conception. Many sedentary marine invertebrates (sponges, starfish, and barnacles) have highly motile larval stages, and these should be included in the analysis for survivorship to be completely understood. Parasitic roundworms and flatworms that have numerous juvenile stages, each found inside a different host, are particularly challenging to the demographer.

The Time-Specific Approach

The survivorship of long-lived species, such as large mammals, is really impossible to determine by the methods given above. Because of their sheer longevity, one could not expect a scientist to be willing to wait decades or centuries until the last member of a cohort dies. Demographers attempt to overcome this problem by using the age distribution of organisms that are alive at one time to infer cohort survivorship. This is often termed a "horizontal" or "time-specific" approach, as opposed to the "vertical" or "age-specific" approach that requires repeated observations of a single cohort. For example, one might construct a time-specific survivorship curve for a population of fish by live-trapping a sufficiently large sample, counting the rings on the scales on each individual (which for many species is correlated with the age in years), and then determining the number of one-year-olds, two-year-olds, and so on. Typically, demographers who use age distributions to infer age-specific survivorship automatically assume that natality and mortality remain constant from year to year. That is often not the case, however, because environmental conditions often change over time. Thus, demographers must be cautious when using age distribution data to infer survivorship.

Methods for determining fecundity are relatively straightforward. Typically, fertile individuals are collected, their ages are determined, and the number of progeny (eggs or live young) are counted. Species that reproduce continually (parasitic worms) or those that reproduce several times a year (small mammals and many insects) must be observed over a period of time.

Demographers usually want to determine whether the production of new offspring (natality) balances the losses attributable to mortality. To accomplish this, they construct a life table, which is a chart with several columns and rows. Each row represents a different age of the cohort, from birth to death. The columns show the survival and fecundity of the cohort. By recalculating the survivorship and fecundity information, demographers can compute several interesting aspects of the cohort, including the life expectancy of individuals at different ages, the cohort's reproductive value (which is the number of progeny that an individual can expect to produce in the future), the length of a generation for that species, and the growth rate for the population.

Uses of Demography

Demographic techniques have been applied to nonhuman species, particularly by wildlife managers, foresters, and ecologists. Wildlife managers seek to understand how a population is surviving and reproducing within a certain area, and therefore to determine whether it is increasing or decreasing over time. With that information, a wildlife biologist can then estimate the effect of hunting or other management practice on the population. By extension, fisheries biologists can also make use of demographic techniques to determine the growth rate of the species of interest. If the population is determined to be increasing, it can be harvested without fear of depleting the population. Alternatively, one can conduct demographic analyses to see whether certain species are being overfished.

An often unappreciated benefit of survivorship analyses is that they can help ecologists pinpoint factors that limit population growth in an area. This may be especially important in efforts to prevent rare animals and plants from becoming extinct. Once the factor is identified, the population can be appropriately managed. Increasing amounts of public and private money are allocated each year to biologists who conduct demographic studies on rare species.

Bibliography

Begon, Michael, John L. Harper, and Colin R. Townsend. *Ecology: Individuals, Populations, and Communities*. 3d ed. Boston: Blackwell Scientific, 1996. A college-level introductory ecology textbook. Covers demography by asking the question "what is an individual?" The discussion of life tables includes many perspectives not found in other texts.

Begon, Michael, Martin Mortimer, and David J. Thompson. *Population Ecology: A Unified Study of Animals and Plants*. 3d ed. Cambridge, Mass.: Blackwell Science, 1996. An up-to-date and readable textbook for those with no background in population ecology. The text is divided into three sections: Single-Species Interactions, Interspecific Interactions, and Synthesis. The first section contains information most relevant to the study of demographics. References.

Brewer, Richard. *The Science of Ecology*. 2d ed. Fort Worth, Tex.: Saunders College Publishing, 1994. This clearly written textbook is aimed at upper-level undergraduates and was written by an author who has experience researching both plants and animals. Contains a succinct, well-presented discussion of life tables and survivorship curves. Some of the evolutionary applications of demography are also treated.

Elseth, Gerald D., and Kandy D. Baumgardner. *Population Biology*. New York: Van Nostrand, 1981. Intended for graduate students and advanced undergraduates, provides rigorous mathematical treatment of population biology. Discussion of demography includes detailed discussions about age structure, the calculation of population growth rates from demographic data, the evolution of demographic traits, and sex ratios.

Gotelli, Nicholas J. *A Primer of Ecology*. 2d ed. Sunderland, Mass.: Sinauer Associates, 1998. Covers the essential mathematical models of ecology. Makes the assumptions and predications of the models explicit, and provides empirical examples of each. Each chapter includes problems and solutions. Written for undergraduate and graduate students.

Hutchinson, G. Evelyn. *An Introduction to Population Ecology*. New Haven, Conn.: Yale University Press, 1978. Presents an engaging account of the study of populations by a very well-respected ecologist. Chapter 2, "Interesting Ways of Thinking About Death," provides the reader with a perspective on survivorship analysis that includes examples from humans, vertebrates, invertebrates, and plants. Also discusses the interrelationships between fecundity and other demographic properties.

Smith, Robert Leo. *Elements of Ecology*. 4th ed. San Francisco, Calif.: Benjamin/Cummings, 2000. This textbook does an excellent job of covering the breadth of topics found in modern ecology. The treatment of the topics is unusually complete and provides a close linkage between theoretical principles and numerous examples from specific ecological situations. Covers population age structure, as well as natality, mortality, and survivorship.

Wilson, Edward O., and William Bossert. *A Primer of Population Biology*. Sunderland, Mass.: Sinauer Associates, 1977. This classic handbook has been used extensively by students wishing to master the basics of population biology. Demography is discussed in a way that emphasizes the estimation of population growth rates from survivorship and reproduction data, as well as the determination of age distributions.

DESERTS

Types of animal science: Ecology, evolution, geography, physiology
Fields of study: Ecology, environmental science, evolutionary science, wildlife ecology

Deserts are home to many living things, despite their treacherous climate. In fact, deserts are second only to tropical rain forests in the variety of plant and animal species that live there. Study of deserts and the organisms that live within them will help us understand and appreciate this unique biome.

Principal Terms

BIOME: a terrestrial ecosystem that occupies an extensive geographical area and is characterized by a specific type of plant community, such as deserts

PERENNIAL: plants that live for several years

RAIN SHADOW: a local dry (desertlike) area created by the modification of rainfall patterns by a mountain range

Deserts are usually defined by their annual rainfall, climate, and the plants and animals that live in them. Most deserts are found in bands along 30 degrees north and south latitude. Other deserts are caused by the rain shadow effect. Deserts are biomes in which less than twenty-five to fifty centimeters of precipitation drops each year. There may be no vegetation or widely spaced vegetation combined with large areas of bare ground. The plants tend to be spaced evenly, as if planted by hand. The desert is a land of extremes: extreme heat and extreme dryness. It is often very hot in the daytime, and somewhat chilly or even very cold at night. The desert is dry most of the year; even the wettest deserts get only ten inches or less of precipitation per year. The scarce precipitation comes from a few very large rains or snows. Due to such extreme conditions, deserts often have names like "Death Valley," "the empty quarter," and "the place from which there is no return." Overall, about one fifth of the land surface of the earth is desert.

Depending upon whether the precipitation comes from rain or snow, deserts can be divided into hot (rain) or cold (snow) deserts. The deserts of Arabia, Australia, Chihuahua, Kalahari, Monte, Sonora, and Thar are all considered hot deserts. Cold deserts include the Atacama, Gobi, Basin, Iranian, Namib, and Turkestan deserts. Regardless of whether the desert is hot or cold, organisms living within desert biomes have to adapt to cope with the scarcity of water and violent swing of temperatures.

Plant Life in Deserts

Desert plant life includes wildflowers, cacti and succulents, and grasses and trees. The desert is renowned for its explosions of spring wildflowers and the succulent cactus that adorn its landscapes. Desert wildflowers assume a variety of shapes and colors; some are beautiful, some are poisonous. Apache plume (*Fallugia paradoxa*) is an evergreen shrub that grows up to six feet high, with small grayish, downy leaves, and round white flowers with yellow centers. Jimson weed (genus *Datura*) has large, white, trumpet-shaped flowers that bloom from March through November. This foul-smelling flower opens after dusk and closes by midmorning of the following day. All parts of datura plants are poisonous and can be fatal if ingested. Desert dandelion (*Malacothrix glabrata*) grows six to fourteen inches high with three- to five-inch leaves. In spring, this bright wildflower will form broad, brilliant patches of gold across the sandy desert floor. Many other species, including desert lily, desert paintbrush, ghost flower, and prickly poppies, help contribute to the beauty of the desert's spring.

The pleated shape of the barrel cactus (genus *Ferocactus*) allows it to expand when it rains so that it can store water in its spongy tissue. It shrinks in size during dry times as it uses the stored water. The fishhook cactus (*Mammillaria microcarpa*) has fishhook-shaped spines that help divert heat and shade the growing tip of the plant. Prickly pear cactus (genus *Opuntia*) includes about a dozen species, all with modified stems and leaves for water storage, photosynthesis, and flower production. The saguaro cactus (*Carnegiea gigantea*) is equipped with a green stem to store water and perform photosynthesis, and large nets of roots that collect water after rain.

The Crucifixion thorn tree (*Chaparro amargosa*) exhibits no leaves but has intricately branched, thick, rigid, sharp spines, which perform photosynthesis and conserve water. The Joshua tree (*Yucca brevifolia*) grows only in the Mojave Desert. This picturesque, spike-leafed evergreen can grow to forty feet tall, with a diameter of one to three feet. Poison ivy (*Toxicodendron rydbergii*) is a small, woody shrub that lacks the climbing, vine-like structure of its better-known eastern relative, *T. radican*. At least ten species and subspecies bear the common name "poison ivy," a notoriously poisonous plant. Plants that live in the desert help animals by providing them with food, water, and shade.

Animal Life in Deserts

Animals living in the desert include mammals, birds and fish, reptiles and amphibians, and insects and spiders. A few examples of mammals

Deserts are arid but not entirely devoid of life: Scrub vegetation, cacti, and animals adapted to dry conditions can flourish there. (PhotoDisc) include bats, bighorn sheep, bobcats, and coyotes. Desert bats, members of the suborder Microchioptera, are often considered to be flying mice, but they are more closely related to primates. Bats are unique among mammals because they can fly. Most bat species also possess a system of acoustic orientation, technically known as echolocation. The bighorn sheep lives in dry, desert mountain ranges and foothills near rocky cliffs. Its body is compact and muscular; the muzzle is narrow and pointed; the ears, short and pointed; the tail, very short. The fur is deerlike and usually a shade of brown, with whitish rump patches. Bighorns are grazers, consuming grasses, sedges, and other low-lying plants. The bobcat (*Felis rufus*) has long legs, large paws, and a short tail (six to seven inches long), with average body weight of fifteen to twenty pounds. However, it is quite fierce and is equipped to kill animals as large as deer. The desert coyote (*Canis latrans*), a member of the dog family, weighs about twenty pounds, less than half the weight of its mountain kin, which can weigh up to fifty pounds. Its body color is light gray or tan, which helps it survive in the desert.

A variety of birds reside in the desert due to the abundance of insects and spiders. Golden eagles (*Aquila chrysaetos*) get their name from the golden feathers on the back of their neck. They are birds of the open country, building large stick nests in trees or cliff walls where they have plenty of room to maneuver. Adults weigh 9 to 12.5 pounds, with females usually larger than males. Ravens (*Corvus corax*) are the largest birds of the crow family, averaging twenty-four inches tall, with a wingspan of forty-six to fifty-six inches. Ravens are strong fliers that can soar like a hawk, and may form large flocks of over several hundred individuals during their autumn migration. The American turkey (*Meleagris gallopavo*), the largest upland game bird in North America, is thirty-six to forty-eight inches long, with four- to five-foot wingspans. Males average ten inches longer than females, which are paler and of a more buff color. Turkeys inhabit a variety of habitats from open grassland and fields to open woodlands and mature deciduous or coniferous forests.

Many species of reptiles and amphibians live in desert, including the black-collared lizard (genus *Crotaphytus*), bullfrog (*Rana catesbeiana*), desert dinosaur (orders Saurischia and Ornithischia), desert iguana (*Dispsosaurus dorsalis*), rattlesnake (genus *Crotalus*), and many others. Insects and spiders include dragonflies (suborder Anisoptera), scorpions (order Scorpionida), and black widow spiders (*Latrodectus hesperus*). It is nothing short of a miracle that such an abundance of lives, both plants and animals, can survive in the extreme conditions of the desert.

The Survival of Plants in the Desert

Desert plants have adapted to the extremes of heat and cold and of aridity by using both physical and behavioral mechanisms. Plants that have adapted by altering their physical structure are called xerophytes, having special means for storing and conserving water. They often have few or no leaves, which reduces transpiration. Phreatophytes are plants that have adapted to arid environments by growing extremely long roots, allowing them to acquire moisture at or near the water table. Other desert plants, using behavioral adaptations, have developed a lifestyle in conformance with the seasons of greatest moisture and/or coolest temperatures. Desert perennials often survive by remaining dormant during dry periods of the year, then springing to life when water becomes available. Most annual desert plants germinate only after heavy seasonal rain, then complete their reproductive cycle very quickly. They bloom prodigiously for a few weeks in the spring, accounting for most of the annual wildflower explosions of the deserts. Their seeds are drought- and heat-resistant and remain dormant until the next year's rains.

Animal Survival in the Desert

Among the thousands of desert animal species, there are many remarkable behavioral and structural adaptations developed for avoiding excess heat. Equally ingenious are the diverse mechanisms various animal species have developed to acquire, conserve, recycle, and actually manufacture water.

Certain species of birds, such as the *Phanopepla*, breed during the relatively cool spring, then leave the desert for cooler areas at higher elevations or along the Pacific coast. The Costa's hummingbird begins breeding in late winter and leaves in late spring when temperatures become extreme. Many birds, as well as other mammals and reptiles, are crepuscular, meaning they are active only at dusk and again at dawn. Many animals, including bats, many snakes, most rodents, and some larger animals such as foxes and skunks, are nocturnal, restricting all their activities to the cooler temperatures of the night, and sleeping in a cool den, cave, or burrow by day. A few desert animals, such as the round-tailed ground squirrel, sleep away the hottest part of summer and also hibernate in winter to avoid the cold season. Yet other animals, such as desert toads, remain dormant deep in the ground until the summer rains fill ponds. They then emerge, breed, lay eggs, and replenish their body reserves of food and water for another long period.

Various mechanisms are employed to dissipate heat absorbed by desert animals. Many mammals have long appendages to release body heat into their environment. The enormous ears of jackrabbits, with their many blood vessels, dissipate heat when the animal is resting in a cool, shady location. Their close relatives in cooler regions have much shorter ears. New World vultures, dark in color and thus absorbing considerable heat in the desert, excrete urine on their legs to cool them by evaporation, and circulate the cooled blood back through the body. Many desert animals are paler than their relatives elsewhere, ensuring that they not only suffer less heat absorption, but also are less conspicuous to predators in the bright, pallid surroundings.

The mechanisms by which water is retained by desert animals are even more elaborate. Reptiles and birds excrete metabolic wastes in the form of uric acid, an insoluble white compound, wasting very little water in the process. Other animals retain water by burrowing into moist soil during the dry daylight hours. Some predatory and scavenging animals can obtain their entire water needs from the food they eat. Most mammals, however, need access to a good supply of fresh water at least every few days, if not daily, due to the considerable water loss from excretion of urea, a soluble compound.

Many desert animals obtain water from plants, particularly succulent ones such as cactus and saguaro. Many species of insects thrive in the desert, as they tap plant fluids for water and nectar. The abundance of insect life permits insectivorous birds, bats, and lizards to thrive in the desert. Certain desert animals, such as kangaroo rats, have multiple adaptation mechanisms to acquire and conserve water. First, they live in underground dens that they seal off to block out heat and to recycle the moisture from their own breathing. Second, they have specialized kidneys with extra microscopic projections to extract most of the water from their urine and return it to the bloodstream. Third, and most fascinating of all, they actually manufacture their water metabolically from the digestion of dry seeds. These are just a few examples of the ingenious variety of adaptations animals use to survive in the desert, overcoming the extremes of heat and the paucity of water.

DETERMINATION AND DIFFERENTIATION

Type of animal science: Reproduction
Fields of study: Anatomy, cell biology, physiology

Determination is the process whereby the fate of embryonic cells becomes fixed, and differentiation is the process whereby cells acquire their ultimate specialized structure and function. These processes lead to the wide diversity of cell types found in multicellular organisms.

Principal Terms

COMMITMENT: the "decision" by an embryonic cell to develop in a certain way, which may be reversed if the cell is removed from its normal surroundings

EMBRYONIC INDUCTION: the point at which one embryonic tissue signals another embryonic tissue to develop in a certain way

GENOME: all the genes of one organism or species

MORPHOGENESIS: the development of form, including the overall form of the organism and the form of each organ and tissue

MOSAIC DEVELOPMENT: the process whereby early embryonic cells are determined by the cytoplasm they receive from the egg; also called determinate development

REGULATIVE DEVELOPMENT: the process whereby early embryonic cells are determined by their interactions with other cells; also called indeterminate development

RESTRICTION: reduction of the developmental potency of a cell

TOTIPOTENT: the ability of a cell to develop into any kind of cell in the body

From the time a fertilized ovum begins to divide (cleavage) until it forms a complete organism, it passes through successive stages in which groups of cells become increasingly specialized. This process of cell specialization involves two key steps: determination, in which cells become committed to a certain developmental pathway, and differentiation, in which cells acquire their ultimate structure and function. The term "differentiation" may also be used in a broader sense to describe the entire process of cell specialization. A third process, called morphogenesis, is needed in order to mold the embryonic cells structurally into the various tissues and organ systems of the mature organism. For example, in eye development the specialized photoreceptor cells of the retina are a product of determination and differentiation, but their organization into the overall structure of the eye is a product of morphogenesis.

The Process of Specialization

In animal development, the fertilized ovum (zygote) has the potential to develop into any type of cell in the body; it is said to be totipotent. As it undergoes cell division beyond the first few cleavages, the resulting cells (blastomeres) lose their totipotency. This point is reached at different stages in different species. In the sea urchin, for example, isolated cells of the two- or four-cell embryo are capable of developing into complete new adults; in other species, such as the tooth shell clam (*Dentalium*), these early cleavage cells, when isolated, do not have the potential to develop into a complete organism. In all animals, the cells of later embryos lose their ability to form complete new organisms. This loss of developmental potency of cells is called restriction and is dictated to some extent both by the type of cytoplasm with which the cell is endowed and the influence of surrounding cells. As development progresses, restricted cells become "committed" to develop into a specific tissue. Under normal conditions, these cells will always develop into this designated tissue; if, however, the cells are moved experimentally to some other part of the embryo or to another embryo, they will develop in a different way. That is why commitment is said to be reversible but determination is not.

Determination occurs when a group of cells becomes irreversibly assigned to develop into a specific tissue. Determination is the final step in restriction; beyond this point, the cells have no other developmental options. Determined cells may or may not look different from other embryonic cells, but they have changed internally so that they are committed to a particular developmental pathway. Determined cells are said to be self-perpetuating, because they can pass on heritable information about their identity and do not require stimulation by surrounding cells to develop in a certain way.

Once the fate of a cell is determined, then differentiation (also called cell differentiation or cytodifferentiation) can take place. During differentiation, the cell undergoes structural and functional changes which result in a highly specialized, mature, differentiated cell. For example, the red blood cell becomes specialized by losing its nucleus and other organelles in order to fill itself completely with the oxygen-carrying molecule hemoglobin. It also maximizes its surface area by becoming flattened and doughnut shaped. Primitive muscle cells, called myoblasts, become specialized by fusing together to form elongated multinuclear cells called myotubes. These cells further specialize by forming contractile organelles called myofibrils, composed primarily of the proteins actin and myosin.

The Role of Genes

At one time it was believed that the genetic determinants (genes) were divided up and parceled out as determination and differentiation progressed, such that each cell type received certain genes. This hypothesis was disproved in several ways, one of them being nuclear transplantation experiments, in which adult cell nuclei were transplanted into fertilized eggs whose nuclei had been removed or inactivated. A small percentage of these eggs were able to develop into normal adults, thus proving that the adult nuclei implanted in them retained all the genes necessary to form a complete organism. These and other experiments have led to the conclusion that both determination and differentiation occur because certain genes are expressed at certain times during the life history of the cell. There remains, however, the question of how genes are turned on and off to control development.

All developmental processes are believed to be controlled by genes as part of an intricate developmental program. The genes of individual cells are activated or deactivated via various signaling mechanisms in order to provide the correct cellular responses at the appropriate times. This process begins very early in development and even occurs in the egg before fertilization. Messenger ribonucleic acid (RNA) and proteins are produced by the egg and distributed unequally in the cytoplasm of different parts of the egg. When cleavage occurs, blastomeres in one part of the embryo receive cytoplasm that differs from the cytoplasm received by blastomeres in another part of the embryo; thus, some cells are endowed with one kind of messenger RNA and protein and other cells with another kind. In some species, cleavage is even unequal, in order to ensure that certain cells receive the desired cytoplasm. For example, in the nematode *Caenorhabditis elegans*, unequal cleavage results in the establishment of five different tissue types by the sixteen-cell stage. As the messenger RNA is expressed in the form of new proteins, it gives unique qualities to the cells. Some of these new proteins and the proteins made earlier in the egg may be signal molecules, which stimulate new and unique gene expression in the nucleus.

Another mechanism for turning genes on and off is called embryonic induction, which occurs when one embryonic tissue influences the development of another by releasing chemical factors called inductors. The inductors are signal molecules that instruct cells of another tissue how to develop by directly or indirectly activating certain genes. Induction is especially noticeable after the formation of distinct tissues, such as the three germ layers, ectoderm, endoderm, and mesoderm. In vertebrates, the mesoderm induces the formation of the neural tube and various other parts of the nervous system.

Another set of mechanisms, similar to embryonic induction, that controls differentiation involves the microenvironment in which the embryonic cells exist. These mechanisms include such parameters as the position of a cell in relation to other cells in the embryo; the interactions of cells with the extracellular milieu, including ions, pH, oxygen, and extracellular matrix proteins such as collagen; direct cell-to-cell contact; and the presence of specific growth and differentiation factors. The cells in one part of the developing embryo will experience a completely different set of microenvironmental influences from that of cells in another part of the embryo and consequently will be prompted to express their genes in different ways. Once the genes have been expressed, there must be a means for the daughter cells to retain the unique gene expression of the parent cell. That is most likely accomplished by proteins passed on to the daughter cells that continue to activate or deactivate the appropriate genes.

Genetic Recombination and Transcription

Although the genome is not modified extensively during embryonic development, there is evidence that certain changes occur in order to enhance differentiation. One of these mechanisms is called genetic recombination and involves breaking and rejoining deoxyribonucleic acid (DNA) at defined sites. For example, in maize, segments of DNA called transposons move around the genome and presumably take control of specific genes at certain times during development. Another example of genome modification occurs in the nematode *Ascaris*, in which parts of the chromosomes are discarded (in a process called chromosome diminution) during cleavage. The discarded chromatin is believed to be composed of extra copies of DNA sequences that are not ordinarily transcribed. The genome is also modified through the making of extra copies of essential genes (gene amplification). For example, some genes in the follicle cells surrounding the maturing oocyte of *Drosophila* are amplified about thirty times in order to code for the large amount of protein needed to make the egg chorion. As cells differentiate, the types of messenger RNA and protein they produce become increasingly selective, so that eventually each cell type has a unique pattern of gene expression. There will always, however, be common genes expressed in every cell that are needed for basic housekeeping processes, such as respiration and transport.

Selective gene transcription is carefully controlled by various mechanisms involving the blocking and unblocking of DNA. Two classes of nuclear proteins are believed to be involved in switching genes on and off: histones and nonhistones. Histones associate with DNA molecules in such a way that they block the DNA from being transcribed. The nonhistones are believed to remove or rearrange histones so that the DNA can be replicated or transcribed. Some nonhistone proteins are gene-regulatory proteins, which recognize a particular DNA sequence. The binding of these proteins with DNA can either facilitate or inhibit transcription. An additional control found only in vertebrates is methylation, by which methyl groups are added to the DNA base cytosine. In general, the inactive genes of vertebrates are more highly methylated than active genes; thus, methylation may serve to strengthen decisions involving gene expression that are made during differentiation.

Once the appropriate messenger RNA has been produced, it still must be translated into protein and the protein must be assembled and made functional. For example, hemoglobin protein (globin) translation is controlled by the presence of heme, the iron-containing portion of the hemoglobin molecule. In the absence of heme, the factor that initiates globin translation is inactivated; thus, even though the appropriate messenger RNA and other necessary ingredients are present, without heme no hemoglobin protein will be produced. Even after proteins are translated, they are subject to further regulatory mechanisms, such as assembly into functional units, activation or inactivation by various enzymes and other factors, and transport to their cellular destination.

Studying Embryology

The study of embryology was transformed from a purely descriptive science into an experimental science by investigators who developed microsurgical techniques in the 1890's. They discovered that the separated blastomeres of some early embryos, such as the sea urchin, could develop into complete normal larva (regulative or indeterminate development) and that the blastomeres of others, such as the tunicate, could form only parts of embryos (mosaic or determinate development). This led to an appreciation of the importance of nuclear-cytoplasmic interactions and the fact that egg cytoplasm distribution plays an important role in determining how certain blastomeres develop. Further microsurgical separation studies on embryos in later stages (thirty-two-cell to sixty-four-cell stages) demonstrated that the microenvironment of some embryos approximates a double gradient consisting of animal pole factors in one half and vegetal pole factors in the other half. These two chemical gradients influence the cell nuclei in their respective zones and cause the cells to become progressively determined in certain ways. Thus, simply by manipulating embryonic cells, scientists were able to demonstrate the concepts of restriction and determination.

Another microsurgical technique developed in the first half of the twentieth century involves transplanting tissue from one embryo to another. When tissue that normally forms the brain is transplanted to an area of another embryo that normally forms skin, the transplanted tissue develops independently and begins to form into brain. Thus, the tissue has become irreversibly committed or determined to form a particular adult tissue. If the same transplant is done at an earlier stage, the transplanted tissue conforms to its surroundings and forms epidermis. These results indicate that tissues are capable of changing their normal fate if they are influenced by another tissue before determination. In some instances, the transplanted tissue induces the surrounding tissue to change its normal fate. Such is the case when tissue from the dorsal lip of the blastopore of an amphibian gastrula is transplanted to the lateral lip area of another gastrula. The transplanted tissue induces the formation of a second complete embryonic axis, resulting in laterally conjoined twins.

Another elementary method that has yielded a large amount of information about determination is cell marking and tracing. At first, investigators took advantage of different natural pigments that are present in certain animal embryos by following the fate of each blastomere. They discovered that each colored cytoplasm gives rise to a specific embryonic fate. For example, the yellow crescent cytoplasm of the tunicate (*Styela partita*) embryo gives rise to adult muscle cells. In other studies, cells were marked with vital dyes, carbon particles, enzymes, radioactive labels, and distinctive cells transplanted from another embryo. By tracing these labeled cells, investigators were able to ascertain their ultimate fate and when and where cell determination takes place.

One question that needed to be answered by experimental embryologists was whether the nuclei of determined and differentiated cells are irreversibly modified. That all the genetic material is present in differentiated cells could be shown by microscopic observations of the chromosomes, especially the large polytene chromosomes of larval flies, such as *Drosophila*. The only way to show whether these chromosomes were functional, however, was to transplant the nucleus of a differentiated cell into an enucleated egg and see if it could direct the development of a complete organism. The technique of nuclear transplantation (sometimes called cloning), developed in the 1950's, did indeed prove that nuclei from differentiated cells are totipotent. Success was not universal with all tissue types, however, and only a small percentage of the transplants actually succeeded, which indicates that restriction of potency does involve changes in the nucleus but not permanent modification of the genome itself.

Methodology

The study of differentiation can be approached by several methods. The simplest is to observe tissues microscopically as they differentiate. That is done most often by fixing embryos at various stages of development and observing thinly sliced sections of them with a light or electron microscope. Another method is to explant cells, tissue, or organs from embryos and observe them in culture (in vitro). By doing so, scientists can manipulate the environment of the cultured cells in order to find out precisely what conditions are necessary for differentiation to occur. In vitro culture also makes possible such techniques as synchronizing cell growth in order to study the relationship between cell division and cell differentiation, and cell fusion in order to see how the contents of one cell affect the behavior of another.

Various biochemical and molecular techniques are used to study the roles of many biological molecules in differentiation. Of particular interest are separation methods that allow scientists to isolate and identify proteins and other factors involved in the differentiation process. These molecules can be isolated by first homogenizing the cells and then separating the desired molecules by centrifugation (based on density), electrophoresis (based on electrical charge), or chromatography (based on molecular size). Once the molecules are isolated, their properties can be studied, including the biological activity. At times it is important to know if a particular sequence of DNA or RNA is present in an embryonic cell. That can be determined by a technique called hybridization, whereby single-stranded DNA is allowed to match up and adhere to a complementary strand of DNA or RNA. Usually one of the strands is radioactively labeled so that the sequence in question can be detected and measured. The usefulness of this technique has become greatly enhanced by the development of recombinant DNA technology, which allows for the construction of specific molecular probes (DNA sequences) that can be radiolabeled and used to detect cellular DNA and RNA by hybridization. One step beyond this is the technique of DNA transformation, whereby isolated genes are modified and then reintroduced into cells to determine the new properties of the altered gene when it is expressed.

Determination and differentiation are the foundations of cell diversification. There are approximately two hundred distinctly different cell types in mammals. Without cell specialization, organisms would not be able to move, breathe, think, or perform any of the many other functions necessary to sustain life.

Bibliography

Alberts, Bruce, Dennis Bray, Julian Lewis, Martin Raff, Keith Roberts, and James D. Watson. *Molecular Biology of the Cell*. 3d ed. New York: Garland, 1994. A readable, complete, and coherent text intended for use in colleges and medical schools. Chapters on the control of gene expression and cellular mechanisms of development provide the details of many processes involved in determination and differentiation. Emphasis is on molecular biology, but the overall processes are well described and illustrated with many diagrams and photographs. Contains an extensive list of references.

Bellvé, Anthony R., and Henry J. Vogel, eds. *Molecular Mechanisms in Cellular Growth and Differentiation*. San Diego, Calif.: Academic Press, 1991. A collection of interdisiplinary essays that address the connections between protooncogenes and oncogenes, and peptide growth factors, as well as the details of molecular mechanisms that are exhibited in specific organ systems.

Carlson, Bruce M. *Patten's Foundations of Embryology*. 6th ed. New York: McGraw-Hill, 1996. A widely available introductory college embryology text. Includes excellent introductory sections on determination and differentiation as well as a complete description of methods used in the study of embryonic development, as well as a more detailed discussion of cell differentiation, especially in muscle and skeletal cells. The book is well referenced and provides many excellent diagrams and photographs.

Gilbert, Scott F. *Developmental Biology*. 6th ed. Sunderland, Mass.: Sinauer Associates, 2000. A college textbook written clearly and concisely and providing an excellent historical perspective, especially with regard to the investigation of determination and differentiation. Includes several chapters dealing with nuclear and cytoplasmic interactions during determination and differentiation. The author cites key original articles on most of the important discoveries in the field of developmental biology and provides many informative diagrams and photographs.

Hennig, W., ed. *Early Embryonic Development of Animals*. New York: Springer-Verlag, 1992. An introductory textbook to the specialty of early embryonic development. Presents a variety of approaches and facets, focusing on the species most used in research: *Drosophila*, *Caenorhabditis*, the mouse, and the increasingly popular zebrafish.

Ruddon, Raymond W. *Cancer Biology*. 3d ed. New York: Oxford University Press, 1995. A widely available book designed as a primary or supplementary text for college and medical school cancer courses. The chapter on regulation of cellular differentiation provides an interesting and readable account of differentiation. The narrative is interspersed with a few helpful diagrams, and the author cites more than two hundred references related to differentiation. An interesting presentation on the relationship between differentiation and cancer is also included.

DEVELOPMENT: EVOLUTIONARY PERSPECTIVE

Type of animal science: Development
Fields of study: Evolutionary science, genetics, invertebrate biology, systematics (taxonomy), zoology

The relationship between ontogeny (individual development) and phylogeny (the evolution of species and lineages) is an enduring theme in the life sciences. Changes in developmental timing produce parallels between ontogeny and phylogeny. The subject illuminates the biology of regulation, the evolution of ecological strategies, and the mechanisms for evolutionary change in form.

Principal Terms

ACCELERATION: the appearance of an organ earlier in the development of a descendant than in the ancestor as a result of an acceleration of development

HETEROCHRONY: changes in developmental timing that produce parallels between ontogeny and phylogeny; changes in the relative time of appearance and rate of development for organs already present in ancestors

NEOTENY: either the retention of immature characteristics in the adult form or the sexual maturation of larval stages

ONTOGENY: the successive stages during the development of an animal, primarily embryonic but also postnatal

PAEDOMORPHOSIS: the appearance of youthful characters of ancestors in later ontogenetic stages of descendants

PHYLOGENY: a series of stages in the evolutionary history of species and lineages

RECAPITULATION: the repetition of phylogeny in ontogeny or of the ancestral adult stages in the embryonic stages of descendants

RETARDATION: the appearance of an organ later in the development of a descendant than in the ancestor as a result of a slowing of development

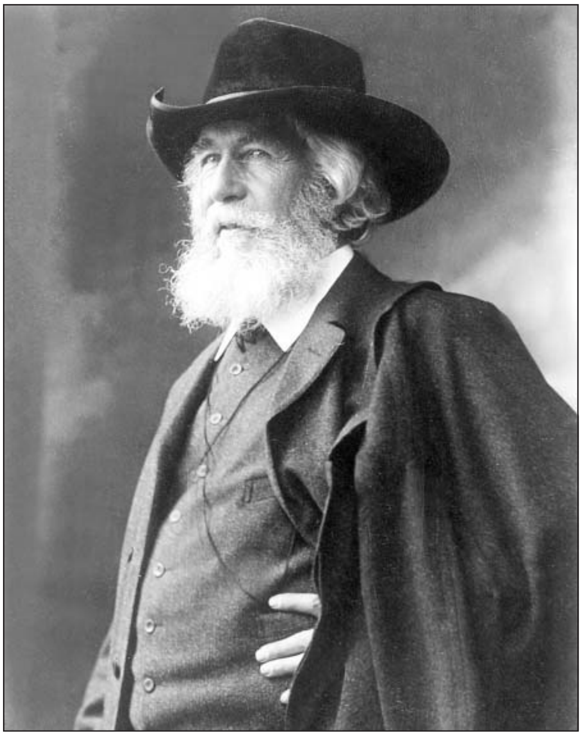
The idea of a relationship between individual development, or ontogeny, and the evolutionary history of a race, or phylogeny, is an old one. The concept received much attention in the nineteenth century and is often associated with the names of Karl Ernst von Baer and Ernst Haeckel, two prominent German biologists. It was Haeckel who coined the catchphrase and dominant paradigm: Ontogeny recapitulates (or repeats) phylogeny. Since Haeckel's time, however, the relations between ontogeny and phylogeny have been portrayed in a variety of ways, including the reverse notion that phylogeny is the succession of ontogenies. Research in the 1970's and 1980's on the parallels between ontogeny and phylogeny focused on the change of timing in developmental events as a mechanism for recapitulation and on the developmental-genetic basis of evolutionary change.

Concepts of Biogenetic Law in the Nineteenth Century

During the early nineteenth century, two different concepts of parallels between development and evolution arose. The German J. F. Meckel and the Frenchman E. R. Serres believed that a higher animal in its embryonic development recapitulates the adult structures of animals below it on a scale of being. Baer, on the other hand, argued that no higher animal repeats an earlier adult stage but rather the embryo proceeds from undifferentiated homogeneity to differentiated heterogeneity, from the general to the specific. Von Baer published his famous and influential four laws in 1828: The more general characters of a large group of animals appear earlier in their embryos than the more special characters; from the most general forms, the less general are developed; every embryo of a given animal, instead of passing through the other forms, becomes separated from them; the embryo of a higher form never resembles any other form, only its embryo.

By the late nineteenth century, the notion of recapitulation and Baer's laws of embryonic similarity were recast in evolutionary terms. Haeckel, and others, established the biogenetic law: That is, ontogeny recapitulates the adult stages of phylogeny. It was, in a sense, an updated version of the Serres-Meckel law but differed in that the notion was valid not only for a chain of being but also for many divergent lines of descent; ancestors had evolved into complex forms and were now considered to be modified by descent. More specifically, Haeckel thought of ontogeny as a short and quick recapitulation of phylogeny caused by the physiological functions of heredity and adaptation. During its individual development, he wrote, the organic individual repeats the most important changes in form through which its forefathers passed during the slow and long course of their paleontological development. The adult stages of ancestors are repeated during the development of descendants but crowded back into earlier stages of ontogeny. Ontogeny is the abbreviated version of phylogeny. These repeated stages reflect the history of the race. Haeckel considered phylogeny to be the mechanical cause of ontogeny.

The classic example of recapitulation is the stage of development in an unhatched bird or unborn mammal when gill slits are present. Haeckel argued that gill slits in this stage represented gill slits of the adult stage of ancestral fish, which in birds and mammals were pressed back into early stages of development. This theory differed from von Baer's notion that the gill slit in the human embryo and in the adult fish represented the same stage in development. The gill slits, explained the recapitulationists, got from a large adult ancestor to a small embryo in two ways: first, terminal addition (in which stages are added to the end of an ancestral ontogeny); and second, condensation (in which development is speeded up as ancestral features are pushed back to earlier stages of the embryo). Haeckel also coined another term widely used currently in another sense: "heterochrony." He used the term to denote a displacement in time of the appearance of one organ in ontogeny before another, thus disrupting the recapitulation of phylogeny in ontogeny. Haeckel was not, however, interested primarily in mechanisms or in embryology for its own sake, but rather for the information it could provide for developing evolutionary histories.



Ernst Haeckel coined the phrase, "Ontogeny recapitulates phylogeny," meaning that in their individual development, animals repeat the major evolutionary steps taken by the species as a whole. (Library of Congress)

Recapitulation in the Twentieth Century

With the rise of mechanistic experimental embryology and with the establishment of Mendelian genetics in the early twentieth century, the biogenetic law was largely repudiated by biologists. Descriptive embryology was out of fashion, and the existence of genes made the two correlate laws to recapitulation—terminal addition and condensation—untenable. One of the most influential modifications for later work on the subject was broached in a paper by Walter Garstang in 1922, in which he reformulated the theory of recapitulation and refurbished the concept of heterochrony. Garstang argued that phylogeny does not control ontogeny but rather makes a record of the former: That is, phylogeny is a result of ontogeny. He suggested that adaptive changes in a larval stage coupled with shifts in the timing of development (heterochrony) could result in radical shifts in adult morphology.

Stephen Jay Gould resurrected the long unpopular concept of recapitulation with his book *Ontogeny and Phylogeny* (1977). In addition to recounting the historical development of the idea of recapitulation, he made an original contribution to defining and explicating the mechanism (heterochrony) involved in producing parallels between ontogeny and phylogeny. He argued that heterochrony—"changes in the relative time of appearance and rate of development for characters already present in ancestors"—was of prime evolutionary importance. He reduced Gavin de Beer's complex eight-mode analysis of heterochrony to two simplified processes: acceleration and retardation. Acceleration occurs if a character appears earlier in the ontogeny of a descendant than it did in an ancestor because of a speeding up of development. Conversely, retardation occurs if a character appears later in the ontogeny of a descendant than it did in an ancestor because of a slowing down of development. To demonstrate these concepts, Gould introduced a "clock model" in order to bring some standardization and quantification to the heterochrony concept.

He considered the primary evolutionary value of ontogeny and phylogeny to be in the immediate ecological advantages for slow or rapid maturation rather than in the long-term changes of form. Neoteny (the opposite of recapitulation) is the most important determinant of human evolution. Humans have evolved by retaining the young characters of their ancestors and have therefore achieved behavioral flexibility and their characteristic form. For example, there is a striking resemblance between some types of juvenile apes and adult humans; this similarity for the ape soon fades in its ontogeny as the jaw begins to protrude and the brain shrinks. Gould also insightfully predicted that an understanding of ontogeny and phylogeny would lead to a rapprochement between molecular and evolutionary biology.

By the 1980's, Rudolf Raff and Thomas Kaufman found this rapprochement by synthesizing embryology with genetics and evolution. Their work focuses on the developmental-genetic mechanisms that generate evolutionary change in morphology. They believe that a genetic program governs ontogeny, that the great decisions in development are made by a small number of genes that function as switches between alternate states or pathways. When these genetic switch systems are modified, evolutionary changes in morphology occur mechanistically. They argue further that regulatory genes—genes that control development by turning structural genes on and off—control the timing of development, make decisions about the fates of cells, and integrate the expression of structural genes to produce differentiated tissue. All this plays a considerable role in evolution.

Description Versus Experimentation

Both embryology and evolution have traditionally been descriptive sciences using methods of observation and comparison. By the end of the nineteenth century, a dichotomy had arisen between the naturalistic (descriptive) and the experimentalist tradition. The naturalists' tradition viewed the organism as a whole, and morphological studies and observations of embryological development were central to their program. Experimentalists, on the other hand, focused on laboratory studies of isolated aspects of function. A mechanistic outlook was compatible with this experimental approach.

Modern embryology uses both descriptive and experimental methods. Descriptive embryology uses topographic, histological (tissue analysis), cytological (cell analysis), and electron microscope techniques supplemented by morphometric (the measurement of form) analysis. Embryos are visualized using either plastic models of developmental stages, schematic drawings, or computer simulations. Cell lineage drawings are also used with the comparative method for phylogenies.

Experimental embryology, on the other hand, uses more invasive methods of manipulating the organism. During this field of study's early period, scientists subjected amphibian embryos to various changes to their normal path of development; they were chopped into pieces, transplanted, exposed to chemicals, and spun in centrifuges. Later, fate maps came into usage in order to determine the future development of regions in the embryo. It was found that small patches of cells on the surface of the embryo could be stained, without damaging the cell, by applying small pieces of agar soaked in a vital dye. One could then follow the stained cells to their eventual position in the gastrula.

Interdisciplinary Studies

Evolutionary theory primarily uses paleontology (study of the fossil record) to study the evolutionary history of species, yet Gould has also used quantification (the clock model, for example), statistics, and ecology to understand the parallels between ontogeny and phylogeny. Most scientists interested in the relationships between ontogeny and phylogeny chiefly use comparative and theoretical methods. They, for example, compare structures in different animal groups or compare the adult structures of an animal with the young stage of another. If similarities exist, are the lineages similar? Are the stages in ontogenetic development similar to those of the development of the whole species?

Yet, the study of relationships between ontogeny and phylogeny is an interdisciplinary subject. Not only are methods from embryology and evolutionary theory of help, but also, increasingly, techniques are applied from molecular genetics. Haeckel's method was primarily a descriptive historical one, and he collected myriad descriptive studies of different animals. Although scientists in those days had relatively simple microscopes, they left meticulous and detailed accounts.

A fusion of embryology, evolution, and genetics involves combining different methods from each of the respective disciplines for the study of the relationship between ontogeny and phylogeny. The unifying approach has been causal-analytical, in the sense that biologists have been examining mechanisms that produce parallels between ontogeny and phylogeny as well as the developmental-genetic basis for evolutionary change. The methods are either technical or theoretical. The technical ones include the use of the electron microscope, histological, cytological, and experimental analyses; the theoretical methods include comparison, historical analysis, observations, statistics, and computer simulation.

Ramifications Beyond Science

The relationship between ontogeny and phylogeny is one of the most important ideas in biology and a central theme in evolutionary biology. It illuminates the evolution of ecological strategies, large-scale evolutionary change, and the biology of regulation. This scientific idea has also had far-reaching influences in areas such as anthropology, political theory, literature, child development, education, and psychology.

In the late nineteenth century, embryological development was a major part of evolutionary theory; however, that was not the case for much of the twentieth century. Although there was some interest in embryology and evolution from the 1920's to 1950's by Garstang, J. S. Huxley, de Beer, and Richard Goldschmidt, during the first three decades of the twentieth century genetics and development were among the most important and active areas in biological thought, yet there were few attempts to integrate the two areas. It is this new synthesis of evolution, embryology, and genetics that has emerged as one of the most exciting frontiers in the life sciences.

Although knowledge to be gained from a synthesis of development and evolution seems not to have any immediate practical application, it can offer greater insights into mechanisms of evolution, and a knowledge of evolution will give similar insights into mechanisms of development. A study of these relations and interactions also enlarges humankind's understanding of the nature of the development of individuals and their relation to the larger historical panorama of the history of life.

Bibliography

Bonner, J. T. *Morphogenesis: An Essay on Development*. Princeton, N.J.: Princeton University Press, 1952. A delightful treatment of ideas and concepts of development. Good introduction on development for both high school and college students.

De Beer, Gavin. *Embryos and Ancestors*. Oxford, England: Clarendon Press, 1951. A short, clearly written argument repudiating the theory of recapitulation. The first part is accessible to both advanced high school and college students; the second part, on his theory of heterochrony, is more difficult and complex.

Gould, Stephen Jay. *Ontogeny and Phylogeny*. Cambridge, Mass.: Harvard University Press, 1977. A detailed history of the relationship between ontogeny and phylogeny from the Greeks to the present. The historical part is accessible to both high school and college students. The portion on Gould's theory is more suitable for advanced college students. Includes glossary of terms and comprehensive bibliography.

_______. "Ontogeny and Phylogeny—Revisited and Reunited." *BioEssays* 14, no. 4 (April, 1992): 275-280. Revisits the topic of his 1977 book.

Hall, Brian K. *Evolutionary Developmental Biology*. 2d ed. New York: Chapman & Hall, 1998. An up-to-date college and graduate-level text book. Covers the historical contexts of evolutionary developmental biology; embryos in development and in evolution; the relationship between embryos, evolution, environment and ecology; heterochrony and heterotrophy; and the principles and processes that underlie evolutionary developmental biology. Heavily illustrated.

Raff, Rudolf A., and Thomas C. Kaufman. *Embryos, Genes, and Evolution: The Developmental-Genetic Basis of Evolutionary Change*. New York: Macmillan, 1983. A cogently argued and comprehensive textbook on the subject of ontogeny and phylogeny with the added modern element of molecular genetics. Includes an introductory historical chapter that differs from Gould's in its emphasis on morphology and its reference to Richard Goldschmidt's influential work on developmental genetics. Comprehensive bibliography with emphasis on recent, not historical, works.

Schwartz, Jeffrey H. *Sudden Origins: Fossils, Genes, and the Emergence of Species*. New York: Wiley, 1999. A popular summary of the "new evolution," covering the rapid advances in genetics and developmental biology of the twentieth century's last two decades. Focusing on homeobox genes and their effects on embryology and development, Schwartz shows that fossils cannot tell the whole story of evolution, since much of it lies within the womb.

DIGESTION

Type of animal science: Physiology
Field of study: Biochemistry

The structure of different organisms' digestive systems and the presence of various digestive enzymes are correlated with the physical and chemical nature of the food they eat. Plant eaters (herbivores) and meat eaters (carnivores) have predominantly carbohydrate- and protein-digesting enzymes, respectively, while omnivores, which feed on both plants and meat, have all enzymes.

Principal Terms

ENZYME: a protein that acts as a catalyst under appropriate physiological conditions to break down bonds of a large protein, fat, or carbohydrate

ESOPHAGUS: the part of the oral cavity (pharynx) that transfers morsels to the stomach; it is usually a long, muscular tube with no digestive function other than transport

HORMONE: a chemical released into the blood for transport to a specific site, where it will perform a specific function; many hormones stimulate chemical and mechanical aspects of digestion

INTESTINE: the part of the digestive system involved in completing the process of digestion and absorption of nutrients; usually divided into the small intestine and the large intestine, which opens to the exterior by way of the anus

MOUTH: the anterior part of the digestive system, used for ingesting food; it leads into the oral cavity, which opens into the esophagus

MUCUS: a secretion of the salivary glands and other parts of the digestive system which lubricates passages

STOMACH: the part of the digestive system where mechanical breakdown of food is completed and chemical digestion begins

The bulk of animal food consists of proteins, carbohydrates, and fats. In addition, smaller molecules that make up these complex molecules—such as vitamins, nucleic acids, and minerals—are essential components of animal food. Animals obtain their food in the form of solutions, suspensions, dry particles, aggregates, and masses of particles, or whole animals and plants and their parts. It is the selection of food and the feeding behavior of animals that distinguish different animal populations and allow them to live together in the same habitat without competing for the same resources. The organs that break down the food mechanically into small particles and particles into molecules by the processes called digestion constitute what is called a digestive system. Usually the fore (anterior) part of the digestive system of animals is adapted for capturing and breaking down food (the bills and beaks of birds and the jaws of mammals are examples), and the remaining system can become specialized to store, chemically digest, and absorb the digested food and eliminate the unabsorbed food.

The Digestive Sequence

A typical functional sequence of digestion can be summarized as follows: First is the mouth, its appendages, and the oral cavity. These are involved in selecting (by taste, smell, touch), capturing, ingesting, and initial breaking down of food. Secretions here can include lubricants (mucus coming from salivary glands as well as other fluids), anticoagulants (in blood suckers), paralyzing toxins (in carnivorous coelenterates, spiders, reptiles), proteases (in cephalopod mollusks), and carbohydrases (in plant eaters). In microphages, locomotory appendages, oral tentacles with cilia, can drive currents of water containing food toward the mouth. In macrophages, locomotory appendages can be modified to capture food and ingest it. Most small aquatic animals and some large ones strain small particulate material with the help of their body surface projections (cilia, setae, bristles, legs, mucus, or nets); these microphages are called filter-feeders. In vertebrates, movable jaws, and in invertebrates, hard structures or surfaces, can be used for crushing food. The mouth leads into an oral cavity whose posterior chamber is a muscular pharynx that opens into the esophagus.

Second, the muscular, tubular esophagus transfers the food, in bits, to the stomach. Sometimes, a distension in this part of the digestive system (the crop, found in cockroaches and birds, for example) is used to store food.

Third, the stomach, a muscular vessel into which the esophagus leads, mechanically breaks down the food through contractions and wavelike motions, and begins the process of chemical digestion via enzymes. Sometimes the stomach is equipped with hard projections (such as the gizzards and gastric mills of birds, cockroaches, earthworms, or alligators). The lining of the stomach or of its diverticula (branches) secretes digestive enzymes and, in vertebrates, hormones and hydrochloric acid. The stomach opens into the next chamber, the intestine.

Fourth, the small intestine completes the digestive process. Its cells and the cells of its glands (the pancreas, liver, hepatic cecae) secrete digestive fluids containing enzymes and hormones that enable absorption of the resulting molecules and water into the cells of the intestine and from there into the blood. The inner lining of the intestine can be thrown into ridges and microridges, which greatly increase the surface area and thus the amount of absorption.

Fifth, the large intestine, or hindgut, reabsorbs water. The undigested food is evacuated in the form of feces through an opening to the exterior called the anus. This part of the digestive tract also stores colonies of microorganisms, especially in plant eaters, to digest cellulose, lignin, and other substances, and to provide some vitamins that the animal cannot synthesize.

Continuous and Noncontinuous Feeders

In animals that feed on soluble or suspended particles, called continuous feeders, digestion is a continuous process. In these animals, which include sponges, coelenterates, and flatworms, the digestive system is in the form of a tube open at one end only, and the chemical digestion of particles takes place inside each cell lining this tube. Annelids, arthropods, mollusks, and echinoderms have digestive systems that are open at both ends. These animals have developed various other systems, and the digestive system has become independent of the circulatory system. The opening of the digestive tube has allowed these animals to specialize their parts into various regions for capturing, grinding, masticating, mechanically breaking down, chemically digesting, absorbing, and eliminating their food. That, in turn, has allowed them to conduct extracellular digestion in the digestive cavity: to become discontinuous feeders.

Hence, with the evolution of a digestive tube dedicated to digestion only, animals started secreting their cellular enzymes into this cavity in response to food. This, then, constituted extracellular digestion. Extracellular digestion is present in small animals that feed on particles (microphages) or larger animals that feed on bulk food (macrophages). The animals with intracellular digestion and those microphages with extracellular digestion feed continuously and nonselectively. The evolution of a complete digestive tract, opening at both ends, and extracellular digestion have allowed evolution of larger, more active, and more advanced animals. These macrophages feed discontinuously and select their food. The time that they have saved from feeding had been spent to perform other activities and evolve complex behavior patterns. Also, ingestion of a large mass of food has enabled them to obtain the bulk of their energy from this food, which provides a tremendous amount of dependable power to move and even fly.

Digestive Specialization

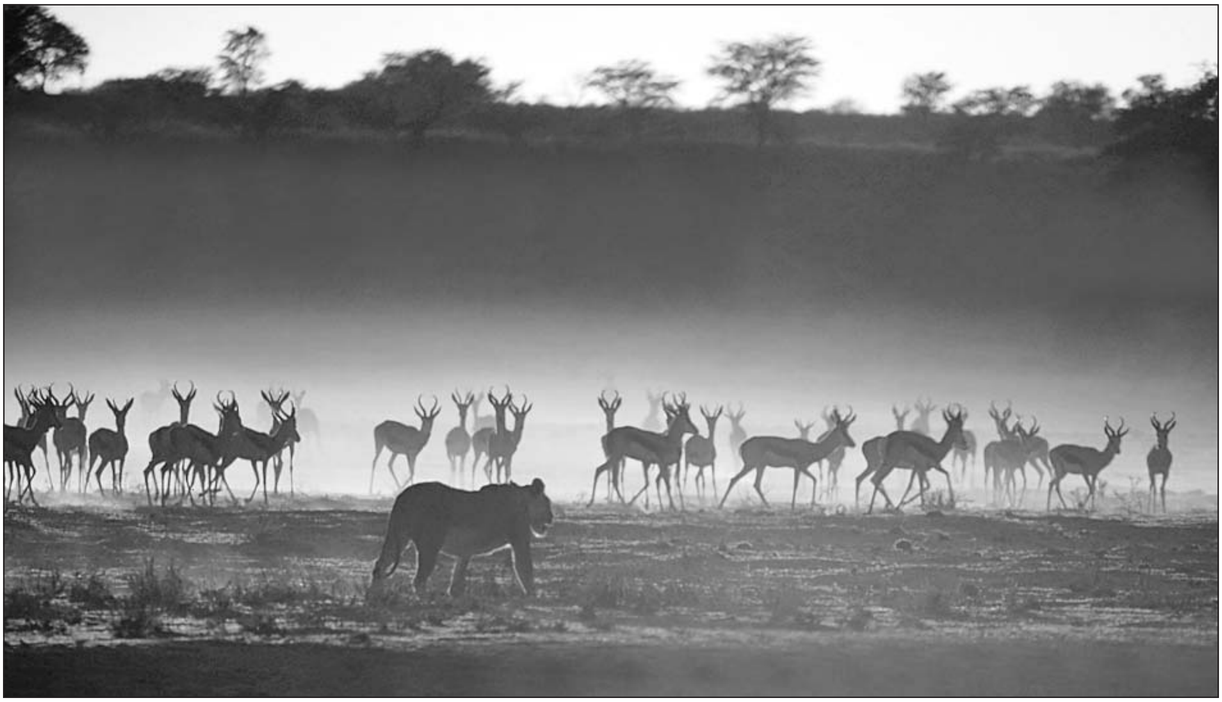
The evolution of a complete digestive tube has resulted in the specialization of its parts for various digestive processes. The general pattern of functional sequence that was outlined above is evident: The digestive system is usually divided into foregut (mouth and its appendages), midgut (for chemical digestion and absorption), and hindgut (for absorption of water and elimination of undigested food). Within this general structure, however, are innumerable and complex variations in adaptation to the type of food and feeding mechanisms of different animals. Those animals that feed on solid food, for example, have appendages (such as jaws and teeth) to enable them to grind, crush, or masticate it. In addition, these may have parts of the stomach modified for storage (such as rumen in ruminants, the crops of birds) or for further grinding (the gizzards of various insects, birds, and alligators). Cows and goats, for example, have four-chambered stomachs, one of which stores colonies of bacteria. These ruminants swallow the food as a whole while grazing. Then, later, while resting, they bring the food and bacteria back to the mouth as cud to mix them together, subsequently swallowing the food. The bacteria then digest cellulose by fermentation. The microorganisms are then digested by the animal in the intestine. These animals also secrete copious amounts of saliva, which prevents abrasive damage by the solid food to the cells lining the foregut.

In fluid feeders, by contrast, the oral end is equipped with sucking apparatus containing piercing devices (as in moths, bees, flies, mosquitoes, and leeches). Some feeders on plant juices ingest large amounts of water with sugars. The last part of their foregut becomes connnected with the anterior part of the hindgut, forming a filtering apparatus (as in insect leaf hoppers). Only water passes from the foregut to the hindgut, while food enters the midgut, which now does not have to process large amounts of water.

The Role of Enzymes

The chemical breakdown of food particles takes place by means of enzyme catalysts, which are proteins that are released into the stomach and intestine (midgut) from their cells or from cells of appendages (hepatic cecae in insects, hepatopancreas in crustaceans and mollusks, and pancreas and liver in vertebrates) opening into the intestine. These enzymes are secreted in response to the entry of food in the gut. Moreover, the presence and release of specific enzymes depend on the chemical nature of the food. In plant-eating herbivores, which eat an abundance of carbohydrates (sugars), these secretions are rich in carbohydrates (carbohydrate-hydrolyzing enzymes), while in animal eaters (carnivores) protein-digesting enzymes, proteases, and fat-hydrolyzing enzymes, lipases, are predominant. In omnivores (which feed on both plants and animals), all three groups of enzymes are present. In food specialists, such as sheep blow flies (which feed on wool keratin), head lice (which feed on hair keratin), cloth moths (which feed on textile fibers), wax moths (which feed on wax), or carpet and leather beetles (which feed on keratin), the digestive fluid is rich in specific enzymes for handling one kind of food. In wood-eating termites, snails (*Helix*), and ruminant mammals, the cellulose is digested by colonies of microorganisms that are carried in parts of these animals' guts.

In addition, different enzymes are present in different stages of an animal's life cycle. For example, maggots feeding on flesh have proteinases, while adult flies feeding on sugars have sucrases. The intestinal enzyme lactase, which breaks down the milk sugar lactose, is always present in land mammals at or before birth. It usually decreases after weaning. Among insects, certain leaf hoppers and moths which feed on soluble sugars (which do not require further breakdown) have no enzymes, while hoppers feeding on mesophyll cells and caterpillars actively chewing plant parts have carbohydrases and lipases. Among bees, nurses have more proteases than foragers; wax bees have no proteases; the carbohydrases are predominant in foragers, especially during midsum-



Herbivores, such as antelope, must have more complex digestive systems in order to obtain sufficient nutrition from plants. Carnivores, such as lions, need much simpler digestive systems in order to process their meat diets. (Digital Stock)

mer, and lipase is found only in wax bees. The carnivorous turbellarians, coelenterates, cephalopod mollusks, crustaceans, scavenger insects, and starfish have more proteases and fewer carbohydrases.

In mammals, most of the enzymes (pepsinogen, trypsinogen, chymotrypsinogen, lipase) are secreted as zymogens (proenzymes) and are activated by other secretions. For example, hydrochloric acid converts pepsinogen into active pepsin in the stomach; enterokinase converts chymotrypsinogen into active chymotrypsin, which in turn activates trypsinogen to trypsin. Secretion of zymogens and their activation are precisely controlled and occur when food is present in the gut. For example, when chyme leaves the stomach, the duodenal hormone enterogastrone inhibits the release of hydrochloric acid from parietal cells so that no activation of pepsinogen occurs; otherwise, pepsin could destroy the proteins in the membranes of cells lining the gastric cavity. The digestive epithelia of animals are thereby protected from damage by physical (solid food) and chemical (enzymes, acids) sources. This digestive strategy became necessary as discontinuous feeding evolved, since the presence of food for digestion was intermittent.

Studying Digestion

A variety of observations and experiments have been performed to study the different types of digestive systems. Simple examination of the anterior (mouth) end of different animals, for example, reveals the broad range of strategies used to collect and initially break down food.

Soluble food feeders, for example, can be examined under the microscope. Observation of a microscopic slide of the head of a human tapeworm shows that it is equipped with hooks and suckers by means of which it attaches itself to the digestive tract of a person. The soluble, predigested food in the intestine needs no further breakdown and is absorbed through the flat body surface of the worm, which lacks any digestive organs. Observed under the microscope, the anterior end of a liver fluke has hooks and suckers to suck fluid; a lamprey has a round mouth and rasping tongue with which to suck the blood of its host fish; a mosquito has a piercing device to break skin and suck blood; and the mouth parts of an adult moth include a long, coiled proboscis designed to suck nectar from flowers.

Intracellular digestion of food by a variety of microorganisms can be observed in progress under the microscope. Amoebas can be starved for one or two days and then transferred to drops of a culture on a shallow depression slide. The amoebas will exhibit phagocytosis (cell eating) with the help of their "feet" (pseudopodia), surrounding the food and ingesting it. A change in the color of the Blepherisma pigment (in the food vacuole of the amoeba) can be seen—from red (indicating acidic) to neutral or colorless (indicating alkaline pH). This indicates that earlier stages of digestion are acidic; later stages, alkaline.

Paramecium can also be observed feeding on starch solution with and without a drop of iodine (which turns starch blue and inhibits feeding). If this procedure is repeated using compressed yeast in a 3 percent solution of Congo red, one can observe the direction of movement of the yeast (which has taken on the red color) as it travels in the direction of the beating of the paramecium's cilia and into the food vacuole, then as it circulates through the cytoplasm. The change in color from red to blue indicates digestion. Paramecia will also reject algae particles and ingest only yeast, indicating the presence of chemical sensory mechanisms.

Solid food eaters, which can be observed with the naked eye, reveal a variety of specially adapted parts: hard, strong mandibles for crushing leaves in the caterpillar; similar mandibles for handling solid food in the cockroach; the "Aristotle's lantern" of the sea urchin, used for grinding; the tentacles of the *Hydra*, which feeds on fine, suspended food particles; and the human jaw and teeth, with incisors, canines, and molars designed to break down a variety of food in a variety of ways.

The activity of various digestive enzymes can be determined by using appropriate substrates (the food molecules) and physiological conditions in a test tube. The source of the enzyme is the part of the digestive tract where it is produced and used. Tissue from this area is ground in a small blender or homogenizer using an appropriate buffer at about 4 degrees Celsius. The homogenate of the tissue is either used as is or fractionated using a high-speed, refrigerated centrifuge, which can fractionate cell membranes, various organelles, and cytoplasm. Then the subcell fraction, where the enzyme is located, can be used as the source of the enzyme. The enzyme is further purified by means of biochemical devices. The substrate is either natural or synthetic. The pH, temperature, and other conditions are controlled in the incubation mixture containing enzyme and substrate. Time-course aliquots (samples) are withdrawn, and the activity of the enzyme is measured by analyzing the hydrolysis product of the substrate using various spectrophotometric devices. The enzymes, from the same tissue or its subcell fraction, of animals feeding on plants, meat, or both are compared to determine how active various enzymes are in these animals. The presence of certain enzymes can be related to the chemical nature of the food.

Digestion and Survival

Food selection, feeding behavior, and the structure and function of the digestive apparatus of animals form an important mechanism of survival, by which animals in a population isolate themselves from other populations to avoid competition for the same source of food. The feeding behavior depends on the type of food available (soluble, suspended, aggregates, or large organisms), and the form of the feeding apparatus (shapes and sizes of bills of birds and jaws and teeth of mammals, for example) depends on the physical nature of the food. The anatomy of the digestive system is closely adapted to the physical nature of the food, while the chemical functioning (enzymes) of the digestive systems depends on its chemical nature.

The adaptations of the digestive systems have enabled the evolution of larger and more active animals, which feed less frequently on greater bulks of food as compared with less active small animals, which may have to feed more often and even continuously.

The broad variety of different digestive systems and their enzymes has enabled animals to make the best use of the food resources available in their environment. Those animals able to exploit their environment more fully than others (such as omnivores, including humans) have a wide array of digestive enzymes that can chemically break down a wide variety of foods. They are more successful at survival than those confined to a particular type of food (food specialists with a limited ability to digest only one type of food) and, hence, are likely to survive longer as a group.

DIGESTIVE TRACT

Type of animal science: Anatomy
Fields of study: Cell biology, histology, physiology

The digestive tract is the group of organs where nutrients brought into the animal from the environment are broken down to molecules that can be absorbed into the animal's body. Knowledge of the digestive tract and its functions allows an appreciation of the importance of correct diet and the causes of gastrointestinal diseases.

Principal Terms

ABSORPTION: the movement of nutrients out of the lumen of the gut into the body

BILE SALTS: organic compounds derived from cholesterol that are secreted by the liver into the gut lumen and that emulsify fats

DIGESTION: the process by which larger organic nutrients are broken down to smaller molecules in the lumen of the gut

DUODENUM: the first part of the small intestine, where it joins the stomach

ENTEROCYTES: the cells that line the lumen of the small intestine

LUMEN: the central opening through the digestive tract, which is continuous from the mouth to the anus

LYMPHATIC VESSELS: very thin tubes that carry water, proteins, and fats from the gut to the bloodstream

MUCOSA: the lining of the inner wall of the gut facing the lumen

PANCREAS: an organ derived from the gut that secretes digestive enzymes; it is connected to the gut by a duct through which its secretions enter the gut

PLEXUS: a group of nerve cells and their connections to one another

SPHINCTER: a ring of muscle that can close off a portion of the gut

Digestion is the process by which food is broken down into molecules that are small enough to be absorbed into the body. Digestion takes place in the digestive tract of animals. The digestive tract is a continuous tube that acts on ingested food in a sequential manner. Each part of the digestive tract is adapted to reduce the size of food particles, either mechanically or enzymatically, until they are small enough to be absorbed into the body. Consideration of the mechanisms of food intake in lower animals will illustrate the evolution of complexity as an adaptation to the changing environments of these animals.

Digestive Tracts of Simple Animals

Sponges are primitive water-dwelling animals that are attached to a fixed point in the water. They bring food into their bodies from currents of water containing particulate food passing through openings in their outer wall. These currents are created by movements of flagella on cells called choanocytes. Food enters the choanocytes by phagocytosis. Phagocytosis is the process in which a cell surrounds a particle with extensions of its cell membrane until the particle is completely surrounded and thus becomes enclosed within a small sac, or vesicle, within the cell. Intracellular enzymes then digest the food particles dissolved in the fluid into their component molecules, which then become available to the metabolic systems in the cytoplasm of the cell. Some cells, called amoebocytes, carry the food particles to other cells in the sponge by crawling through the spaces between the cells. Their travel is by amoeboid motion, in which the cell sends out an extension, called a pseudopod, and then follows it.

This method of feeding and digestion is adequate for a sponge because most of the sponge cells are in close contact with the water currents in which it lives. Thus, these cells can have direct access to food carried in the water currents. The cells that are not in close contact with water currents can be adequately supplied by the amoebocytes. The digestion, or breakdown, must be carried on inside the cells by cytoplasmic enzymes because if these enzymes were released to the extracellular surface, they would be washed away.

The coelenterates, such as jellyfishes or hydras, are more advanced than sponges and require a more elaborate digestive mechanism. These water-dwelling animals are either attached to a surface or float in the water currents. Thus, like sponges, they are dependent on food carried in the water. These animals, however, can eat live prey as well as particulate food. They are equipped with tentacles that can reach out and trap smaller animals and paralyze them with poisoned darts called nematocysts. The tentacles then bring the food into a distinct body cavity, the gastrovascular cavity, through its one opening. The digestive cavity is, at least partially, not in direct contact with the water currents around the animal. Digestion can take place through extracellular enzymes secreted by the cells lining this cavity. The resulting molecules are then absorbed through the cell membranes. Amoebocytes also function in these animals. These animals have limited motion through musclelike cells and this motion moves fluid within the gastrovascular cavity, thus carrying fluid to all parts of the animal.

Flatworms are more advanced than sponges and coelenterates and live in a moist, but not watery, environment. They have a distinct nervous and muscular system and can move to search for food. Their digestiv e tract, as that of sponges, has only a single opening. Food is pushed into this opening by the muscle action of the first part of the digestive tract, which can be protruded to the outside of the animal. Digestion is extracellular and carried to the rest of the animal through muscle contractions of the digestive tract. The digestive tract is highly branched and extends to all parts of the animal.

Digestive Tracts of More Complex Animals

Animals more highly evolved than flatworms, including roundworms, insects, fish, mammals, and birds, have a functionally similar digestive tract. These animals all have similar requirements, which have necessitated further, more efficient digestion. These animals are more active and thus must ingest more food. Their digestive tracts have two openings, allowing a continuous digestion: Food enters at one end and is excreted at the other. In contrast, an animal with only one digestive opening cannot excrete and ingest at the same time. The greater size of these more-evolved animals also requires that digested food be absorbed into the circulatory system so that distribution to the rest of the body cells is quick. The absorbing portion of the gut is therefore surrounded by blood vessels.

Further adaptations have required sophisticated specializations of the digestive tract. These include initial chewing devices that can mechanically reduce the size of food so that it can be swallowed. Parts of the digestive system have evolved to store food until it can be efficiently digested. This adaptation allows animals to eat sporadically, when food is available, and allows time for other activities, such as hunting or hiding. Other portions of the digestive tract have become specialized to secrete powerful enzymes that sequentially break down the molecules in food to smaller and smaller molecules. Last, the terminal portions of the digestive tract retain food and extract any remaining nutritional value and eliminate the rest at a convenient time. Many of these adaptations required the formation of a space, called a coelom, between the digestive tract and the rest of the body. This space allows the gut to coil and thus become much longer than the animal, with a resulting increase in the surface area available for digestion and absorption.

The mouth, or buccal cavity, is designed for the entry of food into the digestive tract. The lips and tongue are highly sensitive to the texture and taste of food. They are capable of very precise movements because their musculature is supplied with an extensive nerve supply. The tongue can move laterally, up and down, and in and out, because it has both longitudinal and circular muscles. Movements of the jaws during chewing (mastication) cause the teeth to crush and tear food in the mouth. The teeth have an outer covering of very tough enamel, which protects them against abrasion. Some animals have teeth that grow throughout their life and replace the worn-out ends. Salivary glands in the sides or base of the jaw secrete saliva through ducts that empty into the mouth at the sides of or under the tongue. Saliva has the primary function of lubricating and wetting chewed food. Saliva contains an enzyme, called salivary amylase, which begins the digestion of starch, although the digestion is greatly slowed after the food enters the acidic stomach lumen.

After the food has been reduced to small particles and mixed with saliva, it is swallowed (deglutition). Swallowing is partly a reflex action, controlled by a center in the base of the brain. The tongue rises to the roof of the mouth, pushing the rounded mass of chewed food, called a bolus, into the opening of the esophagus. Further propulsion is created by contraction of the area between the mouth and the esophagus, called the pharynx. The esophagus is a muscular tube leading to the stomach. Contractions of muscles which encircle the esophagus cause a moving ring of contraction, called peristalsis, which propels the bolus into the stomach.

Mucous Layers

The wall of the gastrointestinal tract is similar throughout its length. The layers, from lumen outward, are the mucosa, submucosa, submucosal nerve plexus, circular muscle, myenteric nerve plexus, longitudinal muscle, and the thin connective tissue covering called the serosa. The stomach and intestines are suspended from the back wall of the abdominal cavity by a sheet of connective tissue called the mesentery. Nerves, blood vessels, and lymphatic vessels reach the gut in the mesentery.

The cavity of the gut, or lumen, is lined by a single sheet of cells called the mucosa. The mucosa contains a wide variety of cell types. Most of the mucosa is composed of a cell type which is called columnar epithelium because the cells are longer than their diameter. Mucous, or goblet, cells secrete mucus, which is the viscous slippery material that protects the cells of the gut against mechanical abrasion and chemical attack. Other cells secrete enzymes into the lumen. Hydrochloric acid is secreted by parietal cells in the stomach. Other cells in the small intestine secrete basic bicarbonate ion. These cells provide the degree of acidity or basicity appropriate to the different regions of the gut. Other cells are adapted to absorb nutrients from or to secrete fluid into the lumen of the gut.

There are also many endocrine cells in the mucosa. These cells secrete hormones into the blood when they are stimulated by nerves or by the contents of the gut. These hormones control the degree of motility or secretion of the gut and the metabolic and physiological responses of the body following feeding. Indeed, the digestive system is the largest endocrine gland in the body. These same hormones are found in the brain, where they act as neurotransmitters, and in other endocrine glands. They have numerous functions revolving around the digestive tract. Some of these hormones can increase or decrease hunger. Others prepare the body for the nutrients that will be absorbed from the digestive tract so that the nutrients can be efficiently utilized. Certain hormones can be released by different types of nutrients in the lumen of the digestive tract. Other hormones can be released through the action of nerves when food is eaten.

The layer next to the mucosa, called the submucosa, is composed of fibrous connective tissue. It provides a mechanical support for the mucosa and also contains the nerve and blood supply leading to and from the mucosa. The lymphatic vessels draining the mucosa also travel through the submucosa.

Nerve and Muscle Layers

The next, more external layer, is a sheet of nerves, called the submucous (Meissner) plexus. These nerves send fibers inward to the mucosa and also outward to the other layers. They respond to the luminal contents and to other nerves and hormones. There are as many nerves in the gut as there are in the spinal cord. They are an intrinsic nervous system of the gut—that is, they begin and end in the gut. They are considered a separate category along with the autonomic (involuntary) and somatic (voluntary) nervous systems.

The next layer of the gut wall is a layer of visceral smooth muscle oriented circularly around the circumference of the gut. Contraction of these muscles causes a ring of contraction that may or may not move down the intestine. Next, there is another layer of nerves called the myenteric (Auerbach) plexus. Both nerve plexuses are responsible for controlling and integrating the functions of the intestine. Motility of the muscles of the gut, absorption of salt, water, and nutrients, and blood flow are all regulated by these nerves. The outermost layer of the gut is composed of visceral smooth muscle oriented longitudinally along the gut. Contractions of these muscles shorten the length of the gut.

There are also rings of smooth muscle, called sphincters, which control the movement from one part of the gut to the adjacent part. These sphincters are found between the esophagus and the stomach, the stomach and small intestine, the small and large intestine, and the large intestine and the outside.

Food that enters the stomach is partially digested by the enzyme pepsin, which is secreted by the chief cells of the gastric mucosa. Pepsin begins the digestion of protein. The hydrochloric acid secreted by the parietal cells has the functions of activating the pepsin and killing bacteria. The most necessary function of the stomach is storage of food (now reduced to a semiliquid state called acid chyme, or chyme) and slowly propelling it into the small intestine. Additionally, the stomach secretes a substance called intrinsic factor, required for absorption of vitamin B12, which promotes red blood cell formation.

Ruminants, such as cattle and sheep, have the end of the esophagus and the beginning of the stomach modified into large chambers, called the rumen and reticulum, in which food is stored. These portions of the stomach are alkaline because of the enormous volume of basic saliva secreted by the animal. Bacterial digestion of the chyme occurs in these chambers. In addition, the contents can be regurgitated into the mouth and this cud then chewed further. After the cud is chewed and reswallowed, it bypasses the previous chambers and enters a third chamber, called the omasum, where it is churned by muscular contractions. Finally, it enters the abomasum, which is similar to the stomach of other animals.

Birds have specialized adaptations of the stomach, called the crop and gizzard. The crop is a large structure at the beginning of the stomach that stores food until it enters the stomach. The gizzard is a muscular portion of the stomach that grinds the food. This grinding by the gizzard is necessary because birds have no teeth. Frequently, birds will ingest small stones, which are stored in the gizzard and help grind the food.

The Small Intestine

The stomach empties into the small intestine. The first portion of the small intestine is called the duodenum, the middle portion the jejunum, and the terminal portion the ileum. There are two large organs that are connected to the duodenum through ducts that empty into its lumen. These organs are the liver and the pancreas. The liver secretes bile salts, which are necessary to emulsify fats into small particles for absorption. Bile salts are stored in the gallbladder between meals. The gallbladder is connected, by a branch, to the duct leading from the liver to the duodenum. The pancreas secretes basic bicarbonate, which helps neutralize stomach acids that enter the duodenum. The pancreas also secretes many different digestive enzymes, which break down proteins, fats, carbohydrates, nucleic acids, and other large molecules. Thus, as soon as chyme enters the duodenum, it is immediately mixed with digestive enzymes and bile salts that entered the lumen from the pancreatic and bile ducts.

The chyme is mixed and propelled along the small intestine by longitudinal and circular muscle contractions. These contractions continually mix the chyme with the pancreatic enzymes and bile salts and present the digested molecules to the mucosal surface, where further digestion takes place. Most of the mucosal cells, called enterocytes, produce enzymes and absorb nutrients. Enterocytes are continuously formed in mucosal pits, called crypts. They migrate up tiny fingerlike projections, called villi, which protrude into the lumen of the gut. It takes about three days for the enterocyte to travel from the base of the crypt to the tip of the villi, and then it is sloughed into the lumen. The villi are thought to increase the surface area of the gut on which digestion and absorption take place. The enterocytes produce enzymes that are attached to the mucosal surface of the cells. These enzymes are responsible for the final stages of digestion, producing the smallest molecules, which are now in a form that can be absorbed by the intestine. Because the digestion takes place on the cells' surface, it is called contact digestion.

After molecules are in their completely digested form, they are absorbed by enterocytes, which transport them from the lumen of the gut to the circulatory or the lymphatic system. Most organic nutrients, such as amino acids, fats, and glucose, are absorbed in the first half of the small intestine, the duodenum and jejunum. Salt, water, and bile salts are absorbed primarily in the ileum. Absorption is virtually complete as long as the digestive system is functioning normally. Usually, the main problems that arise during gastrointestinal disorders are associated with malabsorption of fats. Fats require bile salts to be emulsified. Emulsification is necessary for enzymes to break down fats and also to reduce the final size of the fat microdroplet that results. If any step in this process is not functioning well, then the fats come out of suspension in the intestine and are excreted.

The final contents of the small intestine consist mostly of salts, water, indigestible fiber, and the debris from sloughed enterocytes. The small intestine empties into the large intestine, where some bacterial digestion occurs, which produces mostly small fatty acid molecules. The debris from these bacteria add to the bulk of the undigested material. Muscle contraction propels these feces through the large intestine until it is eliminated by defecation. Sphincters control the final evacuation.

Studying the Digestive Tract

The structural features of the digestive tract can be determined by classical techniques of anatomical dissection and histological examination of the cellular characteristics of the different sections of the digestive tract. The secretions and the digestive steps can be determined by sampling the luminal contents. The sampling can be done by passing a tube through the digestive tract until the end reaches the desired portion and then withdrawing a sample for biochemical analyses.

Motility can be measured by attaching a balloon to a tube passed into the digestive tract and measuring the changes in pressure from muscle contractions. Absorption can be measured by perfusing a solution of known composition from one opening in a double tube and collecting the solution remaining after it has passed through the gut lumen from a second opening.

Motility of the intestine or the presence of obstructions that prevent the passage of food along the gastrointestinal tract can be observed by X-ray techniques. A liquid substance, such as a barium suspension, which is opaque to X rays, is swallowed. A series of X rays is taken, or continuous monitoring by an X-ray camera is used. Obstructions can be visualized from the buildup of barium above the blockade. The speed of movement can be estimated to determine if the overall motility of the gastrointestinal tract is abnormal. X rays can also be used to determine directly the presence of abnormal structures such as gallstones, which form in the bile ducts, or tumors. The bile duct and gallbladder system can be visualized with X rays by administering a radioopaque dye that is secreted by the liver into the duct system.

The overall integrity of the gastrointestinal tract can be determined by ingesting inert substances of different molecular sizes and determining if they appear in the blood. Normally, only relatively small molecules can penetrate the very tight mucosal lining of the gut, unless they are nutrients of the body. The penetration of larger molecules across the mucosa indicates leaks resulting from damage to the gastrointestinal lining.

DINOSAURS

Types of animal science: Classification, evolution
Fields of study: Anatomy, archaeology, evolutionary science, paleontology, physiology, zoology

Dinosaurs were one of the most successful early life-forms, thriving for more than 150 million years before becoming extinct by the end of the Cretaceous period. The reasons behind their longevity and their sudden extinction hold important implications for humankind's own survival.

Principal Terms

ANKYLOSAURS: a group of later ornithischians characterized by heavy armor
CEROTOPSIANS: a group of later ornithischians characterized by a beaked snout and a bony frill on the back of the head
ORNITHISCHIANS: one of the two orders of dinosaurs; it comprises the "bird-hipped" dinosaurs
ORNITHOPODS: the early, bipedal ornithischians
SAURISCHIANS: one of the two orders of dinosaurs; it comprises the "reptile-hipped" dinosaurs
SAUROPODS: the herbivorous, quadrupedal saurischians
STEGOSAURS: a group of later ornithischians characterized by a row of plates down the back
THECODONTS: an order of Triassic reptiles that were the ancestors of dinosaurs, birds, and crocodiles
THEROPODS: the carnivorous, primarily bipedal saurischians

The word "dinosaur," which is derived from the Greek term for "terrible lizard," is the popular name for a group of extinct land-dwelling reptiles. They were the dominant vertebrate animals during most of the Mesozoic era, which began 225 million years ago and ended 65 million years ago. Among the dinosaurs were the largest animals that ever walked the earth, although some of the earliest dinosaurs were very small.

The Mesozoic era is divided into three periods, Triassic, Jurassic, and Cretaceous, of approximately equal length. Dinosaurs first appeared in the later third of the Triassic period. Experts believe that dinosaurs developed from a group of archosauromorph reptiles such as *Marasuchus*, which was a lightly built flesh eater about 1.3 meters long. It was clearly a biped, running on its hind legs, and the long tail was presumably used as a balancing organ.

Dinosaurs are divided into two separate orders, depending on the arrangement and shape of the hip bones, which determine the way an animal walks and holds its body. The saurischians, or "reptile hips," as they are commonly called, arose in the early part of the Late Triassic; the ornithischians, or "bird hips," arose toward the end of the Triassic period.

Saurischians

The earliest dinosaurs were saurischians, which are best known from the Ischigualasto Formation of Argentina. The order Saurischia may be divided into two major suborders: the theropods, or "beast-footed dinosaurs," and the sauropods, or "reptile-footed dinosaurs." The theropods, which were more primitive than the sauropods, were primarily bipedal, although many of them probably used all four feet when walking or resting. The hind legs were strong and bore birdlike feet, while the forelimbs bore sharp, curved claws for seizing and holding prey. All theropods had long tails that functioned as stabilizers. The head was large, and the jaws of most of the theropods contained sharp teeth.

The theropods are divided into two major groups. A basal group, the ceratosaurs, includes such dinosaurs as *Coelophysis*, a small, agile carnivore with a long, narrow skull represented by many hundreds of specimens from the Ghost Ranch Quarry in New Mexico. However, larger dinosaurs, such as *Ceratosaurus*, are included within this group. The remaining theropods, termed tetanurans, include the Maniraptoriformes, which share many advanced characteristics with birds. The largest of these is *Tyrannosaurus rex*, from the Late Cretaceous period of North America, which grew to a weight of 4,500 kilograms, a height of 6 meters, and a length of 15 meters.

The sauropods, which appeared slightly later in the Triassic than the theropods, have come to stand as a symbol of gigantism in land animals. They were all quadrupeds and vegetarians. They had small skulls, long necks and tails, large barrel-shaped bodies, padded feet, and large claws on the innermost toe of the forefoot and the innermost toe of the hind foot. The ancestral stock of the sauropods were the prosauropods, which were much smaller than the sauropods. Like most prosauropods, *Plateosaurus* had blunt, spatulate teeth, was an herbivore, and was quadrupedal, although it was capable of bipedal posture and gait.

The later sauropods had longer necks, and their skulls were relatively small. The limb bones became solid and pillarlike to support their great weight. This category contained the largest of the dinosaurs, *Brachiosaurus*, which is estimated to have weighed 73,000 kilograms. The best known sauropods are *Brontosaurus* and *Diplodocus*, from the Late Jurassic period of North America. Although it was once assumed that these huge beasts had to live in swamps where the water could support their great weight, it is now clear that they were terrestrial animals that used their long necks to eat from trees.

Ornithischians

The sauropods reached their zenith in the Late Jurassic; the ornithischians replaced them as the dominant herbivores in the Cretaceous period. The expansion of this group was associated with the advent of the flowering plants during the Cretaceous period. Characteristically, a horny beak was developed at the front of the mouth, and the toes ended in rounded or blunt hooves instead of claws.

The earliest ornithischians were the ornithopods. A typical example is *Hypsilophodon*, a small, swift dinosaur with a long, slender tail and long, flexible toes. The most specialized of the ornithopods were the "duck-billed dinosaurs," also known as hadrosaurs. Although they had flat beaks and no anterior teeth, the cheek region had rows of grinding teeth. The various types of duck-billed dinosaur can be distinguished by modifications of the bones associated with the nostrils. Some were molded into hollow, domelike crests, bizarre swellings of the nasal region, or long, projecting tubular structures that were used to warm the air or to produce sounds. The remaining three groups of ornithischians presumably evolved from the primitive ornithopods.

The earliest of these three groups of highly specialized quadrupeds was the "plated dinosaurs," or stegosaurs, which first appeared early in the Jurassic period. This large dinosaur was more than 6 meters long. In comparison to its body size, its head was extremely small. *Stegosaurus* had an average of twenty plates arranged alternately in two parallel rows down the back. The plates were originally thought to have been used for protection, but scientists now believe that the plates could have been used for thermoregulation. *Stegosaurus* died out in the Early Cretaceous period.

The "armored dinosaurs," or ankylosaurs, are not very well known, even though their remains have been found over much of the world. Their armor consisted of a mosaic of studs over the body, spikes that protected the legs, and, in some cases, spikes on the tail. They protected themselves by crouching and drawing in their head and legs.

The last dinosaurs to develop were the "horned dinosaurs," or ceratopsians. The skull was characterized by a beaked snout and a bony frill that extended from the back of the head. The ceratopsians were also distinguished from others by various patterns of horns. The skull of *Triceratops*, for example, had three sharp horns, one on the snout and one above each eye. The best known of the small ceratopsians was *Protoceratops*, which was a small, hornless dinosaur from the Gobi Desert in Mongolia.

Studies of dinosaur eggs, nests, trackways, and bone structures have shown that smaller dinosaurs probably had a warm-blooded, or endothermic, metabolism similar to mammals. This is supported by the discovery of small theropods in China that show a covering of feathers, presumably for insulation. Large dinosaurs, such as sauropods, would have been more efficient as ectotherms, similar to most modern reptiles.

Extinction Theories

Several theories regarding the dinosaurs' extinction were first proposed in the late nineteenth and the early twentieth centuries. According to one popular theory, dinosaurs were wiped out because early mammals of the Cretaceous period ate their eggs. Yet the eggs of many modern reptiles have faced the same threat and have survived, primarily because reptiles lay so many eggs. Another theory suggested that the same animals ate the plants on which the dinosaurs depended. Although that is possible, virtual plagues of mammals would have been required to eradicate the dinosaurs. Some early scientists also believed that the dinosaurs became too big for their environment; that is unlikely, however, because gigantic dinosaurs had been successful for millions of years. Changes in the physical environment also occurred in the Late Mesozoic. Evidence indicates that the sea levels fell. Geologic evidence shows, though, that drastic environmental changes had occurred many times during the dinosaurs' reign without any detrimental effect.

A theory proposed in early 1979 by Luis Alvarez and Walter Alvarez suggests that the iridium that has been found in several samples of sedimentary layers between the rock of the Cretaceous and Tertiary periods came from an asteroid that struck the earth at that time. Such a catastrophic event could have caused an enormous cloud of dust to circle the earth and cut off the sunlight, destroying the plants and the dinosaurs that depended on them. This theory, however, fails to explain why so many other animals, such as the mammals, managed to survive.

Another modern theory places the blame on the greenhouse effect. It has been argued that the reduction of the seas that occurred during the Cretaceous period caused a reduction of marine plants. As a result, the amount of carbon dioxide in the air increased, trapping heat from the earth's surface. A similar theory suggests that the eruption of a tremendous volcano produced a fatal amount of carbon dioxide. Neither theory, however, explains why other animals, especially heat-sensitive reptiles, survived.

The main alternative to the extraterrestrial catastrophist explanation is a gradual ecosystem change model. Declines in many groups of organisms that started well before the Cretaceous-Tertiary boundary are seen as being caused by long-term climatic change, as lush tropical environments were replaced by strongly seasonal, temperate climates. The best explanation may be a combination of the two main theories.

Study of Dinosaurs

Scientists study dinosaurs by examining fossils, which are animal remains that have turned to stone. If a dinosaur died near a river or in a swamp, it stood an excellent chance of being preserved. Its body might sink into the mud, or floodwaters might float it downstream, where it would end up on a sandbar, on the bottom of a lake, or even in the sea. After the flesh decayed, the bones would be covered by sediments, such as mud or sand. The weight of accumulated layers of sediment would compress the remains and turn them into rock: mud into shale, sand into sandstone, limey oozes into limestone or chalk.

The way a fossil is studied is determined by the category to which it belongs. The first category is petrified fossils. They may be preserved in two ways. In replacement, minerals replace the original substance of the animal after water has dissolved the soft body parts. In permineralization, minerals fill in the small air spaces in bones or shells, thereby preserving the original bone or shell. The second group of fossils is composed of natural molds that form when the bodies dissolve. Scientists make artificial casts of these molds by filling them with wax, plastic, or plaster. The third type is prints, which are molds of thin objects, such as feathers or tracks. Sometimes, even skin is preserved. Prints are formed when the soft mud in which they are made turns to stone. Scientists can determine the length and weight of the dinosaur that made a set of footprints by studying the depth, size, and distance between them.

Most fossils are found in sedimentary rocks, which lie beneath three-fourths of the earth. The best collecting areas are places where the soil has worn away from the rocks. Areas in Colorado, Montana, Wyoming, and Alberta, Canada, have been especially rich in fossils. Most of the finds consist of no more than scraps of limb bones, odd vertebrae, loose teeth, or weathered lumps of rock with broken bone showing on the surface. Once a

Image Not Available

scientist has discovered a few fossilized fragments, he or she combs the area to find the rest of the animal. If the skeleton is embedded, it is extracted with the help of a wide variety of tools, ranging from picks and shovels to pneumatic drills. Loose fragments are glued back into place, and parts that are too soft or breakable are hardened by means of a special resin solution that is sprayed or painted on.

As the fossil is uncovered, it is encased in a block of plaster of paris. (A more modern method uses polyurethane foam instead of plaster.) After the entire surface is covered, the fossil is rolled over, and another layer of plaster is added. After the fossil has been transported to the museum, the plaster is removed. The "development" stage involves the removal of the rock around the bones. The oldest way is by hand, using tools such as hammers and chisels; a more modern technique uses electrically powered drills similar to dentists' drills. Sandblasting and chemicals may also be employed. After the fossil is cleaned, it is ready for mounting. The bones are fastened to a steel framework that makes the skeleton appear to stand by itself.

Life-Earth Interaction

From the dinosaurs, scientists are learning new lessons about the physiology of such beasts, their relationship to the world in which they lived, their distribution and the bearing of that distribution on the past arrangements of the continents, various aspects of evolution, and the reasons that they became extinct. The dinosaurs played a major part in the shaping of the natural world. Birds, for example, are probably their descendants, as evidenced by the intermediary species *Archaeopteryx*, a primitive bird that lived during the Late Jurassic period; although its beak contained teeth, *Archaeopteryx* also had feathers and could fly.

The disappearance of a species that seemed to rule the world for more than 100 million years brings into question the notion of a "dominant" species. Most people believe that mammals are now the dominant form of life; however, dinosaurs did not "rule," and neither do mammals. If one were to list the biological organisms whose influence on the planet is such that their removal would produce chaos, then that list would be headed by microorganisms so small that they can be seen only through powerful microscopes. The list would also include the green plants and the fungi.

The extinction of the dinosaurs also brings into question the ability of humans to destroy the world. All species, from the simplest microorganism to the largest plant or animal, modify their immediate surroundings. They cannot avoid doing so. The success of one group, however, does not imply the failure of the groups it exploits. The complexity of individual organisms may increase, but the simpler forms do not necessarily disappear. Life continued after the demise of the dinosaurs and would probably continue to do so if humankind were destroyed.

Bibliography

Allaby, Michael, and James Lovelock. *The Great Extinction*. London: Martin Secker & Warburg, 1983. This book posits that the dinosaurs died as the result of some sort of catastrophic occurrence, such as the collision of an asteroid with the earth. The authors support their contention by examining the effects that modern catastrophes, such as the eruption of Mount St. Helens, have had on wildlife. The conclusion discusses the implications that the extinction of the dinosaurs has for humankind's possible extinction. It is well written and well indexed. Suitable for college students.

Bakker, Robert T. *The Dinosaur Heresies*. New York: William Morrow, 1986. Bakker's book paints a revolutionary picture of dinosaurs as dynamic, intelligent, hot-blooded creatures that dominated the earth for more than 150 million years. Bakker suggests, for example, that *Brontosaurus* was not a sluggish, swampbound creature but rather a nimble land-dweller. He also theorizes that the dinosaurs died as the result of diseases transmitted across the land bridge by foreign species. This highly personal account is interesting throughout and written with both the general reader and the college student in mind.

Benton, Michael J. *Vertebrate Paleontology*. 2d ed. London: Chapman and Hall, 1997. This comprehensive text provides a complete outline of the history and development of vertebrates. Designed for college courses but also suitable for the informed enthusiast. The first three chapters deal with the origin of vertebrates and their early development.

Charig, Alan. *A New Look at the Dinosaurs*. New York: Avon, 1983. Charig begins by answering the question "What were the dinosaurs?" and then proceeds to answer other intriguing questions, such as "Were dinosaurs warm-blooded?" "Did birds evolve from dinosaurs?" "Were dinosaurs too heavy to walk on land?" and "Why did dinosaurs suddenly die out sixty-five million years ago?" Charig explains all the known facts and theories with the aid of black-and-white drawings, maps, charts, photographs, and several beautiful watercolor plates.

Colbert, Edwin H. *Dinosaurs: An Illustrated History*. Maplewood, N.J.: Hammond, 1983. This volume, beautifully illustrated with more than one hundred color photographs and paintings, is essentially a condensed version of the following source, although Colbert discusses all the theories regarding the extinction of the dinosaurs in the conclusion. A fascinating book written for the general reader.

Currie, P. J., and Kevin Padian. *Encyclopedia of Dinosaurs*. San Diego, Calif.: Academic Press, 1997. This is an enormous compendium of information on dinosaurs. Includes 275 articles by experts in the field. An extremely useful and user-friendly publication.

Lambert, David. *A Field Guide to Dinosaurs*. New York: Avon, 1983. This book discusses the physical characteristics, behavior, and evolution of all known dinosaur genera, one in five of which has been named since 1970. Also covers the various theories regarding the extinction of dinosaurs, the process of fossilization, and the discovery and display of fossils. Richly illustrated and nontechnical enough for junior high and high school students.

Lucas, Spencer G. *Dinosaurs: The Textbook*. 3d ed. Boston: McGraw-Hill, 2000. This book provides good coverage of the extinction of the dinosaurs. Intended for university undergraduates but readable by anyone with an interest in dinosaurs. Glossary, bibliography, and index.

Witford, John Noble. *The Riddle of the Dinosaurs*. New York: Alfred A. Knopf, 1985. Although Witford relates the history of paleontology in the beginning of this book, his primary purpose is to demonstrate how discoveries made since the 1960's have revolutionized dinosaur theory. He proposes, for example, that some dinosaurs were warm-blooded, quick moving, and good parents. He also discusses the most radical change in dinosaur theory: the idea that they disappeared because of a massive catastrophe, such as global floods, asteroid collisions, or exploding stars. Filled with photographs and color drawings, the book is accessible to the general reader but technical enough for the researcher.

DISEASES

Type of animal science: Pathology
Fields of study: Anatomy, histology, immunology, physiology

Diseases may be caused by infectious agents, such as bacteria or viruses, by parasites, by inheritance, by developmental mistakes, or as a result of aging. The major way in which animals are able to overcome disease is through the activity of the immune system.

Principal Terms

BACTERIA: single-celled microorganisms that are often the cause of infectious diseases in animals

DEVELOPMENTAL DISORDERS: diseases caused by embryonic or fetal mistakes in normal development

DISEASES OF AGING: loss of functions required for health due to age-related degeneration of tissues

GENETIC DISEASES: disorders caused by lack of enzymes or structural proteins caused by mutations

IMMUNE SYSTEM: system that produces antibodies and cells that attack foreign substances and pathogens that invade the body

PARASITES: protozoans, fungi, or animals that survive by obtaining nourishment from a living host, from inside the host or on its surface

PRIONS: infectious proteins that cause neurological diseases such as "mad cow disease"

VIRUSES: noncellular infectious agents that must enter a host cell to infect it

A disease is essentially any disturbance in the structure or function of the body, and may be accompanied by characteristic and well-defined areas of damage, or lesions, of specific tissues. The study of diseases is called pathology, and the causes of a disease are referred to as its etiology. An agent that can cause a disease is a pathogen. A particular disease has characteristic objective physical signs that may be seen by the examining physician or other outside observer, such as redness or swelling. Subjective feelings associated with disease, which can be described by an affected human but not by an animal or outside observer, are symptoms that might include pain or weakness. A set of signs and symptoms associated with a particular disease is called a syndrome. Diseases are often diagnosed by recognizing the signs and symptoms that characterize a particular disease and are not seen together in other diseases.

Inflammation and Immunity

Diseases related to tissue damage may be caused by pathogens such as bacteria and viruses, or by trauma, toxins, heat or cold, or exposure to chemical pollutants. When the body first responds to damage, certain cells release chemicals that produce a localized, nonspecific reaction called inflammation. Histamine causes blood vessels to dilate and become leaky, so inflamed areas show redness, swelling, pain, and heat, and may have a loss of function. Inflamed tissues also send out chemical messages that call in wandering cells (neutrophils and macrophages) from the blood and connective tissues to engulf pathogens and cellular debris by phagocytosis. This response is usually restricted to a localized area where tissue damage has occurred, and the area may be walled off from the rest of the body to restrict movement of pathogens or toxins.

The immune system involves other cells from the blood, lymph, and connective tissues called lymphocytes, which respond to specific antigens, usually small fragments of proteins that are not part of the "self" antigens the lymphocytes recognize. A bacterium may have thousands of different antigens associated with it, fragments produced by a macrophage during processing of the bacterium after phagocytosis. Each lymphocyte can respond against only one kind of antigen, but millions of different kinds of lymphocytes in each individual produce a widespread immune response specific to each foreign antigen associated with the invading pathogens, their toxins, or other materials.

The first time the immune system encounters a foreign antigen, its primary response is slow, and a disease may result from a pathogen's metabolic effects. Eventually, the immune response generates activated lymphocytes and antibodies that kill the bacteria or the virally infected cells to end the disease process. Memory lymphocytes are also produced that will respond against the same antigen if needed later. When the animal recovers, it will usually be immune to a second infection by the same disease-producing agent. The ability to resist a second infection is called immunological memory, and it may last for the life of the individual, as long as the memory lymphocytes live. Modern disease prevention techniques use immunizations to prevent the first experience of disease caused by a pathogen. In immunization, a derivative of the pathogen is injected into the individual to produce the slow primary response, so that memory is generated and the individual will be immune when the same agent is encountered naturally in the environment. In some cases, a booster shot must be given regularly to maintain memory and immunity to that agent, as in repeated immunizations of pets against rabies.

In some cases, however, diseases are caused by an overreaction by the immune system and the inflammation that it helps to generate. Allergies, for example, are not directly caused by pollen or dust particles, but by the body's responses to these allergy-producing antigens, or allergens. An allergic reaction is an immediate hypersensitivity response that may just cause an irritating, itchy swelling of the mucous membranes or skin, or may be extreme and even life threatening. In highly allergic individuals responding to allergens, the respiratory passages close, blood vessels leak fluid into the tissues, and death can result in a hyperallergenic process called anaphylactic shock. Much more often, though, both the inflammatory and immune responses are protective, causing the destruction of invading pathogens or other foreign materials that get into the body past the barriers of the skin and mucous membranes. The extent to which the immune system protects against disease can be seen when it is not functioning, as in humans who have acquired immunodeficiency syndrome (AIDS) and die of infections or cancer

Bacterial Infections and Antibiotic Resistance

Bacteria are prokaryotes (cells without nuclei) that have three basic shapes, called cocci (spheres), bacilli (rods), and spirilla (corkscrews). Most have a cell wall surrounding the plasma membrane and may also have a protective capsule. The cell wall may stain gram-positive (purple) or gram-negative (pink), distinctions that help identify the bacteria, determine what disease they cause, and indicate antibiotics that may be effective in treating infections they produce. Antibiotics are antimicrobial drugs that usually work by interfering with the structure or function of bacterial cell membranes, cell walls, or proteins. Since bacterial cells are so different from those of the infected host animal, antibiotics usually do not affect the host cells. Antibiotics are often given to domestic agricultural animals to increase their rates of growth and productivity. Unfortunately, mutations in normal bacteria can make them resistant to antibiotics, and this resistance can be passed from one bacterium to others, so that many drug-resistant strains of bacteria have resulted, some of which cause diseases that may become untreatable.

Image Not Available

that would be prevented by a fully functioning immune system. Viruses similar to the human immunodeficiency virus (HIV) cause related immunodeficiency diseases and leukemias or anemias in animals as well, including simian immunodeficiency virus (SIV) in monkeys and feline leukemia virus (FeLV) in cats or murine leukemia viruses (MuLVs) in mice. Studying these related viruses has been very important in scientists' understanding of HIV.

Bacterial Diseases

Most inflammatory diseases are caused by pathogenic or infectious microorganisms. Infections occur when pathogens enter the body, replicate, and cause metabolic changes or toxic damage. Pathogens are often easily spread directly from an infected host to uninfected individuals, or may be spread indirectly through air, food, water, soil, or other materials. Infectious and other disease-causing agents include bacteria, fungi, viruses, prions, protozoans, and parasitic animals.

Bacteria are unicellular, prokaryotic organisms that have much simpler cells than those of multicellular organisms such as animals, which are eukaryotic (having a nucleus). Some bacteria are pathogenic in humans and other animals. Bacteria can reside normally on the skin or in the digestive tracts of animals without harmful effects, comprising the "normal flora" of those animals. A common bacterium, *Escherichia coli*, is found in the colons of humans and many other animals, but different strains may cause diseases in some hosts while being harmless in others. *E. coli* strain O157:H7 causes no disease in cattle, but has caused deadly infections in children who ate undercooked hamburger contaminated with fecal material from the infected cattle. *Salmonella* are bacilli common in and on animals such as chickens (and their eggs) and turtles, but can cause food poisoning in humans. In some cases, bacteria that are normal on the skin or in internal organs of an animal may cause diseases when their number increases abnormally or when they are transferred to other body regions. Certain bacteria can cause disease in both animals and humans, such as the anthrax bacterium *Bacillus anthracis*, which may be used in weapons for germ warfare. Infectious anthrax spores can persist in soil or on contaminated wool, leather, or other animal products for many years, then can enter through skin or lungs to cause a lethal disease of animals or humans. Wild animal populations may serve as reservoirs of bacteria that can cause epidemics in both humans and animals, such as plague bacteria in modern-day prairie dogs of the American Southwest. The same bacteria, *Yersinia pestis*, were also a major problem in medieval Europe, when the Black Plague was carried to humans by dying rats and their fleeing fleas.

Viral Diseases

Viruses are not cells, and so are not actually microorganisms, but are still infectious agents. All viruses can infect only certain cells of particular host organisms, and they must be inside host cells to replicate. Viral infections can be latent (the cell is infected but uninjured); in some latent infections the virus is totally silent and inactive, while in others new virus particles may be released into the tissue fluid surrounding the cell. In cytopathogenic infections, host cells may increase in size and number, causing tissue enlargement (hyperplasia), or the cells may die. Some latent viral infections can become activated to produce disease, cell death, and viruses that infect other cells or organisms. Activation of latent viruses occurs when the host's immune defenses are diminished by stress or illness. Antibiotics are ineffective against viruses, whether they are free in tissue fluids or inside host cells, because the actions of antibiotics are directed against bacteria. Drugs that counteract viral infections often kill the infected cells, and may cause toxic reactions in the host as a result. Most viral infections can be handled at some level by the immune system, but in some cases the viruses may be present in the host organism for the rest of the host's life span.

Prion and Fungal Diseases

A very unusual kind of infectious pathogen is an abnormal protein called a prion, not associated with either DNA or RNA. Neurodegenerative diseases such as scrapie in sheep and bovine spongiform encephalopathy (BSE, or mad cow disease), as well as kuru and Creutzfeld-Jacob disease in humans, are prion diseases. The abnormal protein is a refolded form of a normal brain protein, and prions cause the normal proteins to fold into the prion form in brains of infected individuals. Prions are very stable and are not destroyed by heat, light, or acid, so prions eaten in animal proteins can cause rapid or very delayed disease in the individual that ingested the prions. Animal tissues have been banned in animal feed in Europe and elsewhere, and many Europeans have stopped eating beef because of outbreaks of mad cow disease in England.

Fungi are plantlike parasites without chlorophyll, subdivided into yeasts and molds. They may cause skin infections or localized or systemic internal infections. Yeasts are single cells that are much more complex than bacteria, while molds have branching filaments (hyphae) extending into host cells to obtain nutrients. Fungi that colonize the skin (dermatophytes) may cause diseases such as mange or ringworm, while yeasts infect mucous membranes or other moist surfaces. The immune response can often control or eliminate fungal infections, but such infections can be lethal in immunocompromised hosts.

Parasites may enter the body or remain on the body surface as they obtain nutrients from a living animal host. The condition of having parasites is called infestation rather than infection, but disease generally results from the parasites' effects on the host. Diseases caused by protozoan parasites include amebic dysentery, giardiasis, toxoplasmosis, malaria, and pneumocystis pneumonia. Important parasitic worms are roundworms, tapeworms, and flukes, which infest nearly all animals, and often have multiple host species during their complex life cycles. Worms may reside in the digestive tract, heart, liver, lungs, eyes, lymphatic system, skeletal muscle, or other organs and systems, where they can cause malnutrition, tissue damage, and death of the host. Blood-sucking insects such as lice and mosquitoes, or other arthropods such as ticks and mites, may act as vectors that transmit protozoan parasites, bacteria, or viruses to a host animal during blood removal. Arthropod-vectored diseases with animal reservoir hosts have caused many major diseases in humans as well, such as malaria, yellow fever, hantavirus diseases, sleeping sickness, and several forms of encephalitis. All animals are subject to infestation by many parasites against which the immune system responds; reduction of parasite load in humans and domestic animals in industrialized societies is thought to be related to the increased incidence of allergy in both humans and pets.

Genetic and Congenital Diseases

Diseases that result from genetic abnormalities may be present at birth, or may not become apparent until later in life when metabolic processes fail to function because of inherited errors. Both single gene mutations and chromosomal abnormalities may occur, or diseases can be caused by interaction of genetic predisposition and environmental factors. Congenital diseases are present at birth, and can be genetic or developmental in cause. Developmental problems may be associated with nutrient deficiency, intrauterine injury, inadequate placental support for the fetus, or environmental agents such as radiation, toxins, or pathogens. Genetic problems tend to occur particularly in inbred lines of animals, such as purebred dogs, where breeding selection for desirable characteristics also inadvertently produces recessive inherited diseases such as hip dysplasia and deafness. Some congenital defects are considered desirably exotic in companion animals, such as curled ears or stubby tails in cats, droopy ears in rabbits, or short legs, flattened faces, or lack of hair in dogs.

Metabolic, Neoplastic, and Degenerative Diseases

Metabolic disorders include those that are strictly genetic, and those that have a combined etiology involving inheritance and environment. Disturbances of metabolism can include changes in endocrine functions or metabolic imbalances when an enzyme is missing due to a genetic mutation. The enzyme's substrate would then build up and cause damage, while the enzyme's product would not be formed, also causing problems.

Neoplastic diseases are characterized by abnormal cell division and tumors, enlarged growths that may be benign or malignant. Benign tumors do not spread throughout the body, but are usually enclosed in a dense connective tissue capsule. While their cells remain relatively normal aside from their unrestrained growth, benign tumors may grow to enormous size and cause death by compressing organs or blocking passageways.

Finding New Viruses

Viruses are smaller and less complex than cells, and generally contain only a protein coat surrounding either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) as the genetic material. Some viruses may also have a covering membrane derived from the plasma membrane of the host cell from which they budded out during replication. DNA viruses include adenoviruses (respiratory infections); herpesviruses (cold sores, genital herpes, "pox" diseases, mononucleosis); papillomaviruses (certain warts); and hepatitis B virus. Viruses with genetic information in RNA include hepatitis A and C viruses; myxoviruses (measles, mumps, influenzas); picornaviruses (polio, respiratory infections); rabies virus; and retroviruses (AIDS, some leukemias). Viruses that infect animals without causing disease may jump species to infect humans or mutate to produce major disease epidemics, such as influenzas from recombinant bird or pig viruses, or the AIDS and Ebola viruses. In some cases, the animal source or reservoir is known, while often it is unknown. Many emerging diseases in human populations have originated in animals native to rain forest jungles or other habitats that humans have invaded and taken over, encountering previously unknown viruses.

Malignant tumors contain many more abnormal cells, which can leave the primary tumor site and form secondary tumors, especially in the liver, bone marrow, lungs, or brain, that usually cause death in cancer conditions. Malignant cells lose their original characteristics and become much less specialized and less efficient in using nutrients and energy, causing the body to waste away.

Degenerative diseases are associated with the aging process, when body tissues lose the ability to repair themselves effectively. The immune system also becomes less functional in combating foreign antigens or even recognizing the difference between self and foreign antigens, thus attacking self antigens by mistake. In some cases, degenerative diseases are not directly linked to aging, but to damage caused by pathogens, toxins, nutrient deficiency, or even nutrient excess. As normal tissues are damaged by the standard wear and tear of life, repairs become less effective and scar tissue replaces normal tissues such as muscle or liver. Nervous system damage is particularly problematic, since neurons are unable to replicate in mature animals, and lost cells are not replaced, producing sensory reception, muscle control, and memory loss. Problems caused by diseases and trauma lead to continued loss of function over time in aging animals, eventually reaching a point that repairs can no longer be made or infections resisted, and the animal dies.

Bibliography

Campbell, Neil A., Jane B. Reece, and Lawrence G. Mitchell. *Biology*. 5th ed. Menlo Park, Calif.: Benjamin Cummings/Addison Wesley Longman, 1999. This college text discusses bacteria, viruses, fungi, and invertebrate animals in several chapters, discussing their structures and functions in general. It also covers the defensive mechanisms of the body, including inflammation and the immune system.

Crowley, Leonard V. *An Introduction to Human Disease: Pathology and Pathophysiology Correlations*. 5th ed. Sudbury, Mass.: Jones and Bartlett, 2001. While written for nursing students concerned with the human body, this book discusses many general aspects of diseases and their causes. The latter part of the text covers specific diseases of different organ systems and how they can be treated.

Fox, Michael W. *The Animal Doctor's Answer Book*. New York: Newmarket Press, 1984. This general audience paperback written by a scientific director of the U.S. Humane Society lists questions and answers from his newspaper column. It mainly concerns health and diseases in all sorts of pets and even wild animals, but aspects of animal behavior and careers in animal care are also discussed.

Koneman, Elmer W., et al. *Color Atlas and Textbook of Diagnostic Microbiology*. 5th ed. Philadelphia: Lippincott, 1997. The first two chapters in this medical text are introductory and cover basic bacteriology and the diagnosis of infectious diseases. Later chapters consider everything about bacteria, viruses, fungi, and parasites that cause diseases in humans and animals. Color plates show what these pathogens look like in culture and in wounds.

Norris, June, ed. *Diseases.* 2d ed. Springhouse, Pa.: Springhouse, 1997. Written for nursing and allied health professions students, this text examines infections, trauma, neoplasms, and other disorders of every body system. Many tables cover causes, assessment, diagnostic tests, and treatments for these disorders.

DISPLAYS

Type of animal science: Behavior
Fields of study: Ethology, evolutionary science

Displays are specialized behaviors that act as communication signals within, and occasionally between, species.

Principal Terms

APOSEMATIC DISPLAY: use of bright, non-camouflaged colors to indicate toxicity or dangerousness

PAIR-BONDING: prolonged and repeated mutual courtship display by a monogamous pair, serving to cement the pair bond and to synchronize reproductive hormones

PHEROMONE: a modified hormone that, through sense of smell, communicates information to, and has effects on, individuals other than the individual producing it

PRINCIPLE OF ANTITHESIS: the observation that signals communicating opposite meaning tend to be expressed using displays having opposite characteristics

RITUALIZATION: an evolutionary process that formalizes the context and performance of a display so that its meaning is clear and straightforward

SPECIES-SPECIFIC: a behavior or trait that characterizes members of a species, is innate, and is exclusive to that species

STATUS BADGE: a visual feature that, based on its size or color or some other variation, indicates the social status of the bearer

Why do birds sing? Not because they are happy. They sing to communicate. By singing, a bird communicates its location, its species, its sex, its approximate age and size, and perhaps its current reproductive status, territory ownership, health, dominance status, and motivational state. Birdsong and other nonlinguistic forms of communication are called displays.

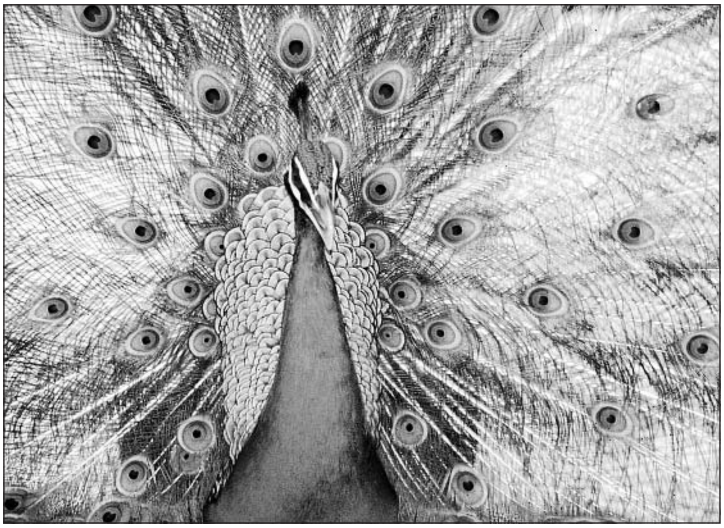
Types of Displays

Some displays involve, literally and simply, the visual display of a physical feature. Among insects, for example, green or brown coloring is often used for camouflage. Insects that are poisonous do not need camouflage and often advertise themselves with warning colors, such as black and red, or black and orange. This is referred to as aposematic coloration or an aposematic display.

Physical features can also indicate an individual's sex, age, and reproductive status—as do peacock tails, turkey wattles, deer antlers, the canine teeth of male baboons, and the swollen genitals of estrous female chimpanzees. Many such features vary in size, shape, or color in relation to an animal's health, hormones, or social status, and are therefore referred to as status badges or signs.

Often, meaningful physical features are further highlighted by behavioral displays. A courting peacock or turkey will fan open his tail and shake it back and forth for emphasis; a challenged buck will load plant material onto his antlers so as to exaggerate their size; an angry baboon will curl back his lip to further expose his canine teeth; and an estrous chimpanzee will approach a friendly male and assume a posture displaying her fertile state.

A particularly energetic or dramatic behavioral display not only calls attention to a physical feature, but indicates the health and vitality of the performer. The principle of honest signaling refers to the fact that large and healthy individuals tend to have brighter or more contrasting colors,



Male peacocks fan their tails and shake them in a courting display to attract female attention. (Digital Stock)

make deeper-pitched and louder sounds, and produce longer, more intense performances than small or weak ones. Such differences in display quality are readily noticed by predators, potential competitors, and potential mates.

Most displays are performed by individuals and are one way: sender to receiver. Threat displays, however, may involve reciprocal signaling between two challengers or between two groups of challengers. Courtship displays also may occur in groups: In some species, males gather together to perform in what is called a lek or a lekking display. Courtship of monogamous species may include long sequences of frequently repeated, ritualized interactions in which both partners participate. Such pair-bonding displays may continue well into the breeding season and the mateship; initially serving to familiarize the pair with one another and to synchronize their hormones and breeding behavior, they may later serve as greeting displays after separation.

Interpreting Displays

Darwin noted that displays having opposite characteristics often signal opposite meaning. In humans, for example, a face with upturned corners of the mouth (a smile) signals friendliness, whereas a face with downturned corners of the mouth (a frown) signals displeasure. In most animals, loud, deep-pitched sounds (for example, roars and growls) indicate aggression, whereas quiet, high-pitched sounds (for example, mews and peeps) indicate anxiety or fear. Similarly, body postures exaggerating size tend to signal dominance, whereas postures minimizing size tend to signal submission. Darwin called his observation the Principle of Antithesis.

Although some rules of display can be applied across species, most displays are specialized for intraspecific (within-species) communication—male to female, parent to offspring, or dominant to subordinate—and are therefore species-specific. That is, the ability to perform and interpret a particular display (such as a particular birdsong) is generally characteristic only of individuals of a particular species and is either innate (inborn) or learned from conspecifics (individuals of the same species) during an early critical period of development.

In order that their meaning is easily and quickly conveyed, most displays also tend to be highly ritualized; that is, they are performed only in certain contexts and always in the same way. This consistency in communication prevents errors of interpretation that could be disastrous. It would be a grave mistake, for example, to interpret an aggressive signal as a sexual overture, or an alarm call (predator alert signal) as an offspring's begging call. Mistakes of interpretation are also minimized by signal redundancy; that is, messages are often conveyed simultaneously in more than one sensory modality.

Display Modality

Displays utilize every sensory modality. Visual displays involve the use of bright, contrasting, and sometimes changing colors; changes in body size, shape, and posture; and what ethologists call "intention movements"—brief, suggestive movements which reveal motivational state and likely future actions. Auditory displays include vocal songs and calls, as well as a variety of sounds produced by tapping, rubbing, scraping, or inflating and deflating various parts of the body. Tactile displays include aspects of social grooming, comfort contacts (such as between littermates or parents and offspring), and the seismic signaling of water-striders, elephants, frogs, and spiders which, respectively, vibrate the water, ground, plants, or web beneath them. Olfactory displays include signals from chemicals that have been wafted into the air or water, rubbed onto objects, or deposited in saliva, urine, or feces.

Olfaction (sense of smell) is the most primitive, and therefore the most common and most important, sense in the animal kingdom. Species of almost every taxonomic group use smell to signal their whereabouts and, generally, their sex and reproductive state. (Birds seem to be an exception.) Animals may also use smell to identify particular individuals, to recognize who is related to them and who is not, and to determine the relative dominance status of a conspecific.

Chemicals used in displays are called pheromones. They may be derived from waste products or hormones, acquired by ingesting certain food items, or obtained directly from plants or other animals. Some pheromones not only communicate information, but also have physical effects on their receivers.

Chemical Aphrodisiacs

For thousands of years, people have used perfumes, lotions, and oils in an effort to enhance their sexual appeal. Several companies have even started to market chemicals thought to be human pheromones. Despite the huge appeal of such supposed aphrodisiacs, there is no evidence that any truly work. In other species, however, there exist naturally occurring chemicals that not only signal reproductive readiness, but also affect other individuals' reproductive capacity.

In many species, a female that is ready to mate will emit a pheromone to attract males. As many pet owners know, when a sexually mature female dog or cat is "in heat," her location and reproductive state can be detected by neighboring males simply through sense of smell.

In some species, males use pheromones as antiaphrodisiacs. When male sweat bees mate, they leave behind a scent which makes the female less appealing to other males who might pass by.

In other species, males use pheromones to intimidate or deter their competitors. Scent from a large bull elephant in musth (a prolonged state of heightened aggression and sexuality) can prevent a smaller male from going into musth, or bring him out of it prematurely.

Male pheromones have also been documented to cause miscarriage or fetal resorption in pregnant females, to hasten ovulation in adult females who are not already pregnant, and to hasten the onset of sexual maturity in young, prereproductive females.

Object Display

Courtship generally entails physical and behavioral displays that advertise the performer's age, sex, health, and vigor. However, males of some species have been discovered to use objects for sexual signaling. The best known of these are the bowerbirds of Australia and New Guinea, which collect colored fruits, feathers, leaves, and shells which they display in a cleared area called a court. Females inspect the decorations that local males have accumulated and mate with the male whose site they like best—generally the one with the most or the best objects. Males of a species of cichlid fish also build bowers: Males with tall, symmetrical sand towers—the most difficult type of bower to build—generally attract the most females.

While bowers have no utility other than display, males of some species display with objects that are of potential value for a female. In an act called courtship feeding, many male insects and spiders court females with food (called a nuptial gift), which the female consumes during mating. Males of vertebrate species, too, may court a female with gifts of food: Fish-eating birds offer fish; insect-eating birds offer insects. In some species, males offer nest material as part of a display, or perform a display which calls attention to a completed nest or nest site: Male weaver finches in Africa advertise nests they have built, as do house wrens in North America, and a variety of freshwater and marine fishes worldwide.

of topics, including antipredator displays, synchronized lekking displays and seismic displays. Because it is about sound production, it does not include spectacular photos, but it does contain informative drawings and diagrams.

Eibl-Eibesfeldt, I. *Ethology: The Biology of Behavior*. Translated by Erich Klinghammer. 2d ed. New York: Holt, Reinhart and Winston, 1975. The most thorough books on animal displays date from the 1960's and 1970's. This text was written by the world's foremost ethologist and includes superlative drawings and diagrams. It should be available in most college libraries.

Guthrie, R. Dale. *Body Hot Spots: The Anatomy of Human Social Organs and Behavior*. New York: Van Nostrand Reinhold, 1976. This pop psychology book was written by an expert large-mammal ethologist, but makes for delightful reading. In each chapter the author describes some form of display (for example, dominance display) or organ of display (such as scent glands) in animals, then describes similar displays and organs in humans. Although culturally out of date with respect to some of the human examples, the general concepts and descriptions remain valid.

Johnsgard, Paul A. *Arena Birds: Sexual Selection and Behavior*. Washington, D.C.: Smithsonian Institution, 1994. Specifically on lekking birds, this volume includes text, color photos, detailed panel drawings of display sequences, and an excellent glossary.

Morris, Desmond. *Animalwatching*. New York: Crown, 1990. Morris is most famous for his BBC television specials on animal and human behavior. This beautiful and user-friendly book is essentially a photo gallery and encyclopedia of animal displays. See also Morris's many other books, including *Manwatching* (1977), *Dogwatching* (1986), *Catwatching* (1986), *Horsewatching* (1988), and *Babywatching* (1992).

Owen, Denis. *Camouflage and Mimicry*. Chicago: University of Chicago, 1980. An early volume of the excellent paperback series Survival in the Wild, this book describes many interspecific displays used by prey to trick predators. Short, useful glossary, index, and lots of pictures.

DOGS, WOLVES, AND COYOTES

Type of animal science: Classification
Fields of study: Anatomy, genetics, zoology

Dogs, wolves, and coyotes are carnivorous mammals which belong to the Canidae family and share similar anatomical and behavioral traits.

Principal Terms

BULLA: hollow bony area
DIGITIGRADE: walks on the toes
LUCID: filled with light
OLFACTORY: related to sense of smell
OS: bone
TAPETUM: membrane layers
TYMPANIC: middle ear

Dogs, wolves, and coyotes represent four species of the thirty-eight dog species of the Canidae family. These carnivorous mammals are descendants of the prehistoric *Tomarctus* that lived fifteen million years ago. According to fossil evidence, dogs were probably the first animals to be domesticated, at least ten thousand years ago. Domestic dogs developed from wolves that humans tamed and selectively bred for hunting, retrieving, and guard duties. Specific wolf traits appear in various dog breeds.

Anatomy

Domesticated dogs vary from small to large animals according to which breed or mix of breeds they represent, such as the tall wolfhounds, standing an average of ninety-nine centimeters (thirty-nine inches) at the shoulder, the heavy St. Bernard weighing about 90 kilograms (200 pounds), and diminutive chihuahuas standing approximately thirteen centimeters (five inches) and weighing 2.7 kilograms (6 pounds). Each dog's skeleton has approximately 320 bones and varies according to tail length. Male dogs also have an additional bone, the os penis. Other exterior physical characteristics such as shape, color, and coat texture and length vary according to genetics.

Puppies have twenty-eight temporary teeth, which they begin to shed around twelve weeks old, and adult dogs have an average of forty-two permanent teeth which emerge when they are six months old. Dogs have twelve small incisors, which they use to groom themselves and to carry objects. Four large, sharp cuspids, often called canines, are used to tear meat, the foundation of dogs' diets. A total of twenty-six premolars and molars chew food. Wild dogs hunt a variety of prey, mostly small mammals such as rabbits, squirrels, and rodents. Dogs have nonretractable claws and walk on their toes. They have five toes on their front paws and four toes on their hind feet, where occasionally there is a dewlap or extra toe. Because they cannot perspire, dogs pant with their tongues to cool their systems.

Senses

Dogs with long, slim faces, such as collies, have eyes on the sides of their heads and can see wide areas, while dogs with short, broad faces, such as bulldogs, have eyes nearer the center of their faces and can view objects in the distance. Although dogs are unable to see objects as clearly as humans can, they are more sensitive to detecting motion. Dogs cannot see colors except for shades of gray. In dogs' retinas, the tapetum lucidum reflects light to enable dogs to see in the dark. These membranes cause dogs' eyes to appear glowing at night.

Dogs' ears are located on the sides of their skulls for optimum hearing. Some dogs, such as

German shepherds, have erect ears that resemble those of wolves and coyotes, while other dogs, such as basset hounds, have floppy ears that hang close to their faces. Dogs can hear high-pitched and distant sounds.

Dogs' olfactory systems are acutely sensitive. Like their wild cousins, dogs mark territories with urine and feces. Dogs use their noses to find food and track smells, often several days old. Scents are a significant way that all canines, both wild and domestic, communicate. Sounds also are important to convey messages. Canines emit noise variations to bark, growl, howl, yip, whine, and woof and engage in playful social behavior. Dogs express themselves with their bodies, eyes, and tail movements.

Life Cycle

Dogs reach sexual maturity before they attain full physical growth. Such maturation varies according to size, with smaller dogs reaching adult size within five to sixth months of birth and larger dogs sometimes not becoming fully grown until they are more than one year old.

Female dogs gestate for about nine weeks before whelping. Litter sizes depend on the mother's size and can average from one to more than ten puppies. Puppies' eyelids and ear canals are closed for almost two weeks. At about three weeks old, they begin walking, barking, wagging their tails, and eating solid food. Puppies are usually weaned at age six weeks. Dogs' life spans depend on their breed and environment, and range from eight to more than fifteen years.

Wolves

Wolves are wild relatives of dogs and are represented by two species, the gray and red wolf, with variations within each species for a total of thirty-two described subspecies. At one time, wolves lived throughout Europe, Asia, and North America. The gray wolf, also called the timber wolf, is the most common wolf species living in North America and can be found mostly in Canada and Alaska. Considered extinct in western Europe, with a few exceptions, gray wolves live in Russia, southeastern Europe, and Asia. Wolves' ranges have decreased due to urbanization. Most wolves live in sparsely populated forest, tundra, wilderness, and mountain regions and tend to avoid people, approaching settled areas only when they are starving or when natural crises, such as floods, fires, and blizzards, cause their migration to populated places to seek emergency food sources.

Gray wolves can attain a body length (from nose to base of the tail) of 1.2 meters (4 feet) and height of 90 centimeters (3 feet) at the shoulder. They average forty-five kilograms (one hundred pounds) in weight, with some wolves weighing twice that amount, and have sharp teeth, thick coats, tall legs, and bushy tails. Gray wolves have primarily gray coats with some black, yellow, and brown fur, although some gray wolves are solid black or white, particularly in the Arctic. An endangered species, red wolves live in the forests and brush of the south central United States and

Dog, Wolf, and Coyote Facts

Classification:
Kingdom: Animalia
Subkingdom: Metazoa
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Carnivora
Suborder: Canoidea
Family: Canidae
Genus and species: Ten genera and thirty-five species, including *Canis familiaris* (domestic dog), *C. lupus* (gray wolf), *C. rufus* (red wolf), *C. latrans* (coyote)

Geographical location: Dogs live on every continent except Antarctica; wolves are not found in Africa, South America, and Australia; coyotes live only in North and Central America

Habitat: Mostly prairies, forests, and mountains

Gestational period: Approximately two months

Life span: Ranges from an average of eight to twelve years, longer in captivity or domestication can be colored a hue ranging from reddish gray to black. Hunting of gray wolves escalated as farmers and ranchers penetrated wolf territory, their livestock offering easy targets for the wolves. Humans' retribution threatened decimation of the gray wolf population. Efforts to replenish the number of wolves include the reintroduction of gray wolves to Yellowstone National Park in 1995.

Pack Behavior

Hunting alone and in packs, wolves usually roam over large territories with a family group consisting of parent wolves and their offspring. Zoologists believe that wolves mate with the same partner for life, producing from three to nine cubs annually in late winter. Digging an underground den or appropriating a cave or hollow tree, wolves give birth and raise their cubs in this space, where the parents bring food until the cubs attain sufficient maturity to hunt. During winter and other stressful conditions, wolf families occasionally establish a larger pack of as many as thirty animals. The leader of a wolf pack, known as the alpha male, disciplines pack members.

Wolves prey on both large and small animals, including deer, moose, rabbits, birds, and mice and also eat vegetables, fruit, and carrion. They tend to hunt at night and can leap over obstacles 4.9 meters (16 feet) high, and travel up to fifty-six kilometers per hour (thirty-five miles per hour) to capture prey, sustaining thirty-two kilometers per hour (twenty miles per hour) for several hours when endurance is necessary to wear down elusive prey. Wolves migrate to follow prey to other areas. Scientists hypothesize that wolves howl in order to communicate with other wolf packs.

Coyotes

The scientific name for coyotes, *Canis latrans*, means "barking dog," which describes coyotes' staccato yips. Colored brown with gray and black flecks, coyotes grow to have a body length of approximately ninety centimeters (three feet) and can attain speeds of sixty-five kilometers per hour (forty miles per hour). Coyotes can adapt to many environmental situations and eat a variety of foods, including vegetables and insects. Although they tend to hunt alone, mostly at night, coyotes

Wolves are endangered by the loss of their natural wilderness habitat. (Corbis)

Working Dogs

Because of their keen senses, strength, and mobility, dogs have proven useful for a variety of jobs. Their endurance, alertness, and heightened hearing and smelling abilities supplement traits of intelligence, loyalty, and obedience. Dogs have served as scouts, messengers, sentries, and bomb detectors during wars. They are also used in peacetime to rescue earthquake victims, herd livestock, assist disabled people, pull dogsleds, and guard homes, stores, and museums. Secret Service dogs protect the United States President and other significant government officials and sites. Dog breeds especially suited for this work include German shepherds, dobermans, Belgian malinois, bloodhounds, and Labrador retrievers.

Dogs' sense of smell ranges from one thousand to ten thousand times greater than humans, depending on circumstances. Using their adept olfactory capacities, dogs can detect narcotics, explosives, termites, and humans, both alive and dead. Cadaver dogs can even find bodies underwater. Police and military dogs track criminals and sniff out illegal drugs and hidden explosives. Dogs' detection of illegal substances can be used as legal evidence in courts. Scientists and trainers at Auburn University's Institute for Biological Detection Systems and Canine Detection Training Center are preparing dogs for use in American schools as bomb and weapon detectors to deter violence.

Working dogs, such as the sled dogs who delivered diphtheria medicine to an ice-bound Alaskan town and Chips, a World War II military dog who located enemy snipers, have often become heroes celebrated in books and movies. In November, 2000, federal legislation was approved to discontinue the practice of automatically euthanizing retired American military working dogs. Memorials around the world have commemorated working dogs.

sometimes cooperate to kill a large animal such as an elk. Unafraid of people, coyotes often can be found in suburbs. The western coyote lives in western North America, from Panama to Alaska. The eastern coyote, considered a subspecies of the western coyote who probably mated with wolves, is larger than the western coyote and has darker fur.

Coyotes use abandoned dens to raise their pups, ranging from six to ten per litter. Born blind, the pups rely on their mother for milk at first, then eat food regurgitated by their parents before they are able to chew and hunt on their own. Most pups leave their parents by age one and start their own families, while other pups remain in the den to assist their parents to raise their siblings and learn parenting skills. The average coyote is fully mature by age two. Scientists believe that coyotes mate for life.

The *Canis* species can breed with each other and produce fertile offspring known as hybrids. Some people raise coydogs, a combination of coyotes and domestic dogs, while others, especially Eskimos, prefer wolf-dog genetic crosses, which result in strong animals capable of withstanding extreme climatic conditions and pulling heavy loads.

DOLPHINS, PORPOISES, AND OTHER TOOTHED WHALES

Type of animal science: Classification
Fields of study: Anatomy, marine biology, physiology, zoology

Toothed whales are cetaceans, suborder Odontoceti. They use teeth to capture cuttlefish, squid, and other prey. Some are endangered species perceived to be quite intelligent.

Principal Terms

AMBERGRIS: waxy material from the intestines of sick sperm whales, used in perfume

CUTTLEFISH: a squidlike marine mollusk, eaten by Odontoceti

DIGIT: a finger, toe, or related bony animal structure

ECHOLOCATION: batlike location, from sound echoes, of unseen objects, used by toothed whales

SPERMACETI: a waxy substance in heads of sperm whales; usable for candles, ointments, lubricants, and cosmetics

Dolphins and porpoises are toothed whales of the order Cetacea, suborder Odontoceti. Like their distant relatives, baleen whales, toothed whales are mammals that spend their entire lives in earth's waters. Most toothed whales are found in oceans, but some inhabit harbors and rivers. Odontoceti make up sixty-seven of seventy-seven cetacean species, in six families: river dolphins (five species), porpoises (six species), dolphins (thirty-two species), sperm whales (three species), white whales (two species), and beaked whales (eighteen species).

All male toothed whales are larger than females. Male sperm whales, the largest toothed whales, are the largest toothed animals in the world. They grow to seventy-foot lengths and seventy-five-ton weights. Sperm whales dwarf all other Odontoceti—Herman Melville's "Moby Dick" was a male sperm whale. Like all whales, toothed whales are thought to be descended from a land animal, believed to have been an ungulate (hoofed mammal). However, their earliest ancestor was not the same as that of baleen whales. Why ancestors of toothed whales entered the oceans, seventy million years ago, is unknown. It may be that their return to the oceans was due to the need for a new food supply or to escape from predators.

Physical Characteristics of Odontoceti

The most characteristic physical feature of toothed whales is teeth that seize prey. Prey range from small crustaceans for small river dolphins, to squid and cuttlefish for larger dolphins and sperm whales, to walruses and seals or other whales for killer whales. As in all whales, evolution produced streamlined, fishlike mammals, whose front legs became flippers. Flipper bones resemble jointed limbs and some flippers show evidence of digit bones. External hind limbs are long gone, although their vestiges are still seen, internalized. Horizontal tail flukes that propel toothed whales are not anatomically related to hind limbs. As in baleen whales, flukes are made of boneless fibrous-elastic tissue, oriented horizontally, unlike fish tail fins, which are oriented vertically and differ in composition.

The bodies of whales are surrounded by thick blubber (fat) layers. This enhances buoyancy, insulates by preserving body heat, and is a fine energy store. Toothed whales are very fast, some swimming twenty-five miles per hour for prolonged periods and forty miles per hour in short bursts. Specially adapted Odontoceti lungs enable dolphins to dive to depths of almost one-quarter mile. Larger species dive deeper; for example, sperm whales dive to over 1.25 miles. This is because of the presence of waxy spermaceti around sperm whale nostrils. Cooling the spermaceti—by filling nasal passages with cold seawater—raises the whale's density and helps account for tremendously deep sperm whale dives.

Toothed whales have lungs and breathe air through a nostril. Nostrils, in blowholes atop the head, are closed tightly just before dives. Submerged indefinitely, out-of-breath Odontoceti would drown, though some can submerge for over an hour. Part of the ability to remain submerged is that 30 to 40 percent of oxygen in Odontoceti bodies is stored in muscle in a usable form (compared to 10 to 13 percent in humans). Also helpful to Odontoceti—especially dolphins—is the ability to move blood bidirectionally in blood vessels. This minimizes the effects of diving on the blood pressure and allows blood shunting to or from different organs as needed.

Toothed Whale Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Cetacea (whales)
Suborder: Odontoceti (toothed whales)
Families: Delphinidae (dolphins, seventeen genera); Monodontidae (white whales, two genera); Platanistidae (river dolphins, four genera); Phocoenidae (porpoises, three genera); Physeteridae (sperm whales, two genera); Ziphiidae (beaked whales, five genera)

Geographical location: Found in all earth's oceans, harbors, and some rivers

Habitat: Salt water in oceans, brackish water, or freshwater, depending on family

Gestational period: Between nine and sixteen months, depending on species; one large, well-developed calf (occasionally two) born, tail first; calves often half as long as mothers

Life span: Estimated twenty-five to forty years, depending on species

Special anatomy: Toothed mouth; lungs like land mammals; blow hole; flippers evolved from front legs; horizontal tail, nasal cavity that produces echolocation and vocalization

Dolphins, family Delphinidae, travel in groups that vary in number from thousands to a few members. Most dolphins are found in oceans and seas and have, as special characteristics, beaks of varied length. Best known are common dolphins (*Delphinus delphis*) and bottle-nosed dolphins (*Turisops truncatis*). Common dolphins, in legend and in reality, are great friends of humans. Bottle-nosed dolphins are frequent performers in marine aquariums. Both species cavort in the open oceans, leaping with backs arched from waters near ships. Smaller river dolphins live in Asia and South America. Examples are near-sighted buffeo dolphins (*Sotalia fluviatilis*) and blind Ganges dolphins (*Platanista gangetica*), which navigate solely by echolocation. Other beakless Delphinidae are large, dangerous killer whales (*Orcinus orca*) and intelligent pilot whales (*Globocephala malaena*).

The seven porpoise species are smaller than dolphins. They have beakless, rounded heads and triangular dorsal fins. Porpoises are rarely seen in open seas. The most plentiful, harbor porpoises (*Phocoena phocoena*), inhabit estuaries and inlets of large rivers. They do not follow ships or leap like dolphins. There are also three sperm whale species, the huge sperm whales (*Physeter catadon*) and two eight- to ten-foot dwarf or pygmy Kogia species. All have spermaceti in their heads. Arctic white whales lack dorsal fins and spermaceti. Male narwhals (*Monodon monoceros*) have spiral horns up to nine feet long, prized by the people who hunt narwhals for food. The white whale (*Delphinapterus leucas*, or beluga) is also sought for food. Beaked whales, family Ziphidae, are poorly studied and known

Dolphins, such as these Atlantic spotted dolphins, navigate by means of echolocation to identify other objects in the water. (Digital Stock)

most for toothed beaks and their ability to dive deeper and stay submerged longer than any other marine organism.

Special Senses and Odontoceti Intelligence

Odontoceti, especially dolphins, were thought very intelligent by the ancient Greeks. Current belief in dolphin intelligence has intensified due to the ability of captive dolphins, in sea aquariums, to learn complex tricks and invent games for themselves and their human keepers. Limited study of sperm whales suggests intelligence, supported by the twenty-pound brains of adult males. Intelligence is extrapolated to other Odontoceti, most of which have not been studied well. Almost all species have brains bigger than the three-pound brains of humans.

Many believe that dolphins and sperm whales have spoken languages. These are reported as vocalizations, including calls that keep groups together and signal danger. Dolphins appear chatty, almost constantly making variegated whistling sounds for alarm, sexual arousal, and other emotions. Moreover, they are very social. They show great affection and caring for each other and their calves. In addition, isolated from other dolphins and human keepers, captive dolphins pine away and die. Most linguistic authorities see dolphin and sperm whale intelligence as close to that of primates, but do not rate their communication as language.

Odontoceti and baleen whales have small eyes, lack external ears and noses but have well developed inner ears, and some river dolphin species are blind. These characteristics led to proof that Odontoceti use sound and hearing the way vision and smell are used by land mammals. In addition to vocalization (pseudolanguage) they make echolocation clicks as air moves between nostrils and nasal passages to the lungs. Clicks are bio-

Some Odontoceti Species

Bottle-nosed dolphin (*Turisops truncatis*): The dolphins usually found in sea aquariums; up to thirteen feet long; dark gray body and lighter gray belly and face; short, wide beak; inhabits temperate and tropical parts of all oceans.

Common dolphin (*Delphinus delphis*): This dolphin cavorts around ships; up to nine feet long; black, with white belly and face and yellow, white, or gray side stripes; black markings around eyes and across the long, narrow beak; inhabits temperate parts of all oceans.

Ganges dolphin (*Platanista gangetica*): The blind river dolphin; up to eight feet long; small dorsal fin, eighteen-inch beak; inhabits India's rivers.

Harbor porpoise (*Phocoena phocoena*): The common porpoise; up to six feet long; black, with white belly; has dorsal fin but no beak; inhabits shallow waters and estuaries of North Atlantic and North Pacific, as well as the Black Sea and Mediterranean Ocean.

Killer whale (*Orcinus orca*): A dolphin that grows up to thirty feet long; glossy black back, white marks on sides and belly, dorsal fin six feet tall, no beak; preys on other whales; inhabits coastal regions of all oceans.

Narwhal (*Monodon monoceros*): A member of the white whale family; up to twenty feet long; eight- to nine-foot-long spiral horn (actually the left top incisor); inhabits the Arctic Ocean.

Pilot whale (*Globocephala malaena*): Black dolphin; up to thirty feet long; square head with very short beak; tall, narrow dorsal fin and long flippers; inhabits temperate and tropical regions of all oceans.

Sperm whale (*Physeteridae catodon*): Up to seventy feet long; dark gray, shading to white belly; head 30 percent of body length; no dorsal fin, small flippers; inhabits all oceans; migrates to poles in spring and equator in autumn.

White whale (*Delphinapterus leucas*): Beluga whale; up to twenty-three feet long; white as adult, has no dorsal fin; lives mostly in the Arctic Ocean.

sonar, as in bats. That is, echolocation is the way Odontoceti explore the world. Directing clicks outward toward objects in the environment causes sound waves to hit the objects. Waves that bounce off are picked up by the whales and identify object size, distance, and so on. The great ability of water to carry and amplify sound is deemed to be why cetaceans discarded external ears. Operation of this sensory system has uses in navigation and predation in murky oceans.

The Life Cycle of Odontoceti

Toothed whales reproduce like other mammals, but in the water. Adults participate in complex courtship: swimming close together, caressing, nuzzling, and rubbing bodies. After copulation, females carry young for nine to sixteen months, depending on species. Then, a large, well-developed calf (occasionally two) emerges underwater, tail first. Only the reproduction of bottle-nosed dolphins and sperm whales is well studied. In both cases, when a calf is born, other females (aunts) ensure it gets to the surface quickly for a first breath. They reportedly continue to help the mother to protect her offspring.

Calves nurse from teats on the mother's belly. The milk is rich in minerals, protein, and fat, so calves grow quickly. High maternal affection and protection of calves is found in bottle-nosed dolphins, sperm whales, and the other Odontoceti studied. Calves are weaned in one to two years. They are adults, capable of reproduction, in five years. Life spans vary from twenty-five to forty years. As with other wild animals, not all whales—actually, only a few—get to grow old.

Odontoceti as an Endangered Species

In the past, uncontrolled whaling for spermaceti, blubber, and ambergris made sperm whales and narwhals endangered species. At the beginning of the twenty-first century, there is little sanctioned whaling for large Odontoceti, initially due to quotas set by the International Whaling Commission (IWC). By the early 1990's, most whaling by IWC nations stopped. These actions and the absence of clandestine whaling may allow whales to make a natural comeback. Dolphins, never hunted as much as baleen and sperm whales, are endangered because they are trapped and drown in nets used to catch tuna, a species with which many dolphin species swim. This has been reduced by the refusal of tuna canneries to buy tuna from fleets that do not protect dolphins, an attitude driven by activist consumer public opinion. A 1972 U.S. Marine Mammal Protection Act—amended in 1988 and 1992—diminishes exploitation of dolphins and related mammals.

DOMESTICATION

Type of animal science: Evolution
Fields of study: Anatomy, anthropology, archaeology, genetics, ethology, physiology, reproduction science

Animal domestication is the process of bringing an animal species under the control of humans and gradually changing it, through careful selection, mating, and handling, so that it becomes more useful to humans. Some animals are more amenable to being domesticated than others. Domestication is a symbiotic relationship between humans and the animals involved, and has been integral to the development of human societies.

Principal Term

DOMINANCE SOCIAL BEHAVIOR: organization around a dominant leader, whom the rest of the group follows

Although taming a wild animal, that is, acclimating it to the presence of people, is invariably a first step in domestication, the critical aspect is directing its breeding toward a functional goal. Genetic selection for desirable traits and against undesirable ones is a crucial feature of domestication. Captive wild animals in zoos or circuses cannot be considered domesticated, although they may be quite tame and their breeding is controlled by humans. However, this breeding is not directed toward some functional goal. Mere propagation of a species or maintaining genetic diversity is insufficient to constitute domestication. Domestication is a synergistic relationship between humans and the animals involved. Humans benefit from the resources and services that the animals provide, such as food, fiber, shelter, clothing, work, sentinel duty, and companionship. Animals benefit by having humans protect them from harm, provide for their needs, and increase their numbers and range.

Characteristics of Animals Favoring Domestication

In 1865, the English naturalist Francis Galton suggested the following six physiological and behavioral characteristics that make some animals good candidates for domestication: hardiness, dominance social behavior, herd behavior, utility to humans, facile (easy) reproduction, and facile husbandry. First, by hardiness, he refers to the ability of the young to be removed from its mother and to be around humans. The guinea pig is perhaps an extreme example of tolerating removal from its mother, as it is born ready to eat solid food. Most mammals, on the other hand, initially depend on their mother's milk. Primates are poor subjects for domestication because of their helplessness at birth and their relatively long dependence on their mothers for food and nurturing.

Second, dominance social behavior is in contrast to territorial behavior and refers to one animal assuming leadership, with the rest of the group acquiescing to him or her in the hierarchy. In domestication, humans co-opt the function of the leader, and animals remain submissive even as adults. Third, herd animals are contrasted to solitary animals, or ones that disperse in response to danger. Domesticated animals are penned or otherwise restricted at various times. If they remain together in herds, they are easier to manage. Fourth, utility to humans includes their use for food, fiber, work, companionship, and even worship. Humans would not make the effort to domesticate an animal unless it had some perceived value. The purpose for domestication may change with time, however. It is likely that the initial motivation for domesticating cattle was for worship—to capture the strength and aura of these animals, which were revered and used in religious ceremonies. Work, such as pulling carts, packing, and riding, became a subsequent goal, while contemporary utility in Western societies involves meat and milk production.

The fifth characteristic is facile reproduction under confined conditions; animals with finicky reproductive behaviors and/or elaborate courtship rituals make poor candidates for domestication. Sixth, facile husbandry refers to placid disposition and versatility in terms of nutrition. Animals that are high-strung or dependent on unique foodstuffs would be weak prospects for domestication. Koalas, which eat leaves from only certain eucalyptus trees, are poor candidates. On the other hand, pigs and goats are excellent choices because they are not very fastidious in their eating habits. These six characteristics, enunciated more than a century ago, apply strongly to livestock species, but less well to dogs and cats; with regard to the latter, it has been argued that cats are not so much domesticated as merely tolerant of humans.

Cats are the only species to have been domesticated since prehistory. (Corbis)

History of Animal Domestication

Archaeological evidence suggests that agriculture developed about ten thousand years ago, after the last ice age, at a time when the climate became warmer and more stable. Predictability of the weather is particularly crucial for plant domestication, which apparently developed synergistically with animal domestication, leading to agriculture. Domesticated animals simplified the acquisition of food and provided food storage, in the form of "walking larders"; larger animals, such as cattle, buffalo, and horses, permitted heavier work to be done and larger distances to be covered. Farming the land made it possible for humans to abandon the nomadic lifestyle of hunter-gatherers and to adopt a more sedentary lifestyle. This allowed for development of new technologies, professional specializations, and new forms of social organization.

Domestication of any animal did not occur at once, but rather over a substantial period of time, perhaps hundreds of years. Furthermore, estimating the dates for domestication is subject to considerable uncertainty and may need to be modified as new information becomes available. For some species, domestication occurred independently at more than one location. The process may have begun almost accidentally, as by raising a captured young animal after its mother had been killed and observing its behavior and response to various treatments. The domestication of an animal subsequently spread from the site of origin through trade or war.

Animal domestication occurred in various parts of the world. In the Middle East, the Fertile Crescent, stretching from Palestine to southern Turkey and down the valley of the Tigris and Euphrates Rivers, was an important site. Sheep, goats, cattle, and pigs were domesticated there by around 6000 B.C.E. The Indian subcontinent and east Asia were independent sites for domesticating cattle and pigs, respectively. Llamas, alpacas, and guinea pigs were domesticated in the Andes Mountains of South America. Domestication of cats occurred in Egypt and of rabbits in Europe. No native animals were domesticated in Australia, likely because none of them were suitable for domestication. It is worthy of note that few domestications have occurred in the past thousand years. It is also of interest that domesticatable species were not evenly distributed over the globe, which probably has had a lasting effect on the differential development of various cultures.

Archaeology, coupled with the natural history of domesticated animals and their wild relatives, has been essential in reconstructing the history of domestication. Examining skeletal remains at archaeological sites for changes in morphology and distribution by age and sex has helped scientists to deduce the extent of domestication. Lately, traditional archaeology has been supplemented by the methods of molecular biology. Examining extant breeds for their genetic relatedness has been particularly useful in distinguishing single versus dual sites of domestication.

Early Domesticates: Dogs and Reindeer

Dogs (*Canis familiaris*) are generally recognized as the earliest known domesticated animals. They were widespread across the Northern Hemisphere before other animals were domesticated. They were derived from wolves (*Canis lupus*), with whom they are fully interfertile. The earliest known dog is in a burial site in Northern Iraq that dates from 12,000 to 10,000 B.C.E. Other sites, dating from 10,000 to 7000 B.C.E., have been documented in England, Palestine, Japan, and Idaho. While it may have first occurred in China (a Chinese wolf has some of the detailed physical features of dogs), domestication probably occurred at a number of separate sites. Dogs accompanied the American Indians when they occupied the Americas in several waves prior to the end of the last ice age. Dingoes were brought to Australia by trade from Asia long after the Aborigines settled that continent 40,000 years ago. While dogs were considered a food animal, they have long been used for guarding, hunting, and companionship. Subsequently, they were developed for herding.

Reindeer (*Rangifer tarandus*) were another early domesticate, dating from around 12,000 B.C.E. in northern Scandinavia and Russia. The reindeer has been little changed by domestication and its range has not been extended by the process. They are well-suited to their environment, but attempts to establish reindeer industries in Canada and Alaska have not been successful. Herding reindeer continues as a principal occupation of the Laplanders of Finland, Sweden, and Norway. Reindeer are used for draft (pulling loads), clothing and shelter (skins), tools (antlers), and food (meat and milk). Farming several other deer species (such as *Cervus dama* and *Cervus elaphus*) has recently gained in importance in New Zealand and western Europe, where they are raised for meat (venison) and "velvet," the new growth of antlers, the basis for traditional medicines in Asia. However, because these latter species have had little opportunity to be changed, they cannot be considered domesticated.

Sheep, Pigs, and Cattle

Sheep (*Ovis aries*) were the first of the common food animals to be domesticated. They were derived from wild sheep (*Ovis orientalis*) and were first domesticated in the western Fertile Crescent around 7000 B.C.E. Goats (*Capra hircus*), derived from Persian wild goats (*Capra aegarus*), were first domesticated in the central Fertile Crescent slightly later, between 6000 and 7000 B.C.E. Sheep and goats were used for food, skins, and fiber (wool or hair). Both were later selected for milk production.

Pigs (*Sus domesticus*) probably originated at two separate sites, the central Fertile Crescent around 6000 B.C.E. and in eastern Asia around 5000 B.C.E. Derived from wild pigs, they were primarily raised for meat. Despite restrictions against eating pork by Muslims and Jews, it has long been the principal meat consumed in the world. The most populous country, China, has nearly 50 percent of the world's pigs.

Cattle (*Bos taurus* and *Bos indicus*) are derived from now-extinct wild cattle (aurochs, *Bos primigenius*) that ranged over much of Europe and Asia. They were probably domesticated independently at two locations, the western Fertile Crescent around 6000 B.C.E. for *Bos taurus* and the Indian subcontinent around 5000 B.C.E. for *Bos indicus*. Initially, the animals were worshiped and used in religious ceremonies. Reverence for cattle is still practiced by Hindus in India. Subsequently, they were developed for work, meat, and milk. Their hides are made into leather. Traditional cattle in Africa are derived from initial importations of *Bos taurus* and subsequent importations of male *Bos indicus*.

Other Domesticated Animals

Asiatic buffaloes (*Bubalus bubalis*) were domesticated as the water buffalo in India (3000 B.C.E.) and as the swamp buffalo in east or southeast Asia (2000 B.C.E.). While both were developed as draft animals, the water buffalo has also been selected as a dairy animal. Fully half of the milk production in India comes from buffaloes. In spite of its tropical origin, the Asiatic buffalo is not very heat tolerant and compensates by immersing in water or mud. Neither the African buffalo (*Syncerus caffer*) nor the American buffalo (more properly, bison, *Bison bison*) have been domesticated. Yaks (*Poephagus[Bos] grunniens*) were domesticated around 3000 B.C.E. in Tibet or surrounding areas, where they are used as pack animals and as a source of milk, hair, hides, and, usually after an otherwise productive life, meat.

Horses (*Equus caballus*) originated from wild horses in the Caucasus Mountains around 4000 B.C.E. Originally used for food and skins, they were also developed for draft and, much later, for riding. Because they came to the Middle East after the development of written language, their arrival is documented, so scholars do not need to depend solely on the archaeological record. Donkeys (*Equus asinus*) were domesticated in the Middle East or Northern Africa (3000 B.C.E.). They are used for carrying material or people, as is the mule, an infertile cross between a horse and a donkey.

Llamas (*Lama glama*) and alpacas (*Lama pacos*) were domesticated in Peru by Incas around 4000 B.C.E. Llamas are from wild guanacos and alpacas from wild vicuñas, found at higher elevations. Llamas are used as pack animals, alpacas are valued for their fine wool, and both serve as sources of meat. Camels, the one-humped dromedary (*Camelus dromedarius*) and the two-humped Bactrian (*Camelus bactrianus*) were domesticated in Arabia (2000 B.C.E.) and Central Asia (1500 B.C.E.), respectively. Both are pack animals, with the dromedary also used for meat.

Guinea pigs (*Cavia porcellus*) were domesticated in Peru around 3000 B.C.E. They continue to be used as a meat animal in parts of South America. Rabbits (*Oryctlagus cuniculus*) were domesticated between 600 and 1000 C.E. in France. They are primarily raised for meat and fur, with angora rabbits producing a fine wool.

Cats (*Felis catus*) are the animals least changed, morphologically, by domestication. In addition, they are quite capable of surviving without human intervention. Their domestication occurred relatively late, around 2000 B.C.E., in Egypt, the home of the African wild cat (*Felis catus libyca*), which resembles domestic tabby cats. The early Egyptians adopted cats enthusiastically, deifying them and prohibiting their export. After conversion to Christianity, Egyptians ceased worshiping cats, which were carried to all parts of the Roman Empire and thence to the rest of the world. Cats have been used for companionship and for rodent control.

Chickens (*Gallus gallus*), along with ducks and geese (from China, the Middle East and Europe), turkeys (from North America), Muscovy ducks (from South America), and guinea fowl (from Africa) are avian species that have been domesticated. Chickens were probably derived from wild red junglefowl in southeast Asia before 2000 B.C.E. Cockfighting was an initial purpose for their domestication. They acquired religious significance and were also used for meat and feathers. Their selection for egg production has been a recent development. Because of improvements in breeding, feeding, and management, poultry meat production is increasing rapidly and is second to pork worldwide. In the past few centuries, two other avian species, ostriches (from Africa) and emus (from Australia), have been farmed, but it is probably incorrect to call them domesticated, as they have so far been little changed from their wild relatives.

Two insects have also been domesticated: honeybees and silkworms. Honeybees were domesticated shortly after the last ice age and were the primary source of dietary sweetener until two hundred years ago. They were also valuable for wax and venom, the latter for medicinal purposes. Silkworms, one of the ten varieties of silk-producing insects, were domesticated around 3000 B.C.E. in China, producing fiber used in apparel.

DONKEYS AND MULES

Type of animal science: Classification
Fields of study: Anatomy, evolutionary science, zoology

The donkey was domesticated from the African wild ass at least six thousand years ago. The mule is the result of crossing a male donkey (jackass) with a female horse (mare).

Principal Terms

BROWSERS: eaters of bushes, scrub vegetation, and bark

EQUIDS: members of the horse family (Equidae) including horses, asses (including the donkey), zebras, and their crosses (including the mule and the hinny)

GRAZERS: eaters of grasses

HYBRID: an organism resulting from the crossing of two species

HYBRID VIGOR OR HETEROSIS: the tendency of hybrids to be larger and more durable than their parent species

UNGULIGRADE: walking on the tips of the toes

The donkey and mule are members of the horse family (Equidae). Like other equids, they are fast runners adapted for life on open grasslands and deserts. Their posture is unguligrade, meaning that they run on the tips of their toes. Their legs are long and adapted for speed. Each foot has only one toe—the hoof—another adaptation for speed. Equids are grazers and sometimes browsers. Asses especially will browse.

The Donkey

The donkey or domestic ass is descended from the African wild ass. Donkeys first appeared on wall paintings and in burials six thousand years ago in Egypt and western Asia. They have been used widely by farmers and traders as pack animals and to pull wheeled vehicles.

Donkeys have been bred to be smaller than their ancestor, the African wild ass. The goal was to produce a thrifty animal that gave the greatest amount of work for the least amount of feed. Being descended from a desert animal, donkeys are better suited to the Mediterranean climate than to

Donkeys, descended from the African wild ass, have been domesticated for over six thousand years. They are used as pack animals and to pull wagons, but they are very uncomfortable to ride. (Corbis)

Donkey and Mule Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Subclass: Eutheria
Order: Perissodactyla
Family: Equidae (horses)
Genus and species: Equus asinus (donkeys or domestic asses); *E. asinus* bred with *Equus caballus* (mules)
Geographical location: The domestic donkey is descended from the wild ass of the hot deserts of Africa and Arabia; both the donkey and the mule were introduced to wide areas of Europe, Asia, Africa, and later to both North and South America
Habitat: Donkeys and mules are well-adapted to hot, dry deserts, yet selective breeding has produced donkeys that thrive in the damp climate of Ireland
Gestational period: 11.5 months
Life span: Twenty to twenty-five years on average
Special anatomy: Long ears dissipate heat; broad single toe (hoof) on each foot is an adaptation for running; capable of digesting large quantities of low-protein fodder

northern Europe. Donkeys were introduced to China in the third century B.C.E. Donkeys were brought to the Americas by the Spanish, who call them "burros," beginning in the seventeenth century.

It is possible, but awkward, to ride a donkey. Because of the animal's low withers, a human rider must sit far back in the donkey seat to avoid sliding forward. This produces a bumpy ride and has precluded the donkey's use as a mount in hunting or battle.

The Mule

The mule is the offspring of a male donkey (jackass) and a female horse (mare). The opposite cross—a female donkey (jenny) bred to a male horse (stallion)—produces a hinny. A mule has a donkey's large head and long ears, the body of a horse, and an asslike tail. Its voice is a bray that is somewhat different than that of the ass. Some mules are quite large: as much as sixteen hands (sixty-four inches) at the withers.

Mules are strong and durable. They are more surefooted and can bear heavier loads than either the horse or the donkey. This is a good example of hybrid vigor or heterosis: the tendency of hybrids to be larger and more durable than their parent species. It is often said that a mule is smarter than a horse because a horse may overeat and "lounder" (become ill from overeating) if given unlimited access to grain, but a mule will not. Mules are almost always infertile, apparently due to differing numbers of chromosomes in the gametes of the horse and the donkey.

Donkeys and Mules in History

Donkeys have been used in agriculture and transport for at least six thousand years. Mules were essential in transport for at least three thousand years, from ancient times until the invention of the steam engine and the building of railroads. Mules can be ridden but were used mostly in mule teams or mule trains to pull wheeled vehicles in both peace and war. For example, the twenty-mule teams of Death Valley, California, hauled two wagons loaded with borax plus a water wagon with a combined weight of over twenty-seven tons.

Wild populations of equids have been greatly reduced by humans through hunting and habitat destruction, some to the point of extinction. Domestic horses, donkeys, and mules, however, have thrived for thousands of years in association with humankind. Despite being largely replaced by mechanical power, domestic equids are still common.

DUCKS

Type of animal science: Classification
Fields of study: Anatomy, ornithology

Ducks are among the most common and widespread of aquatic birds. Like other members of the Anatidae family, they have webbed feet, a boat-shaped body, a dense covering of feathers, and a broad and somewhat flattened bill.

Principal Terms

ANATIDAE: the bird family that includes the ducks, swans, and geese

ECLIPSE PLUMAGE: the drab plumage of male ducks following the postbreeding molt in which their bright courtship feathers are replaced by dull earthy feathers that provide inconspicuous coloring

EIDERDOWN: rich, downy feathers of eider ducks noted for its insulation value; eiderdown has been gathered for centuries for use as stuffing for mattresses or parkas

HYBRID: the offspring of parents of different stock; hybrid ducks may result from the mating of mallards and barnyard geese

POLYGAMY: mating behavior in which a male mates with more than one female at the same time

POSTNUPTIAL MOLT: replacement of feathers following the mating season

RETICULATE: netlike covering of scales on legs

SCUTELLATE: overlapping of platelike or shieldlike scales

Some of the most common and widespread of all aquatic birds are the ducks. They breed on all continents except Antarctica, and are noted for their long-distance seasonal migrations along well-established flyways. Many species such as the mallard (*Anas platyrhynchos*) and northern pintail (*Anas acuta*) are indicator species of wetlands, waterways, and water courses, but others, such as the Baikal teal (*Anas formosa*) and Laysan duck (*Anas laysanensis*) are very limited in numbers and distribution. Most waterfowl are important food resources for native peoples, and revenues from duck hunters promote local economies and fund wildlife refuges. Wildlife enthusiasts value the rich variety of ducks and the brilliant colors of the males, called drakes, of many species.

Physical Characteristics

Ducks are placed in the avian order Anseriformes along with the screamers, swans, and geese. The long-legged screamers lack webbed feet and are placed in their own family, the Anhimidae. The ducks, geese, and swans are gathered in the family Anatidae and are collectively called waterfowl. The anatids are united in having webbed feet, a boat-shaped body, a dense covering of feathers, and a broad and somewhat flattened bill that is variously modified for straining minute surface organisms, gathering shellfish, grazing on aquatic plants, or catching fish.

Ducks differ from swans and geese in several ways. They are generally smaller and have shorter necks and legs, which are set well back on the body. They are good swimmers but walk with a peculiar waddling gait on land. Ducks are also distinguished in having scutellate (overlapping) scales on the front of their legs, while geese and swans have netlike or reticulate scaling.

Unlike their larger kin, ducks have two molts each year. The first molt occurs after breeding in males and shortly later in females. During this molt, ducks shed their flight feathers and males trade their bright breeding plumage for the plain plumage colors similar to those of females, called an eclipse plumage or hiding plumage. The plain colors of the eclipse plumage camouflages the flightless birds until their new flight feathers grow. The second molt occurs in late summer or early fall and produces the bright breeding plumage of males in preparation for courtship on their wintering grounds.

Ecologically, all ducks are birds of aquatic habitats that reach their greatest abundance in the innumerable ponds, shallow lakes, and marshes of the world. Several species are sea ducks that frequent shore habitats, estuaries, and coastal marshes during the nonbreeding season.

Courtship and Nesting

Courtship and pair formation occurs on wintering grounds as males and females engage in species-specific displays. Males of many species perform intricate head and tail jerks that "point" to the bright metallic colors of their wing speculum. Many sea ducks add a courtship finale by flicking water spurts with their head or feet, all the while bowing and cooing. The stiff-tailed ducks of the tribe Oxurinae twist their heads far over their backs, then violently thump their bills against the inflated necks, uttering a stream of bubbles and a series of burps.

Following courtship the female builds a nest of reeds, sedges, and grasses in marshes or along the shallow, weed-choked margins of lakes and ponds. The mergansers and wood ducks nest in cavities in trees, while shelducks are unique in selecting burrows in which to lay their eggs.

In most species, the female alone builds the nest of nearby materials and lines it with downy feathers plucked from her breast. The down feathers provide wonderful insulation for the eggs and are arranged in layers over the eggs for protection from predators when the female leaves the nest to find food.

Most ducks lay relatively large clutches of eight to twelve smooth, white eggs. A few species, such as the black-headed duck (*Heteronetta atricapilla*) of South America, are brood parasites that lay their eggs in nests of other ducks, coots, and ibis.

Incubation begins when the clutch is complete, ensuring that all of the young hatch at the same time. Incubation takes about a month (twenty-two to forty-one days). The precocial young are densely covered in a fluffy coat of down feathers. In most species, the young abandon the nest shortly after hatching to accompany the female, who leads them to nearby feeding grounds. The young instinctively feed themselves under the watchful eye of the female, who marshals them to safety in the weeds if danger threatens. Predation often decimates the young of a nest, as snapping turtles, fish, foxes, coyotes, hawks, and owls are quick to snap up the defenseless young. Those that survive fledge in about a month and may remain in the company for several more weeks.

In some species, the young accompany the female on the southward migration, but most young migrate on their own, relying on inbuilt genetic programming to fly hundreds and sometimes thousands of miles using the sun or stars or both as navigation aids. Many species memorize landmarks such as lakes and river courses, which supplement celestial navigation aids on future migrations. Studies have also suggested that at least some ducks are able to tap into the earth's magnetic field for directional aid on overcast days, when other cues are unavailable.

Duck Tribes: Anatini

The ducks are subdivided into several tribes on the basis of anatomical and behavior differences. Several tribes contain forms intermediate between ducks and their near relatives, the geese.

The familiar puddle ducks of ponds and marshes belong to the tribe Anatini. They are called tippers or dabblers because of their habit of tipping up to feed in shallow waters of ponds, marshes, and rivers. The dabblers have feet set farther forward on their bodies than other ducks and bound into the air when taking flight. Males of this group usually have a brightly colored, iri-

The mallard duck is a common sight on the ponds and lakes of North America. (Digital Stock)

bottom. Smaller species such as teals feed in shallower waters or on mudflats. The broad, spatulate bill of the northern shoveler (*Anas clypeata*) strains minute organisms from the water surface.

Dabblers are found on all continents, but they are especially plentiful along interior ponds, marshes, and creeks. In most dabblers, the male is jealously attentive to the female during courtship but deserts her shortly after the eggs are laid, leaving her to defend the nest and raise the young entirely on her own. She builds a crude nest of grasses and weeds lined with down from her breast. After abandoning the female, the male may seek another female to repeat the performance. If none is available, they spend the rest of the breeding season loafing and hiding while in the eclipse plumage. After their second molt, the males sport bright new feathers to enter the winter months, during which courtship and pair formation for the following breeding season takes place.

descent wing patch or speculum and are often brightly colored about the head and neck, while females are drab colored.

There are about forty-one species of dabbling ducks worldwide, of which ten breed in North America. Some typical dabblers include the teal, widgeons, pintails, gadwalls, and shovelers. The best-known dabbler is the mallard, which occurs in both wild and domesticated forms. Most of the domestic species, such as the barnyard duck and Indian duck, are probable descendants of the mallard. Dabbling ducks are surface or shallow water feeders of creeks, ponds, and marshes. Some strain food from soft mud, others feed on the water surface, and still other species tip up and then stretch their necks down into the water, taking food from submerged vegetation or feeding on the vegetation itself. Food consists of the leaves, roots, tubers, and seeds of floating or submerged vegetation and a wide variety of small animals, mostly shrimp, scuds, shellfish, and insects. Long-necked dabblers like the northern pintail (*Anas acuter*) tip up to feed directly on the

Aythyinae, Mergini, Cairini, and Oxyurinii

The pochards (redheads), canvasback (*Aythya valisineria*), and scaups belong to the tribe Aythyinae, which are called sea ducks or bay ducks. They frequent coastal locations in winter but build a floating nest among the reeds and grasses of interior lakes, rivers and marshes. Most diving ducks have short tails and wings, but large paddle feet with a distinctive, paddlelike flap on the hind toe for diving. They feed mostly on underwater plants and animals. If danger threatens, diving ducks submerge and can swim underwater for long distances. They take flight by skittering along the top of the water. Because they have short wings on large bodies, most bay ducks fly with rapid wing beats and always appear in a hurry in flight.

The tribe Mergini includes a varied mix of mergansers, scoters, eiders, goldeneyes, and the spectacularly colored harlequin (*Histrionicus histrionicus*) and oldsquaw (*Clangula hyemalis*). Mergansers are powerful divers that pursue fish underwater, catching and holding them with their narrow, serrated bill. They nest in cavities in trees or in rock crevices along rivers and streams, as do the goldeneyes of this tribe. The tribe also includes eiders, which nest in the circumpolar Arctic tundra. Eiders are the source of eiderdown, which the female plucks from her breast to line the nest and insulate the eggs and young. The most striking of the Mergini is the harlequin duck, with its patchwork quilt of chestnut, blue, and white plumage. Harlequins feed in cold, fast-flowing Arctic streams.

Members of the tribe Cairini have long legs and sharp claws which enable them to clamber about branches and limbs. Called wood ducks or tree ducks, they include the gorgeously colored wood duck (*Aix sponsa*) of North America and mandarin duck (*Aix galericulata*) of southeast Asia. This tribe also includes the drab muscovy (*Cairina moschata*), which occurs widely in both wild and domesticated forms. Unlike other tribes, the wood ducks frequent the gallery forests of rivers and lakes, forested swamps, and woodland pools. They typically nest in tree cavities just adjacent to water. When old enough, the downy young half tumble and half jump into the water below the nest cavity.

The ruddy duck (*Oxyura jamaicensis*) exemplifies the tribe of stifftails called Oxyurinii. These dumpy little ducks are predominantly reddish or brownish in color and have upright tails for which they are named. Except for teals, the stifftails are small ducks that are noted for laying exceptionally large eggs for their body size. For example, the female ruddy duck, although scarcely weighing a pound herself, lays a clutch of fourteen eggs, weighing a total of nearly three pounds, with each egg averaging over 2.5 by 1.75 inches in length and width.

Dendrocygnini, Merganettini, and Tadorini

The long-legged members of the tribe Dendrocygnini are whistling ducks. Considered by some to be more closely related to geese than to ducks,

Duck Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Order: Anseriformes (screamers, swans, geese, and ducks)
Suborder: Anseres (swans, geese, and ducks)
Family: Anatidae (swans, geese, and ducks)
Subfamily: Anatinae (ducks)
Tribes: Tadornini (steamer ducks and shelducks, eight genera, twenty-one species); Cairinini (wood ducks and allies, eight genera, fourteen species); Dendrocygnini (whistling ducks, one genus, eight species); Anatini (dabbling ducks, six genera, fifty-six species); Aythyini (pochards and allies, two genera, fifteen species); Mergini (mergansers, scoters, and allies, six genera, sixteen species); Oxyurini (stiff-tails, four genera, nine species); Somateriini (eiders, two genera, four species); Merganettini (torrent duck); Anseranatini (pied goose)

Geographical location: Worldwide, except Antarctica

Habitat: Freshwater ponds, shallow lakes, and marshes; some also live in coastal marshes and estuaries

Gestational period: Clutches of eight to twelve eggs are incubated approximately one month

Life span: Eight to twenty-three years for dabbling ducks, twelve to twenty-one years for diving ducks, eleven to eighteen years for sea ducks

Special anatomy: Webbed feet, broad bills, overlapping (scutellate) scales on legs they are named for the sound of their wings during flight and for their characteristic whistle when taking off. Like the wood ducks to which they are sometimes allied, whistling ducks frequent forested swamps and rivers where they feed by straining organisms from the water surface.

The smallest and perhaps the most unusual tribe of ducks is the Merganettini, which consists of a single species, the torrent duck. This long-legged duck seems to be the Latin American equivalent of the harlequin, as it makes its home in swift-flowing streams of the high Andes.

Several intermediate forms of waterfowl also take the name duck. The shelduck and sheldgeese of the tribe Tadorini are coastal forms that resemble geese but are probably related to the dabbling ducks. Mostly Old World in distribution, the males have the bright wing patch characteristic of the dabblers. They are larger ducks with heavy bills for pulling up rotting roots and tubers or extracting molluscs from bottom mud. The tribe also includes the steamer ducks of South America and the Falkland Islands. Although powerful swimmers and divers, two of the three steamer species are flightless. They typically wade in shallows or walk on water lilies and other aquatic plants as they feed on a variety of organisms. The magpie goose (*Anseranas semipalmata*) of Australia (tribe Anseranatini) is a gooselike duck with a long hind toe and slightly webbed feet. It differs from ducks in having a gradual molt so that a flightless period does not occur. Like geese, the magpie goose spends much time on land foraging for grains and other vegetation matter.

Food, Hunting, and Recreational Opportunities Offered by Waterfowl

All ducks are of interest to wildlife enthusiasts and birders because of their spectacular massed migrations, colorful males, and often intricate behaviors. For centuries, native peoples on all continents have found many species to be an important seasonal food source, eating the meat of adults and young and harvesting eggs. Eiderdown is famous for its heat-retaining qualities and has been used by generations of northern peoples for stuffing pillows, mattresses, quilts, and outerwear.

The ever-increasing impact of hunting resulted in a decline of many of the more desirable species which led, in turn, to the establishment of hunting regulations which strictly regulate bag limits. Since these regulations were established early in the twentieth century, the populations of most ducks have recovered and are now the basis of the single most popular and economically important sport hunting in North America.

Bibliography

Bellrose, F. C., ed. *The Ducks, Geese, and Swans of North America*. Harrisburg, Pa.: Stackpole Press, 1976. The classic book on North American waterfowl covers all aspects of the biology and ecology of ducks. Written by a team of scientists for scientists, sportsmen, and wildlife enthusiasts.

Burk, B. *Waterfowl Studies for Decoy Makers and Collectors, Hunters, Bird Watchers, Waterfowl Artists, and Naturalists*. New York: Winchester Press, 1976. A profusely illustrated book that has something for everyone and every interest in ducks.

Del Hoya, Josep, A. Elliott, and Jordi Sargatal. *Ostriches to Ducks*. Vol. 1 in *Handbook of the Birds of the World*. Barcelona, Spain: Lynx Editions, 1992. The first volume in this magnificent series. Wonderful summary of the order along with detailed accounts of all species of waterfowl. Highly recommended.

Madge, S., and H. Burn. *Waterfowl: An Identification Guide to the Ducks, Geese, and Swans of the World*. Boston: Houghton-Mifflin, 1988. This attractive and well-illustrated book illustrates and details information on all of the world's seven hundred species of waterfowl. Information presented about each of species includes field identification, description, geographical variation, habitat, distribution, and population.

Palmer, R. S., ed. *Handbook of Birds of North America*. New Haven, Conn.: Yale University Press, 1975-1976. Volumes 1 and 2 provide concise but very complete scientific summaries of the taxonomy, ecology, and behavior of all ducks of North America.

Phillips, J. C. *A Natural History of the Ducks*. 4 vols. Toronto: Dover, 1984. This four-volume set is an unabridged reprint of the 1922-1926 publication of the same name. Keys and detailed species accounts augment the beautiful illustrations by Allen Brooks, Frank W. Benson, and Louis Agassiz Fuertes.

EAGLES

Type of animal science: Classification
Fields of study: Anatomy, ornithology

The eagles of the world are swift, powerful birds of prey long admired for their power, ferocity, and regal bearing. All are characterized by a large, hooked bill, keen vision (called "eagle-eyed sight"), and long, broad wings for lifting prey.

Principal Terms

ACCIPITRIDAE: family of Falconiformes that includes the eagles, along with harriers, kites, accipiters, and hawks

EAGLE: name given to large to very large, diurnal birds of prey; although not a strictly taxonomic term, most eagles have large, hooked bills and long, broad wings, and are entirely carnivorous

FALCONIFORMES: avian order of diurnal birds of prey that includes the hawks, eagles, kites, falcons, and harriers

TALONS: the long, curved, and sharply pointed claws of a bird of prey; used for slashing and killing, for holding and carrying of prey, and for defense

TERRITORIALITY: all behaviors involved with the establishment, proclamation, and defense of a specific area; territory is the defended part of a home range

The eagles of the world are swift, powerful birds of prey long admired for their power, ferocity, and regal bearing. They range in size from the great Philippine eagle (*Pithecanthropos jefferyi*) of the Philippines and New Guinea to the Nicobar serpent-eagle (*Spilornis klossi*), which occurs only on the Great Nicobar Island off the coast of Malaysia, and is smaller than many hawks.

In the strict taxonomic sense, the term "eagle" is a generic term applied to any large, swift, and powerful bird or group of birds of prey. All are characterized by a large, hooked bill, keen vision (called "eagle-eyed sight"), and long, broad wings for lifting prey. The name "eagle" was originally applied to the largest birds of prey found in the northern hemispheres. The discovery of many species of tropical eagles that are smaller than some hawk species removed the eagle as the king of birds, at least in size. Furthermore, the four groups of birds of prey that bear the name eagle are apparently not very closely related; some are more similar to harriers, others to kites, and still others to buteo hawks.

Taxonomically, all eagles are placed in the avian order Falconiformes, which is split into two families, the slimmer and swifter falcons in the family Falconidae and the others—the harriers, kites, accipiters, and eagles—in the family Accipitrinae. The four groups of eagles include the sea eagles, snake or serpent eagles, crested eagles, and booted eagles.

The Fish Eagles

The eleven species of sea and fish eagles seem mostly closely related to the kites. They occur along all the world's oceans and inland along large lakes and waterways, being absent only from Latin America. All have bare legs and show white in their heads or backs. Two of the most familiar and most widespread of the sea eagles include the bald eagle (*Haliaetus leucocephalus*) of North America and the European sea eagle (*Haliaetus albicilla*) of Eurasia. The largest is the Steller's sea eagle (*Haliaetus pelagicus*), which has an eight-foot wingspan and can weigh fifteen pounds. These powerful eagles feed mainly on live or dead fish but are capable of taking sea calves. The smallest fish eagle is the fish and crab-eating Madagascar fish eagle (*Haliaetus vociferoides*), which is now confined to the northwest coast of Madagascar.

Ecologically, sea eagles often build large stick nests in trees, in sea stacks, or on ledges. Fish and offal are dietary mainstays, along with an occasional gull or other water bird. They scavenge carrion along beaches, waterways, and offshore islands. Some are kleptoparasites that pirate food from other birds such as the osprey. Sizable numbers of bald eagles winter along the coasts of the Pacific Northwest. Notable wintering concentrations also occur in the Wasatch front range of the Rockies, where their food is mostly jackrabbits and other medium-sized mammals. Because of the dietary mainstay of fish, the sea and fish eagles have proven most susceptible to chlorinated hydrocarbon pollution, which accumulates in their tissues and reduces nesting success and productivity. Several are considered threatened or endangered, although captive breeding programs have successfully led to the recovery of the bald eagle. Included in this group is the vulturine fish eagle (*Gypohierax angolensis*) of southern Africa, which feeds on the pericarp of oil palm nuts along with some crabs and fish. Some authorities prefer to regard this species separately from the bald eagle and rename it the palm-nut vulture.

The Snake and Serpent Eagles

The fifteen species of snake and serpent eagles are a primitive group that have long wings and bare legs as an adaptation for killing venomous snakes. They belong to the subfamily Circaetinae and may be allied to kites. All are Old World species; most live in Africa and southeast Asia, but one, the short-toed snake eagle (*Circaetus gallicus*) occurs as a breeding species across much of Europe. Serpent eagles are generally large, brown or grayish eagles with yellow eyes, and short toes adapted for killing reptiles. They feed almost entirely on snakes, lizards, and amphibians, mainly frogs. Serpent eagles hunt entirely by the perch-and-wait method and most have little difficulty in killing even the larger venomous snakes of Africa and southeast Asia. They are not immune to venom, but rather depend on quickness to avoid being fatally bitten. The European serpent or short-toed eagle (*Circaetus gallicus*) is also included in this group, although it seems more closely related to harriers. Another aberrant form is the dark, long-winged bateleur (*Terathopius ecudatus*) of central and southern Africa. Unlike the other snake eagles, the bateleur hunts for small mammals and reptiles across the African plains and savanna in low, searching flights, attacking in tight downward spirals. Groups of immature bateleurs gather to feed on abundant insects, especially at termite mounds when alates emerge.

The Crested Eagles

A third eagle group consists of four species of buzzardlike eagles, which are closely related to the buteo hawks and sometimes grouped with them in the subfamily Buteoninae. These include

Eagle Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Order: Falconiformes
Families: Accipitridae
Subfamilies: Buteoninae, Circaëtinae
Genus and species: Twenty-one genera and fifty-three species, including *Haliaetus leucocephalus* (bald eagle), *Aquila chysaetos* (golden eagle), *Harpia harpyja* (harpy eagle), *Haliaetus pelagicus* (Steller's sea eagle)
Geographical location: All continents except Antarctica
Habitat: Woods and woodland edges, grasslands, near water for fish-eating species
Gestational period: Thirty to forty-five days, depending on species
Life span: Twenty to thirty years in the wild; up to fifty years in captivity
Special anatomy: Talons; exceptionally keen eyesight; strong legs; sharp, hooked bills

The bald eagle became endangered through the use of DDT, which builds up toxicity as it makes its way up the food chain. Runoff into streams and lakes caused the pesticide to accumulate in the flesh of the fish caught and eaten by the eagles. (Corbis)

the largest and most powerful birds of prey in the world, the huge harpy and crested eagles and their relatives such as the harpy eagle (*Harpya harpyja*) of South America and the great Philippine eagle of the Philippines and New Guinea. These large to very large raptors can take monkeys and other medium-sized and larger mammals of the tropical rain forests.

Booted or True Eagles

The largest eagle group is the "booted" or aquiline eagles, which consists of thirty-three species found worldwide. Sometimes placed in the subfamily Aquilinae, all are large and some are very large, powerful birds of prey. They differ from all other eagles in having a fully feathered tarsus down to their toes. Booted eagles are more common in the Old World, but several species, such as the golden eagle (*Aquila chrysaetos*), are very widely distributed. The booted eagles also include many small forest species, such as the *spizaetus* species of Asia and South America. Many of these forest eagles have shorter wings and long tails for hunting birds and mammals within the triple-tiered forest canopy.

Most booted eagles are entirely carnivorous, taking a wide variety of vertebrates, especially medium-sized mammals and birds. The largest species, such as the Siberian golden eagle (a subspecies of the golden eagle) take wolves, foxes, and other large mammals. More specialized booted eagles include the black eagle (*Ictinateus malayensis*) of southeast Asia, which regularly robs nests of eggs and young, and the tawny eagle (*Aquila rapax*) of Africa and India, which seems to consume everything from termites to carrion up to dead elephants.

Conservation and Economic Importance of Eagles

Even after decades of environmental education, humans still remain the greatest threat to the eagles of the world. Many eagles are shot each year by hunters and sportsman who prefer live target practice. As with other birds of prey, some eagles are hunted for the taxidermy market, a few are taken for falconry, and some are captured as part of the lucrative international trade in zoo specimens, despite the fact that eagles are protected in most countries of the world.

Because of their position at the top the food chain, eagles accumulate pesticides and industrial wastes in their tissues, which can reduce nesting success and endangers the life of the eagle. Many toxic chemicals have been found in the eagles of the world, but the fish-eating eagles are most at risk.

Eagles need comparatively large home ranges and are constantly at risk from habitat destruction and fragmentation. The rapid demise of tropical rain forests places tropical eagles in the greatest risk. Several eagles are listed as endangered or threatened species in many areas of their range. Conservation efforts have included protective legislation, along with recovery programs that included captive breeding, nesting platforms, and reintroduction programs. Both the bald eagles and the white-tailed sea eagle (*Haliaetus albicilla*) in Scotland have benefitted from extensive and expensive recovery efforts. Conservation programs continue to target the protection of harpy eagles in Latin America and the great Philippine eagle of the Philippine Islands.

Bibliography

Bent, Arthur C. *Life Histories of North American Birds of Prey*. Dover, Del.: Dover Press, 1938. Bent exhaustively summarized all of the available reports on ecology, behavior, and food of North American eagles. Still an important reference.

Brown, Leslie, and Dean Amadon. *Eagles, Hawks, and Falcons of the World*. 2 vols. New York: McGraw-Hill, 1968. Somewhat dated now, but still considered by many to be the defining work on diurnal birds of prey by two of the world's acknowledged experts. Each species is exhaustively treated with range maps. Includes great paintings of each of the world's diurnal raptors.

Del Hoyo, Josep, Andrew Elliott, and Jordi Sargatal, eds. *New World Vultures to Guineafowl*. Vol. 2 in *Handbook of the Birds of the World*. Barcelona, Spain: Lynx Edicions, 1994. Twenty authors contributed to this massive, oversized volume that summarizes our information about all of the diurnal birds of prey of the world. Each group—falcons, accipiters, eagles, and so forth—is proceeded by a detailed summary that includes information on habits and habitat, relationships to humans, conservation status, and other timely topics.

Grambo, R., ed. *Eagles, Masters of the Sky*. Stillwater, Minn.: Voyageur Press, 1997. This slim book offers a multitude of views about eagles from the perspective of native peoples, scientists, and wildlife enthusiasts.

Johnsgard, Paul A. *Hawks, Eagles, and Falcons of North America*. Washington, D.C.: Smithsonian Institution Press, 1990. Interesting and entertaining descriptions of all of the diurnal birds of prey of North America. Drawing extensively from the scientific literature, Johnsgard summarizes all that is known about the distribution, subspecies, description, identification, habitats and ecology, diet, social behavior, breeding biology, evolutionary relationships, and status of each species. The tome also includes several introductory sections tracing evolution and comparing foods and feeding, behavior and reproductive biology, and ecology. Appendices contribute a key, origins of names, a glossary, twelve pages of drawings detailing anatomy and field identification, and an extensive list of references.

Newton, Ian. *Population Ecology of Raptors*. Berkhamsted, England: Poyser, 1979. Good analysis of factors affecting raptor populations. Of the many chapters in this book the sections on population biology and behavior are particularly good. Excellent presentation of appropriate figures, charts and tables complement the major points.

Palmer, Ralph S., ed. *Handbook of North American Birds*. 2 vols. New Haven, Conn.: Yale University Press, 1988. Written by a team of authors, this two-volume set is part of the series on North American birds published by Yale University. The ecology and life history of each North American species of diurnal raptor are succinctly summarized. Includes a very complete review of the literature.

EARS

Types of animal science: Anatomy, physiology
Fields of study: Anatomy, physiology

Although there is no standard structure identifying the variety of hearing organs found in the animal kingdom, an ear can be considered as any organ which has developed primarily for the purpose of hearing and which has the perception of sound as its principal function. Considering their usefulness, it is surprising that ears developed only in arthropods (crabs and insects) and in vertebrates. The simplest type of ear senses danger, detects prey, and helps locate mates. More complex ears are used in social communication and for detecting emotional expressions, such as the cries of a distressed infant.

Principal Terms

BASILAR MEMBRANE: the flexible partition connected to the cochlea along which are attached neural hair cells

CERCAL ORGANS: tufts of hair supplied with nerves, located on insects' abdomens, which respond to aerial sounds

COCHLEA: the vertebrate neural organ which transduces sound waves into nerve impulses

OSSICLES: the small bones of the middle ear

OTOLITH: a dense mineral frame supported by sensory hair cells immersed in aqueous fluid; used in the auditory system of lower animals to detect acceleration

TYMPANIC MEMBRANE: eardrum or other surface which serves the purpose of converting sound waves into mechanical vibration

Sound is vibration in a gas, liquid, or solid medium capable of being perceived by an ear when activating an auditory mechanism. For land-dwelling animals the medium is air, although some creatures also hear surface vibration transmitted through their skeletons. Aquatic life hears vibrations propagated through water, but sea mammals also perceive airborne sounds.

Due to the variety of structures and physical operating principles that exist among animals to detect sound, the ear will be defined, by its functional specialization, as an organ developed primarily for the purpose of hearing, with the reception of sound as its principal function. Although the primitive ears found in many lower life forms only faintly resemble the complicated hearing organs of higher vertebrates, they may be justifiably termed "ears" if the mechanism evolved to allow sound perception.

Invertebrate Ears

Only a few of the millions of insect species are known to possess organs capable of detecting sound. These include grasshoppers and crickets, cicadas, the waterboatman, moths, and mosquitoes. The ears of invertebrates are located on various parts of their bodies: Crickets and katydids have ears on the first walking legs; grasshoppers' ears are on the first segment of the abdomen; while the waterboatman hears through its first thorax segment. Moths have uncomplicated ears located either on the first segment of the abdomen or the rear part of the thorax; mosquitoes hear through sensors associated with their antennae. Insects can produce and perceive a variety of different highly species-specific sounds for communication and mating. Although not sensitive to pitch, information is conveyed by changes in intensity, duration, and sound patterns.

One of several different structures may serve as the hearing organ of insects: tympanal membranes, cercal organs, or antennae. The auditory system of grasshoppers and crickets is anatomically connected to the respiratory system, which conducts air from openings in the thorax to the muscles of the legs. Tympana, very thin membranes located on the forelegs or on the abdomen, are found on the body surface of a respiratory tube. Impinging sound waves cause the tympana to flex, which in turn induces tension changes in the attached scolophores, highly specialized sensory structures that transmit nerve impulses to the central nervous system. Moths have simple tympanal organs containing only two or four scolophores, while the highly developed auditory mechanism of cicadas may contain over a thousand sclorophores. The grasshopper ear, with about one hundred sclorophores, has a tympanic membrane hidden beneath the base of the wing cover.

Roaches and certain crickets respond to a wide range of sound frequencies by means of cercal organs located at the tip of the abdomen. The mosquito ear, located at the base of the antenna where an expanded sac contains many scolophores, is stimulated when the antenna shaft vibrates. The stimulation is greatest when the antenna is pointed toward the source of sound, which enables mosquitoes to determine the direction of sounds. For male mosquitoes, the frequency region which responds with the greatest intensity is the same as the hum of the female's vibrating wings, which enables him to find her when mating.

The bodies of spiders contain many slitlike openings, called lyriform organs, one of which (located on the next to last segment of each of the eight legs) is close to the joint between this segment and the last leg segment (tarsus). The tarsus is the sensing element which transmits vibrations to the lyriform organ. The small leg segments respond to the changing velocity of oscillating air particles, enabling some species to hear over a frequency range from 20 hertz to 45,000 hertz.

Fish and Amphibians

Although fish can detect very low frequency compression waves as bodily vibration, this is not considered hearing, since no ear is employed. For ears, diverse species utilize different mechanisms, either singly or in combination. These include the lateral line organ, otolith detectors, and the swim bladder. The lateral line organ is a line of sensory hair detectors, spaced along each side of the fish, that responds to water flow. These sensors are inefficient acoustic detectors because sound waves produce little relative motion between the fish and its environment, but the organ's extension along the body suggests that it locates the direction of a sound. Primitive fish, such as sharks, react to sounds in water with two mechanisms: macular organs, which give information about the orientation of the head, and the lateral-line apparatus.

It is in the bony fishes that an organ of hearing first appears among the vertebrates. Because fish flesh has a density close to that of water, however, sound detection becomes problematic; the waves tend to pass right through the fish's body. Consequently, accessories to hearing, such as the otolith detector, developed to make the fish ear more effective. The dense minerals of this detector respond sluggishly to incoming waves, resulting in an out-of-phase vibration with the surrounding tissue; the relative motion stimulates the hair cells, enabling fish to hear, albeit inefficiently. In some species the efficiency is increased by means of an air sac, a discontinuity whose surface oscillation, responding to incoming vibration, is detected by special receptors. The frequency of greatest sensitivity for most fish species is about 350 hertz, with an upper limit between 1000 and 3000 hertz.

Frogs have no visible external ears, but they possess an otic notch on either side of the skull, which houses the eardrum, and a well-developed middle ear structure. The eardrum consists of a disk of skin-covered cartilage connected to the oval window by a bony rod. When the eardrum vibrates, this rod transmits the vibration to the fluids of the inner ear, which in turn stimulates sensory hair cells similar to those found in other vertebrates. Experiments indicate that bullfrogs are capable of hearing frequencies between 50 and 3,500 hertz.

Salamanders, lacking the otic notch, eardrum, and middle-ear cavity of frogs, transmit sound through the forelimb and shoulder blade to a muscle that passes from the shoulder blade to a bony structure connected to the inner ear.

Reptiles

Lizards are the lowest form of vertebrate possessing cochlea in which different regions respond to different frequencies of sound, thus enabling pitch differentiation. Studies have shown that most lizards have good auditory sensitivity over a range from 100 to 4,000 hertz. As with frogs, a lizard has no visible outer ear, but possesses a tympanic membrane connected to the oval window of the inner ear through a two-part ossicular chain. This chain consists of a bony part ending in a stirrup at the oval window and a cartilage structure embedded into the tympanic membrane. Although the inner ear contains a basilar membrane and hair cells which are stimulated when the fluid of the inner ear vibrates, the form of the basilar membrane is different from that of frogs. Among lizards, hair cell stimulation by two or more different arrangements within the same cochlea is not uncommon; one method provides greater sensitivity, while the parallel system is more resistant to possible damage from very loud sounds.

Image Not Available

Although snakes evolved from primitive lizards, the fact that they show no external ear and their seeming indifference to aerial sound has led to the supposition that they are deaf and only perceive vibrations transmitted through the ground. Actually, snakes can perceive aerial sounds through a device consisting of a thin bony plate, detached from the skull but held in place by ligaments, which vibrates in response to sound waves. A bony structure transmits this vibration through a stirruplike plate to the oval window. Because this mechanism is somewhat inefficient, snakes can perceive only low-frequency tones lying in the range from about 100 to 700 hertz. By the relative intensity of sound in each ear, snakes can localize the direction of a sound.

The turtle's ear is not a degenerate organ as is sometimes assumed; its hearing acuity is quite good in the low-frequency range. A plate of cartilage on each side of the head serves as a tympanic membrane. The ossicular chain consists of a two-element bony structure, ending in a stirrup which covers the oval window. As the stirrup moves inward and outward in response to a sound wave, it causes the fluid in the otic capsule (the inner ear) to move back and forth, thus activating the hair cells. This rather bulky mechanism is quite effective at low frequencies, but the sensitivity to sound decreases rapidly as frequency increases. Experiments indicate that the turtle's ear can respond to aerial sounds having frequencies between 100 and 1,200 hertz, with the greatest sensitivity for tones below 500 hertz.

Crocodile and alligator ears, while obviously reptilian, have several unusual features. A short, external passageway with a closeable earlid leads to a tympanic membrane on the surface of the middle ear. The left and right middle ear cavities are connected by an internal air channel, enabling sound entering one ear to reach the other. A typical reptilian ossicular chain connects the tympanic membrane to the oval window at the entrance to the otic capsule. The inner ear is highly developed, containing approximately eleven thousand sensory hair cells (seven times as many as found in the most sophisticated lizard ear). Studies indicate that crocodilian ears respond to frequencies between 20 and 15,000 hertz.

Birds and Mammals

Avian ears are similar to reptilian ears, but the longer and more sensitive cochlea gives birds an enhanced ability to discriminate pitch. The outer ear consists of a short tube, with a muscle to partially close the opening. The eardrum of songbirds consists of two separate membranes, an outer (which protects the inner), and an inner membrane attached to the ossicular chain. As in lizards, the ossicular chain consists of a cartilaginous structure at the eardrum connected to a bony column ending in a stirrup. The inner ear is similar to that of crocodiles, with a basilar membrane enclosed within the cochlea. Studies of the hearing of small birds indicate a hearing range from about 100 hertz to above 12,000 hertz, with the greatest sensitivity in the low and middle frequencies. It is believed that certain species use echolocation when flying in the dark; owls are known to locate prey solely by means of auditory cues.

The ear of mammals is typically composed of three parts: an outer ear, a middle ear, and an inner ear. The outer ear is the visible portion (pinna) and ear canal, which terminates in the tympanic membrane, or eardrum. The middle ear is a small chamber containing three small bones (auditory ossicles), the hammer, anvil, and stirrup. The hammer is attached to the eardrum and transmits vibration through the anvil to the stirrup. The stirrup's footplate covers the oval window—the entrance to the inner ear. The inner ear (cochlea), re-

Echolocation

Echolocation is the use, by certain species, of self-generated reflected sounds to "see" their environment. This animal sonar is found in whales, dolphins, shrews, and a few birds, but is particularly well developed in bats. They emit short bursts of high-frequency sound well above the range of human hearing and decode the echoes returning from nearby objects. Their perceived sonic environment enables them to navigate, track prey, avoid predators, and perhaps to communicate. The echolocation pulses of bats are produced by vibrating membranes in the larynx and are emitted via the nose or mouth. The ultrasonic signals spread out in a cone-shaped region from the bat's head. When the signals encounter an object, the sound is reflected, scattered, absorbed, or reradiated. The returned signals are received by the bat's large external ears and transmitted through the middle ear to the inner ear, both of which are particularly sensitive to high-frequency sounds. In addition, the bat's auditory complex is acoustically isolated from the skull, enhancing its ability to determine the direction of a sound source by minute differences in the waves perceived by each ear. Typically, the region of maximum sensitivity of hearing for bats corresponds exactly with the most prominent frequencies of the emitted echolocation signals. The prominent frequencies may range from 12,000 hertz to more than 150,000 hertz.

Acoustic orientation is also important for mammals that inhabit deep or murky waters. Both dolphins and whales use echolocation for navigating and for finding food in the dark, or when visibility is low.

sembling a snail's shell, is a fluid-filled chamber which transforms mechanical vibrations into nerve impulses, which are sent to the brain. The cochlea is divided lengthwise into two compartments, separated by a slightly flexible fluid-filled duct. On the duct's lower surface is the basilar membrane, containing thousands of hair cells, which create nerve impulses when stimulated. Aerial sounds cause the tympanic membrane to vibrate; this vibration is transmitted to the fluid of the inner ear by the ossicular chain. The vibrating cochlear fluid induces traveling waves on the basilar membrane, flexing the hair cells, causing them to send nerve impulses to the brain. The brain decodes this information as sound; the frequency information is encoded by the place along the basilar membrane responding to the vibration, while the loudness is proportional to the number of nerve firings per second.

The sensitivity and hearing range vary among species, as they are dependent upon the size and mass of the moving parts. Dogs and cats can perceive frequencies as high as 40,000 hertz, and bats can detect sounds above 150,000 hertz. Adult human ears are capable of perceiving sound waves having frequencies between 16 hertz and 16,000 hertz; chimpanzees and monkeys can hear frequencies above 30,000 hertz. The delicacy and precision of pitch discrimination, dependent upon the number and distribution of hair cells along the basilar membrane, are most highly developed in primates.

In the course of adapting to the sea, marine mammals have eliminated or greatly reduced the size of their pinna and acquired a movable flap to close the outer ear when diving. Seals have remarkably acute underwater hearing, responding to frequencies up to 160,000 hertz, without sacrificing the ability to hear airborne sounds. The whale, however, has sacrificed aerial hearing for increased underwater discrimination. The external ear opening is a pinhole, the eardrum serves no useful purpose, and the bones of the middle ear are too massive to respond well to high frequencies. Underwater sounds pass through the tissues of the head directly to the middle and inner ear, the fat-filled cavity of the lower jaw helping funnel low-frequency sounds. The ossicle mass functions like the otolithic organ of fish; inertia causes the ossicles to vibrate out of phase with the surrounding tissues when sound energy is present. This relative motion is conducted to the cochlear fluid through the stirrup and excites the hair cells of the inner ear. The middle and inner ear are housed within a heavy solid complex, which is not connected directly to the skull but supported by air sacs connecting to the respiratory tract. These sacs acoustically isolate each ear from the other, and isolate both ears from sounds produced by the animal itself. Because they use echolocation, cetaceans have acute hearing and can perceive sounds up to at least 100,000 hertz; the bottle-nosed dolphin can hear to about 150,000 hertz.

ECHINODERMS

Type of animal science: Classification
Fields of study: Anatomy, invertebrate biology, physiology

Echinoderms are radially symmetrical, free-moving marine organisms, such as starfishes, sea urchins, brittle stars, sea cucumbers, and sea lilies.

Principal Terms

BILATERAL SYMMETRY: an arrangement of body parts of an organism down a central axis which, when divided down the midline, produces right and left mirror images

CALCAREOUS: a material composed primarily of calcium compounds

MADREPORITE: a fine-meshed sieve that opens from the sea water into the water vascular system of the echinoderms

METAMORPHOSIS: the transformation of a larval form into an adult form

RADIAL SYMMETRY: an arrangement of body parts of an organism like the pieces of a pie around an imaginary central axis

The echinoderms represent a biological puzzle for zoologists. Biologists generally agree that bilateral symmetry is adaptive for free-moving animals and radial symmetry is adaptive for sedentary animals, but the echinoderms are free-moving yet exhibit radial symmetry. Since the echinoderm larval stages are bilaterally symmetrical, they obviously evolved from bilateral ancestry; however, the larvae metamorphose into radially symmetrical adults. The echinoderms live in marine environments and include a varied group that is considerably different from all other members of the animal kingdom. Echinoderms include the starfishes, sea urchins, brittle stars, sea cucumbers, and sea lilies. A calcareous skeleton is present in all members of the phylum, and their name is derived from the presence of external spines or protuberances.

General Characteristics of the Echinoderms

Because of the tremendous diversity in this group of animals, a complete description of all echinoderm characteristics is beyond the scope of this article. Externally, the arms or rays are joined at the center to form a disc that bears the madreporite. Many echinoderms are protected from predators by a spiny skeleton made up of calcareous plates just below the epidermis. Many of the plates bear tubercles (bumps) and spines. In addition, predators are often discouraged by the presence of pedicellariae (tiny pincers) scattered over the body. When stimulated, these snap vigorously and remain shut for several days on anything they catch.

The mouth is in the center of the ventral surface and is surrounded by a membranous area, the peristome. The mouth opens directly into a large cardiac stomach, which in turn opens into a smaller pyloric stomach. A small intestine extends upward from the pyloric stomach and ends at an anus in the middle of the upper surface of the disc. Five gastric glands extend out of the rays and open into the pyloric stomach. When feeding, the cardiac stomach everts through the mouth and spreads over the food. A fluid containing digestive enzymes is secreted and rapidly breaks down the food materials. The nervous system is composed of a nerve ring around the mouth and five radial nerves to the lower epidermis. Other nerve fibers are located in the walls of the digestive tract and inside the upper body wall. The nervous system exhibits reciprocal inhibition. The nerve centers on one side of the body inhibit those on the other side, permitting the animal to move in a coordinated manner in one direction.

The circulatory system is composed of circular and radial vessels filled with a fluid similar to that of the body cavity and which is very different from sea water. The vessels lie above the nervous system and are enclosed in their own body cavity. Some of these vessels have been observed to contract. A pair of gonads is located in the base of each ray, with one on each of the gastric glands. These gonads hang free in the body cavity except where they are attached by a short duct to a reproductive pore opening externally between the bases of adjacent rays.

Representative Echinoderms

Most starfish (class Asteroidea) have five rays and a relatively small disc, but in some species the body is pentagonal rather than star-shaped and the disc is large relative to the rays. The animals in one genus, *Leptasterias*, have six rays, while the number of rays in other starfishes may be as high as twenty-five or fifty. In general, if the number of rays is greater than seven, the number will be variable within a species. When the number exceeds five, the embryo develops five rays first and the others later. Most starfishes eat only small bivalves and other organisms that are swallowed whole. Many of the larger species, ranging from one to three feet in diameter, feed primarily on other echinoderms.

Sea lilies (class Crinoidea) are echinoderms that attach to the ocean floor by a stalk. The mouth is directed upward, and the anus is located to one side. The rays generally branch to form graceful patterns. Ciliated grooves flanked on both sides by tube feet without suckers extend out of the mouth along the upper surfaces of all the rays and branches. Food is trapped and swallowed when tiny organisms and food particles are pushed against the ciliated groove by the action of the tube feet. Movement in sea lilies is restricted to spreading and folding together of the branches and postural changes of the body. In the feather stars, the larvae attach and

Echinoderm Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Echinodermata
Subphylum: Pelmatozoa
Classes: Crinoidea (sea lilies and sea feathers), Heterostella (extinct), Cystidea (extinct), Blastoidea (extinct), Edrioasteroidea (extinct)
Subphylum: Eleutherozoa (stemless unattached echinoderms)
Classes: Holothuroidea (sea cucumbers; armless, poorly developed skeleton); Echinoidea (sea urchins and sand dollars; armless, well-developed skeleton); Asteroidea (starfishes; arms, well-developed skeleton, locomotion with tube feet); Ophiuroidea (brittle stars; arms, flexible skeleton, locomotion with prehension); Concentricycloidea (sea daisies; armless, disc-shaped with marginal skeleton); Ophiocistioidea (extinct)
Orders: Holothuroidea (five living orders); Echinoidea (three living orders, five extinct orders); Asteroidea (three living orders, five extinct orders); Ophiuroidea (two living orders); Concentricycloidea (one living order); Ophiocistioidea (one extinct order)

Geographical location: Found all over the world

Habitat: Marine, from the shoreline to the ocean depths

Gestational period: Varies among species, but most species lay eggs within a few days after fertilization; eggs usually hatch within a few days to a few weeks after being deposited

Life span: Varies among species; can be as short as a year and up to several years

Special anatomy: Body unsegmented with radial, pentamerous (five or more radiating areas) symmetry; no head or brain and few specialized sensory organs; endoskeleton of calcareous ossicles with spines; a unique water vascular system that extends from the body surface as a series of tube feet; excretory system is absent; development through free-swimming bilateral larval stages that metamorphose into radial adult grow a short stalk like that of the sea lilies, but later break loose. The general anatomy and method of feeding is unchanged, but the feather stars differ from the sea lilies in their locomotion. Feather stars can crawl through vegetation using the rays as prehensile organs, and they can swim by raising and lowering the ten arms more than one hundred times per minute.

Echinoderms, such as starfish, are unusual in that they are radially symmetrical yet are capable of movement. Most animals that move are bilaterally symmetrical. (PhotoDisc)

Sea cucumbers (class Holothuroidea) creep or burrow in the mud or sand. Since the calcareous plates are small, the body is soft and flexible. The body is elongated between the mouth and anus, but one side usually becomes the permanent lower side, causing the radial symmetry to be imperfect. While five rows of tube feet extend from mouth to anus, often only three of the rows have suckers and are used for locomotion. A circle of branched tentacles form from the tube feet near the mouth. Sea cucumbers are notable for their ability to throw away their viscera. When environmental conditions are unfavorable, the sea cucumber contracts violently and ejects the entire digestive system, which can later be regenerated.

The skeletons of the echinoids (class Echinoidea) form rigid boxes. Five grooves with tube feet radiate from the mouth up around the sides and end near the anus. The tube feet on the upper surface are often long and filamentous and apparently used for respiration, while the lower tube feet usually have suckers and are utilized in locomotion. Sea urchins possess numerous long spines, some of which are used to aid the tube feet in walking. The urchins move about slowly, using their five sharp teeth to scrape and chew whatever they encounter. The sand dollars are a group of much-flattened echinioids. They usually creep about slowly on their short lower spines under the surface of the sand.

Brittle stars (class Ophiuroidea) possess slender rays attached to a circular disc. Each ray is composed of a row of large cylindrical skeletal pieces joined together by short, powerful muscles. Each ray is very supple, and the tube feet are poorly developed. Brittle stars move by pulling or pushing on surrounding objects, and thus slither like a snake. Most brittle stars feed on debris and mud, but some capture prey with their prehensile rays and bring it to the mouth, which opens into a simple saclike stomach. Undigested remains are eliminated through the mouth because no other digestive organs are present.

The group commonly called sea daisies (class

The Echinoderm Water Vascular System

One of the unique characteristics of the echinoderms is the presence of a water vascular system. This system is primarily utilized for locomotion and food gathering, but it also has respiratory and excretory functions. A prime example of this system is illustrated in the starfishes. Starfishes move slowly on a multitude of tube feet, delicate projections that end in suckers. Each tube foot is connected to a radial canal by a small lateral canal. The five radial canals join to form a circular canal, and from this a stone canal leads upward to the madreporite. The tube feet project from deep grooves along the lower surface of each ray. The tube feet are arranged in two longitudinal rows, which are staggered to look like a double row. Each tube foot operates as an independent hydraulic mechanism. The foot cavity extends inward through the body wall and expands inside the body as a bulb or ampulla. When the muscles lining the ampulla contract, the fluid in the cavity is forced into the foot, which expands to create suction. A suction cup at the end of the foot sticks tightly once it is pressed against a smooth surface. The foot is released when longitudinal muscle fibers contract and lift the edges of the sucker. The tube feet work synchronously to produce a creeping motion. Each foot elongates in the direction of motion, attaches to the bottom, and then is swung under the body so as to propel the body forward.

Concentricycloidea) is a class of echinoderms discovered in 1986 off the coast of New Zealand. They have no arms, and the tube feet are located around the periphery of the disc rather than in grooved areas, as in other echinoderms. Only two species have been identified. One has a small, saclike stomach but no intestine or anus, and the other lacks any digestive organs. This latter species apparently absorbs nutrients from the environment.

ECOLOGICAL NICHES

Type of animal science: Ecology
Field of study: Evolutionary science

An ecological niche is the physical space in which an animal lives and all the interactions with the other living organisms and components of its environment. Ecological niches are important in the preservation of organisms that are vulnerable to certain activities of human beings.

Principal Terms

COMMUNITY: all the populations of plant and animal species living and interacting in a given habitat or area at a given time

ENVIRONMENT: all the external conditions that affect an organism or other specified system during its lifetime

FOOD PYRAMID: diagram representing organisms of a particular type that can be supported at each trophic level from a given input of solar energy in food chains and food webs

HABITAT: place or type of place where an organism or community of organisms naturally thrives

ORGANISM: any form of life

TROPHIC LEVEL: a level in a food chain or food web at which all organisms consume the same general types of food

The idea of the niche probably had its first roots in ecology in 1910. At that time, Roswell Johnson wrote that different species utilize different niches in the environment. He theorized that individuals of a particular species are only in certain places because of food supply and environmental factors that limit their distribution in an area. Later, in 1924, Joseph Grinnel developed his concept of niche that centered on an organism's distribution having limits set on it by climatic and physical barriers. At the same time, Charles Elton was defining his own idea of niche. His description of niche involved the way an organism makes its living—in particular, how it gathers food.

Trophic Levels

For many years, ecologists focused on Elton's definition and referred to niche in terms of an organism's place in the food pyramid. The food pyramid is a simplified scheme in which organisms interact with one another while obtaining food. The food pyramid is represented as a triangle, often with four horizontal divisions, each division being a different trophic level.

The base of the food pyramid is the first trophic level and contains the primary producers: photosynthetic plants. At the second trophic level are the primary consumers. These are the herbivores, such as deer and rabbits, which feed directly on the primary producers. Secondary consumers are found at the third trophic level. This third trophic level contains carnivores, such as the mountain lion. The members of the uppermost trophic level are the scavengers and decomposers, including hyenas, buzzards, fungi, and bacteria. The organisms in this trophic level break down all the nutrients (such as carbon and nitrogen) in the bodies of plants and animals and return them to the soil to be absorbed and used by plants.

It should be noted that no ecosystem actually has a simple and well-defined food pyramid. Many organisms interact with more organisms than those at the adjacent trophic levels. For example, a coyote could be considered to belong to the third trophic level with the carnivores, but the coyote also occasionally feeds on fruits and other primary producers. Basically, all living things are dependent on the first trophic level, because it alone has the capability to convert solar energy to energy found in, for example, glucose and starch. The food pyramid takes the geometric form of a triangle to show the flow of energy through a system.

Photosynthetic plants lose 10 percent of the energy they absorb from the sun as they convert solar energy into glucose and starch. In turn, the herbivores can convert and use only 90 percent of the energy they obtain by eating plants. Hence, less energy is found at each higher trophic level. Because of this reduction in energy, fewer organisms can be supported by each higher trophic level. Consequently, the sections of the pyramid get smaller at each higher trophic level, representing the decreasing levels of energy and number of members.

Interrelationships Among Organisms

Through the years, two concepts of niche have evolved in ecology. The first is the place niche, the physical space in which an organism lives. The second is the ecological niche, and it encompasses the particular location occupied by an organism and its functional role in the community.

The functional role of a species is not limited to its placement along a food pyramid; it also includes the interactions of a species with other organisms while obtaining food. For example, the methods used to tolerate the physical factors of its environment, such as climate, water, nutrients, soils, parasites, and the like, are all part of its functional role. In other words, the ecological niche of an organism is its natural history: all the interactions and interrelationships of the species with other organisms and the environment.

The study of the interrelationships among organisms has been the focus of ecological studies since the 1960's. Before this time, researchers had focused on the food pyramid and its effect on population changes of merely a single species. One example, the classic population study of the lynx and the snowshoe hare of Canada, originally focused on the interactions of the species in the food pyramid. It was discovered that the lynx had a ten-year population cycle closely following the population cycle of its prey, the snowshoe hare. The lynx population appeared to rise, causing a decline in the population of the snowshoe hare. In the investigations that followed, however, studies diverted the focus from the food pyramid to other elements of the niche of the two species. For example, the reproductive nature of the hare provided a contradiction to the simple predator-prey explanation. The hare has a faster rate of reproduction than the lynx. It seemed impossible that the significantly lower population of lynx could effectively place sufficient predator pressure on the hare to cause its drastic decline in numbers. Therefore, it appeared that the population dynamics of the hare and lynx was regulated by more than simply a predator-prey relationship.

Later studies of the lynx and hare suggested that the peaks and dives in the two populations may also be a factor of parasites of the hare that are carried by the lynx. A rise in the lynx population increases the carriers of parasites of the hare. Therefore, it is thought that, although the hare has a much greater reproduction rate than the lynx, the population of hares will still decline because of the combination of predation by the lynx and the increased frequency of parasites of the hare. This study involved looking at more than one dimension of the ecological niche of a species and broke away from concentrating on only the interactions between organisms in the food pyramid.

Niche Overlap

The goal of understanding how species interact with one another can also be better accomplished by defining the degree of niche overlap, the degree of the sharing of resources between two species. When two species use one or more of the same elements of an ecological niche, they exhibit interspecific competition. It was once believed that interspecific competition would always lead to survival of only the better competitor of the two species. That was the original concept of the principle of the competition exclusion law of ecology:

No two species can utilize the same ecological niche. It was conjectured that the weaker competitor would either migrate, begin using another resource not used by the stronger competitor, or become extinct. It is now believed that the end result of two species sharing elements of ecological niches may not always be exclusion.

Ecologists theorize that similar species do, in fact, coexist, despite the sharing of elements of their ecological niches, because of character displacement, which leads to a decrease in niche overlap. Character displacement involves a change in the morphological, behavioral, or physiological state of a species without geographical isolation. Character displacement occurs as a result of natural selection arising from competition between one or more ecologically similar species. Examples might be changes in mouth sizes so that they begin to feed on different sizes of the same food type, thereby decreasing competition.

Species Specialization

The more specialized a species, the more rigid it will be in terms of its ecological niche. A species that is general in terms of its ecological niche needs will be better able to find and use an alternative for the common element of the niche. Since a highly specialized species cannot substitute whatever is being used, it cannot compete as well as the other species. Therefore, a specialized species is more likely to become extinct.

For example, a panda is a very specialized feeder, eating mainly bamboo. If a pest is introduced into the environment that destroys bamboo, the panda will probably starve, being unable to switch to another food source. On the other hand, the coyote is a generalized feeder. It has a broad variety of food types that make up its diet. If humans initiate a pest-control program, killing the population of rabbits, the coyote will not fall victim to starvation, because it can switch to feeding predominantly on rodents, insects, fruits, and domesticated animals (including cats, dogs, and chickens). Hence, species with specialized ecological niche demands (specialists) are in greater danger of extinction than those with generalized needs (generalists). Although this fundamental difference in survival can be seen between specialists and generalists, it must be noted again that exclusion is not an inevitable result of competition. Many cases of ecologically similar species coexist.

When individuals of the same species compete for the same elements of the ecological niche, it is referred to as intraspecific competition. Intraspecific competition has the opposite effect of interspecific competition: niche generalizations. In increasing populations, the first inhabitants will have access to optimal resources. The opportunity for optimal resources decreases as the population increases; hence, intraspecific competition increases. Deviant individuals using marginal resources may slowly begin to use less optimal resources that are in less demand. That can lead to an increase in the diversity of ecological niches used by the species as a whole. In other words, the species may become more generalized and exploit wider varieties of niche elements.

Representing a situation on the opposite end of the spectrum from that of two organisms competing for the same dimension of an ecological niche is the vacant niche theory. This ecological principle states that when an organism is removed from its ecological niche, space, or any other dimension of the niche, another organism of the same or similar species will reinvade.

Field Research

Theoretical studies of ecological niches are abstract, since humans are limited to three-dimensional diagrams, and there are more than three dimensions to an ecological niche. This multidimensionality is referred to as the *n*-dimensional niche. This abstract *n*-dimensional niche can be studied mathematically and statistically, but ecology is mainly a field science. Therefore, the focus of techniques is on those used for field research of the ecological niche.

Research that attempts to describe all the elements of the *n*-dimensional ecological niche would require extensive observations. Yet, ecological niches are difficult to measure not only because of the plethora of data that would have to be collected but also because of the element of change in nature. The internal and external environment of an organism is always dynamic. Nothing in life is static, even if equilibrium has been established.

These constant fluctuations create daily and seasonal changes in space and ecological niches. Therefore, because of the constant fluctuations, any merely descriptive field observations would not be reliable depictions of an organism's ecological niche. Ecologists must also resort to quantitative data of measurable features of an organism's ecological niche. For example, the temperature, pH, light intensity, algae makeup, predators, and activity level of the organism are measurable features of an ecological niche in a pond community. The difficulty is in the collection of each of the necessary measurements making up an ecological niche. The ecologist would have to limit the data to a manageable number of specific dimensions of the niche based on conjecture and basic intuition. Such limitations often lead to incomplete and disconnected measurements that can at best only partially describe a few of the dimensions of the ecological niche.

Ecologists realize that complete observations and measurements of all the dimensions of an organism's ecological niche are unattainable. The focus in understanding how a species interacts with its community centers on determining the degree of niche overlap between any two species—in other words, the level of competition for niche space and resources. Studies of this niche overlap are typically limited to dimensions that can be quantitatively measured. Yet, there is still the problem of deciding which of the dimensions are involved in the competition between the two species. Again, the ecologist must usually rely on inherent knowledge about the two species in question. Often, researchers investigating niche competition measure no more than four ecological niche dimensions to determine the niche overlap in an attempt to understand how two individuals competing for the same space, resources, or other ecological niche features can coexist.

Field methods for observations and quantitative measurements of elements of ecological niches, niche overlap, and niche competition are probably endless. To name a few, describing an organism's niche may involve fecal samples to determine its diet, fecal samples of possible predators to identify its primary predator, animal and plant species checklists of its space niche along

Image Not Available

with soil components, climatic trends, and the like. Niche competition and overlap often can be studied first in the laboratory under controlled situations. One method might involve recording the population dynamics of the species as different elements in the ecological niche are manipulated to determine which is the better competitor and what is the resource that is most responsible for limiting the population size.

Niche and Community

The shift in meaning and study from merely space and trophic level placement in the food pyramid to ecological niche of *n* dimensions has been beneficial for the field of ecology. This focus on community ecology is obviously much more productive for the goal of ecology, the understanding of how all living organisms interact with one another, and with the nonliving elements in the environment.

Perhaps more important is the attempt to describe niches in terms of community ecology, which can be essential for some of humankind's confrontations with nature. For example, it becomes more and more apparent that synthetic chemicals are often too costly and too hazardous to continue using for control of crop pests and carriers of diseases. The goal is to control pests effectively with biological controls. Biological controls can involve the introduction of natural predators of the undesirable pest or the introduction of a virus or bacteria that eliminates the pest and is harmless to humans and wildlife.

The success of a biological control is directly proportional to the knowledge of the pest's *n*-dimensional ecological niche and the other organisms with which it comes in contact. A classic example of the havoc that can result from manipulations of nature without adequate ecological information is when Hawaii attempted to use biological controls to eradicate a population of snakes, which humans had accidentally introduced. The biological control used was the snake's natural predator, the mongoose. One very important dimension of the ecological niche of both species was ignored. One species was active only at night, while the other was active only during the day. Needless to say, this particular venture with a biological control was not a success.

Another relevant function of community-oriented studies of ecological niches involves endangered species. In addition to having aesthetic and potential medicinal values, an endangered organism may be a keystone species, a species on which the entire community depends. A keystone species is so integral to keeping a community healthy and functioning that if the species is obliterated, the community no longer operates properly and is not productive.

Habitat destruction has become the commonest cause of drastic population declines of endangered species. To enhance the habitat of the endangered species, it is undeniably beneficial to know what attracts a species to its particular preferred habitat. This knowledge involves the details of many of the dimensions of its ecological niche integral to its population distribution. Another common cause of endangering the survival of a species is when an introduced organism or exotic species competes for the same resources and displaces the native species. Solving such competition between native and introduced species would first involve determining niche overlap.

It is often stated that an ounce of prevention is worth a pound of cure. Thus, the researching and understanding of all the dimensions of ecological niches are integral components of preventing environmental manipulations by humankind that might lead to species extinction. Many science authorities have agreed that future research in ecology and related fields should focus on solving three main problems: species endangerment, soil erosion, and solid waste management.

This focus on research in ecology often means that studies of pristine communities, those undisturbed, will be the most helpful for future restoration projects. Although quantitative and qualitative descriptions of pristine areas seem to be unscientific at the time they are made, because there is no control or experimental group, they are often the most helpful for later investigations. For example, after a species has shown a drastic decline in its population, the information from the observations of the once-pristine area may help to uncover what niche dimension was altered, causing the significant population decrease.

ECOLOGY

Type of animal science: Ecology
Fields of study: Evolutionary science, systematics (taxonomy)

Ecology is the study of the relationships of organisms to their environments. By examining those relationships in natural ecosystems, principles can be discovered which may help humankind understand its own role on this planet.

Principal Terms

ADAPTATION: a genetic (intrinsic) feature of an organism which, through natural selection, enhances its fitness in a given environment

COMMUNITY: all the populations that exist in a given habitat

ECOSYSTEM: the biological community in a given habitat, combined with all the physical properties of the environment in that habitat

ENVIRONMENT: all the forces and things external to an organism that directly affect it

FITNESS: the contribution of an organism to future generations; the perpetuation of its genes through reproduction

HABITAT: the place where an organism lives; for example, a pond or forest

NATURAL SELECTION: a change in the genetic makeup of a population as a result of different survival and reproduction rates (fitness) among its members

NICHE: the role of an organism in its environment; the sum of all factors that define its existence (temperature, energy requirements, and so on)

POPULATION: all the individuals in a habitat which are of the same species

RESOURCE: a requirement for life, such as space for living, food (for animals), or light (for plants), not including conditions such as temperature or salinity

Ecology is the study of how organisms relate to their natural environments. The two principal concerns of ecologists are the distribution and abundance of organisms: Why are animals, plants, and other organisms found where they are, and why are some common and others rare? These questions have their roots in the theory of evolution. In fact, it is difficult (and not often worthwhile) to separate modern ecological matters from the concerns of evolutionary biologists. Ecology can be divided according to several levels of organization: the individual organism, the population, the community, and the ecosystem.

Environment and Natural Selection

An ecologist views organisms as consequences of past natural selection brought about by their environments. That is, each organism represents an array of adaptations that can provide insight into the environmental pressures that resulted in its present form. Adaptations of organisms are also revealed by other features, such as the range of temperature an organism can tolerate, the amount of moisture it requires, or the variety of food it can exploit. Food and space for living are considered resources; factors such as temperature, light, and moisture are conditions which determine the rate of resource utilization. When ecologists have discovered the full range of resources and conditions necessary for an organism's existence, they have discovered its niche.

Many species, such as many insects and plants, have a large reproductive output. This compensates for high mortality imposed by natural selection. Other species, such as large mammals and birds, have fewer offspring. Many of these animals care for their young, thus increasing the chances that their offspring will survive to reproduce. These are two different strategies for success, based upon the principle that organisms have a finite energy budget. Energy acquired from food (animals) or sunlight (plants) must be partitioned among growth, maintenance, and reproduction. The greater the energy allocated to the care of offspring, for example, the fewer the offspring that can be produced.

The concept of an energy budget is a key to understanding evolutionary strategies of organisms, as well as the energetics of ecosystems. The amount of energy fixed and stored by an organism is called net production; this is the energy used for growth and reproduction. Net production is the difference between gross production (the amount of energy assimilated) and respiration (metabolic maintenance cost). The greater the respiration, the less energy will be left over for growth and reproduction. Endothermic animals, which physiologically regulate their body heat (mammals and birds), have a very high respiration rate relative to ectotherms (reptiles, amphibians, fish, and invertebrates), which cannot. Among endotherms, smaller animals have higher respiration rates than larger ones, because the ratio of body surface area (the area over which heat is exchanged with the environment) to volume (the size of the "furnace") decreases with increasing body size.

Demography and Population Regulation

Although single organisms can be studied with regard to adaptations, in nature most organisms exist in populations rather than as individuals. Some organisms reproduce asexually (that is, by forming clones), so that a single individual may spawn an entire population of genetically identical individuals. Populations of sexually reproducing organisms, however, have the property of genetic variability, since not all individuals are identical. That is, members of a population have slightly different niches and will therefore not all be equally capable of living in a given environment. This is the property upon which Charles Darwin's theory of natural selection depends: Because not all individuals are identical, some will have greater fitness than others. Those with superior fitness will reproduce in greater numbers and therefore will contribute more genes to successive generations. In nature, many species consist of populations occupying more than a single habitat. This constitutes a buffer against extinction: If one habitat is destroyed, the species will not become extinct, because it exists in other habitats.

Two dynamic features of populations are growth and regulation. Growth is simply the difference between birth and death rates, which can be positive (growing), negative (declining), or zero (in equilibrium). Every species has a genetic capacity for exponential (continuously accelerating) increase, which will express itself to varying degrees depending on environmental conditions: A population in its ideal environment will express this capacity more nearly than one in a less favorable environment. The rate of growth of a population is affected by its age structure—the proportion of individuals of different ages. For example, a population which is growing rapidly will have a higher proportion of juvenile individuals than one which is growing more slowly.

Populations may be regulated (so that they have equal birth and death rates) by a number of factors, all of which are sensitive to changes in population size. A population may be regulated by competition among its members for the resource that is in shortest supply (limiting). The largest population that can be sustained by the available resources is called the carrying capacity of the environment. A population of rodents, for example, might be limited by its food supply such that as the population grows and food runs out, the reproductive rate declines. Thus, the effect of food on population growth depends upon the population size relative to the limiting resource. Similarly, parasites that cause disease spread faster in large, dense populations than in smaller, more diffuse ones. Predators can also regulate populations of their prey by responding to changes in prey availability. Climate and catastrophic events such as storms may severely affect

Of particular concern in the study of ecology is the question of population size in relation to available resources. (Digital Stock)

populations, but their effect is not dependent upon density and is thus not considered regulatory.

Interactions Between Species

Competition occurs between, as well as within, species. Two species are said `to be in competition with each other if and only if they share a resource that is in short supply. If, however, they merely share a resource that is plentiful, then they are not really competing for it. Competition is thought to be a major force in determining how many species can coexist in natural communities. There are a number of alternative hypotheses, however, which involve such factors as evolutionary time, productivity (the energy base for a community), heterogeneity of the habitat, and physical harshness of the environment.

Predator-prey interactions are those in which the predator benefits from killing and consuming its prey. These differ from most parasite-host interactions in that parasites usually do not kill their hosts (a form of suicide for creatures that live inside other creatures). Similarly, most plant-eating animals (herbivores) do not kill the plants on which they feed. Many ecologists classify herbivores as parasites for this reason. There are exceptions, such as birds and rodents that eat seeds, and these can be classified as legitimate predator-prey interactions. Predators can influence the number of species in a community by affecting competition among their prey: If populations of competing species are lowered by predators so that they are below their carrying capacities, then there may be enough resources to support colonization by new species.

In many cases, the interaction between two species is mutually beneficial. Mutualism is often thought to arise as a result of closely linked evolutionary histories (coevolution) of different species. Termites harbor protozoans in their guts that produce an enzyme which can break down cellulose in wood. The protozoans thus are provided with a habitat, and termites are able to derive nourishment from wood. Some acacia trees in the tropics have hollow thorns which provide a habitat for ants. In return, the ants defend the trees from other insects which would otherwise damage or defoliate them.

Communities of organisms are composed of many populations that may interact with one another in a variety of ways: predation, competition, mutualism, parasitism, and so on. The composition of communities changes over time through the process of succession. In terrestrial communities, bare rock may be weathered and broken down by bacteria and other organisms until it becomes soil. Plants can then invade and colonize this newly formed soil, which in turn provides food and habitat for animals. The developing community goes through a series of stages, the nature of which depends on local climatic conditions, until it reaches a kind of equilibrium. In many cases this equilibrium stage, called climax, is a mature forest. Aquatic succession essentially is a process of becoming a terrestrial community. The basin of a lake, for example, will gradually be filled with silt from terrestrial runoff and accumulated dead organic material from populations of organisms within the lake itself.

Ecosystems

Ecosystems consist of several trophic levels, or levels at which energy is acquired: primary producers, consumers, and decomposers. Primary producers are green plants that capture solar energy and transform it, through the process of photosynthesis, into chemical energy. Organisms that eat plants (herbivores) or animals (carnivores) to obtain their energy are collectively called consumers. Decomposers are those consumers, such as bacteria and fungi, that obtain energy by breaking down dead bodies of plants and animals. These trophic levels are linked together into a structure called a food web, in which energy is transferred from primary producers to consumers and decomposers, until finally all is lost as heat. Each transfer of energy entails a loss (as heat) of at least 90 percent, which means that the total amount of energy available to carnivores in an ecosystem is substantially less than that available to herbivores.

As with individual organisms, ecosystems and their trophic levels have energy budgets. The net production of one trophic level is available to the next-higher trophic level as biomass (mass of biological material). Plants have higher net productivity (rates of production) than animals because their metabolic maintenance cost is lower relative to gross productivity; herbivores often have higher net productivity than predators for the same reason. For the community as a whole, net productivity is highest during early successional stages, since biomass is being added more rapidly than later on, when the community is closer to climax equilibrium.

In contrast to the unidirectional flow of energy, materials are conserved and recycled from dead organisms by decomposers to support productivity at higher trophic levels. Carbon, water, and mineral nutrients required for plant growth are cycled through various organisms within an ecosystem. Materials and energy are also exchanged among ecosystems: There is no such thing in nature as a "closed" ecosystem that is entirely self-contained.

Descriptive, Experimental, and Mathematical Ecology

The science of ecology is necessarily more broadly based than most biological disciplines; consequently, there is more than one approach to it. Ecological studies fall into three categories: descriptive, experimental, and mathematical.

Descriptive ecology is concerned with describing natural history, usually in qualitative terms. The study of adaptations, for example, is descriptive in that one can measure the present "value" of an adaptive feature, but one can only conjecture as to the history of natural selection that was responsible for it. On the other hand, some patterns are discernible in nature for which hypotheses can be constructed and tested by statistical inference. For example, the spatial distribution (dispersion) of birds on an island may be random, indicating no biological interaction among them. If the birds are more evenly spaced (uniform dispersion) than predicted assuming randomness, however, then it might be inferred that the birds are competing for space; they are exhibiting territorial exclusion of one another. Such "natural experiments," as they are called, depend heavily upon the careful design of statistical tests.

Experimental ecology is no different from any other experimental discipline; hypotheses are constructed from observations of nature, controlled experiments are designed to test them, and conclusions are drawn from the results of the experiments. The basic laboratory for an ecologist is the field. Experiments in the field are difficult because it is hard to isolate and manipulate variable factors one at a time, which is a requisite for any good experiment in science. A common experiment that is performed to test for resource limitation in an organism is enhancement of that resource. If food, for example, is thought to be in short supply (implying competition), one section of the habitat is provided more food than is already present; another section is left alone as a control. If survivorship, growth, or reproductive output is higher in the enhanced portion of the habitat than in the control area, the researcher may infer that the organisms therein were food-limited. Alternatively, an ecologist might have decreased the density of organisms in one portion of the habitat, which might seem equivalent to increasing food supply for the remaining organisms, except that it represents a change in population density as well. Therefore, this second design will not allow the researcher to differentiate between the possibly separate effects of food level and simple population density on organisms in the habitat.

Mathematical ecology relies heavily upon computers to generate models of nature. A model is simply a formalized, quantitative set of hypotheses constructed from sets of assumptions of how things happen in nature. A model of population growth might contain assumptions about the age structure of a population, its genetic capacity for increase, and the average rate of resource utilization by its members. By changing these assumptions, scientists can cause the model population to behave in different ways over time. The utility of such modeling is limited to the accuracy of the assumptions employed.

Modern ecology is concerned with integrating these different approaches, all of which have in common the goal of predicting the way nature will behave in the future, based upon how it behaves in the present. Description of natural history leads to hypotheses that can be tested experimentally, which in turn may allow the construction of realistic mathematical (quantitative) models of how nature works.

All-Encompassing Nature

People historically have viewed nature as an adversary. The "conquest of nature" has traditionally meant human encroachment on natural ecosystems, usually without benefit of predictive knowledge. Such environmental problems as pollution, species extinction, and overpopulation can be viewed as experiments performed on a grand scale without appropriate controls. The problem with such experiments is that the outcomes might be irreversible. A major lesson of ecology is that humans are not separate from nature; we are constrained by the same principles as are other organisms on the earth. One object of ecology, then, is to learn these principles so that they can be applied to our portion of the earth's ecosystem.

Populations that are not regulated by predators, disease, or food limitation grow exponentially. The human population, on a global scale, grows this way. All the wars and famines in history have scarcely made a dent in this growth pattern. Humankind has yet to identify its carrying capacity on a global scale, although regional famines certainly have provided insights into what happens when local carrying capacity is exceeded. The human carrying capacity needs to be defined in realistic ecological terms, and such constraints as energy, food, and space must be incorporated into the calculations. For example, knowledge of energy flow teaches that there is more energy at the bottom of a food web (producers) than at successively higher trophic levels (consumers), which means that more people could be supported as herbivores than as carnivores.

The study of disease transmission, epidemiology, relies heavily on ecological principles. Population density, rates of migration among epidemic centers, physiological tolerance of the host, and rates of evolution of disease-causing parasites are all the subjects of ecological study.

An obvious application of ecological principles is conservation. Before habitats for endangered species can be set aside, for example, their ecological requirements, such as migratory routes, breeding, and feeding habits, must be known. This also applies to the introduction (intentional or accidental) of exotic species into habitats. History is filled with examples of introduced species that caused the extinction of native species. Application of ecological knowledge in a timely fashion, therefore, might prevent species from becoming endangered in the first place.

One of the greatest challenges we face is the loss of habitats worldwide. This is especially true of the tropics, which contain most of the earth's species of plants and animals. Species in the tropics have narrow niches, which means that they are more restricted in range and less tolerant of change than are many temperate species. Therefore, destruction of tropical habitats, such as rain forests, leads to rapid species extinction. These species are the potential sources of many pharmaceutically valuable drugs; further, they are a genetic record of millions of years of evolutionary history. Tropical rain forests also are prime sources of oxygen and act as a buffer against carbon dioxide accumulation in the atmosphere. Ecological knowledge of global carbon cycles permits the prediction that destruction of these forests will have a profound impact on the quality of the air.

Bibliography

Begon, Michael, John L. Harper, and Colin R. Townsend. *Ecology: Individuals, Populations, and Communities*. 3d ed. Cambridge, Mass.: Blackwell Science, 1996. A college-level textbook on the distribution and abundance of different types of organisms, with an emphasis on applied issues and concepts such as biodiversity, global warming, and sustainability. The four sections concentrate on organisms, interactions, overviews, and communities. Contains a glossary, bibliography, organism index, and subject index.

Carson, Rachel. *Silent Spring*. Boston: Houghton Mifflin, 1962. This book often has been credited with launching the environmental movement in the United States. Carson presents a chilling look at what can happen when we cause our environment to deteriorate. As timely today as when it was written, this book will appeal to concerned members of the general populace; no scientific training is required to understand its message.

Elton, Charles. *Animal Ecology*. New York: Macmillan, 1927. Written by one of the founders of the field, Elton's book is not only of historical interest but also surprisingly timely. Much of the philosophy behind modern approaches to ecology stems from this work. Especially noteworthy is Elton's development of the niche concept.

Hutchinson, G. Evelyn. *The Ecological Theater and the Evolutionary Play*. New Haven, Conn.: Yale University Press, 1969. The author, arguably the father of modern ecology, writes lucidly and incisively about the interplay between ecology and evolution.

His approach is strongly historical, and his accounts of "the naturalist as art critic" are both informative and entertaining. Hutchinson's philosophy of science, well detailed herein, has influenced generations of ecologists and evolutionary biologists.

Krebs, Charles J. *The Message of Ecology*. New York: Harper & Row, 1987. As the author notes in his preface, this book was designed to introduce readers to the scope of modern ecology without "all the detail that is necessary in a more conventional textbook." The subject matter includes all levels of ecology: individuals, populations, communities, and ecosystems. While not exhaustive in any of these areas, this small book is sufficient to give the novice reader a feeling for the ecologist's world.

Pianka, Eric R. *Evolutionary Ecology*. 6th ed. San Francisco: Benjamin/Cummings, 2000. An introductory text covering the whole spectrum of evolutionary ecology, starting with the environment and working up to complex animal and human communities.

Ricklefs, Robert E. *Ecology*. 4th ed. New York: Chiron Press, 1999. This is one of the best general texts in the field; it covers more ground more thoroughly than many other texts do. Suitable for a college-level course, it requires some background in general biology and genetics at the college level. The writing style is clear enough, however, that even the reader with less background can glean much from Ricklefs's discussion of adaptations of organisms to their environments.

ECOSYSTEMS

Type of animal science: Ecology
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology

The ecosystem is the fundamental concept in ecology. It is viewed by ecologists as the basic unit of nature, consisting of the complex of interacting organisms inhabiting a region with all the nonliving physical factors that make up their environment. Ecologists study structural and functional relationships of ecosystem components to be able to predict how the system will respond to natural change and human disturbance.

Principal Terms

BIOMASS: the weight of organic matter, often expressed in terms of grams per square meter per year

CONSUMERS: animals, fungi, and bacteria that get energy by feeding on organic matter

FOOD CHAIN: an abstract chain representing the links between organisms, each of which eats and is eaten by another

FOOD WEB: a network of interconnecting food chains representing the food relationships in a community

PHOTOSYNTHESIS: the process by which green plants and algae use sunlight as energy to convert carbon dioxide and water into energy-rich compounds such as glucose

PRIMARY PRODUCTION: the energy assimilated by green plants and stored as organic tissue

PRODUCERS: green plants and chemosynthetic organisms that can produce food from inorganic materials

RESPIRATION: the release of chemical energy to do work in plants and animals; a reversal of the photosynthetic process

TROPHIC LEVEL: a feeding level on the pyramid of numbers, consisting of all the kinds of animals that feed at comparable levels on food chains

The ecosystem is essentially an abstract organizing unit superimposed on the landscape to help ecologists study the form and function of the natural world. An ecosystem consists of one or more communities of interacting organisms and their physical environment. Ecosystems have no distinct boundaries; thus the size of any particular ecosystem should be inferred from the context of the discussion. Individual lakes, streams, or strands of trees can be described as distinct ecosystems, as can the entire North American Great Lakes region. Size and boundaries are arbitrary because no ecosystem stands in complete isolation from those that surround it. A lake ecosystem, for example, is greatly affected by the streams that flow into it and by the soils and vegetation through which these streams flow. Energy, organisms, and materials routinely migrate across whatever perimeters the ecologist may define. Thus, investigators are allowed considerable latitude in establishing the scale of the ecosystem they are studying. Whatever the scale, though, the importance of the ecosystem concept is that it forces ecologists to treat organisms not as isolated individuals or species but in the context of the structural and functional conditions of their environment.

Development of the Ecosystem Concept

Antecedents to the ecosystem concept may be traced back to one of America's first ecologists, Stephen Alfred Forbes, an eminent Illinois naturalist who studied food relationships among birds, fishes, and insects. During the course of his investigations, Forbes recognized in 1880 that full knowledge of organisms and their response to disturbances would come only from more concentrated research on their interactions with other organisms and with their inorganic (nonliving) physical surroundings. In 1887, Forbes suggested that a lake could be viewed as a discrete system for study: a microcosm. A lake could serve as a scale model of nature that would help biologists understand more general functional relationships among organisms and their environment. Forbes explained how the food supply of a single species, the largemouth bass, was dependent either directly or indirectly upon nearly all the fauna and much of the flora of the lake. Therefore, whenever even one species was subjected to disturbance from outside the microcosm, the effects would probably be felt throughout the community.

In 1927, British ecologist Charles Elton incorporated ideas introduced by Forbes and other fishery biologists into the twin concepts of the food chain and the food web. Elton defined a food chain as a series of linkages connecting basic plants, or food producers, to herbivores and their various carnivorous predators, or consumers. Elton used the term "food cycle" instead of "food web," but his diagrams reveal that his notion of a food cycle—that it is simply a network of interconnecting food chains—is consistent with the modern term.

Elton's diagrams, which traced various pathways of nitrogen through the community, paved the way for understanding the importance of the cycling of inorganic nutrients such as carbon, nitrogen, and phosphorus through ecosystems, a process that is known as biogeochemical cycling. Very simply, Elton illustrated how bacteria could make nitrogen available to algae at the base of the food chain. The nitrogen then could be incorporated into a succession of ever larger consumers until it reached the top of the chain. When the top predators died, decomposer organisms would return the nitrogen to forms that could eventually be taken up again by plants and algae at the base of the food chain, thus completing the cycle.

Elton's other key contribution to the ecosystem concept was his articulation of the pyramid of numbers, the idea that small animals in any given community are far more common than large animals. Organisms at the base of a food chain are numerous, and those at the top are relatively scarce. Each level of the pyramid supplies food for the level immediately above it—a level consisting of various species of predators that generally are larger in size and fewer in number. That level, in turn, serves as prey for a level of larger, more powerful predators, fewer still in number. A graph of this concept results in a pyramidal shape of discrete levels, which today are called trophic (feeding) levels.

Ecosystems in Twentieth Century Thought

Although the basic concept of an ecosystem had been recognized by Forbes as early as 1880, it was not until 1935 that British ecologist Arthur G. Tansley coined the term. Though he acknowledged that ecologists were primarily interested in organisms, Tansley declared that organisms could not be separated from their physical environment, as organism and environment formed one complete system. As Forbes had pointed out half a century earlier, organisms were inseparably linked to their nonliving environments. Consequently, ecosystems came to be viewed as consisting of two fundamental parts: the biotic, or living components, and the abiotic, or nonliving components.

No one articulated this better than Raymond Lindeman, a limnologist (freshwater biologist) from Minnesota who in 1941 skillfully integrated the ideas of earlier ecological scientists when he published an elegant ecosystem study of Cedar Bog Lake. Lindeman's classic work set the stage for decades of research that centered on the ecosystem as the primary organizing unit of study in ecology. Drawing on the work of his mentor, G. Evelyn Hutchinson, and Charles Elton, Arthur Tansley, and other scientists, Lindeman explained how ecological pyramids were a necessary result of energy transfers from one trophic level to the next.

By analyzing ecosystems in this manner, Lindeman was able to answer a fundamental ecological question that had been posed fourteen years earlier by Elton: Why were the largest and most powerful animals, such as polar bears, sharks, and tigers, so rare? Elton had thought the relative scarcity of top predators was due to their lower rates of reproduction. Lindeman corrected this misconception by explaining that higher trophic levels held fewer animals not because of their reproductive rates but because of a loss of chemical energy with each step up the pyramid. It could be looked upon as a necessary condition of the second law of thermodynamics: Energy transfers yield a loss or degradation of energy. The predators of one food level could never completely extract all the energy from the level below. Some energy would always be lost to the environment through respiration, some energy would not be assimilated by the predators, and some energy simply would be lost to decomposer chains when potential prey died of nonpredatory causes. This meant that each successive trophic level had substantially less chemical energy available to it than was transferred from the one below and, therefore, could not support as many animals.

Ecologists soon expanded the principle of Elton's pyramid of numbers to model other ecosystem processes. They found, for example, that the flow of chemical energy through an ecosystem could be characterized as an energy pyramid; the biomass (the weight of organic material, as in plant or animal tissue) in a community could be plotted in a pyramid of biomass. Collectively, such pyramidal models became known as ecological pyramids.

Rachel Carson's book Silent Spring *brought the dangers facing the earth's ecosystems to public consciousness and was one of the contributing factors to the growth of environmentalism in the late twentieth century.* (Library of Congress)

Energy Production and Transmission

Lindeman subdivided the biotic components of ecosystems into producers, consumers, and decomposers. Producers (also known as autotrophs) produce their own food from compounds in their environment. Green plants are the main producers in terrestrial ecosystems; algae are the most common producers in aquatic ecosystems. Both plants and algae are producers that use sunlight as energy to make food from carbon dioxide and water in the process of photosynthesis. During photosynthesis, plants, algae, and certain bacteria capture the sun's energy in chlorophyll molecules. (Chlorophyll is a pigment that gives plants their green color.) This energy, in turn, is used to synthesize energy-rich compounds such as glucose, which can be used to power activities such as growth, maintenance, and reproduction or can be stored as biomass for later use. These energy-rich compounds can also be passed on in the form of biomass from one organism to another, as when animals (primary consumers) graze on plants or when decomposers break down detritus (dead organic matter).

The energy collected by green plants is called primary production because it forms the first level at the base of the ecological pyramid. Total photosynthesis is represented as gross primary production. This is the amount of the sun's energy actually assimilated by autotrophs. The rate of this production of organic tissue by photosynthesis is called primary productivity. Plants, however, need to utilize some of the energy they produce for their own growth, maintenance, and reproduction. This energy becomes available for such activities through respiration, which essentially is a chemical reversal of the process of photosynthesis. As a result, not all the energy assimilated by autotrophs is available to the consumers in the next trophic level of the pyramid. Consequently, respiration costs generally are subtracted from gross primary production to determine the net primary production, the chemical energy actually available to primary consumers.

Measuring Ecosystem Productivity

The carrying capacity for all the species supported by an ecosystem ultimately depends upon the system's net primary productivity. By knowing the productivity, ecologists can, for example, estimate the number of herbivores that an ecosystem can support. Consequently ecosystem ecologists have developed a variety of methods to measure the net primary productivity of different systems. Productivity is generally expressed in kilocalories per square meter per year when quantifying energy, and in grams per square meter per year when quantifying biomass.

Production in aquatic ecosystems may be measured by using the light and dark bottle method. In this technique two bottles containing samples of water and the natural phytoplankton population are suspended for twenty-four hours at a given depth in a body of water. One bottle is dark, permitting respiration but no photosynthesis by the phytoplankton. The other is clear and therefore permits both photosynthesis and respiration. The light bottle provides a measure of net production (photosynthesis minus respiration) if the quantity of oxygen is measured before and after the twenty-four-hour period. (The amount of oxygen produced by photosynthesis is proportional to the amount of organic matter fixed.) Measuring the amount of oxygen in the dark bottle before and after the run provides an estimate of respiration, since no photosynthesis can occur in the dark. Combining net production from the light bottle with total respiration from the dark bottle yields an estimate of gross primary production.

Other studies have concentrated on quantifying the rate of movement of energy and materials through ecosystems. Investigations begun in the 1940's and 1950's by the Atomic Energy Commission to track radioactive fallout were eventually diverted into studies of ecosystems that demonstrated how radionuclides moved through natural environments by means of food-chain transfers. This research confirmed the interlocking nature of all organisms linked by the food relationship and eventually yielded rates at which both organic and inorganic materials could be cycled through ecosystems. As a result of such studies, the Radiation Ecology Section at Oak Ridge National Laboratory in Tennessee became established as a principal center for systems ecology.

Ecologists sometimes extend the temporal boundaries of their studies by utilizing the methods of paleoecology (the use of fossils to study the nature of ecosystems in the past). Research of this type generally centers on the analysis of lake sediments, whose layers often hold centuries of ecosystem history embodied in the character and abundance of pollen grains, diatoms, fragments of zooplankton, and other organic microfossils.

More general trends in the methods of studying ecosystems include a continuing emphasis on quantitative methods, often using increasingly sophisticated computer modeling techniques to simulate ecosystem functions. Equally significant is a trend toward a "big science" approach, modeled on the Manhattan Project, which employed teams of investigators working on different problems related to nuclear fission in different parts of the country. The well-known international biological program, the Hubbard Brook Project in New Hampshire, and continuing projects on long-term ecological research all serve as examples of ecosystem studies that involve teams of researchers from a wide range of disciplines.

Responding to Disturbance

One of the practical benefits of studying ecosystems derives from naturalist Stephen Forbes's suggestion, made in 1880, that the knowledge from biological research be used to predict the response of organisms to disturbance. When disturbance is caused by natural events such as droughts, floods, or fires, ecologists can use their knowledge of the structure and function of ecosystems to help resource managers plan for subsequent recolonization and succession of species.

The broad perspective of the ecosystem approach becomes particularly useful in examining the effects of certain toxic compounds because of the complexity of their interaction within the environment. The synergistic effects that sometimes occur with toxic substances can produce pronounced impacts on ecosystems already stressed by other disturbances. For example, after the atmosphere deposits mercury on the surface of a lake, the pollutant eventually settles in the sediments where bacteria make it available to organisms at the base of the food chain. The contaminant then bioaccumulates as it is passed on to organisms such as fish and fish-eating birds at higher trophic levels. Synergistic effects occur in lakes already affected by acid deposition; researchers have found that acidity somehow stimulates microbes to increase the bioavailability of the mercury. Thus, aquatic ecosystems that have become acidified through atmospheric processes may stress their flora and fauna even further by enhancing the availability of mercury from atmospheric fallout. The complexity of such interactions demands research at the ecosystem level, and ecosystem studies are prerequisite for prudent public policy actions on environmental contaminants.

A collection of essays addressing the theme that sustaining ecosystems requires sustaining species, which requires sustaining a diverse habitat. Primarily addressed to forest managers and policy makers, but useful for anyone interested in ecosystem management.

Odum, Eugene P. *Ecology and Our Endangered Life-Support Systems*. Sunderland, Mass.: Sinauer Associates, 1989. This is a classic introductory textbook from one of the original ecosystem ecologists. Combines a strong environmental science message with a discussion of ecological principles. Well illustrated.

Real, Leslie A., and James H. Brown. *Foundations of Ecology: Classic Papers with Commentaries*. Chicago: University of Chicago Press, 1991. Contains many of the classic works in the literature of ecology; a solid first attempt to consolidate the classics in ecology. Some of the commentaries attempt to place this literature in historical context.

Smith, Robert Leo. *Ecology and Field Biology*. 6th ed. San Francisco: Benjamin/Cummings, 2001. This comprehensive, introductory-level college textbook is the best illustrated ecology text available and is supported by a study guide for students. Unfortunately, readers need to watch out for serious errors in some of the figures. Chapters 10 to 16 cover ecosystem ecology. Contains an appendix on sampling plant and animal populations, journals of interest to ecologists, a glossary, a bibliography, and an index.

EELS

Type of animal science: Classification
Fields of study: Anatomy, ethology, marine biology, physiology, zoology

Eels are a variety of fishes possessing an elongate, snakelike body form. Eels inhabit both freshwater and marine environments, and some eel species move back and forth between the two environments at different stages of their life cycles. Although eels are not the most charismatic of aquatic organisms, their life histories make them some of the most fascinating and poorly understood marine animals.

Principal Terms

GUANINE: a chemical deposited in the skin of freshwater eels as they return to the marine environment

LEPTOCEPHALUS: the larval form of most eel species, bearing little resemblance to the adult eel

SARGASSO SEA: an area in the southwestern North Atlantic Ocean noted for large accumulations of sargassum weed; the breeding ground for North American and European freshwater eels

Eel is the name given to any fish that possesses an elongated, snakelike or ribbonlike body form. Although many eels are closely related to each other as members of the order Anguilliformes, other eel-like fishes are not closely related to this order, an example of convergent evolution of body form.

Freshwater Eels

The most commonly encountered and familiar eels are the freshwater eels of North America (*Anguilla rostrata*) and Europe (*Anguilla anguilla*). Both species are members of the same family, the Anguillidae. For many years the life cycle of these eels, which are commonly encountered in freshwater ponds and streams, remained shrouded in mystery, and egg-bearing females and early juveniles were never encountered. In the last half of the twentieth century, however, the story of the eel's life cycle has become better known, and it is a remarkable tale. All of the eels in North America and Europe are spawned in an area of the southwestern North Atlantic that is known as the

Moray eels lurk in holes and crevices of coral reefs, waiting for fish to swim past. (Digital Stock)

Sargasso Sea. From there the larval eels, which are known as leptocephalus larvae, are carried by the North Atlantic currents including the Gulf Stream, to the shores of North America and Europe. The leptocephali bear little resemblance to the adult eels; they are long, ribbonlike, and transparent. Upon arrival at the coastlines of North America and Europe, the eels metamorphose into the more familiar eel-like adult form and penetrate freshwater rivers and streams. Eels also have been shown to travel through underground streams into seemingly isolated ponds and lakes. They spend most of their adult lives in such freshwater systems.

Upon reaching sexual maturity, the eels return to the Atlantic Ocean, and during this journey they undergo another metamorphosis. Guanine deposits in the skin give the eels a silvery appearance, as opposed to their usual dark olive color, the eyes enlarge, and their physiology changes in order to cope with the new demands of living in the ocean depths. Upon entering the ocean, the eels become deep-water fishes, and are very rarely seen as they return to spawn in the Sargasso Sea. How these fish manage to navigate to, and locate, their spawning grounds in the Sargasso Sea from freshwater ponds and streams while traveling in the ocean's depths is completely unknown. For years, there has been speculation among scientists that the two species of North American and European freshwater eels are members of the same species and are randomly scattered by the ocean's currents to North America and Europe. Recent genetic studies have suggested, however, that the two groups may at least be separate breeding populations if not actually separate species. Nevertheless, much remains to be learned about the life histories of these remarkable animals.

Eel Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Superclass: Gnathostomata
Class: Osteichthyes
Subclass: Actinopterygii
Superorder: Teleosteii
Order: Anguilliformes
Suborder: Anguilloidei
Families: Anguillidae (freshwater eels, one genus, two species); Muraenidae (moray eels, four genera, six species); Moringuidae (spaghetti eels, two genera, four species); Synaphrobranchidae (cutthroat eel); Congridae (conger eels, four genera, four species); Nemichthyidae (snipe eels, two genera, two species); Myrocongridae, Muraenesocidae (pike eels, one genus, three species); Heterocongridae (garden eel); Ophichthyidae (snake eels, two genera, three species); Illyophidae; Simenchelyidae (snubnosed eel); Serrivomeridae (two genera, two species); Cyemidae (deepwater eel)

Geographical location: Worldwide, in temperate and tropical freshwater and marine systems

Habitat: Highly variable, from freshwater ponds and streams to open ocean, coral reefs, and ocean bottom

Gestational period: None; as in most bony fishes, fertilization is external and the larval eels develop as plankton in the water column

Life span: Variable and frequently unknown

Special anatomy: Elongate, snakelike or ribbonlike body forms; pelvic fins and supporting skeleton are generally not present and pectoral fins and skeletal pectoral girdle are also missing in some forms; typically have dorsal, caudal, and anal fins fused together to form a single fin extending along the dorsal surface, around the tail, and onto the ventral surface; gill opening is typically small and located low on the body; body form is specialized for squeezing into cracks or crevasses, burrowing on soft bottom substrates, and occasionally for a pelagic existence, swimming in the open waters of the ocean

Moray Eels

Another type of eel commonly encountered by divers and snorkelers is the moray eel, a member of the family Muraenidae. These eels typically inhabit holes and crevasses in coral reefs. They lack pectoral fins and are often brightly colored and patterned. Some species, such as *Gymnothorax*, have impressive, fanglike teeth and feed on reef fishes; others have blunt, crushing teeth and feed primarily on invertebrates. Although morays have a sinister reputation, in general they are inoffensive to humans and will bite only if provoked by the intrusion into their burrows of fingers, which they may mistake for an octopus. At some dive sites, resident moray eels have been semi-tamed and are hand-fed and handled; however, such treatment occasionally results in the handlers being bitten. Studies have demonstrated that morays are hermaphroditic, starting their mature life as males and later becoming females. A few species are synchronous hermaphrodites, possessing both male and female reproductive organs at the same time.

ELEPHANT SEALS

Type of animal science: Classification
Fields of study: Anatomy, conservation biology, ecology, marine biology, physiology, zoology

Elephant seals are carnivorous marine mammals that spend time on land and in the ocean. There are two distinct species: the northern and the southern elephant seal. Both species have claws on their front flippers and both lack external ears. A trunklike nose anatomically differentiates the males. Blubber provides buoyancy and insulation. Elephant seals swim using their rear flippers.

Principal Terms

CARNIVORE: an animal that eats flesh
ESTRUS: a time during which females are receptive to mating
HAREM: a group of breeding females controlled by a single male
SHEDDING: a process through which organisms lose and replace their external covering; in elephant seals this involves loss of hair and portions of worn-out skin

Elephant seals are the largest seals on earth. Male northern elephant seals attain a mature length of thirteen to sixteen feet, and may weigh between 4,500 and 6,000 pounds. Males of the southern species are larger and heavier than their northern cousins, and may reach a length of twenty feet, and weigh as much as 8,700 pounds. Females of both species are smaller. Their weight varies according to certain conditions. Adult elephant seals are gray in color, which is more pronounced in the females. They have no fur, but have areas covered with short, firm hairs.

An adult male has a large, trunklike extension of the nasal canal. This organ plays a vital role in the behavior and communication of these animals. The trunk, which can be described as short, baglike, and fleshy, hangs downward and is longer in the northern species of elephant seals. The skull is large and serves as a point of attachment for powerful muscles that move the trunk. Adult males have huge canine teeth.

Reproduction, Behavior, and Communication

Elephant seals communicate by producing loud barks and snorts with their trunks and mouths. These noises are often highly specific within isolated groups. Several different dialects have been identified. Elephant seals reach sexual maturity rapidly. Females give birth and mate in specific breeding grounds. Males are competitive and battle with raised heads, facing each other. They use their canine teeth as weapons. Dominant males

Elephant Seal Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Carnivora
Suborder: Pinnipedia
Family: Phocidae
Genus and species: Mirounga angustirostris (northern elephant seal), *M. leonina* (southern elephant seal)

Geographical location: Northern species inhabit the Pacific coastline from Mexico as far north as Alaska, and the waters of the northeastern Pacific Ocean; southern species inhabit specific areas of the southwestern Atlantic Ocean, the Kerguelen Islands in the southern Indian Ocean, and Macquarie Island off the coast of New Zealand

Habitat: Marine waters or coastal shores of temperate or subarctic seas

Gestational period: About eleven months, which includes a delayed implantation of the fertilized ovum

Life span: Twelve to twenty years; females generally live longer than males

Special anatomy: Massive size; presence of large, trunklike extension of the nasal cavity in the males; hind flippers for swimming

mate with a large harem of females that may number between forty and fifty. Pups are born on land and have a black fur coat at the time of birth. They are suckled for three weeks before they are abandoned. Females enter estrus and mate again immediately after weaning their last pup. Most mature females become pregnant every year.

Because of the value of their oil, both elephant seal species were hunted to near extinction. Successful reproduction and protection against hunting have enabled elephant seal populations to recover, but have left the northern elephant seal population with a limited gene pool. It is unknown how this lack of genetic diversity will affect the survival and future of this species.

Alternating between land and sea, a single elephant seal may travel up to thirteen thousand miles in one year. The migratory cycle starts toward the end of winter, after females give birth and conceive again. Females leave their breeding grounds and are soon followed by the males. Elephant seals search for food in specific foraging sites for about three months. Since they do not eat while on land, they dive continuously to great depths for their preferred diet of squid or bottom-dwelling fish. Once they haul themselves out of the sea onto land, it is time to shed. Shedding can take several weeks. When shedding is completed, the seals return to the ocean for up to eight months and search for food. Elephant seals are the most migratory marine mammals on earth.

ELEPHANTS

Type of animal science: Classification
Fields of study: Anatomy, behavior, ecology, physiology

Found in parts of Africa and Asia, the elephant is the largest land animal, anatomically differentiated by tusks, a trunk, and a massive head. Elephants are herbivores, with distinct behavioral and physical characteristics.

Principal Terms

BROWSER: feeding on shoots and leaves
GRAZER: feeding on grasses and pasture
JACOBSON'S ORGAN: a sense organ in the mouth, which detects reproductive chemical signals
MUSTH: aggressive rutting behavior during mating
TEMPORAL GLAND: located between the eyes and the ears, and active during reproduction

Although all elephants have a number of similarities, African elephants are different from Asian elephants. The highly muscular trunk is common to both and is described as a modified nose. Elastic, cartilaginous tissue cushions the soles of the feet, making elephants silent walkers that can move up to twenty-five miles per hour. Elephants lose body heat through their ears.

Adult African elephants can weigh up to 1,500 pounds. They have large ears and two fingerlike lips at the tips of their trunks. Anatomically, the African elephant has a concave back, with shoulders that rise above the head. In this species, both sexes have tusks.

Adult Asian elephants can weigh eleven thousand pounds. They have smaller ears and one lip at the tip of the trunk. Anatomically, the Asian elephant has a convex back with shoulders that lie below the bulbous head. In this species, some males have tusks. Easier to domesticate than the African variety, Asian elephants are used for transport and logging. Their trunks have a characteristic flexibility and a greater range of motion that makes them more suitable for such activities. Asian elephants are an endangered species, and African elephants are a threatened species, because of destruction to their habitat and illegal poaching for their valuable ivory tusks.

Diet

The elephant is a herbivore that consumes up to four hundred pounds of vegetation per day. Large molars chew vegetation, which may take up to nineteen hours to digest. Molar teeth do not all erupt at once; when one molar wears down, it is replaced by a new one. This replacement happens six times, and after that the elephant may starve to death.

The trunk serves to siphon up gallons of water to facilitate digestion and ensure hydration. These animals are unselective browsers that use their tusks to chisel away tree bark and, in the process, often uproot trees. Over time, these destructive habits can transform the ecology of the environment.

Protection, Defense, and Communication

Elephants use their tusks for defense and sharpen them on tree bark. An aggressive elephant will fan out its ears, kick sand, sway from side to side, and trumpet and scream when angry and excited. Males travel with female herds until puberty. At approximately twelve years of age, males leave female herds and form smaller male herds. Mature males join a herd when a female is in heat. Older males are solitary.

A matriarch leads the herd, which is mainly female. Males in musth and females in heat advertise their condition by producing infrasonic rumbles not audible to humans. Since elephants have poor eyesight and hearing, these sounds allow for long-distance coordination of mating.

Reproduction and Birth

Elevated testosterone levels cause notable physical changes in elephants. The male secretes fluid down the sides of his face from the temporal glands. He also dribbles urine that often stains the insides of his hind legs. The male is now ready to mate: He is in a musth state. The male in musth is hostile and aggressive toward other males, viewing them as competitive suitors in his quest to mate successfully. Meanwhile, the female's urine emits a distinct odor that invites the male's advances. A male interprets a female's readiness to mate through his Jacobson's organ. Females mate once every three to five years. A female will exhibit aggressive behavior, including

Elephant Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Chordata
Subphylum: Vertebrata
Class: Mammalia
Order: Proboscidae
Family: Elephantidae (modern elephants)
Genus and species: Loxodonta africana (African elephant), *Elephas maximus* (Asian elephant)

Geographical location: African elephants are abundant south of the Sahara desert; Asian elephants occur in India, Sri Lanka, and south and east to Sumatra

Habitat: Mostly forest and savanna biomes, which are never far from water

Gestational period: Twenty-two months

Life span: Sixty years in the wild; eighty years in captivity

Special anatomy: Gray coloration; massive head with trunk and tusks; large, flaplike ears

Elephant herds are led by matriarchs and are composed of females and prepubertal males. (Corbis) fighting to kill, when aggressors threaten her calves.

Elephants also grieve the death of the aggressor soon after they have killed it. They may cover the dead animal with leaves and sand. This is noteworthy, as such behavior is rare in the animal kingdom.

Elephants are extremely intelligent mammals. Aggressive and defensive, protective and devoted to their young, elephants are majestic herbivores with muscular, serviceable trunks and magnificent ivory tusks.

ELK

Types of animal science: Behavior, classification, ecology
Fields of study: Ecology, wildlife ecology, zoology

Elk, also known as wapiti, are members of the mammal order Artiodactyla. They are noted for their large antlers.

Principal Terms

ANTLERS: outgrowths from the skull, composed entirely of bone, shed after breeding season
HERBIVORE: an animal that feeds on plants for its diet
MANE: long, thick hair growing from the neck
PIEDMONT: area at the base of mountains
PELAGE: a mammal's fur coat
PREDATOR: an animal that preys on other animals for its food
RUT: activities associated with bull elk mating behaviors
UNGULATE: mammals with cloven hooves
VELVET: a hairy skin richly endowed with blood vessels that covers developing antlers

Elk are the largest members of the red deer group of the Artiodactyla. This order has more than two hundred other species including pigs, peccaries, wild boars, warthogs, hippos, cows, goats, sheep, moose, caribou, giraffes, camels, pronghorns, llamas, and deer. Antarctica and Australia are the only continents without any members of Artiodactyla. The fossil record of Artiodactyla dates back at least fifty million years. Female elk (cows) weigh about 360 kilograms at maturity, while males (bulls) weigh about 450 kilograms. Elk calves weigh about 15 kilograms at birth and add 30 kilograms within the next two weeks. Calf survival is highly variable; researchers have reported a range of eighteen to seventy calves at six months for every one hundred cows. The environment and the available nutrition influence all of the average weights above.

Physical Characteristics

As in many of the deer species, calves have creamy colored spots on their reddish-brown pelage. Bulls are distinctly different from cows in their winter coat color. During the winter, bulls have a dark colored mane, in vivid contrast to their cream colored coats, whereas cows are somewhat darker and lack the mane.

Elk Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Class: Mammalia
Order: Artiodactyla
Family: Cervidae (deer)
Genus and species: Cervus elaphus (red deer, twelve subspecies), *Cervus canadensis* (American elk or wapiti, thirteen subspecies); *Alces alces* (moose or European elk, six subspecies)
Geographical location: Across North America and Eurasia
Habitat: Grasslands, piedmonts, forests, and mountain ranges
Gestational period: 7.5 to 8.5 months
Life span: Up to twenty years
Special anatomy: Four-chambered stomachs; bulls have antlers that can weigh more than thirteen kilograms

Bull elk begin growing antlers in mid to late May, with full antler development finished by August, when velvet rubbing begins. Rubbing the velvet from the antlers, gives an elk a highly polished rack. In aspen trees stands, elk leave scars on the tree trunks at about head height during the removal of the velvet. Antler lengths have been recorded at as much as 150 centimeters. Elk antlers are branched and have tines (points) at their ends. March is the usual month for shedding of the antlers. No good correlation exists between age of the bull and number of tines.

Unlike some other horned species, the number of tines on a bull elk's antlers is not connected with its age. (PhotoDisc)

After copulation, which usually occurs in September and October, a cow delivers one calf seven months later. Although twins are produced, it is uncommon. Mature cows have an extremely high pregnancy rate, averaging 90 percent in some cases, although older cows (more than eight years old) appear to be less fertile. The decline in fertility may be related to nutritional status. First-year bulls can be fertile but it is more common for bulls in their third year to be the ones participating most in mating events. Bulls mate with more than one cow in their harems, which they defend from other bulls during the rutting season. Presently there is insufficient evidence to support declining bull fertility with increasing age.

Lifestyle

Foraging habits of elk are similar to those of other ungulates. Elk adapt their diet according to the seasons. Some elk populations migrate between spring and winter habitats in search of a better environment and food resources. Other populations do not migrate, remaining in their selected habitat year around because there is adequate forage and cover. During the winter season, dried grasses and shrub branches and shoots are eaten. In the spring and summer, new shoots of grasses and other plants, such as aspens, oaks, and willows are selected. In certain areas of national forests in the southwest, areas are fenced off to prevent elk from grazing on young aspens.

Although wildlife experts have reported that elk can live more than twenty years, most do not. At birth the sex ratios are reported to be one male for every female, but this changes dramatically as elk attain adult status (thirty males per one hundred females). Wolves and mountain lions are the primary predators of elk.

Elk are social animals, tending to form loose congregations that are segregated by sex most of the year. Herds of elk are not constant; individuals tend to move about, leaving one herd and joining another. During the rutting season, bugling by the bull elk can be heard. In addition to bugling, other behaviors used by males during the rutting season to establish harems and territory include antler rubbing, digging with the forelimbs, posturing with head and neck, and lowering of the ears.

EMBRYOLOGY

Types of animal science: Development, reproduction
Fields of study: Cell biology, developmental biology, embryology, reproduction science

Embryology is the study of the development of animals, from the formation of gametes until birth, hatching, or metamorphosis.

Principal Terms

CLEAVAGE: cell division in the early embryo that, unlike division in adults, involves little or no growth between divisions

FERTILIZATION: the process by which the egg and sperm unite to form the zygote

GAMETES: the haploid cells, ova and spermatozoa, that fuse to form the diploid zygote

GASTRULA: the stage of development during which the endoderm (gut precursor) and the mesoderm (muscle and connective tissue precursor) are internalized

HAPLOID: having only one of each kind of chromosome

ZYGOTE: the single cell formed when gametes from the parents (ova and sperm) unite, a one-celled embryo

For thousands of years, humans have wondered how they and other organisms came to be. By 340 B.C.E., Aristotle had described the development of the chicken in the egg, but since most early embryos are too small to be seen by an unaided eye, his and later descriptions of development started with larger, more formed embryos. That did not change very much until the late 1600's, when development of the microscope gave a glimpse of life too small to be seen unmagnified. By the early eighteenth century, the developmental patterns of many organisms had been observed and described. There was, however, still much disagreement about how the early stages progressed. The majority of scientists believed in the theory of preformation, which said that a preformed embryo was present in the gametes. There were two main factions among the preformationists. The ovists believed that inside the egg was a tiny, fully formed organism that was stimulated to grow by the seminal fluid. Their opponents, the spermists, believed that the fully formed miniature organism was in the sperm and was nourished in its growth by the ovum. Thus seventeenth and eighteenth century drawings of sperm and of eggs often show fully formed bodies within. By the end of the eighteenth century, more and more scientists were deserting preformation in favor of the theory of epigenesis, first proposed by Caspar Wolff in 1789, which stated that development occurs through growth and remodeling of embryonic cells. Karl Ernst von Baer, who had published a collection of his observations and the observations of others, proposed that general features that are common to large groups of taxonomically related organisms appear earlier in development than more specialized features of individual species. After Darwin published his evolutionary theories, Müller, Haekel, and other proponents of Baer's law and of evolution proposed that the embryonic development of an organism (ontology) mirrored its evolution (phylogeny). Although this has been shown not to apply to all organisms or to all developmental sequences, it can be seen in the development of many embryos.

During the late nineteenth and early twentieth centuries, scientists' understanding of embryonic development increased dramatically as they began applying recently discovered knowledge in evolution, genetics, and cell biology to embryology. Edwin Ray Lankester and Hans Speeman were two prominent scientists who studied comparative embryonic development at that time. Also at that time, the new science of experimental embryology began as Wilhelm Roux and G. Schmidt manipulated the cells of amphibian embryos and began to discover how and why development occurred. Today, new discoveries in biology and chemistry are applied to the study of embryonic development.

Gametogenesis

The formation of gametes, eggs and sperm, is usually considered the beginning of embryology. In sperm formation, two things need to occur, reduction of chromosomes to the haploid state and maturation of the cytoplasm. During the first part of spermatogenesis, immature cells, called spermatogonia, form four haploid cells, called spermatids, by meiosis. Spermatids then go through a maturation process in which they become streamlined and motile. They also develop an acrosome that has enzymes needed to penetrate the egg. Like sperm, eggs must become haploid and mature, but both the timing and maturation are quite different. Maturation of the cytoplasm often begins before meiosis. All the cytoplasm of the early embryo comes from the egg, so immature ova are aided by various helper cells that increase each ovum's cytoplasm and add food stores, called yolk. The amount of yolk varies considerably, from mammals that have no yolk, to birds that have huge amounts. Depending on the species, meiosis can begin at any time during cytoplasmic maturation and can be a continuous process or have one or more pauses. In sea stars and many other organisms, meiosis is complete before fertilization, while in others, such as nematodes, the egg matures fully and is released by the ovary before any meiosis begins. Sperm penetration then triggers the onset of meiosis.

Fertilization and Development

Once sperm have reached the egg, the acrosomal enzymes must digest the various protective layers that surround the egg, and recognition structures on the surface of the sperm must be complementary to recognition structures on the egg cell membrane. The sperm's nucleus then enters the egg and fuses with the haploid egg nucleus. This forms a diploid cell called the zygote. Interestingly, when a sperm first penetrates the egg, the polarity of the cell changes and chemicals are released by the membrane, which make it impossible for other sperm of that species to enter the same egg.

Following fertilization, a period known as cleavage begins. During this time, cells divide rapidly with little or no growth between cell divisions. Cells become smaller and more numerous. At the end of cleavage, a structure called the blastula is formed. In some animals, such as echinoderms, amphibians, and nonvertebrate chordates, the blastula is a hollow ball of cells. In higher vertebrates, the blastula is a flat, dish-shaped structure, often called the blastodisc. In mammals, the blastula is called a blastocyst, and consists of a hollow ball of cells, called the trophoblast, and a group of internal cells, called the inner cell mass. During gastrulation, surface cells become internalized to form the three germ layers—ectoderm, mesoderm, and endoderm—that are seen in most animal embryos. A second internalization, this time of some ectodermal cells, forms the beginning of the central nervous system. After this neurulation, the various body organs begin to form from the three germ layers. As these changes progress, cells become less general and more specialized, a process called differentiation. Once the major organs have differentiated, the embryo matures and grows, a process usually called gestation. The time it takes for embryonic development varies considerably. In chickens and small rodents, the process takes about three weeks; in humans, it takes approximately nine months, while in elephants, the process can take almost two years. Some organisms emerge in very immature states that require more development. Amphibians and arthropods hatch as feeding larvae that must grow before they begin a metamorphosis that leads to the adult. Marsupials are also born at a very immature stage and must complete their embryonic development inside the mother's pouch.

Sir Edwin Ray Lankester

Born: May 15, 1847; London, England
Died: August 15, 1929; London, England
Fields of study: Anatomy, embryology, evolutionary science, marine biology
Contribution: Lankester elucidated the structures and developmental anatomy of many marine organisms and was also a champion of Darwin's theories of evolution.

From childhood, Edwin Ray Lankester was exposed to some of the greatest scientific minds of his day. His father, Edwin Lankester, was an eminent physician, numbering among his friends Charles Darwin and Thomas Henry Huxley, who were frequent visitors to the Lankester home. These men first exposed the younger Lankester to scientific thought, and he became their ardent disciple. After completing his university studies, Edwin Ray Lankester trained in Vienna, Leipzig, and Naples, before becoming a fellow at Oxford. He was a professor at University College, London (1874-1890), and at Oxford (1890-1898). During this time he continued his studies on animal development. He was the first to show that movement of cells through the primitive streak was by delamination (a movement of individual cells) and not by invagination (a term he coined for the inward migration of a layer of cells). He also coined the terms blastopore, for the opening formed during gastrulation, and stomadeum, for the embryonic region that gives rise to the mouth. While he was at University College, he was the prime mover in the founding of the Marine Biological Laboratory at Plymouth.

He left his professorship at Oxford in 1898 to become director of the natural history division of the British Museum, from which post he retired in 1907 to devote more time to his writing. He was a prolific writer, who wrote both for his scientific colleagues and for the popular press. He made biology, especially evolution and natural history, accessible to the nonscientist in weekly newspaper columns that were later collated and published in book form. Another of his books, *Extinct Animals* (1905), was the first book to introduce dinosaurs to the general public. He despised what he thought was quackery and was one of the first scientists to dismiss spiritualists and mediums as quacks. He was also vehemently opposed to the Lamarkian idea of the inheritance of acquired characteristics. Because of his tenacity in debate, he was often likened to a bulldog.

In 1911, a partial human skeleton was discovered near Piltdown in Sussex. Although the cranium was quite human in appearance, the lower jaw was more apelike. Many crude stone tools and bone fragments of extinct animals were also found in the same area. Lankester and many other scientists thought that this might be the skeleton of a species ancestral to modern humans. Sadly, the man who exposed spiritualists and Lamarkism had himself fallen for a hoax. Many years after its discovery, the Piltdown man skull was shown to be a composite of parts of a human cranium and a juvenile orangutan's jawbone that had been modified to look a bit more human. Lankester never knew of his mistake. He died in 1929, long before the hoax was unmasked.

—Richard W. Cheney, Jr.

EMOTIONS

Types of animal science: Behavior, evolution
Fields of study: Developmental biology, ethology, evolutionary science

The idea that animals experience a wide range of emotions continues to be a controversial concept among scientists. Although it is a popular belief supported by numerous anecdotal reports, scientific researchers often stringently dismiss such evidence as signs of anthropomorphism.

Principal Terms

- AMYGDALA: subcortical brain structure related to emotional expression
- ANTHROPOMORPHISM: attributing human characteristics to animal behavior
- DOPAMINE: neurotransmitter involved in movement and reward systems
- FIELD OBSERVATIONS: observing behavior in naturalistic settings
- LIMBIC SYSTEM: brain structures related to the regulation of emotions
- OXYTOCIN: hormone involved with pleasure during bonding
- PRIMARY EMOTIONS: emotions related to innate motivations
- SECONDARY EMOTIONS: emotions with a strong social component

In attempting to prove the existence and extent of emotions in animals, researchers have struggled with the question of how to identify and measure feelings in various species. For many scientists, it is nonsense to speak of animal emotions without the capacity to objectively define and measure them. Such scientists have an aversion to the nonscientific tendency to ascribe humanlike characteristics to animals. Anthropomorphism is the term used to describe this tendency.

Defining and Communicating Emotions

Defining emotions can be difficult even in humans. Psychologists view emotions as organized psychological and physiological reactions to change in one's relationship to the world. An emotion is a positive or negative transitory experience that is felt with some intensity. Emotional reactions are partly subjective experiences and partly objectively measurable patterns of behavior and physiological arousal. The subjective experiences can include how a person appraises a situation and what actions result from that appraisal. For example, when a student receives a passing grade on an extremely difficult exam, she may experience joy after appraising the situation as a success. Even with this appraisal, however, humans cannot decide to experience joy or some particular emotion. The subjective aspects of emotions are triggered by the thinking self and felt as happening to the self. Objective aspects of emotions include learned and innate physiological responses and expressive displays. The expressive displays include smiles, frowns, and squinting of the eyes. The innate physiological responses are biological adjustments needed to perform the actions generated by the emotional experience. For example, if anger develops in a person, heart rate increases in order to supply additional oxygen to the muscles.

Since animals do not have the capacity of speech, any inner states cannot be expressed directly to a scientific observer. Consequently, field observations of behavior are often used to infer emotions in animals. There are problems, however, in assessing emotions through behavioral manifestations. It becomes difficult or impossible to attribute an emotion to an act with many possi-

The Mirror Test

In order to determine whether animals have the capacity for self-awareness, researchers commonly utilize the mirror test. The mirror test involves a basic procedure to test for self-consciousness. In one basic procedure, after an animal is anesthetized, patches of a bright dye are placed on different parts of the face. After awakening, the animal's reflection is shown in a mirror. If the subject touches the dyed parts of its face, self-consciousness is inferred. Many animals, including primates, elephants, birds, and dolphins, have been tested with this procedure. Only chimpanzees, orangutans, and humans have consistently shown the results indicative of self-recognition. Researchers concluded that most species cannot conceive of a self. Correctly identifying one's own reflection indicates senses of identity and of personal awareness. Without this capacity an animal would not be able to identify or model the mental states of other creatures or sympathize when witnessing the suffering of another animal. Humans routinely make inferences about what other people are feeling because of this capacity for self-awareness. Apparently, only a few other primates have the rudimentary capacity for self-consciousness, yet even those who pass the mirror test do not show a consistent pattern of being able to empathize with others. In general, some researchers have been critical of the mirror test, stating that chimpanzees may have clever minds, but they are blank minds. Chimpanzees may be able to learn, memorize, and problem solve sufficiently to pass the mirror test, but be unable to utilize their situation to take into account the experiences of others.

ble motivations. If a dog chews on the shoes of an owner who is out on a date, does this indicate jealously, anger, boredom, or merely a poorly trained pet?

Historically, animals have been seen from a mechanistic perspective as being without the capacity for humanlike emotions. Behaviorism dictated that instincts and patterns of reinforcement in the environment provided the motivation for the behavior of animals. For centuries, Christian religions also promoted the idea that animals lacked humanlike emotions. The role of animals was to serve the needs of humans. The concept of "speciesism" suggested that only humans were capable of emotions because of their special place in creation. Charles Darwin was one of the first scientists to study animal emotions, and to utilize field observations to ascribe emotions to animals. In his book, *The Expression of the Emotions in Man and Animals* (1872), Darwin stressed the communicative aspects of emotion. Positive inner states were expressed through a signal for sociability, while aggressiveness indicated a desire for isolation. He believed that species developed special social signals to indicate how they would react to a social encounter. Yet the behavioristic view of animals continued to dominate the debate about animal emotions. Over a hundred years later, Jane Goodall, in her book *The Chimpanzees of Gombe: Patterns of Behavior* (1986), was criticized by the scientific community for suggesting that chimpanzees had personalities and experienced excitement and joy.

Primary and Secondary Emotions

Today even the most critical scientists accept the fact that many animals experience a core group of emotions that are similar to those found in humans. Making the distinction between primary and secondary emotions, there exists some agreement about the basic emotions of fear and aggression. The primary emotions, such as fear, involve instinctual tendencies that are essential to survival. Fear permits escape from dangerous situations or predators. The fight-or-flight response is an instinctual pattern of behavior found in response to danger. The primary emotions, which are instinctual or hardwired into many species, can be demonstrated quite easily. When a specific stimulus is presented to an animal, a predictable response takes place. For example, if the shadow of a hawk is projected on the ground among a group of chickens, the birds will respond with "fear" and attempt to get under cover.

It is the realm of secondary emotions that creates the most controversy between those with opposing views about the extent of animal emotions. Expressions of love, grief, or jealousy may be commonplace among humans, but it is debatable whether they can be inferred in animals. Grief is commonly reported during field observations of various animals. The behaviors of elephants, chimpanzees, sea lions, and geese suggesting grief in response to the loss of a mate or offspring have been well documented. The dolphin who carries a dead baby around for several days is inferred to be experiencing both grief and love. Love has been attributed to animals such as swans or geese because of lifelong bonds that are established with a mate. Critics of these interpretations point out that animals may behave as if they are grieving or in love, yet there is no way of knowing whether this is an accurate reflection of their inner states. A central issue about the capacity of animals to experience a wide range of secondary emotions involves the ability to show self-consciousness. If an animal is able to be aware of its own inner states, it would then have the capacity to infer the mental states of others. With self-awareness comes the capacity for sympathy and empathy.

The Biology of Emotions

The scientists examining the biology of emotions have discovered some similarities between the brains of humans and animals that help to explain the basic primary emotions. Emotions seem to arise from the parts of the brain that are located below the cortex and are part of the limbic system. These regions of the brain have remained intact across many species throughout evolution. So far, the amygdala has been identified as the central site of emotion. This almond-shaped structure is at the center of the brain. Neuroscientists have found that rats will show a pattern of fear when a particular section of the amygdala is stimulated. If the amygdala is damaged, a rat will not show the normal behavioral responses to danger, such as freezing or running away. The rat with a damaged amygdala also will not demonstrate the accompanying physiological reactions to danger, such as increased heart rate or blood pressure. Research with humans has highlighted the amygdala's critical role in the learning of emotional associations and the recognition of emotional expressions in other individuals. Magnetic resonance imaging studies have shown that the amygdala shows activation to fearful stimuli. In humans, the brain is also involved in the control of emotional facial expressions. Smiles that occur spontaneously as a result of genuine happiness are involuntary. The extrapyramidal motor system, which depends on subcortical areas, governs involuntary smiles and fear reactions.

The chemistry of the brain also plays an important part in animal and human emotions. The neurotransmitter dopamine is released in copious amounts during periods of pleasure and excitement. Researchers have found that rats experience an increase of dopamine when engaging in activities that appear to suggest play. Research has also shown that if dopamine production is blocked in rats through the administration of a dopamine-blocking agent, the rat's play activity disappears. The effects of the hormone oxytocin have been studied in small mammals and appear to be related to sexual activity and bonding behaviors. In humans, oxytocin is released in mothers who are nursing their infants and is considered to aid in the mother-child bond. Researchers have investigated the role of oxytocin in bonding among voles. If a female vole is injected with oxytocin, the animal will quickly select a mate. When a female vole is given a drug to block oxytocin, however, mate selection never takes place.

Many scientists contend that it is illogical to believe that emotions appear suddenly in humans. If evolution takes place through the process of natural selection, the emotions found in humans would be present in early evolutionary ancestors. The similarities in brain anatomy and chemistry between animals and humans would then support the idea that some basic emotions exist in various species. Darwin believed that some facial expressions in humans are universal. These expressions are genetically determined and evolved as the most effective at telling others something about how a person is feeling. Research with infants shows the innate capacity to grimace in pain or to smile in pleasure. For the most basic emotions, people in all cultures show similar facial responses to similar emotional situations. For example, anger is linked with a facial expression recognized by almost all cultures. Perhaps it is this line of reasoning from the evolutionary context that provides the strongest support for the existence of a wide range of emotional reactions in animals.

Bibliography

Bekoff, Marc. *The Smile of a Dolphin*. New York: Discovery Books, 2000. A series of true stories about animal emotions are presented under the headings of love, grief, joy, aggression, anger, and fellow feelings. The research completed by over fifty scientists in the realm of animal emotions is discussed. The book also includes a number of attractive color pictures.

Griffin, Donald R. *Animal Minds*. Chicago: University of Chicago Press, 1992. This book was written to counteract the behavioristic tradition of John Watson and B. F. Skinner. The book is a key to the understanding of cognitive ethology, and emphasizes the richness of the animal mind.

Marshall, Elizabeth. *The Hidden Life of Dogs*. Boston: Houghton Mifflin, 1993. As an anthropologist and ethologist, the author provides unique insights into the behavior of dogs. The behavior of a pack of dogs over the course of thirty years is documented.

Masson, Jeffrey M. *When Elephants Weep*. New York: Delacorte Press, 1995. The author is a strong advocate for the recognition of emotions in animals. After discussing the impediments in the scientific community to the serious study of animal emotions, the author presents groupings of emotions expressed by animals. He presents numerous examples to support the wide range of emotions he attributes to animal behavior.

Panksepp, Jaak. *Affective Neuroscience: The Foundation of Human and Animal Emotions*. New York: Oxford University Press, 1998. This book presents a very thorough and scientific exploration of the neurochemicals associated with emotions. The author shows how the basic emotions and motivational processes are controlled by brain chemistry.

Sheldrake, Rupert. *Dogs That Know When Their Owners Are Coming Home.* New York: Crown, 1999. The author is a scientist and philosopher who presents numerous incidents of unusual abilities found in dogs. The information on animal empathy is particularly informative.

ENDANGERED SPECIES

Types of animal science: Ecology, evolution
Fields of study: Conservation biology, genetics, population biology, reproduction science, systematics (taxonomy), wildlife ecology, zoology

Endangered species are those varieties of plants and animals that are in immediate danger of becoming extinct.

Principal Terms

ECOSYSTEM: a biological community and the physical environment contained in it

ENVIRONMENT: the physical, chemical, and biological conditions of the region in which a plant or animal lives

EXTINCTION: the complete destruction of a species

HABITAT: the place in which a plant or animal lives

SPECIES: a group of similar individuals that can breed among themselves and produce offspring

According to the U.S. Fish and Wildlife Service, 529 plant species and 432 animal species in the United States are in immediate danger of extinction. Another 192 species of plants and 40 species of animals are designated as threatened, meaning likely to become endangered in the near future. Globally, the International Union for Conservation of Nature and Natural Resources (IUCN) places more than two thousand species on its list of endangered and vulnerable species. About five species are added to the IUCN list every month. The International Council for Bird Preservation has announced that 1,029 of the 9,040 species of birds are endangered. Fish, especially freshwater fish, are among the most immediately threatened types of animals. About one-fourth of the number of species worldwide are in a state of dangerous decline.

Causes of Species Endangerment

The destruction of species is caused in four major ways: Humans have hunted other species out of existence; habitats, the environments in which plants or animals grow and develop, have been destroyed; new species, such as rats, cats, goats, or ground-covering plants, have been introduced into regions and displaced native species; and nonnative plants and animals have introduced diseases into environments, killing the existing species. For much of history, hunting was the major cause of species extinction. However, hunting has become less of a factor because governments and conservation authorities have imposed strict controls on the practice. In the second half of the twentieth century, habitat destruction and invasion by exotics (nonnative plants and animals) and the diseases they carry caused the most damage. Most biologists agree that whatever the factors involved, the rate of extinction has increased rapidly since the 1950's.

Some people have argued that the destruction of a single species of fish, bird, or flower would make little or no difference to the future of human life or the earth. They also suggest that extinctions have always taken place, even before human beings existed, and therefore are simply part of the natural process of existence. Who, for instance, would really want to have "saved" the dinosaurs? We should be glad they are gone. At least ten million species exist, so who would miss a few dozen or a few hundred of them? These arguments omit an important point. Individual species each inhabit a small part of an entire ecosystem, a community of plants and animals that are closely associated in a chain of survival. For example, plants absorb from the soil chemicals and minerals that are essential to their health. Animals then eat the plants—grasses, fruits, leaves, or flowers—and digest the nutrients they need for energy. Other animals, meat eaters (carnivores), then eat these plant eaters and get their energy from them. If a single species is removed from this chain, the whole ecosystem can suffer unknown and perhaps terrible consequences.

The death of an entire species constitutes a loss that cannot always be measured in economic terms. The American biologist William Beebe made the point that any species that is lost diminishes the quality of life for everyone:

> The beauty and genius of a work of art may be reconceived, though its first material expression can be destroyed; a vanished harmony may yet inspire the composer, but when the last individual of a race of living things breathes no more, another heaven and another earth must pass before such a one can be again.

Deaths of entire species grew more frequent in the 1900's.

How Species Are Lost

One example of this loss was the passenger pigeon, a bird so numerous in the 1820's that John James Audubon, the famous American painter and collector, wrote that the flapping of wings of flocks numbering in the hundreds of millions on the Great Plains sounded like the roar of thunder. More than nine billion of the pigeons were alive in 1850, yet slightly more than sixty years later, exactly one bird, Martha, survived, in the Cincinnati Zoo, where she had been taken in 1912. The population fell from nine billion to one in little more than half a century, then to zero when Martha died on September 1, 1917. People had found these pigeons delicious to eat and easy to kill. They formed hundreds of hunting parties, killing more than fifty thousand birds a week. No one dreamed the passenger pigeon could ever be exterminated.

The same fate almost befell the American bison, often called the buffalo. Before the coming of railroads and white settlers in the 1860's and 1870's, the bison numbered more than 100 million. Native Americans hunted the bison, eating their flesh and using the skins for clothing and shelter, but they killed only what they needed. The settlers, however, saw the bison as a problem that needed to be solved. Huge herds of bison crossed railroad tracks, forcing passenger trains to stop, and the animals interfered with farming, knocking down fences and trampling grain fields. Railroad companies and the U.S. Army sent out hunting parties to get rid of the bison. By 1890 fewer than one thousand bison survived in a herd that had managed to escape far into northern Canada. The extermination ended only after this small herd was given protection by the Canadian government.

Stories of other near extinctions are numerous and frightening but demonstrate that action can be taken to save some if not all of the endangered species. Whales, which had been hunted since the 1600's, faced possible extinction until action was taken to reduce hunting in the 1970's. Whales were easy to kill and provided oil and bone. Whale oil was the major substance burned in lamps until the electric light largely replaced oil-burning lamps in the 1880's. Europeans hunted the Atlantic whale, called the right whale because it was the "right" one to kill, into virtual extinction by the 1860's. When the right whale became too hard to find, hunters turned to the Pacific right whale and then the bowhead whale before action was taken by the world community to save remaining whales.

Greed and Ignorance

Human greed has brought death or near death to many species. The desire for fur coats has killed nearly all jaguars, snow leopards, and various species of fur seals. Pribilof Island fur seals were hunted nearly into extinction in the late 1800's. A treaty between the United States, Canada, and Russia established limits on killing the species in its remote northern Pacific island habitat, but enforcement has proved difficult, and thousands of seals have been slaughtered despite international protection.

The belief that some animals are nuisances has led to the near extinction of wolves, grizzly bears, cougars, and coyotes. These predators have been poisoned and shot by the thousands and have become endangered species as a result. Attempts to kill insects with pesticides in order to control the spread of disease and improve crop yields were successful but had an unfortunate side effect. Chemicals from the pesticides worked their way into ecosystems, killing millions of other forms of life. In the 1950's, dichloro-diphenyltrichloroethane, or DDT, was used to kill malaria-carrying mosquitoes, but the chemical infested the whole food chain. It entered plants that were eaten by animals and affected birds, fish, and butterflies. Pesticide poisoning also diminished the numbers of the bald eagle and peregrine falcon, which started to come back only after rigid controls on pesticides were established.

Events on the island of Madagascar, a large island in the Indian Ocean off the east coast of Africa, demonstrate most fully the deadly consequences of habitat destruction. About 180 million years ago, the island was attached to the African continent, then was split off after a series of geological catastrophes and ended up 250 miles to the east. The split occurred just at the time mammals were emerging as a class of animals in Africa. One mammal species, the monkeylike lemur, became isolated on Madagascar and increased abundantly. Other animals caught on the island included several kinds of giant birds, including one that weighed a thousand pounds and stood ten feet tall. The island was isolated for millions of years, allowing hundreds of species found nowhere else in the world to evolve in the diverse island ecosystems. Madagascar had deserts, rain forests, dry forests, and seashores. About 99 percent of its reptiles, 81 percent of its plants, and 99 percent of its frogs were unique and tied specifically to the island's food chain. About nine thousand years ago, the Malagasy people began to arrive on the island. They hunted, fished, began to grow crops, and in the process destroyed more than 90 percent of the forests that covered Madagascar. Dozens of species died as a result, including the giant elephant bird, which was gone by 1700. Ten out of thirty-one species of lemur had died out by 1985. The loss of Madagascar's forests caused terrible erosion, which resulted in flooding and the destruction of more trees. Madagascar's entire ecological system is now threatened, and hundreds of unique species are listed as endangered. Only major restrictions on farming and habitat destruction can save these animals.

The United States' Endangered Species Preservation Act

The implications of species and habitat destruction were first described in books such as Rachel Carson's *Silent Spring* (1962). Carson, a biologist with the U.S. Department of Interior, wrote about the effects of DDT and insecticides on birds and other animals. Her book inspired Congress to pass the Endangered Species Preservation Act in 1966. This law authorized the secretary of the interior to protect certain fish and wildlife through the creation of a National Wildlife Refuge System. Congress strengthened the law in 1969 by restricting importation of threatened species and adding more domestic species to the list of those deserving protection.

The U.S. Department of the Interior published its first list of endangered species in 1967. The list included seventy-two native species of animals, including grizzly bears, certain butterflies, bats, crocodiles, and trout. No plants were on this list. In 1973, President Richard M. Nixon signed into law an Endangered Species Act that gave the secretaries of the interior and of commerce responsibility for creating a list of endangered animals and plants, or species in immediate danger of extinction. Another list would include species threatened with extinction, or those likely to become endangered in the foreseeable future. Once an animal or plant was on either of the lists, no one could kill, capture, or harm it. Penalties for violators were increased, and international or interstate trade of listed species was prohibited. Fines

Recoveries from Near Extinctions

In the wild, herds of American bison (*Bison bison*) were decimated to extinction east of the Mississippi River by 1830, and in the west by 1897. When the American Bison Society formed in 1905, only about 25 protected bison remained in Yellowstone National Park. A census of captive herds taken in 1908 indicated that 1,116 bison were held in 15 zoos and private collections. Starting in 1907 with fifteen animals from the New York Zoological Park, captive bison were relocated to newly established reserves. By 1933, the bison herds numbered 4,404 animals. Today, bison are once again common in their western range.

Likewise, the European bison, or wisent (*Bison bonasus*), became extinct in the wild in the 1920's. The International Society for the Protection of Wisent was founded in Europe in 1923. The Frankfurt Zoo staff, and later the Warsaw Zoo staff, established a studbook for wisent in 1932. Cooperative breeding programs among European zoos increased wisent herds in captivity, which were then used to restock the wild forests. Another animal saved from extinction by European zoos was the Przewalski's horse (*Equus caballus przewalskii*). When the Polish general for whom the horse is named found the last herd in western Mongolia in the 1870's, he brought some of the horses back to Poland. From this initial captive stock, zoos bred enough horses to release them back into their natural habitats in the wild.

The Catholic missionary Armand David, who also collected natural history specimens for the natural history museum in Paris, found a herd of Père David's deer (*Elaphurus davidianus*) at a Chinese royal game park in 1865. Not sure of what they were, he obtained some living deer and brought them back to the London and Berlin Zoos. While the captive herds were increasing at European zoos, the wild herd in China had died out by 1920, due to flooding of the park by the nearby Yellow River in 1894, and decimation of the herd for food during the Boxer Rebellion of 1900. To further increase the deer population, the eleventh Duke of Bedford gathered the European animals onto his Woburn Abbey estate between 1893 and 1895. This propagation effort increased the herd to 88 animals in 1914 and 255 by 1948. By 1986, there were some 1,500 deer in England, and some were sent back to China to repopulate their natural habitat, including the park where the last herd was originally found.

Arabian oryx (*Oryx leucoryx*) were hunted to extinction on or about October 18, 1972. However, this possibility was anticipated by the Fauna Preservation Society, which captured four animals before the last remaining herd was gone. A captive propagation program began at the Phoenix Zoo, in Arizona, and in 1975 the herd had increased to forty-five. Some of these were sent to other zoos to form additional herds. By 1986, there were 172 oryx in thirteen American collections, six European collections had another 30 animals, and ten collections in the Middle East had 528 oryx. Reintroduction of the oryx to its native habitat began in 1978 and has achieved good success; however, hunting has again become a problem. Nevertheless, despite a need for improved conservation education and protection, the Arabian oryx remains in the wild.

—Vernon N. Kisling, Jr.

up to ten thousand dollars could be imposed for knowingly violating the act and one thousand dollars for unwittingly violating it.

A separate provision of the law mandated that federal agencies could not engage in projects that would destroy or modify a habitat critical to the survival of a threatened or endangered plant or animal. This provision became a very important tool in the battle to save species. Friends of wildlife used it to block highway and dam projects, at least until government officials could prove that construction would have no major impact on a fragile ecosystem. The law even called for affirmative measures to aid in the recovery of listed species. The secretaries of the interior and of commerce were required to produce recovery plans detailing steps necessary to bring a species back to a point where it no longer needed protection.

Poaching

Poaching is the illegal hunting, trapping, or taking possession of nongame wildlife. Many animals are killed so that their body parts can be sold. Others are trapped and sold as pets. Poaching poses a major problem for protecting and sustaining wildlife populations throughout the world. In some areas, it is causing a devastating effect on some of the wildlife, particularly endangered species.

Trophy heads of bighorn sheep, elk, moose, deer, goats, and bears all fetch high prices, as do the fetuses, antler velvet, hooves, and tails of deer, elk, and caribou, the feathers of eagles, hawks, and other birds of prey, and the hides, gallbladders, paws, genitals, claws, and teeth of bears. An adult grizzly bear can be worth up to $15,000 on the black market. Its gallbladder can be worth $1,000 or more, a paw worth $500, and a large claw worth $300. The bile from the gallbladder is highly valued in traditional Asian medicines. Paws are culinary treats in some Asian communities.

The demand for its gallbladders has pushed the Asiatic black bear to the brink of extinction. A dramatic decline has also occurred in recent years with the California black bear. Canada's estimated 300,000 black bears are not yet endangered, but it is estimated that 40,000 black bears are poached for body parts in Canada every year.

Numerous animal populations in Africa, particularly tigers, rhinos, and elephants, have severely diminished due to poaching. There are only a few hundred tigers left. Some African countries have declared war on poachers to save the rhinoceros from extermination. Approximately 600,000 African elephants, over half of the population, were killed during the 1970's and 1980's for their ivory tusks. Some African countries have called for eased restrictions on a global ivory trading ban enacted in 1989, so that they can sell their stockpiled tusks to raise funds for domestic conservation programs. If allowed, this could send a dangerous signal to poachers that elephant ivory is again in demand on the world market.

India's elephant population is teetering on the brink of extinction due to rampant poaching and brutal training methods. Unlike African elephants, only male Asian elephants have tusks, and fewer than eight hundred are left in India. As a result of ivory poaching, the Indian male elephant population is dropping by 10 percent every year.

Image Not Available

Poaching has greatly contributed to many animal species becoming rare and vulnerable to extinction. Some of these include whale sharks, giant pandas, orangutans of Indonesia, leatherback turtles, Chinese river dolphins, giant tortoises in the Galápagos, blue crabs, and mountain gorillas of central Africa. As members of a species become rare, they get the dubious distinction of being listed as a threatened or endangered species, which only makes them more valuable to poachers.

—Alvin K. Benson

Money was appropriated for states to design recovery programs, and most states established plans of their own to deal with local crises.

A major threat to the 1973 law arose in 1978 during the Tellico Dam controversy. The Tennessee Valley Authority, a federal government agency, proposed building a hydroelectric dam on the Tennessee River in Loudon County, Tennessee, in the late 1970's. Shortly after plans were made public, a scientist from the University of Tennessee discovered a three-inch-long fish, the snail darter, that was unique to that area. Building the dam, a $250 million project, would destroy that snail darter's habitat and eliminate the fish. Environmentalists successfully argued in federal court that the dam had to be abandoned. The U.S. Supreme Court supported the ruling of the lower court, arguing that when Congress passed the law, it had intended that endangered species be given the highest priority regardless of the cost or other concerns involved. However, in 1981, Congress enacted a special exemption that excluded "economically important" federal projects from the act. A federal judge then found the Tellico Dam to be without economic importance, and construction was again halted. Congressmen friendly to dam interests then slipped an amendment directing completion of the dam onto an unrelated environmental bill, which passed, and Tellico was constructed. However, the principle of protection remained intact, and the 1973 act remained in force. The snail darter apparently survived, too, as scientists found it living in a river not far from the spot where it was originally discovered.

International Trade Bans

The 1973 act also made the United States a partner in the Convention on International Trade in Endangered Species of Wild Flora and Fauna. This treaty came out of a conference in Washington, D.C., attended by representatives from eighty nations. It created an international system for control of trade in endangered species. Enforced by the International Union for Conservation of Nature and Natural Resources (IUCN) headquartered in Switzerland, the convention has more than one hundred members. The IUCN publishes a series of lists in its *Red Data Book* designating three categories of species. Category one consists of those in immediate danger and therefore absolutely banned from international hunting and trading. Animals and plants in categories two and three are not immediately threatened but require special export permits before they can be bought and sold because their numbers have been seriously reduced.

This convention has a major flaw, a loophole that can be exploited by any member. A nation can make a "reservation" on any listed species, exempting itself from the ban on trade. Japan has been the most frequent user of the reservation, exempting itself from controls on the fin whale, the hawksbill turtle, and the saltwater crocodile, all on the IUCN's most endangered list. Unless this loophole is closed, the IUCN can do little to save extremely threatened species.

Successes in Restoring Endangered Species

Several species in the United States—the California condor, the black-footed ferret, whooping cranes, and a bird called the Guam rail—have been saved from extinction because of the 1973 Endangered Species Act. The road to extinction has also been reversed for the brown pelican, found in the southeastern states, the American alligator, which had been hunted almost to death in Florida, and the perigrine falcon in the eastern states. Other species, however, such as the dusky seaside sparrow and the Palos Verdes butterfly, have totally disappeared.

The spotted owl, found in parts of the rain forest in Oregon and Washington, has attracted a good deal of attention because of efforts to save it. The case of the owl points to the most difficult questions raised by the act: Which comes first, the welfare of the plant or animal or the economic needs of people? Each pair of spotted owls needs six to ten square miles of forest more than 250 years old in which to hunt and breed. The owls also need large hollow trees for nesting, plus large open fields in which to search for mice and other small animals. A suitable ecosystem that meets all these needs is found only in parts of twelve national forests in the region. At the same time, loggers in the areas need jobs. The two interests, the lumber industry and environmentalists, collide, and it is left to the courts to determine which interest will prevail or whether a compromise can be arranged.

Outside the United States, the future of endangered species appears much grimmer. Scientists at IUCN think several hundred thousand species will disappear by the end of the second decade of the twenty-first century. Many of these species have never even been identified or named. The most endangered habitats in the world are the tropical rain forests, which have been reduced by half, nearly 3.5 million square miles, during the twentieth century. About 43,000 square miles is destroyed each year, mainly to provide farms and cattle ranches. The most threatened large animal species in these forests are the large cats, including tigers, jaguars, and leopards; fifteen of the twenty-five species of cats that live in the forests are on the most endangered list. One solution to forest destruction has been the creation of large wildlife refuges. Several African nations have created one or more of these, but there are limits to the amount of land available for conservation efforts. Another solution is the establishment of more wildlife zoos. Several zoos have successful programs for saving species on the very edge of extinction. However, capacity is limited, and the very small numbers of animals in a zoo's herd create problems of interbreeding and the handing down of recessive genes.

For many species, it is too late to do very much, so scientists and biologists divide populations into three groups: those that can survive without help, those that would die whatever help was provided, and those species that might survive with help and would certainly die without it. Environmentalists focus their efforts on the plants and animals that fall into the third category. Resources are limited, however, and much work needs to be done, or extinctions will take place at a pace as yet unseen in the history of living things.

U.S. Fish and Wildlife Service. *Endangered and Threatened Wildlife and Plants*. Washington, D.C.: U.S. Government Printing Office. Updated by monthly supplements, this is the official list of species covered by the 1973 law kept by the U.S. Fish and Wildlife Service, Division of Endangered Species.

Wilson, Edward O. *The Diversity of Life*. New York: W. W. Norton, 1993. This award-winning book by the famous Harvard biologist and zoologist tells the story of how life evolved on earth and how it is threatened by the deterioration of the physical environment in the modern world. Easy to understand, with a useful discussion of the importance of saving every species. Has sixteen pages of photographs, an extensive bibliography, and a detailed index.

ENDOCRINE SYSTEMS OF INVERTEBRATES

Type of animal science: Physiology
Fields of study: Anatomy, biochemistry, invertebrate biology

Many invertebrates have endocrine systems almost as complex as vertebrate endocrine systems. In most invertebrate phyla, the principal source of hormones is neurosecretory cells. Neurosecretory hormones have been found in all the larger invertebrate phyla.

Principal Terms

BUDDING: a form of asexual reproduction that begins as an outpocketing of the parental body, resulting in either separation from or continued connection with the parent, forming a colony

DIAPAUSE: a resting phase in which metabolic activity is low and adverse conditions can be tolerated

MOLT: the process of replacing one exoskeleton with another

NEURONS: cells specialized for the conduction of electrical signals and the transmission of information (nerve cells)

NEUROSECRETORY CELLS: specialized neurons capable of manufacturing and releasing hormones (neurosecretions or neurosecretory hormones) and discharging them directly into circulation

PHOTOPERIOD: the measure of the relative length of daylight as it relates to the potential physiological responses that exposure to daylight evokes

TARGET ORGAN: a specific body part that a particular hormone directly affects

TROPHIC HORMONE: a hormone that stimulates another endocrine gland

The endocrine systems of many invertebrates are nearly as complicated as vertebrate endocrine systems. The principal source of hormones in most invertebrate phyla is neurosecretory cells. These hormonal mechanisms have been found in arthropods, annelid worms, mollusks, and echinoderms. The physiological processes that are affected are generally fundamental, long-term ones that include such biological phenomena as growth, regeneration, reproduction and development, and certain metabolic processes.

The subkingdom of animals made up of all vertebrates and most invertebrates (protozoa and sponges are not included) is called the Metazoa, which is defined by the presence of nervous and endocrine systems in the animals in the group. These systems coordinate the activities of the animal so it can function as a whole. The nervous system is important in rapid communication, such as contraction of muscles for movement, while the endocrine system controls long-term processes within the body, such as the growth of organs or maintenance of appropriate metabolic concentrations. Chemical messengers released by the endocrine systems have to travel to specific target organs to exert their effects. The means of travel is the circulatory system. Because it takes time for the chemicals to accumulate to effective concentrations, they must be stable enough to remain in the body without undergoing chemical changes and without being excreted. These chemical messengers—hormones—are, then, well suited to working over long periods of time. The nervous and endocrine systems do not work independently of one another, however. It is probable that most animals' central nervous systems are strongly affected by hormones much of the time.

Neurosecretory Cells

In 1928, German chemist Ernst Scharrer hypothesized that certain nerve cells have qualities of both nerve and endocrine gland cells. These neurosecretory cells are neurons which are cellularly like gland cells, but are widespread within the invertebrate body. They receive nervous impulses, but rather than communicating through synapses with other neurons or effector cells, they terminate close to the circulatory system and release substances which travel to act on organs or upon endocrine glands. These neurosecretory substances, therefore, are themselves hormones. Neurosecretory cells are usually found in clusters within the central nervous system. Extending from the cell bodies are axons that terminate in swollen knobs associated with blood spaces. Terminals that are aggregated into a body are called neurohemal organs. Neurosecretory material is produced by the cell bodies, transported down the axons, and stored in the swollen knobs. Release is accomplished by exocytosis.

To be classified as a neurosecretory cell, three criteria must be met: The cell must have the structural features of a neuron (cell body and axonlike fibers); the axons must not synapse with other cells but end in close association with an area of body fluid (generally a blood vessel or sinus, the combination making a neurohemal organ); the neuron must contain membrane-bound vesicles within the cytoplasm. There are, in addition, two physiological criteria: Destruction of these clustered cells, or the areas or organs where they are found, produces an alteration of existing internal conditions within the organism that can be restored by replacing the removed organ or injecting an extract from it; implantation of an organ thought to be neurosecretory into a normally functioning animal brings about a change in internal state by either prompting or inhibiting the occurrence of certain events.

Neurosecretions in invertebrates may influence behavior or target another endocrine gland by trophic neurosecretions or trophic hormones. For example, in many insects neurosecretions from neurosecretory cells in the brain exert a trophic effect on the prothoracic glands, which then produce and release the hormone ecdysone that controls molting, the developmental sequence of insects. There are other examples of how hormonal release is dependent on and dictated by the nervous system. Most animals respond developmentally to environmental changes, such as seasonal variations throughout the year. If unfavorable conditions develop, the animal may compensate by going into dormancy or migrating, or may overcome the conditions by other changes in habit or physiology. Even brief fluctuations, such as a temporary shortage of food or the absence of suitable mates, may dramatically affect development. The mating act in a female insect may speed up the development of her eggs; the changing day length may control when metamorphosis begins in annelids. Stimulation of sense organs sets up nervous messages that result in changes in the amounts of circulating hormones, which generate these “new” responses.

The Roles of Invertebrate Hormones

Invertebrate hormones play as many roles as there are invertebrate phyla. In the less highly organized invertebrates, endocrine glands are apparently absent; hormonal coordination depends on neurosecretions. Hormones released in the plant hydra are believed to come from the hypostomal region (the nerve ring around the oral opening) and from actively growing areas and are thought to regulate growth, regeneration, and the development of sexuality. Little is known about substances termed “wound hormones” in planarians, but their presence in wounded tissues has been inferred, even though their site of production is unclear.

All annelids possess neurosecretory cells in the brain that control growth, reproduction, and maturation. In nereids, reproductive body forms releasing eggs and sperm are controlled by at least one brain neurohormone, and normal reproductive development appears to depend on the gradual withdrawal of brain neurohormones with increasing age. Regeneration, too, is probably controlled by neurohormones.

In starfish and sea urchins, spawning of eggs is preceded by release of a "shedding hormone" found only in the radial nerves. This hormone, known as gonad-stimulating substance, also stimulates the manufacture and secretion of a second substance by the gonads called meiosis-inducing substance (MIS). MIS causes the follicle cells to pull away from the gametes so the gametes can be expelled more easily; it induces meiosis within the oocytes, and, after diffusing into the coelomic fluid, stimulates muscle contractions which cause spawning.

Many mollusks have neurons resembling neurosecretory cells that change their apparent secretory activity with conditions such as reproductive state. In a few cases, evidence has been found for neurosecretory control of reproduction, water balance, or heart function. Cephalopods such as squid, however, are one of the few classes of animals that possess endocrine glands. The cephalopod brain is connected to the optic lobes by short optic stalks bearing optic glands. As the animal matures, the size of these glands increases. These glands function in the control of reproductive development. Glands on the gills, called mesodermal branchial glands, are also endocrine organs and are thought to function similarly to vertebrate adrenal glands.

Certainly the best-studied invertebrate system is that of insects. Insects possess discrete clusters of neurosecretory cells, well-developed neurohemal organs, and even nonneural endocrine glands. The insect endocrine system has four major components: the corpora cardiaca, a group of neurosecretory cells in the brain, the corpora allata, and the thoracic glands. The corpora cardiaca, closely associated with the heart, store and secrete hormones from the brain as well as producing their own inherent hormones. Along with the brain's neurosecretory cells, they compose the cerebral neurosecretory system. Molting is controlled by hormones called ecdysteroids produced under the brain's direction. Secretion of these ecdysteroids stimulates the release of ecdysone from the prothoracic gland. Ecdysone, also called the molting hormone, stimulates the development of adult structures but is held in check by juvenile hormone (JH), which favors the development of juvenile characteristics. During juvenile life, JH predominates and each molt yields a larger juvenile. High levels of JH are released by the corpus allatum during early stages of life. Its major function, then, is to ensure that when molting is triggered by ecdysone secretion, the next larval stage results. When the final stage is reached, ecdysone production dramatically falls, but sufficient levels are produced to induce a molt that will result in the adult stage. Similar systems are found in the crustaceans.

Because invertebrates make up about 95 percent of the species in the animal kingdom, one might anticipate a great diversity of invertebrate endocrine mechanisms. Eventually, this expectation may be confirmed; but knowledge of endocrine systems in many invertebrate groups is, for the most part, incomplete. What is known is that in most groups of invertebrates, neurosecretory systems are distinctly more prominent than nonneural endocrine glands, which occur in very few cases.

Refinement of Study Techniques

Until the 1960's, the search for hormonal regulators in invertebrates was largely unsuccessful because early experiments on gonad transplantation from insects of one sex to those of the other and injection of vertebrate hormones into invertebrates yielded negative results. Strides made in the last twenty-five years are mostly the results of refinements of microscopic, operative, and analytical techniques, both chemical and physical. Arthropods have provided the most accessible material for study, and more is known about the phenomenon in crustaceans and insects than in any other group. The range of investigation is expanding, however, and neurosecretion in invertebrates is not only accepted but recognized as widespread among them.

Many problems are generally associated with determining the functions of the neurosecretory system. The classical experimental method involves removal of the suspected endocrine gland

and then reimplanting it at another location in the body. If the effects of removal are reversed and normal conditions return when the organ is relocated, then a hormonal mechanism is probably involved. The problem arises, however, because removing a neurohemal organ will leave behind the cut ends that may continue to release hormones, perhaps in an uncontrolled manner. A new neurohemal organ may be rapidly regenerated so that the effects of lessened amounts of neurosecretory hormones cannot be observed. In addition, reimplanting the organ may produce several hormones in the animal in abnormal concentrations or proportions. Hormonal deficiency may not be obvious immediately because hormones stored outside the neurohemal organ may be secreted or leached out for some time after the organ's removal. Yet another problem encountered is the lack of distinct neurohemal organs; instead, scattered neurosecretory cells may be found throughout the nervous system. It is therefore difficult to determine the exact function of the mechanisms because of the virtual impossibility of removing and testing these individual cells. In these cases, the neurosecretory nature of the cells is deduced based on their structural and chemical similarity to those whose function has been already verified in other animals.

Typical of the early work on insect growth hormones was the work done in the 1930's in England by Vincent B. Wigglesworth on the metamorphosis of a bloodsucking insect named *Rhodnius*. This insect goes through five immature stages, each separated by a molt, until it reaches adulthood. During each of these stages, it engorges and stretches its abdomen by ingesting a blood meal. This filling meal apparently stimulates the release of hormones that cause molting at the end of a specified time interval following the meal. Usually, the final molt (to adulthood) occurs about twenty-eight days after the blood meal. If the insect is decapitated during the first few days after its meal, molting does not occur, even though the animal may live for several months longer. Decapitation more than eight days after the blood meal does not interfere with molting, although a headless adult is produced. Wigglesworth further showed that joining the circulatory system of a later-decapitated insect to that of an earlier-decapitated insect allows both to molt into adults. It appears obvious that some stimulus passes via the blood from one insect to the other and induces molting; it is assumed that the stimulus is a hormone that is secreted about eight days after the blood meal.

Since Wigglesworth's time, studies typical of his work have shown evidence of hormonal activity and control of many other invertebrate phyla. Experimentation with insects still outweighs all other studies, however, since they are so available and easy to work with because of their size.

Comparing Vertebrate and Invertebrate Hormones

The study of invertebrate hormones began as an attempt to draw parallels between invertebrate hormones and known vertebrate hormones. Experimenters were virtually forced to look for these similarities because of legal restrictions placed on the use of vertebrates for experimental study. The end results, however, have shown that invertebrate hormones share little with vertebrate hormones.

One of the few similar hormones, in structure at least, is prothoracicotropic hormone (PTTH), isolated from the heads of adult silkworms. (PTTH stimulates the prothoracic gland to release ecdysone, which then regulates molting and growth.) Though structurally similar to vertebrate insulin, insect insulin has no functional link with vertebrate insulin.

The interaction of neurohormones and the nervous system has been studied using the lobster, tying the release of neurohormones to its behavior. By introducing neurohormones via injection, one can induce behavioral changes, such as increased aggression. By working with these crustaceans, the apparent relationship among neurohormones, the nervous system, and behavior modification may be used in observing and controlling animal behavior.

An intermediate college-level text that endeavors to cover both the functional systems and diversity of invertebrates. Chapter 16, "Control Systems," details some of the research and methods, mostly concerning insects, but with some space given to lower invertebrates. Sources of further reading are noted following each chapter. Glossary.

Hickman, Cleveland P., Larry S. Roberts, and Frances M. Hickman. *Biology of Animals*. 7th ed. Boston: MacGraw-Hill, 1998. The goal of this intermediate college text is to acquaint the major or nonmajor student with the various animal phyla. Also included is a section devoted to animal form and function. Chapter 11, "Chemical Coordination: Endocrine Systems," specifically, but briefly, defines the types of endocrine systems found in invertebrates. Selected references. Glossary.

Hill, Richard W., and Gordon A. Wyse. *Animal Physiology*. 2d ed. New York: Harper & Row, 1989. A very readable college-level text that provides a comprehensive introduction to comparative animal physiology. It places emphasis on animals' ecological relations to show their natural state. The book is written systematically, and the chapter on endocrine and neuroendocrine physiology is particularly helpful. Selected readings conclude each chapter.

Keeton, William T., and James L. Gould. *Biological Science*. 6th ed. New York: W. W. Norton, 1996. A complex textbook used for introductory college-level biology. Much space is devoted to the cellular level of living organisms. Chapter 16, "Chemical Control in Animals," has a brief, up-to-date look at invertebrate hormones with emphasis on insects. Glossary.

Laufer, Hans, and Roger G. H. Downer, eds. *Endocrinology of Selected Invertebrate Types*. New York: Liss, 1988. Focuses on the endocrinology of invertebrates other than insects. More than half of the volume is devoted to crustaceans and mollusks, with the rest covering the less-studied invertebrates, including arthropod groups often neglected in such studies. Illustrated.

Matsumoto, Akira, and Susumu Ishii, eds. *Atlas of Endocrine Organs: Vertebrates and Invertebrates*. New York: Springer-Verlag, 1992. An easy-to-understand atlas of the endocrine systems of both vertebrates and invertebrates. Abundantly illustrated with multicolor, three-dimensional drawings and photomicrographs.

ENDOCRINE SYSTEMS OF VERTEBRATES

Types of animal science: Development, physiology
Fields of study: Developmental biology, reproduction science

Endocrinology is a relatively young branch of physiology. It deals with chemical messengers, carried in the blood, that stimulate specific responses. The responses are agents in the control of growth, development, metabolism, osmotic and ionic regulation (hydromineral metabolism), reproduction, and control of hormone secretion itself.

Principal Terms

FEEDBACK: in endocrinology, this usually refers to one hormone controlling the secretion of another that stimulates the first, usually in the form of negative feedback, in which the second hormone inhibits the first

GLAND: a tissue composed of similar cells that produce a hormone

HORMONE: a blood-borne chemical messenger

RECEPTOR: a protein molecule on or in a cell that responds to the hormone by binding to it and initiating a series of events that compose the response

TARGET: cells that contain hormone receptors

Endocrine systems have been known only since the early twentieth century. The first known hormone was discovered around 1902 when William Bayliss and Ernest Starling discovered, in dogs, secretin, a hormone that stimulates pancreatic exocrine secretion in response to acid in the small intestine. Since that date, dozens of other hormones have been discovered, which control all aspects of growth, metabolism, and reproduction.

The endocrine system consists of glands that secrete chemical substances called hormones in response to specific signals. The hormones are secreted into the blood stream, where they travel to specific target cells or tissues, which contain specific receptors that allow the hormones to bind, initiating the response. Classically, hormones were thought to belong to two very different groups, the polypeptide (small protein) hormones and the steroid (cholesterol-like) hormones. It is now known that hormones can be composed of several different kinds of molecules, including fats (prostaglandins) and even gases (nitric oxide). Proteinlike hormones bind receptors found on external cell membranes to stimulate second messengers, such as cyclic adenosine monophosphate (cAMP), which activate enzymes and other cellular substances to produce a response. Steroid hormones enter target cells and bind intracellular receptors. The hormone-receptor complexes migrate to the nucleus and activate gene expression, which results in the response. This, like descriptions of many concepts in biology, is an oversimplification, and many hormones appear to work by a combination of the two mechanisms.

Endocrine Control Systems

The endocrine secretions are controlled by the nervous system through a complex chain of command. Receptors around the body monitor sensory signals and alert the brain, which then relays the information to specific cells in the median eminence of the hypothalamus. For example, temperature receptors in the skin detect cold and inform the brain of potential body cooling. The brain then relays the information to cells in the hypothalamus, which secrete a molecule called thyrotropin-releasing hormone into a blood vessel called the hypothalamo-hypophysial portal vessel. This blood vessel delivers the releasing hormone to the anterior pituitary gland, which in turn secretes a hormone called thyroid-stimulating hormone (TSH), or thyrotropin, into the blood. The TSH travels to the thyroid gland to stimulate the secretion of thyroid hormones, which stimulate metabolism in liver, muscle, and other cells. Heat produced as a by-product of metabolism warms the body. Some hormones are under dual control. Growth hormone (somatotropin) is stimulated by a releasing hormone called somatocrinin and inhibited by somatostatin. There are about seven anterior pituitary hormones that are controlled by similar mechanisms. Adrenocorticotropic hormone (ACTH) is controlled by corticotropin-releasing hormone. Melanocyte-stimulating hormone (MSH) and prolactin are under dual control by both releasing hormones and inhibiting hormones. The gonadotropins—follicle-stimulating hormone (FSH) and luteinizing hormone (LH)—are under the control of a single releasing hormone called gonadotropin releasing hormone. All of these control systems are subject to feedback loops which usually involve negative feedback (for example, TSH secretion being inhibited by thyroid hormone), but positive feedback loops exist (estrogen feeding back positively to stimulate LH secretion).

Hormones Controlling Growth, Development, and Metabolism

The major control of growth is carried out by somatotropin (STH) from the anterior pituitary. STH does not act directly, however. Cells in the liver respond to STH to produce somatomedin, which stimulates bone growth and muscle production. Prolactin, a protein similar to STH, stimulates breast development in female mammals. In an interesting case of hormone evolution, thyroid hormone stimulates amphibian metamorphosis (tadpole to frog transition); however, in warm-blooded vertebrates, this same hormone has evolved to stimulate metabolism for the purpose of heat production in birds and mammals. Several hormones stimulate metabolism for different reasons. Epinephrine (adrenaline), in addition to elevating blood pressure, mobilizes glucose from glycogen, in response to stress. Steroid hormones, also produced in the adrenal glands, stimulate the production of glucose from noncarbohydrate molecules (gluconeogenesis). The stimulus for this is prolonged stress, for example, starvation. These glucocorticoids, such as cortisol and corticosterone, evolved early and are very important in combating stresses resulting from migration among birds and even fish. The pancreatic hormones insulin and glucagon also effect energy metabolism. These two proteins regulate blood sugar, fat, and protein levels. After eating, insulin stimulates transport of these molecules into liver, fat, and muscle cells and then stimulates the incorporation of the simple molecules, such as glucose, amino acids, and fatty acids, into larger storage molecules, such as glycogen, protein, and fats. Glucagon has opposite actions. After a prolonged period without food intake, glucagon stimulates breakdown of complex molecules, such as glycogen and fats, into simple molecules, which are released into the blood and made available to metabolizing cells. These two hormones act independently of the pituitary and respond directly to blood-borne signals such as glucose concentration. This regulation ensures a steady delivery of nutrients to metabolizing cells in animals who only eat intermittently.

Control of Water and Salt Balance

The state of hydration and salt levels in the body are of critical importance to vertebrate animals. Dehydration has obvious severe detrimental consequences. The salt composition of body fluids is equally important. For enzymes and other proteins such as antibodies and even hormones to function properly, salt concentrations (ionic concentrations) must be maintained. For example, blood levels of sodium and potassium must be maintained at approximately 145 and 4 millimolers, respectively, in most vertebrates. These levels are lower in amphibians (100 and 2 millimolers). Water content of the body is controlled primarily by a posterior pituitary hormone called antidiuretic hormone (ADH). When the body becomes dehydrated, both concentration receptors and volume receptors in the brain trigger the secretion of ADH. This small peptide then stimulates thirst and water retention in the kidneys. In amphibians, it also stimulates water absorption by the skin and urinary bladder. A steroid hormone produced in the adrenal glands called aldosterone stimulates the kidney and large intestine to conserve sodium. The kidneys also excrete increased amounts of potassium in response to aldosterone. Aldosterone secretion is stimulated by angiotensin II. When blood sodium levels decrease, there is a consequent loss of water and thus body fluid volume. Pressure receptors in the kidneys trigger the release of renin, which initiates a complex series of enzymatic reactions in the blood leading to the appearance of angiotensin II, which stimulates the secretion of aldosterone. When blood pressure increases, aldosterone secretion decreases, sodium excretion increases, and other hormones appear which also help eliminate sodium. Pressure receptors in the heart cause that organ to secrete atrial natriuretic peptide (ANP). ANP inhibits sodium conservation in the kidneys. Increased pressure in blood vessels activates nitric oxide synthetase, which produces nitric oxide locally. Nitrous oxide increases the excretion of sodium by the kidneys.

Calcium and phosphate are also controlled by hormones. The parathyroid hormones respond

Endocrine Control of Pregnancy, Parturition, and Lactation

During an ovarian cycle, a pregnancy can occur if the ovum becomes fertilized. The events that occur during pregnancy are also controlled by hormones.

In mammals, fertilization normally occurs in the oviduct. When the fertilized embryo is implanted in the uterus, it is nourished as a result of the glandular and vascular buildup of the uterine wall. This buildup is maintained by estrogen and progesterone secreted by the corpus luteum. As the embryo grows, it begins to produce a portion of the placenta; the other portion is produced by the uterus. Cells in the embryonic chorion of the placenta produce chorionic gonadotropin, which "rescues" the corpus luteum and prevents its becoming deactivated by a prostaglandin produced by the ovary as a signal to deactivate the corpus luteum if fertilization has not occurred. During the latter stages of a pregnancy, the placenta takes over the production of estrogen and progesterone in some species. During pregnancy, chorionic gonadotropin will be present in the urine. During the last days of pregnancy, the ovary begins to produce a new hormone called relaxin. Relaxin is a very ancient hormone; it has been found in sharks and birds as well as mammals. Relaxin softens the ligaments connecting the bones in the birth canal. It also stimulates uterine contractions. The uterine contractions begin the process of labor, resulting in birth. The signal for the onset of labor is a fetal hormone, cortisol. Cortisol crosses the placenta to the maternal blood, where it causes the synthesis of another prostaglandin. The strongest support for this conclusion comes from experiments in which the adrenal glands were removed from fetal goats; the result of such in utero surgery is significantly delayed parturition (birth). This uterine prostaglandin intensifies the uterine contractions to initiate labor and thus parturition.

Following birth, the suckling of the infant at the mother's mammary glands stimulates the release of the posterior pituitary hormone oxytocin. Oxytocin stimulates contraction of muscles in the mammary glands to eject milk. Oxytocin also stimulates uterine contraction to pass the placenta (afterbirth) through the vagina. Prolactin, which stimulates mammary development during pregnancy, has nothing to do with milk ejection during lactation. Prolactin is also present in lower vertebrates that lack mammary glands. In fish, prolaction stimulates sodium conservation. In amphibians, prolactin decreases skin water permeability and increases sodium uptake across the skin. In some salamanders, prolactin initiates "water drive," which is the migration of adults back to water for reproduction. In pigeons and similar birds, prolactin stimulates the production of crop-sac milk, which the mother regurgitates to feed her young; a process remarkably similar, in effect, to lactation.

directly to blood calcium concentrations. When calcium levels are low, parathyroid hormone (PTH) is secreted into the blood to stimulate three centers. In bone, PTH mobilizes calcium to elevate blood levels of this ion. Because mobilization of bone also elevates phosphate, which can be toxic at high concentrations, the kidneys become important. PTH stimulates the kidneys to increase calcium conservation and potassium excretion. PTH also stimulates uptake of calcium in the small intestine. Vitamin D enhances the action of PTH. Working antagonistically to PTH, calcitonin, produced in the thyroid gland, responds directly to high blood calcium to move this ion into bone.

Digestive Hormones

The digestion and assimilation of food are also controlled by hormones. In meat-eating animals, beginning in the stomach, stretch and the presence of protein stimulate the secretion of gastrin into blood vessels in the wall of the stomach. This gastrin stimulates the secretion of hydrochloric acid into the lumen of the stomach to digest protein. When the partially digested food enters the small intestine for the completion of digestion and assimilation, a slightly alkaline pH is required. The walls of the small intestine detect the acidity and secrete another pair of hormones into blood vessels. Secretin travels to the pancreas and stimulates sodium bicarbonate secretion. The sodium bicarbonate travels through the common bile duct to the small intestine, where it neutralizes the acid. Gastric inhibitory polypeptide travels to the stomach to inhibit acid secretion and stomach contractions. Another peptide, cholecystokinin-pancreozymin (CCKPZ), responds to fats and proteins in the small intestine and is thus secreted into the blood. This hormone travels to the gallbladder, causing it to contract and release its bile through the common bile duct to aid digestion of fats in the small intestine. CCKPZ also stimulates secretion of a whole host of enzymes by the pancreas. These enzymes also move through the common bile duct to the small intestine to aid in the digestion of carbohydrates, fats, and protein. At least two other digestive hormones have been discovered that are not well understood at present. Motilin is secreted by the small intestine and stimulates stomach muscle contractions. Vasoactive intestinal polypeptide also is secreted by the small intestine and it, in turn, stimulates sodium bicarbonate secretion by the walls of the small intestine. Both hormones are of obvious benefit, but key details of their function, such as what triggers their secretion, are not clearly understood. It is important to realize that all of the hormones of the stomach and small intestine are secreted into the blood vessels in the walls of the organs, not into their lumens.

Reproductive Hormones

The two pituitary hormones that are involved in reproduction are called the gonadotropins, FSH and LH. These hormones are identical in males and females. The gonadal hormones differ between the two sexes. Females produce estrogens and progesterone in their ovaries. Males produce androgens (primarily testosterone) in the testes.

The mammalian menstrual cycle has two components. Both the ovarian cycle and the uterine cycle proceed simultaneously and last approximately four days in rats, sixteen days in sheep, and twenty-eight days in humans. The length and pattern of the cycle vary with species. For the sake of comparison, the human cycle is described here. The first five days of each cycle is called the menstrual period, and during this period the built-up walls of the uterus (resulting from the previous cycle) are shed and discharged through the vagina. At this time the concentrations of FSH and LH in the blood are about the same. From the close of the menstrual period until ovulation is the follicular cycle. FSH stimulates the ovaries to begin the growth and maturation of an egg-containing follicle. This follicle produces estrogen. Estrogen feeds back negatively on FSH, causing its levels in the blood to drop. At the same time, estrogen is feeding back positively on LH, causing its levels to rise.

At the midpoint of the ovarian cycle, LH peaks and causes the now mature follicle to burst and eject an egg (ovum) into the oviduct. The ruptured follicle now becomes a corpus luteum and continues to secrete estrogen, but also begins to secrete progesterone. The estrogen, and now the progesterone, stimulate the walls of the uterus to thicken and produce glandular tubes and blood vessels. This goes on for the final half of the cycle, which is called the follicular phase in the ovaries and the proliferative phase in the uterus. If fertilization of the ovum in the oviduct fails to occur during this period, a hormone, probably a prostaglandin, builds up in the corpus luteum, causing it to stop producing estrogen and progesterone. With the loss of these two steroids, the thickened wall of the uterus is shed and the menses flows during the first five days of the next cycle.

Male reproductive endocrinology is much different. The first striking difference is that, although the pituitary hormones FSH and LH are the same, the patterns of secretion are different. Instead of the cyclic peaks found in females, males secrete constant levels of gonadotrophins. FSH stimulates sperm production and maturation in the seminiferous tubules of the testes. LH stimulates testosterone secretion by the interstitial cells of the testes. Testosterone helps FSH to stimulate sperm maturation. This androgen also stimulates such primary sex characteristics as penis and epididymal growth during puberty. The epididymis is a tubular structure that stores sperm in preparation for ejaculation. Testosterone also stimulates secondary sex characters, such as the deepening of the voice and development of muscle mass that manifest during puberty in humans.

ENDOSKELETONS

Type of animal science: Anatomy
Fields of study: Biochemistry, developmental biology

Endoskeletons are a distinctive primary feature of most of the members of the phylum Chordata. Their evolution eventually provided vertebrates with many advantages over invertebrate animals. Study of the various types of tissues that make up endoskeletons is important to the study of both medicine and evolution.

Principal Terms

APPENDICULAR SKELETON: one of two main divisions of vertebrate skeletal systems, composed of the bones of the pelvic girdle, the shoulders, and the limbs

AXIAL SKELETON: the other main division of vertebrate skeletal systems, made up of the bones of the skull, the vertebral column, the ribs, and the sternum

CANCELLOUS BONE: spongy bone that is composed of an open, interlacing framework of bony tissue oriented to provide maximum strength in response to normal strains and stresses

CARTILAGE: a soft, pliable typically deep-lying tissue that constitutes the endoskeletons of primitive vertebrates, such as sharks, as well as the embryonic skeletons and jointing structures of adult higher vertebrates

COMPACT BONE: a dense type of bone, often termed lamellar bone, formed of a calcified bone matrix having a concentric ring organization

HAVERSIAN SYSTEMS: narrow tubes surrounded by rings of bone, called lamellae, that are found within compact bones of animals having endoskeletons; the tubes contain blood vessels and bone

OSTEOBLAST: a bone-secreting cell found in vertebrates, that is instrumental in the process of ossification

The study of endoskeletons can be approached in three basic ways. First, endoskeletons can be approached as gross structures—that is, as primarily mechanical or architectural systems. Second, they can be viewed as types of tissue—bone and cartilage—which involves study at the microscopic level. Third, endoskeletons can be considered products of the evolution of the endoskeletal organism. This area examines such factors as the organisms' development from protochordates and the intrinsic biological advantages of the endoskeleton over the exoskeleton.

The Development of Endoskeletons

The evolution of vertebrate animals, such as fishes, reptiles, and mammals, having articulating endoskeletons represents a biological quantum leap forward for the phylum Chordata. The development of endoskeletons permitted several significant structural advantages that allowed the higher chordates to compete successfully with invertebrates and eventually to become dominant in many varied ecosystems.

The evolution of endoskeletons allowed a greater degree of general body efficiency and organization. Coupled with a great increase in the rapidity, power, and control of movement with which endoskeletons and their improved musculature endowed their possessors, endoskeletons allowed vertebrates to become the highest and fastest flyers, the swiftest runners and swimmers, and the widest ranging of animals. The organizational plan of the endoskeleton of the more highly evolved vertebrates is exemplified by that of mammals. The mammalian endoskeleton is articulated in many ways, giving it a great degree of flexibility and great range of movement. Cartilaginous joints facilitate the articulations. The endoskeleton itself is typically made of bone material composed of calcium phosphate. Other than the endoskeleton proper, minor externalizations can take the form of fingernails and toenails, claws, hooves, antlers, and horn cores, as well as teeth. In these cases, materials other than bone can sometimes originate at or near the body surface or in the skin. These expressions can be present in the form of scales or plates, though this is the exception rather than the rule among this vertebrate class. All these external expressions can be considered, in a way, forms of a limited exoskeleton.

Axial and Appendicular Skeletons

Aside from such exceptions as pangolins and armadillos among mammals, and turtles and tortoises among reptiles, exoskeletal tissue does not usually constitute an architectural structure that the animal's other organs or structures depend on for support or protection. The one exception among the various bones of the vertebrate endoskeleton is the bones of the cranium, or skull. The cranial bones are a group of hard, thick bones, usually ovoid or spheroidal in general geometry, that offer extensive protection to the brain and primary sensory organs, such as the eyes and ears. The cranium is such a universal feature among vertebrates that the subphylum is sometimes referred to as the craniates. Evolutionarily lower vertebrates tend to have larger numbers of skull bones. Some fish have as many as 180 skull bones. Higher taxonomic groups have inversely lower numbers of skull bones: Amphibians and reptiles possess between fifty and ninety-five, while mammals have thirty-five or fewer. The skull itself is a member of two fundamental divisions between which the entire endoskeleton is usually subdivided; it is part of the axial skeleton. The axial skeleton also includes the bones of the vertebral system, the ribs, and the sternum. Possession of all axial features is not universal. Some vertebrates, such as the leopard frog, do not possess ribs, while others, such as the snakes, do not have sternums.

The other endoskeletal subdivision is called the appendicular skeleton, and it is made up of the bones of the pelvic girdle, shoulders, and limbs. The components of the appendicular system exhibit a great degree of variation from vertebrate group to vertebrate group and even among species, as do those of the axial system, and reflect the many different environments and lifestyles to which their respective possessors have adapted. A case in point is the numerous variations in form and length found among limb bones. The various lengths represent adaptations to such external environmental factors as the medium through which the animals move from place to place (air, water, ground surface, and subsurface) and speed. The lower and upper limb bones themselves are connected by joints. The jointing arrangements of limb bones are highly efficient mechanical developments. Two basic types of limb joint exist: the pulley joint and the ball-and-socket joint. Pulley joints are exemplified by finger and toe joints and represent great freedom of motion in one plane. Ball-and-socket joints are exemplified by shoulder or hip joints and represent freedom of universal motion. Still another joint type is a cross between these two. Such a combination of pulley and ball joints is exemplified by the elbow joint in humans.

Histology

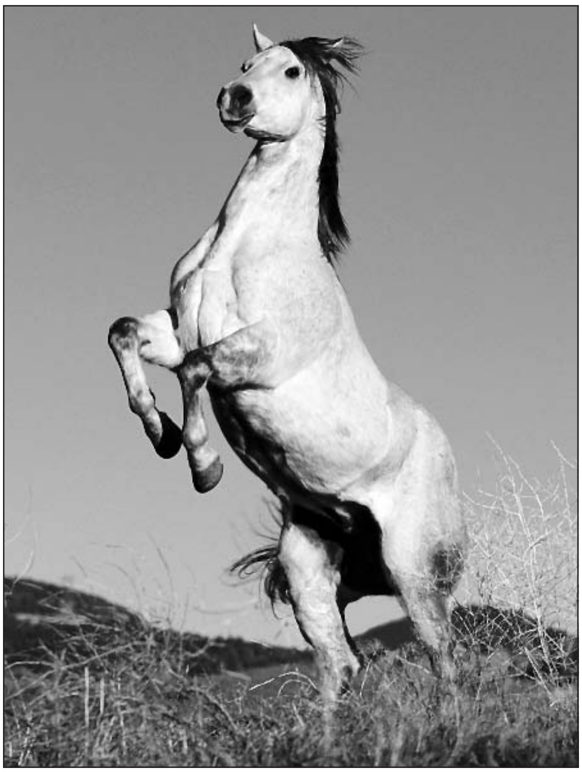
Another major approach to the study of the endoskeleton is its histology, or the fine details of tissues and how these tissues develop. Bone material itself is active metabolically—that is to say, it is alive. It can be considered not only an architecture along which the vertebrate body is arranged but also a complex and specialized connective tissue. As an organic material, it possesses a number of unique properties that are derived from the fact that it has evolved to perform its various duties efficiently for the size, weight, and arrangement of the materials of which it is composed. It is engineered like structurally reinforced concrete, having fibers of collagen, a tough, fibrous binding protein that is analagous to the function of steel rods.

The mineral calcium is analogous to the concrete in a building. Bone is formed in two different ways, depending on type. One process involves a means of growth of two bone types, termed lamellar bone (compact bone) and cancellous bone (spongy bone). Lamellar bone, sometimes also called membrane bone, develops through the process of ossification when certain cells called osteoblasts become bone-secreting. The osteoblastic cells, in association with numerous fibers of connective tissue cells, form a network in which layers of calcium mineral salts, called lamellae, are deposited. This network slowly builds up a plate that expands along its margins. As the plate thickens, some osteoblasts remain alive and are incorporated into the bone growth. At this point, they begin to have irregular shapes and are termed osteocytes. Spaces in which the osteocytes are sited are termed lacunae (cavities) and develop long, omnidirectional, branching processes, termed canaliculi. Neighboring canaliculi eventually link up and create a network through which life-supporting blood containing oxygen and food can reach the growing bone tissue. The canaliculi system grows such that no bone cell is more than 0.1 millimeter from a blood-carrying capillary. This overall arrangement is termed a Haversian system.

Cartilage tissue is another endoskeletal material that forms the adult skeletons of higher vertebrates, such as mammals, when they are still in early developmental stages. In mammals, this type of tissue is not formed directly, but rather by a replacement process. In mammalian embryos, most of the skeletal structure is initially laid down in the form of cartilage and then subsequently replaced by true bone. The process does not reach completion in the higher vertebrates until the animal is full-grown; in humans, this is as late as twenty-five or twenty-six years of age. Cartilage is not as hard or rigid as bone, but it is extremely tough and is resistant to forces of compression or extension. Under microscopic examination, it appears as a clear matrix which possesses numerous, embedded cells termed chondroblasts. These chondroblasts lie in fluid-filled voids termed lacunae. Chondroblasts secrete the matrix called chondrin, which surrounds the lacunae. Both the chondrin and the fluids act in an elastic manner and are resistant to compression and external shocks. Various types of cartilage have collagen fibers. The amounts of collagen fiber present determine the amount of extension that the cartilage can resist. The total effect of the cartilage's unique composition is to render it a good skeletal material for young, rapidly developing, vulnerable animals, such as mammal embryos.

Vertebrate Evolution

The last basic approach to the study of endoskeletons is that of examining the evolutionary development of the phylum Chordata in general and the subphylum of vertebrates in particular. The earliest history of the chordates is only very sketchily understood; the remains of early, ances-



Endoskeletons provide the interior support and locus for muscle attachment, allowing vertebrates a wide range of motion. (Corbis) tral forms of this group made poor candidates for the fossilization process because they lacked hard body parts. A line of hypothesized evolution, therefore, has been drawn through surviving marine animals called protochordates, which presently are sessile or stationary for most of their life cycles, although before attaining this current form, they were capable of locomotion. These curious animals are considered invertebrate chordates as they possess notochords, or flexible skeletal rods that run up the long axes of their bodies. Among this group are such animals as the amphioxus and the so-called sea squirts or tunicates.

Further evolved along the path that eventually led to the present diversity of endoskeleton-possessing vertebrates are animals possessing bone matter, such as the agnathan (jawless) fishes. Later fishes evolved jaws and eventually true teeth and progressed from having cartilaginous skeletons (the class Chondrichthyes) to having true, bony endoskeletons (the class Osteichthyes). These more advanced fishes eventually gave rise to the land-pioneering class Amphibia and ultimately engendered the vertebrate classes of Reptilia (reptiles), Aves (birds), and Mammalia. The reason that bone tissue evolved at all in the lower vertebrates is a subject that is still open to debate. Several rival theories exist; one holds that bone evolved simply as a more improved, harder material for exoskeletons superior to such material as calcium carbonate, the most common building material for invertebrate exoskeletons. Another suggests that bone evolved as a phosphate reserve as one component for energy storage and transfer for metabolic processes within the bodies of ancestral vertebrates. Still another theory postulates that bone materials such as dentine and enamel evolved originally simply as effective insulation for the electrosensory organs found in primitive, marine vertebrates. Other theories integrate versions of the theories above in complex, interactive arrangements.

Endoskeletal Research

Histological research of endoskeletal tissues has in the past been the most productive approach to obtaining the large body of data on bone tissues and processes that currently exists. The majority of the data accumulated with this approach has been gained in the laboratory and has involved specialized equipment and the use of techniques tailored to produce useful information on bone cells, their composition, related tissues, and the various organic processes involved. These techniques and laboratory tools and appliances were developed laboriously over the centuries. Real progress in the field had to wait until the advent of the simple microscope. Believed to be invented by the Dutch scientist Antoni van Leeuwenhoek or one of his contemporaries in the seventeenth century, the simple optical microscope—utilizing only one lens—allowed the first close-up look at living structures at or near the cellular level. Examination of Leeuwenhoek's original equipment has revealed that he was able to obtain the respectable magnification of as much as 250 times. His lenses thus allowed humans an entry into a world that had hitherto been barred to them: the world of the very small. Subsequent development in microscopes produced compound optical microscopes with several lenses working in series and an eventual exponential increase in magnifying power. Biologists quickly recognized that the new tool underscored the relation between structure and function of organic materials at the microscopic level. It is this critical concept that has been the key to unlocking the many secrets of the organic microstructures of living things, among them endoskeletons.

Hand in hand with the development of research using optical microscopes has been the preparation of histological sections. These are extremely thin, transparent shavings of organic tissues prepared in such a way as to facilitate microscopic examination. With the increased sophistication of the use of microscopy has come the perfected use of many different types of staining and dying. The use of stains and dyes has been selectively employed to highlight the different types of tissue being observed. A further refinement in microscopy has been the use of various lens filters, such as polarizing filters, that have added control of the light target to emphasize or de-emphasize various features.

Late Twentieth Century Advances

After the advent of applied nuclear physics during World War II, a new technique called autoradiography appeared; this enhanced the resources available to histological research. Autoradiography involves the introduction of radioactive substances into animals; consequently, these substances are incorporated into various tissue components. The great advantage to this technique is that it can provide direct information on how long it takes for the various tissue components to be synthesized and on how long they last.

As the spectrum of isotopic labels expanded and became refined, it became possible to label and study in great detail almost every common tissue component found in animals. The study of the most intricate or delicate endoskeletal tissues thus became realistic along with the added advantage of being able to determine the durations of the metabolic processes involved in development, decay, and replacement.

A solution to the magnification limitation of the light microscope was reached when the first electron microscope (EM) was built in 1931. Further improvements were made until the 1950's saw the widespread use of more technologically advanced devices called scanning electron microscopes (SEMs), which allow observation and SEM photography, termed electron micrography, of target objects considerably less than 1 micron in diameter.

Still newer technologies, such as the use of fiber-optic probes inserted into the living bodies of animals and humans, allow benign observation of tissues in their natural state in the midst of normal processes. Fiber optics involves the transmission of light (and therefore images) through very fine, flexible glass rods by internal reflection. Fiber-optic instruments called fiberscopes allow the viewing of extremely small, and normally dark, internal structures such as skeletal tissues.

ESTIVATION

Types of animal science: Behavior, ecology, physiology
Fields of study: Ecology, herpetology, invertebrate biology, physiology, wildlife ecology

Estivation, like hibernation, is a dormant state that enhances an animal's ability to survive when environmental conditions are harsh. In hot, arid climates, estivating animals reduce water losses and energy requirements during long periods of drought when little water or food is available.

Principal Terms

EPIPHRAGM: covering or sealing membrane
HYGROSCOPIC: able to retain moisture
NEMATODE: a long, cylindrical worm; some are parasitic
POIKILOTHERM: cold-blooded or ectothermic; any organism having a body temperature that varies with its surroundings; in general, reptiles, amphibians, fish, and invertebrates
TORPID: dormant, numb, sluggish in action

During true estivation, metabolic processes including oxygen consumption, respiration, heart rate, and neurological activity decrease substantially, but the term is often used loosely to describe the activity of any animal that spends part of the warmer, drier season in a torpid state. Except for the environmental stimuli that trigger them, estivation and hibernation appear similar, although they differ physiologically, and occur most often in the poikilotherms. Among the animals most likely to estivate are mollusks, arthropods, fish, amphibians, and reptiles, although some small desert mammals estivate as well.

Invertebrate Estivation

A seemingly lifeless desert may be teeming with estivating life underground, waiting for seasonal rains that will awaken them to resume their life cycles. Snails, slugs, earthworms, insects, spiders, and nematodes, along with cocoons, eggs, grubs, larvae, and pupae, may all lie dormant in the soil, in building foundations and rock crevices, or under rotting logs or other vegetation. The animals are not just dormant; some of them will also be in an arrested state of sexual development called diapause. Some tropical snails can estivate for years at a time. To prepare, a snail digs a deep burrow in moist ground or under rocks. Next, it forms an epiphragm (a sealing membrane for the shell) to prevent evaporation and desiccation. Finally, its metabolism slows dramatically until it detects favorable environmental cues such as increased moisture.

Lungfish Estivation

Among the fishes, the process of estivation is best known in the air-breathing lungfishes of Africa (*Protopterus*) and South America (*Lepidosiren*). Adult fish have paired lungs and vestigial gills; in fact, they will drown if held underwater. Both abilities—to estivate and to breathe air—have contributed to their survival in areas that experience severe seasonal droughts. When the rivers, lakes, and marshes they inhabit dry up, lungfish dig burrows deep in the mud, leaving air passages to the surface. They curl up inside and wait out the arid conditions until rain fills up their burrows with water. *Protopterus* secretes a mucous coating that hardens, forming a tough, cocoonlike hygroscopic chamber with only one opening, connected to its mouth. When the rains come and flood the passage, the dormant fish awakens with a cough. *Lepidosiren* burrows more deeply than *Protopterus* and plugs the entrance to its air tube with perfo-

Image Not Available

rated clay. Its burrow is somewhat larger and usually contains some water. It coats the walls with a jellylike substance to maintain moisture. During estivation, lungfish are so torpid that they make easy prey for local fisherman, who spear them in their burrows.

During estivation, energy required for reduced metabolism is provided by the breakdown of tissue protein. The waste product is urea, which is excreted in large amounts once the fish is again submerged in water. Lack of oxygen can become a problem for lungfish sealed in their burrows, but the aerobic metabolism of an estivating *Protopterus* is only 20 percent of its normal resting metabolism. Similarly, *Lepidosiren* and the swamp eel (*Synbranchus*) can survive a lack of oxygen for long periods during estivation.

Estivation in Reptiles and Amphibians

During the summer, many reptiles and amphibians estivate. Some frogs and toads insulate themselves in cocoons composed of many layers of unshed skin. The eastern spadefoot toad digs backward into sandy soil with its spade-shaped hind feet to estivate for periods of weeks; experiments indicate that the sound of rain falling rather than moisture itself may trigger the toad's arousal. The mud turtle *Kinosternon* abandons its drying pond for a burrow where it estivates up to three months. Desert tortoises of the North American Southwest spend much of their summers estivating in burrows but emerge to drink and browse after infrequent thunderstorms. In the same region, the lizard called the chuckwalla stops eating and estivates in rock crevices, emerging every third day for about an hour at sunset.

Estivation in Mammals and Birds

Among the few estivating mammals are small desert rodents, lemurs, and hedgehogs. Some ground squirrels remain dormant in their burrows from late summer, merging estivation with hibernation. They reappear in early spring to take advantage of new growth after winter rains. The round-tailed ground squirrel of southern Arizona (*Citellus tereticaudus*) avoids the hot, dry autumn by disappearing in August and September. Generally, the period of estivation coincides with the period most prone to scarcity of vegetation.

While a few birds may hibernate, it is unlikely that they estivate. They can migrate to more attractive regions, or, like many reptiles and most mammals, they cope with high temperatures by confining their activities to cooler parts of the day.

ESTRUS

Types of animal science: Behavior, physiology, reproduction
Fields of study: Anthropology, ethology, reproduction science

Estrus is the recurring period of sexual excitement and receptivity in female mammals. A central feature of most mammalian species' reproductive lives, it helps structure social and communicative behavior as well.

Principal Terms

COPULATION: mating; the insertion of the male's penis into the female's vagina to fertilize her ova

ESTROGENS: a group of female sex hormones which regulate the estrous cycle

ESTRUS CYCLE: the cycle of females' bodily changes related to reproductive potential

OVA: eggs released from the females' ovaries at the height of estrus

PROGESTERONE: a female sex hormone produced chiefly in the latter half of the cycle

The physiological and behavioral events which make up estrus are complex and intertwined. For successful mating to occur, it is usually necessary that male and female cooperate in the act. Estrus ensures that both sexes are impelled to do so at the same time, when the female's body is ready for a pregnancy.

During the days prior to estrus, ova in follicles ripen rapidly within the ovary. Estrogens, produced by cells in the follicle walls, increase rapidly in this phase, causing not only follicular growth but thickening of the vagina walls and the various signs of "coming into heat," and then of estrus itself. In most species, the ova spontaneously burst from their follicles at the peak of estrus and enter the oviduct, which leads to the uterus, ready to join with sperm. Females of several species, however, including the rabbit and the cat, require the added stimulus of mating for release of their ova. Once the ova are released, the ruptured follicles begin secreting progesterone in place of estrogen; this hormone prepares the uterus to support a pregnancy. This internal process is regulated through feedback connections between the ovaries and the hypothalamus in the brain. The hormonal effects which make females eager for mating also originate largely in the hypothalamus, sensitizing the nervous system to respond strongly to the presence of and stimulation by their male counterparts.

Variations Between and Within Species

External estrus signals vary greatly by species. In every case, they are largely produced by hormonal influences, and are keyed to evoke specific sexual response from the male of the species. Such signals may be visual, behavioral, auditory, or scent-based, or may possibly draw on senses imperceptible to human observers.

Visual signals are often found among social mammals. These have been most observed in primates. Chimpanzee and bonobo females show a spectacular pink swelling of their genitals during estrus, which recurs every five weeks if pregnancy does not occur. Certain monkeys develop an estrus flush on their faces as well as their buttocks.

Scent and sound signals can alert males who are not initially within sight range of the receptive female. As such, they are effective for species who do not live in groups, although these signals are not confined to such species. Urine markings are among the most common scent signals. A female black rhino in estrus leaves a long trail of scent posts, which the male follows. Other scent signals are partly airborne, like those of domestic cats and dogs. Mating calls are given by many females, such as the female gibbon's ascending call, which is then answered by the male.

Behavioral changes during estrus are almost universal, as both sexes concentrate on the quest for one or several partners. The initial stages, which may suggest female coyness to an observer, are part of the courtship process. For example, the female cheetah leads several males on a headlong run across the plain, finally selecting one with whom to mate. Pet owners notice a restlessness in their dogs and cats; female cats in heat are especially likely to roam. The penultimate female signal in many species is lordosis, an arched-back posture which allows the male to mount. Mammalian species are normally either monestrous—having a single estrus period a year—or polyestrous—with several estrus periods recurring annually. The latter situation is more common.

Environmental changes can cause variations in these patterns. Such factors include climate shifts, changes in available light, nutrition, and the presence of a new male. In monestrous mammals, the estrus period usually falls at a time when resulting births will take place in the optimal season for young animals to thrive and grow. Domestication may disrupt this pattern. For instance, a female dog typically comes into heat twice a year with no regard to seasons. Her ancestor the wolf has one estrus period a year, sometime between January and April, depending upon latitude.

The length of estrus also varies by species: It lasts four to nine days in the mare, and only fourteen hours in the rat. In a few species, such as the ferret, estrus lasts for several weeks if copulation has not occurred. There are also infrequent phenomena such as "silent heats," in which the animal ovulates but the usual external signs are absent.

Estrus, Evolution, and Ethology

Sexual reproduction provides genetic diversity and adaptability to a species. However, in order to proceed successfully, it requires a fairly complex series of events. Estrus is central in this process. It communicates to males a female's readiness at the same time that it impels that female to mate and primes her body for pregnancy. Nature plays many

The Northern Fur Seal

Estrus behavior has seldom been studied closely by biologists. More often it has been a practical concern of livestock breeders and pet owners, or subsumed in general studies of reproductive behavior. However, as part of a study of the northern fur seal, Roger L. Gentry and colleagues made detailed observations on estrous females over a six-year span.

Like many animals, the seals have a definite seasonal breeding time, typically July 7 through 14 of each year. Females come ashore and huddle in large groups on breeding beaches, where mating occurs. The seals' known sex ratio is sharply skewed, with forty or more females to each male. The male in the territory works his way through the group, mating with many females as each one reaches the peak of her receptivity. This arrangement is efficient for both sexes.

Several unusual species-specific features were discovered by Gentry's study. Fur seals go into estrus only five days after giving birth. Any resulting pregnancy enters an embryonic diapause, or delayed implantation, until the newborn seal is weaned the following fall. The actual period when female seals are receptive is brief, usually only twenty-four hours.

Unlike many other female animals, who choose mates based on status, appearance, or other traits, fur seal females seem indifferent to which male they mate with. Some are almost comatose by the time copulation occurs. Gentry concludes that female choice cannot be an evolutionary factor in this species; males are selected for reproduction solely by direct competition among themselves. The pattern seems to be an optimum one, though, for a species which spends most of its time at sea without opportunity to mate.

The Human Puzzle

Humans are unusual, but not unique, among mammals in lacking a perceptible estrus period. Did humans, or their hominid ancestors, once have estrus and lose it? Is this absence just another oddity in the amazingly wide spectrum of mammalian reproductive traits? The fossil record gives no clues, nor are they likely to be found in the future.

This silence has not kept anthropologists, ethologists, and others from speculating. The prevailing theory until the 1980's asserted that loss of estrus was essential to becoming human, because only a female's continuous sexual availability secures a monogamous pair bond and keeps the male from wandering away.

This theory has many problems. Monogamous pair bonding now appears to be a "hard-wired" trait in some species, unrelated to continual sexual contact. The bonobo, and to some extent other primate species, copulate even when the female is not in heat. Humans (and presumably their primate ancestors) are innately social animals. Without group backup, a lone prehistoric or hominid hunter would not fare well. Loss of estrus would also seem to have disruptive social possibilities. Rape, fetish obsessions because males have no instinctual guide to what is sexy, and a double standard denying that females have sexual desires—all are made possible by the lack of clear female signals.

Anthropologist Sarah Hrdy suggests that the human pattern may simply resemble that of species such as orangutans, who show no visible estrus signals. Study subjects ranging from Connecticut college women to Kalahari hunter-gatherers have reported peaks of female sexual interest around their time of ovulation.

If hominid or prehistoric human females did have full estrus, what was the evolutionary advantage or mechanism of its loss? The subject is one of those puzzles unlikely to be solved, but fascinating to speculate about.

variations on this basic theme, each connecting the species' estrous cycle to its environment and its whole life cycle.

Because the survival of young mammals requires maternal care, and often that of the father and/or other adult animals as well, estrus patterns are significant for social structure. In some species, estrus may help secure a pair bond, a polygynous herd, or bonds within a troupe or pack. It can also cause disruption, as when males battle for access to estrous females, or a new male takes over a harem and kills the young, hastening their mothers' next heat.

Humans have known of estrus ever since they first domesticated animals. Charles Darwin's *On the Origin of Species* (1859) credits estrous females' mate choices with being an evolutionary mechanism, giving many examples. Ethologists' field studies have recently described many details about species-specific estrus behavior, as well as its role in life cycles and social behavior.

However, direct estrus observations are hard to make and sometimes hard to interpret, especially in wildlife.

ETHOLOGY

Type of animal science: Ethology
Fields of study: Genetics, neurobiology

Ethology is the study of animal behavior from the perspective of zoology. The information acquired through ethology has helped scientists better understand animals in all their variety.

Principal Terms

ADAPTATION: a structure, physiological process, or behavioral pattern that gives an organism a better chance of surviving and of reproducing

BEHAVIORAL ECOLOGY: the systematic study of the strategies animals use to overcome environmental problems and the adaptive value of those strategies

BEHAVIORISM: the school of psychology that focuses on the investigation of overt behaviors and rejects allusion to inner processes as a means of explaining behavior

COMPARATIVE PSYCHOLOGY: the branch of psychology that uses comparative studies of animals as a means of investigating phenomena such as learning and development

EVOLUTIONARILY STABLE STRATEGY: a behavioral strategy that will persist in a population because alternative strategies, in the context of that population, will be less successful

IMPRINTING: a specialized form of learning characterized by a sensitive period in which an association with an object is formed

SOCIOBIOLOGY: the scientific discipline that examines social behavior in the context of evolutionary theory

Ethology is the branch of zoology that investigates the behavior of animals. Behavior may be defined as all the observable responses an animal makes to internal or external stimuli. Responses may be either movements or secretions; however, the study of behavior is much more than a descriptive account of what an animal does in response to particular stimuli. The ethologist is interested in the how and why questions about the behaviors observed. Answering such questions requires an understanding of the physiology and ecology of the species studied. Those who study animal behavior are also interested in the ultimate or evolutionary factors affecting behavior.

The Roots of Ethology

Ethology is a young science, yet it is also a science with a long history. Prior to the late nineteenth century, naturalists had accumulated an abundance of information about the behavior of animals. This knowledge, although interesting, lacked a theoretical framework. In 1859, Charles Darwin published *On the Origin of Species*, and with it provided a perspective for the scientific study of behavior. Behavior was more central to two of Darwin's later books, *The Descent of Man* (1871) and *Expression of the Emotions of Man and Animals* (1873). By 1973, the science of ethology was sufficiently well developed to be acknowledged by the presentation of the Nobel Prize for Physiology or Medicine to Nikolaas Tinbergen, Konrad Lorenz, and Karl von Frisch for their contributions to the study of behavior. The work of these men was central to the development of modern ethology.

The experimental studies of Frisch revealed the dance language of the honeybee and ways in which the sensory perception of the bees differed from our own sensory world. An awareness of species-specific sensory abilities has provided an important research area and has emphasized a factor that must be considered in the experimental design and interpretation of many types of behavioral research.

Tinbergen studied behavior in a variety of vertebrate and invertebrate organisms. He was good both at observation of animals in their natural habitat and in the design of simple but elegant experiments. His 1951 book, *The Study of Instinct*, is a classic synthesis of the knowledge that had been gained through the scientific study of animal behavior at that time.

Konrad Lorenz is considered by many to be the founder of ethology, because he discovered and effectively publicized many of the classic phenomena of ethology. Pictures of Lorenz being followed by goslings are almost a standard feature of texts that discuss the specialized form of learning known as imprinting. In natural settings, imprinting allows young animals to identify their parents appropriately. Another contribution of Lorenz was his book *King Solomon's Ring: New Light on Animal Ways*, published in 1952. This extremely readable book raised public awareness of the scientific study of animal behavior and kindled the interest of many who eventually joined the ranks of ethologists.

Ethology and Neurobiology

Many of the features of ethological research characteristic of the work of Lorenz, Tinbergen, and von Frisch have continued to be characteristic of the field. They were concerned that the behavior of animals be understood in the context of the species' natural habitat and that both proximate and ultimate levels of explanation would be examined. Their research strategies have been supplemented by an increase in laboratory-based research and by the introduction of new types of experimental design. These developments have softened the distinctions between ethology and another field of behavioral study, comparative psychology. The focus of comparative psychology is comparative studies of the behavior of nonhuman animals. Initially, questions about learning and development were the major problems investigated in comparative psychology. Although the animals most frequently studied were primates and rodents, those doing the research were interested in gaining insight into the behavior of humans. Comparative psychology was long dominated by behaviorism, a school of thought that assumes that the ultimate basis of behavior is learning. The behaviorists employed rigorous experimental methods. Because such methods require carefully controlled conditions, behavioral research is typically laboratory based, and animals are therefore tested in surroundings remote from their natural environments. Over time, comparative psychology has broadened both the questions it asks and the organisms it studies. The boundaries between comparative psychology and ethology have been further blurred by the rising number of scientists crossing disciplinary lines in their research. Each discipline has learned from the other, and both have also profited from knowledge introduced through neurobiology and behavioral genetics.

Neurobiology investigates the structure and function of the nervous system. One area of ethology that has been directly enriched through neurobiology is the study of sensory perception in animals. The techniques developed in neurobiology allow the investigator to record the response of many individual neurons simultaneously. The neurobiologist examines phenomena such as stimulus filtering at the level of the cell. Stimulus filtering refers to the ability of nerve cells to be selective in their response to stimuli. For example, moths are highly sensitive to sounds in the pitch range of sounds made by the bats that are their chief predators. Neurobiology provides a powerful tool for understanding behavior at the proximate level.

Behavioral Genetics

Another source of information for the ethologist is behavioral genetics. Because of the evolutionary context of ethology, it is important to have an understanding of the genetic basis of behavior. If there were no genetic component in behavior, behavior would not be subject to natural selection. (Natural selection refers to the process by which some genes increase in frequency in a population while alternates decrease because the favored genes have contributed to the reproductive success of those organisms that have them.) While the ethological approach to behavior assumes that behavior patterns are the result of interactions between genes and environment, investigators often ask questions about the genetic programming of behavior.

Early ethologists performed isolation and cross-fostering experiments to discover whether behaviors are learned or instinctive. If a behavior appears in an individual that has been reared in isolation without the opportunity to learn, the behavior is considered instinctive. Observing the behavior of an individual reared by parents of a different species is similarly revealing. When behavior patterns of conspecifics appear in such cross-fostered individuals, such behaviors are regarded as instinctive. Instinctive behaviors typically are innate behaviors that are important for survival. For example, one very common instinctive behavior is the begging call of a newly hatched bird. Isolation and cross-fostering experiments are still a part of the experimental repertoire of ethologists, but behavioral genetics permits the asking of more complex questions. For example, a behavior may accurately be labeled instinctive, but it is more revealing to determine the developmental and physiological processes linking a gene or genes to the instinctive behavior.

The ethologist is also interested in determining whether behavior is adaptive. It is not sufficient to identify what seems to be a commonsense advantage of the behavior. It is important to show that the behavior does in fact contribute to reproductive success in those that practice the behavior and that the reasons the behavior is adaptive are those that are hypothesized. When behaviors are tested, they frequently do turn out to be adaptive in the ways hypothesized. This type of research, however, has provided many surprises. Research on the adaptive value of behaviors in coping with environmental problems that affect reproductive success is known as behavioral ecology; this is a major area of modern ethology.

Behavioral ecology addresses a variety of questions, in part because the process of evolution is opportunistic. For any environmental problem there are alternate solutions, and the solution a particular species adopts is dependent upon the possibilities inherent in its genes. Questions addressed include such things as whether a species is using the optimum strategy or how a species benefits from living in a group. Because alternate strategies are possible even within a species, behavioral ecologists are interested in evolutionarily stable strategies. An evolutionarily stable strategy is a set of behavioral rules that, when used by a particular proportion of a population, cannot be replaced by any alternative strategy. For example, the sex ratio present in a particular population will determine the optimum sex ratio for the offspring of any individual.

Sociobiology

Sociobiology is another major area of modern ethology. Sociobiology examines animal social behavior within the framework of evolution. Animal species vary in the degree of social behavior they exhibit; other variables include group size and the amount of coordination of activities occurring within the group. The sociobiologist is interested in a number of questions, but prominent among them are the reasons for grouping. Hypotheses such as defense against predators or facilitation of reproduction can be tested. The particular advantage or advantages gained by grouping varies among species. Two important concepts in sociobiology are kin selection and inclusive fitness.

Kin selection refers to the differential reproduction of genes that affect the survival of offspring or closely related kin. Behavior such as the broken-wing display of the killdeer is an example. The behavior carries risk but would be promoted by selection if the offspring of individuals using the display were protected from predators often enough to compensate for the risk. Inclusive fit-

As a result of imprinting in the moments immediately after hatching, baby geese automatically follow their mother in a line wherever she goes. (Corbis)

ness is the term used to recognize the concept that fitness includes the total genotype, including those genes that may lower the individual's survival as the price of leaving more genes in surviving kin. The concepts of kin selection and inclusive fitness help to address one problem raised by Darwin, the question of altruistic behavior. Ethology is a young science but a very exciting one, because there are so many questions that can be asked about animal behavior within the context of evolution.

Studying Ethology

The methods and tools of ethology cover the entire spectrum of complexity. One simple, but demanding, method is to collect normative data about a species. In its simplest form, the scientist observes what an animal does and writes it down in a field notebook. Finding and following the animal, coping with field conditions such as bad weather and rugged terrain, and keeping field equipment in operating condition add challenge and variety to this approach. The ethologist uses various techniques to get data as unbiased as possible. One of these is to choose a focal animal at random (or on a rotation) and observe the focal animal for a specific amount of time before switching observation to another member of the population. This prevents bias in which individuals and which behaviors are observed. The sampling of an individual's behavior at timed intervals is an even more effective way of avoiding bias.

When all or most of an animal's behavioral repertoire is known, a list known as an ethogram can be constructed. This catalog can be organized into appropriate categories based on function. Ethograms provide useful baseline information about the behavior of a species. For animals that are difficult or impossible to follow, radio-tracking techniques have been developed. Collars that emit radio signals have been designed for many animals. Miniaturization has made it possible for radio tracking to be used even on relatively small animals.

In field studies, animals are often marked in some way so that observers are able to follow individual animals. A number of techniques have been developed, including banding birds with colored acrylic bands. Color combinations can be varied so that each member of the population has a unique combination. Marking allows the observer to get information such as individual territory boundaries and to determine which animals interact.

Models are frequently used in experiments. For example, a model can be used to determine whether individuals in a species need to learn to identify certain classes of predators. Models were used in many of the classic experiments in ethology. Modern technology has allowed the development of much more sophisticated models. One of the most interesting is a "bee" that can perform a waggle dance (used by bees to indicate location) so effectively that its hivemates can find the food source. Whether a model is simple or sophisticated, it can provide a tool to determine the cues that trigger an animal's response.

Neurobiologists use electrodes and appropriate equipment to stimulate and record the responses of neurons. They can also stimulate specific regions of the nervous system by using tiny tubes to deliver hormones or neurotransmitters. Genetic technology has made it possible to examine the deoxyribonucleic acid (DNA) of individuals in a species. This tool can be used, for example, to determine whether females in monogamous species are completely monogamous or whether some of their offspring are fathered by males other than their mates.

Tape recorders have become very important in studies of animal vocalizations. Recorders are used in two ways. The animal's vocalizations may be recorded and the recording used to make sound spectrographs for analysis. The recordings may also be used to determine whether individuals can discriminate between the vocalizations of neighboring and nonneighboring individuals in their species. Playbacks can also be used to simulate intruders in the territory of an individual and can be applied to many other experimental situations in both field and laboratory.

The methods used by ethologists are as varied as the problems they investigate. Because the skill of the observer is still a vital link in the investigation of animal behavior, ethology remains one of the more approachable areas of scientific investigation.

Uses of Ethology

The investigation of animal behavior has a number of benefits, both practical and abstract. Some animals are pests, and knowledge of their behavior can be used to manage them. For example, synthetic pheromones have been used to attract members of some insect species. The insects may then be sampled or killed, depending upon the application. To the extent that researchers develop behaviorally based pest management strategies and reduce pesticide use, they will be promoting our own safety as well as that of other species.

It is sometimes important for humans to be able to understand the communication signals of other species and the characteristics of their sensory perception. The knowledgeable individual can recognize the cues that indicate risk that a dog might bite, for example, and can also avoid behavior that the dog will regard as threatening. Understanding the behavior of the wild animals most likely to be encountered in one's neighborhood is an important factor in peaceful coexistence.

The study of animal behavior is providing one of the more fascinating areas of evolutionary biology. Ethology has demonstrated more effectively than most fields of study how diverse the solutions to a given problem can be and has provided insight into human behavior from a biological perspective. Knowledge of animal behavior also enriches human lives simply by satisfying some of our natural curiosity about animals.

The style is succinct. The book is challenging to read, but more because of the format and type size than the style. Illustrations include black-and-white photographs, drawings, tables, and graphs. Glossary, bibliography, and index.

EVOLUTION: ANIMAL LIFE

Types of animal science: Evolution, fields of study
Fields of study: Developmental biology, evolutionary science, genetics, human origins, zoology

Evolution is the change in the gene pool of a population over time by such processes as natural selection, genetic drift, mutation, and migration.

Principal Terms

GENE: the basic unit of heredity

GENE FLOW: the movement of genes from one population to another

GENETIC DRIFT: change in gene frequencies in a population owing to chance

INTERBREEDING: the mating of closely related individuals, which tends to increase the appearance of recessive genes

MIGRATION: the movement of individuals, resulting in gene flow, changing the proportions of genotypes in a population

MUTATION: alteration in the physical structure of the DNA, resulting in a genetic change that can be inherited

NATURAL SELECTION: the process of differential reproduction in which some phenotypes are better suited to life in the existing environment and thus are more likely to survive

SPECIATION: the formation of new species as a result of geographic, physiological, anatomical, or behavioral factors

SPECIES: the basic category of biological classification representing a group of potentially or actually interbreeding natural populations which are reproductively isolated from other such groups

TAXON (pl. TAXA): group of related organisms at one of several levels such as the family Canidae, the genus *Canis*, or the species *Canis lupus*

Current consensus holds that the so-called big bang—the high-temperature, high-density event that marked the beginning of the universe—occurred some fifteen billion years ago, with the sun and Earth formed about four and a half billion years ago. Four billion years ago, the relatively newly created sun shone with only 70 percent of its current strength. The atmosphere had no free oxygen. No bacteria, no viruses, no plants, and no animals were in existence. Subsequently, as chemical processes are assumed to have created oxygen and an organic "soup," microbial life in the form of the simplest cells without a nucleus, prokaryotes, developed out of this primordial ooze. These bacteria were the only living organisms for about two billion years. After that time, about 1.5 billion years ago, more complex cells with nuclei, eukaryotes, appeared. Thus, in all, for some 5.5 billion years, bacteria were the only existing animal organisms.

The Beginnings of Animal Life

Eventually, the two kingdoms, the botanical and the zoological, started to diverge and millions of animals came into being, multicelled and with specialized body parts, distinguished from plants primarily but not exclusively by their methods of feeding, locomotion, and reproduction. Most of the phyla seem to have appeared during the Precambrian period, an immense span of geological time that ended about 590 million years ago. Few fossils have remained from these prehistoric times, but the most explosive period for the development of life was the Cambrian, some 590 to 505 million years ago. In a relatively short span of ten million years, all the animal phyla currently known came into being, perhaps encouraged by an increase in oxygen in the seas, where animal life began.

Eventually, animals developed a nervous system enabling them to control their movements more appropriately, as well as sense organs to help them find suitable food. At the margins, however, the dichotomy between the botanical and the animal world has remained ambiguous, since there are many microorganisms which defy clearcut classification At times, these difficult cases are known as Protista, or Protists.

In all forms of life, including the animal kingdom, no phylum has been produced by a single evolutionary event. Nor have different animal orders appeared as a result of sudden evolutionary changes. Rather, all have come about, whether in gradual or punctuated manner, by the cumulative effect of small steps in different directions. This, at least, is the theory posited by Charles Darwin's explanation of evolution.

The time line of the animal kingdom is closely connected with this evolutionary chronology. Darwin's theory of the origin of species through natural selection, nearly universally accepted in the scientific community but at times opposed on Biblical creationist grounds and in some circles of the lay community, has it that animals, like plants, have changed since the beginning of life on earth and are still evolving today. In this view, there was no sudden creation of all species. Instead, over long periods of time, new species have evolved from isolated populations of existing species. These came to occupy new niches separate from the niches of the original species. Thus, all current species are changed descendants of others that existed previously. If there are fewer apparent links between phyla than between families further down the classification ladder, the reason is that phyla have had a longer history and so have experienced more opportunities for the elimination of intermediate forms. From an evolutionary viewpoint, the difference between species down an evolutionary line are even more recent than those between families, and so on. On average, it takes about 500,000 generations for one species to evolve into another. For species to have survived in their environments—with simultaneous changes in ecology, climate, and flora—many animal forms are now more complex and efficient than their ancestors used to be.

Genes and Evolution

Life began in the seas, so for animals to live in freshwater, let alone on dry land or in the air, many obstacles had to be overcome. The impetus to conquer these inhospitable realms came from competition, according to Darwin's theory of the survival of the fittest. Those fauna that managed to surmount the problems were the ones that underwent waves of adaptive measures and evolved into new kinds of animals.

It was only in the twentieth century that it was discovered that the characteristics of a species are passed on from parents to offspring by genes. Genes provide cells for particular features, such as webbed feet. With such characteristics inherited by offspring from parents, there is a resemblance among generations. However, at times a parent may produce quite a different offspring because of genetic change. The young, in turn, may replicate this difference in their own descendants in a process known as mutation, which may occur spontaneously for unknown reasons, but also may occur due to known causes, such as exposure to radiation. At times, mutations may be useful in allowing the species to adapt better to its environment; for instance, darker moths have a better chance of survival in a forest than lighter ones because the latter are more visible to their predators than the former. Other mutations may be harmful, such as larger size that slows down a species, making its flight from danger more difficult.

Whatever the case, within a time frame of 1 to 10 million years, animals may remain the same, may evolve, or may become completely extinct, as did the dinosaurs about 60 million years ago, after being dominant for some 350 million years.

Adaptation to Environment

Natural selection leading to a new species may be accelerated when members of the original species move to a new environment, whether voluntarily or driven by the elements. Separated populations may develop different traits as they adapt to their new condition. Eventually, they will become sufficiently different to be unable to produce offspring with members of their original population. This process has repeated itself many times, over millions of years, and accounts for the large diversity in the animal world, not to mention the additional diversity consequent on artificial breeding by humans, widely observed among domesticated animals such as horses, cattle, and dogs.

Animals occupied new environments as species living in water moved to the land or later to the air. Thus, the step from fish to amphibian was essentially one from living in water for the whole life to living on land for the adult stage of the life cycle. The step from amphibian to reptile was one of increasingly proficient adaptation to land life at all stages of the life cycle.

Birds and mammals evolved in different directions from the reptiles, the first in adaptation to an arboreal and finally a flying life and the second as a further advance in the maintenance of an even and high body temperature—homeothermy—by combining an insulating external layer such as hair with a variety of physiological thermostats.

Events in geology, climate, and flora also determined the geographic distribution of species. Thus, marsupials are currently found almost entirely in Australasia and South America. The tiger exists only in India and Southeast Asia. The lion is restricted mainly to Africa. This pattern reflects the way in which these groups have evolved in relation to the physical world.

New animal groups evolve into many different forms, especially when they become dominant. For instance, when mammals came to occupy the dominant position, some became meat-eaters while others became vegetarians; some became smaller while others became larger; some became runners while others ended up as burrowers or flyers; still others returned to the water. This trend allowed the descendants of the original type to

Image Not Available

exploit a much greater range of environments and resources. Essentially, those species whose sense organs or brain morphology and functions improved the most ended up being dominant—primates in general and humans in particular.

Time Frame

The exact time of the origins of animals during earth's evolutionary history is not known because the early species were soft-bodied, at first single-celled and later multicellular life forms, that did not fossilize well. Fossils are the best material evidence of archaic times. Fossils do not appear earlier than 650 to 500 million years ago, not only because the animal life of the time was inappropriate for fossilization, but also because continued crustal shifts in the ensuing eons disturbed the very early rock formations. Accordingly, fossil evidence is unavailable for the entire early history of animals, which must consequently remain speculative. Current taxonomic interrelationships suggest the early history, and taxonomic diagrams may be regarded as presumptive evolutionary diagrams as well. However, a ball of carbon discovered in a cavity etched in a rock some 3.86 billion years old suggests that some life on earth was already possible at that time.

Knowledge is also limited by the fact that, even though over a million different species of animals have been identified, it is suspected that a similar number remain to be discovered or became extinct before such identification could be made. In the United States alone, some forty species of birds, about thirty-five species of mammals, and twenty-five other species have become extinct in the last two hundred years alone—less than a blip on earth's time scale—as a result of human activities such as the destruction of animal habitats through urbanization, the clearing of land for agricultural purposes, pollution, the introduction of new species from other parts of the world which turned out to be predatory to domestic specimens, hunting, and especially human population growth. It is widely predicted that climatic change triggered by greenhouse gases will continue, even enhance, this process, thereby endangering more animal species. Whatever the future, however, evolutionary biologists estimate that some 99 percent of all species that have ever lived on earth are now extinct.

Despite these and other caveats, here is a very approximate timetable of the evolution of animal life:

Life Form	Date of Emergence
Simplest single-celled Protozoa	3.5 billion years ago
Invertebrates evolving from Protozoa	670 to 640 million years ago
First vertebrates evolving from invertebrates	500 million years ago
First mammals	200 million years ago
Hominids (modern man) from apelike hominoids	200,000 to 25,000 years ago

Translated in terms of a single year:

January 1: Big Bang
March 22: Bacteria, the first living animals
November 9: Invertebrates
November 22: Vertebrates
December 16: Mammals
December 28: Primates, the highest order of mammals
December 31, a few minutes before midnight: Modern man, the dominant primate

Evolution of Existing and Extinct Human Species and Australopithecines

The root of the hominid evolutionary tree is still imperfectly known. The earliest australopithecine species, *Australopithecus anamensis*, is believed to be over four million years old, by which time that branch had diverged from African apelike ancestors. This species was followed by the *Australopithecus afarensis* nearly 3.5 million years ago. Much later came *Homo habilis*, called "skillful man" since they could presumably produce primitive tools, some two million years ago. They were followed by *Homo erectus*, "upright man," about one million years ago. Finally, *Homo sapiens*, "knowing man," emerged about 200,000 years ago. In the meantime, the australopithecine branch, after evolving through a number of intermediate species such as *A. africanus*, *A. aethiopicus*, and *A. robustus*, died out about one million years ago. To date, the earliest unearthed fossil, that of Lucy, a three-foot-tall female discovered in Ethiopia, is about four million years old. Modern humans are believed to have radiated out of Africa into Asia and Europe. Subsequently, cultural evolution became more prominent than biological evolution, but as modern humans evolved over the last four million years to their current condition, they developed manipulative skills, bipedalism, a change from specialized to omnivorous feeding habits, and especially, a threefold increase in cranial capacity from *H. afarensis* to *H. neanderthalensis*, together with behavior appropriate to the control of the environment.

Although humans are not the only animals capable of conceptual thought, they have refined and extended that ability until it has become their hallmark. Thus, thanks to the symbolic language of *Homo sapiens*, modern humans make possible the accumulation of experience from one generation to the next. Such cultural evolution is possessed by few, if any other animal species. It is for this reason that humans, more than other animals, have found ways to mold and change their environment according to need rather than in response to environmental demands. Because of this ability and humans' control of technology, the species has more say about their biological future than any other.

EVOLUTION: HISTORICAL PERSPECTIVE

Type of animal science: Evolution
Fields of study: Ecology, embryology, evolutionary science, genetics, paleontology, population biology, zoology

Evolution is the process of change in biological populations. Historically, it is also the theory that biological species undergo sufficient change with time to give rise to new species.

Principal Terms

- ADAPTATION: the possession by organisms of characteristics that suit them to their environment or their way of life
- CATASTROPHISM: a geological theory explaining the earth's history as resulting from great cataclysms (floods, earthquakes, and the like) on a scale not now observed
- DARWINISM: branching evolution brought about by natural selection
- ESSENTIALISM (TYPOLOGY): the Platonic-Aristotelian belief that each species is characterized by an unchanging "essence" incapable of evolutionary change
- GENOTYPE: the hereditary characteristics of an organism
- GEOFFROYISM: an early theory of evolution in which heritable change was thought to be directly induced by the environment
- LAMARCKISM: an early evolutionary theory in which voluntary use or disuse of organs was thought to be capable of producing heritable changes
- SCALE OF BEING (CHAIN OF BEING): an arrangement of life forms in a single linear sequence from "lower" to "higher"
- UNIFORMITARIANISM: a geological theory explaining the earth's history using processes that can be seen at work today

Evolution is the theory that biological species undergo sufficient change with time to give rise to new species. The concept of evolution has ancient roots. Anaximander suggested in the sixth century B.C.E. that life had originated in the seas and that humans had evolved from fish. Empedocles (fifth century B.C.E.) and Lucretius (first century B.C.E.), in a sense, grasped the concepts of adaptation and natural selection. They taught that bodies had originally formed from the random combination of parts, but that only harmoniously functioning combinations could survive and reproduce. Lucretius even said that the mythical centaur, half horse and half human, could never have existed because the human teeth and stomach would be incapable of chewing and digesting the kind of grassy food needed to nourish the horse's body.

For two thousand years, however, evolution was considered an impossibility. Plato's theory of forms (also called his "theory of ideas") gave rise to the notion that each species had an unchanging "essence" incapable of evolutionary change. As a result, most scientists from Aristotle to Carolus Linnaeus in the eighteenth century insisted upon the immutability of species. Many of these scientists tried to arrange all species in a single linear sequence known as the scale of being (also called the chain of being and the *scala naturae*), a concept supported well into the nineteenth century by many philosophers and theologians as well. The sequence in this scale of being was usually interpreted as a static "ladder of perfection" in God's creation, arranged from higher to lower forms.

The scale had to be continuous, for any gap would detract from the perfection of God's creation. Much exploration was devoted to searching for "missing links" in the chain, but it was generally agreed that the entire system was static and incapable of evolutionary change. Pierre-Louis Moreau de Maupertuis, in the eighteenth century, and Jean-Baptiste Lamarck were among the scientists who tried to reinterpret the scale of being as an evolutionary sequence, but this single-sequence idea was later replaced by Charles Darwin's concept of branching evolution. Georges Cuvier finally showed that the major groups of animals had such strikingly different anatomical structures that no possible scale of being could connect them all; the idea of a scale of being lost most of its scientific support as a result.

The Struggle to Conceptualize Evolution

The theory that new biological species could arise from changes in existing species was not readily accepted at first. Linnaeus and other classical biologists emphasized the immutability of species under the Platonic-Aristotelian concept of essentialism. Those who believed in the concept of evolution realized that no such idea could gain acceptance until a suitable mechanism of evolution could be found. Many possible mechanisms were therefore proposed. Étienne Geoffroy Saint-Hilaire proposed that the environment directly induced physiological changes, which he thought would be inherited, a theory now known as Geoffroyism. Lamarck proposed that there was an overall linear ascent of the scale of being but that organisms could also adapt to local environments by voluntary exercise, which would strengthen the organs used; unused organs would deteriorate. He thought that the characteristics acquired by use and disuse would be passed on to later generations, but the inheritance of acquired characteristics was later disproved. Central to both these explanations was the concept of adaptation, or the possession by organisms of characteristics that suit them to their environments or to their ways of life. In eighteenth century England, the Reverend William Paley and his numerous scientific supporters believed that such adaptations could be explained only by the action of an omnipotent, benevolent God. In criticizing Lamarck, the supporters of Paley pointed out that birds migrated toward warmer climates before winter set in and that the heart of the human fetus had features that anticipated the changes of function that take place at birth. No amount of use and disuse could explain these cases of anticipation, they claimed; only an omniscient God who could foretell future events could have designed things with their future utility in mind.

The nineteenth century witnessed a number of books asserting that living species had evolved from earlier ones. Before 1859, these works were often more geological than biological in content. Most successful among them was the anonymously published *Vestiges of the Natural History of Creation* (1844), written by Robert Chambers. Books of this genre sold well but contained many flaws. They proposed no mechanism to account for evolutionary change. They supported the outmoded concept of a scale of being, often as a single sequence of evolutionary "progress." In geology, they supported the outmoded theory of catastrophism, an idea that the history of the earth had been characterized by great cataclysmic upheavals. From 1830 on, however, that theory was being replaced by the modern theory of uniformitarianism, championed by Charles Lyell. Charles Darwin read these books and knew their faults, especially their lack of a mechanism that was compatible with Lyell's geology. In his own work, Darwin carefully tried to avoid the shortcomings of these books.

Darwin's Revolution in Biological Thought

Darwin brought about the greatest revolution in biological thought by proposing not only a theory of branching evolution but also a mechanism of natural selection to explain how it occurred. Much of Darwin's evidence was gathered during his voyage around the world aboard HMS *Beagle*. Darwin's stop in the Galápagos Islands and his study of tortoises and finchlike birds on these islands are usually credited with convincing him

Comte de Buffon (Georges-Louis Leclerc)

Born: September 7, 1707; Montbard, France
Died: April 16, 1788; Paris, France
Fields of study: Anthropology, biology, botany, chemistry, geology, mathematics, paleontology, zoology
Contribution: The greatest naturalist of the eighteenth century, Buffon popularized zoology and botany through his publications. He tried to separate science from religious and metaphysical ideas and rejected teleological reasoning and the idea of God's direct intervention in nature.

Born to a noble family in Dijon, Buffon was admitted to the French Academy of Sciences in 1734 and the Académie Française in 1753. In 1739 he was appointed director (*Intendant*) of the Jardin du Roi, the royal botanical garden. Between 1749 and his death, he published (with associates) thirty-six volumes of the *Histoire Naturelle* (44 vols., 1739-1804; *A Natural History, General and Particular*, 10 vols., 1807) which took in the formation of the earth, geology, paleontology, zoology, and botany. The last eight volumes were posthumous. A master of style, his books were among the most popular in the eighteenth and early nineteenth centuries.

Buffon believed that the study of Earth was a necessary prerequisite to botany and zoology, and wrote two important texts on geology and paleontology. The first, *Théorie de la terre*, was published in 1749, the other, *Époques de la nature*, in 1778. From experiments on the cooling of globes, he estimated the age of the earth to be 85,000 years, significantly at variance with his contemporaries' estimation of an origin around 4000-6000 B.C.E. Buffon's cosmogony replaced the intervention of God by a cause whose effects are in accord with the laws of mathematics.

Buffon postulated that new varieties of plants and animals (including humans) were produced in nature by external geographical influences. Such influences could also cause degeneration. He was against classifying nature, as "... everything that can be, is." He gave "species" a purely biological definition: animals that by means of copulation perpetuate themselves and preserve their similarity. He thought families were artificial creations made by man. He therefore thought Linnaeus' classification of plants based on sexual characters was too rigid. He arranged animals in order of their utility to humans (later he rearranged them according to distinctive characteristics) and believed that some forms might have degenerated from others over time—thus, the ass might be a degenerate form of the horse. Buffon thus alluded to a form of "evolution" where physical characteristics produced by external influences could be passed down the generations.

The Comte de Buffon was perhaps the greatest naturalist of the eighteenth century, rejecting religious explanations of the state of the world in favor of scientific research. (Library of Congress)

Buffon tried to separate science from religious and metaphysical ideas, and rejected teleological reasoning and the idea of God's direct intervention in nature. His theories went against the accepted theological belief of immutability of species and he was reprimanded by the Faculty of Theology at the University of Paris for this. Buffon apologized but did not change his views.

Buffon was made a count in 1773 by Louis XV. He was greatly respected by his contemporaries and was made a member of almost every learned society in Europe.

—Ranès C. Chakravorty

that evolution was a branching process and that adaptation to local environments was an essential part of the evolutionary process. Adaptation, he later concluded, came about through natural selection, a process that killed the maladapted variations and allowed only the well-adapted ones to survive and pass on their hereditary traits. After returning to England from his voyage, Darwin raised pigeons, consulted with various animal breeders about changes in domestic breeds, and investigated other phenomena that later enabled him to demonstrate natural selection and its power to produce evolutionary change.

Darwin's greatest contribution was that he proposed a suitable mechanism by which permanent organic change could take place. All living species, he said, were quite variable, and much of this variation was heritable. Also, most organisms produce far more eggs, sperm, seeds, or offspring than can possibly survive, and the vast majority of them die. In this process, some variations face certain death while others survive in greater or lesser proportion. Darwin called the result of this process "natural selection," the capacity of some hereditary variations (now called genotypes) to leave more viable offspring than others, with many leaving none at all. Darwin used this theory of natural selection to explain the form of branching evolution that has become generally accepted among scientists.

Darwin delayed the publication of his book for seventeen years after he wrote his first manuscript version. He might have waited even longer, except that his hand was forced. From the East Indies, another British scientist, Alfred Russel Wallace, had written a description of the very same theory and submitted it to Darwin for his comments. Darwin showed Wallace's letter to Lyell, who urged that both Darwin's and Wallace's contributions be published, along with documented evidence showing that both had arrived at the same ideas independently. Darwin's great book, *On the Origin of Species by Means of Natural Selection*, was published in 1859, and it quickly won most of the scientific community to a support of the concept of branching evolution. In his later years, Darwin also published *The Descent of Man and Selection in Relation to Sex* (1871), in which he outlined his theory of sexual selection. According to this theory, the agent that determines the composition of the next generation may often be the opposite sex. An organism may be well adapted to live, but unless it can mate and leave offspring, it will not contribute to the next or to future generations.

Acceptance of Darwinism in the Twentieth Century

In the early 1900's, the rise of Mendelian genetics (named for botanist Gregor Mendel) initially resulted in challenges to Darwinism. Hugo de Vries proposed that evolution occurred by random mutations, which were not necessarily adaptive. This idea was subsequently rejected, and Mendelian genetics was reconciled with Darwinism during the period from 1930 to 1942. According to this modern synthetic theory of evolution, mutations initially occur at random, but natural selection eliminates most of them and alters the proportions among those that survive. Over many generations, the accumulation of heritable traits produces the kind of adaptive change that Darwin and others had described. The process of branching evolution through speciation is also an important part of the modern synthesis.

The branching of the evolutionary tree has resulted in the proliferation of species from the common ancestor of each group, a process called adaptive radiation. Ultimately, all species are believed to have descended from a single common ancestor. Because of the branching nature of the evolutionary process, no one evolutionary sequence can be singled out as representing any overall trend; rather, there have been different trends in different groups. Evolution is also an opportunistic process, in the sense that it follows the path of least resistance in each case. Instead of moving in straight lines toward a predetermined goal, evolving lineages often trace meandering or circuitous paths in which each change represents a momentary increase in adaptation. Species that cannot adapt to changing conditions die out and become extinct.

Studying Evolution

Evolution is studied by a variety of methods. The ongoing process of evolution is studied in the field by ecologists, who examine various adaptations, including behavior and physiology as well as anatomy. These adaptations are also studied by botanists, who examine plants; zoologists, who examine animals; and various specialists, who work on particular kinds of animals or plants (for example, entomologists, who study insects). Some investigators capture specimens in the field, then bring back samples to the laboratory in order to examine chromosomes or analyze proteins using electrophoresis. Through these methods, scientists learn how the ongoing process of evolutionary change is working today within species or at the species level on time scales of only one or a few generations.

The long-term results of evolutionary processes are studied among living species by comparative anatomists and embryologists. Extinct organisms are studied by paleontologists, scientists who examine fossils. Biogeographers study past and present geographic distributions. All these types of scientists make comparisons among species in order to determine the sequence of events that took place in the evolutionary past. One method of reconstructing the branching sequences of evolution is to find homologies, deep-seated resemblances that reflect common ancestry. Once the sequences are established, functional analysis can be used to suggest possible adaptive reasons for any changes that took place. The sequences of evolutionary events reconstructed by these scientists represent the history of life on the earth. This history spans many species, families, and whole orders and classes, and it covers great intervals of past geologic time, measured in many millions of years.

The Historical Context of Evolutionary Theory

The historical development of evolutionary theory should be viewed in two contexts: that of biological science and that of cultural history. The concept of evolution had been talked about for many years before 1859 and was usually rejected because no suitable mechanism had gained widespread acceptance. The fact that the phenomenon of natural selection was independently discovered by two Englishmen shows both that the time was ripe for the discovery and that the circumstances were right in late nineteenth century England.

Evolutionary biology is itself the context into which all the other biological sciences fit. Other biologists, including physiologists and molecular biologists, study how certain processes work, but it is evolutionists who study the reasons why these processes came to work in one way and not another. Organisms and their cells are built one way and not another because their structures have evolved in a particular direction and can only be explained as the result of an evolutionary process. Not only does each biological system need to function properly, but it also must have been able to achieve its present method of functioning as the result of a long, historical, evolutionary process in which a previous method of functioning changed into the present one. If there were two or more ways of accomplishing the same result, a particular species used one of them because found it easier to evolve one method rather than another.

Everything in biology is thus a detail in the ongoing history of life on the earth, because every living system evolves. Living organisms and the processes that make them function are all products of the evolutionary process and can be understood only in that context. As biologist Theodosius Dobzhansky once said, "Nothing in biology makes sense, except in the light of evolution."

Jean-Baptiste de Lamarck

Born: August 1, 1744; Bazentin-le-Petit, Picardy, France
Died: December 18, 1829; Paris, France
Fields of study: Evolutionary science, invertebrate biology, paleontology, zoology
Contribution: Lamarck established the division of animal life into the vertebrate and invertebrate categories, and he formulated an evolutionary theory based on the premise that acquired traits are inheritable.

Jean-Baptiste de Lamarck is best known for his theory that acquired physical traits may be inheritable. (Library of Congress)

After studying briefly for the priesthood at the Jesuit seminary in Amiens, Jean-Baptiste de Monet, chevalier de Lamarck, served as an army officer in the Seven Years' War. Following an accident in 1768, he began to study botany and medicine. In 1778, he published his three-volume *Flore français* (French plants), which was widely used as a manual of identification.

Lamarck was then employed as assistant botanist at the royal botanical gardens of Paris, and he was also appointed to the prestigious Academy of Sciences. Count Georges-Louis de Buffon engaged him as tutor to his son, which allowed him to tour European botanical gardens for two years. When the Jardin des Plantes (the National Museum of Natural History) was founded in 1793, he was placed in charge of the collection of invertebrates (a term that he coined).

During the early nineteenth century, Lamarck published numerous books about invertebrates, paleontology, and biological evolution. His *Système des animaux sans vertèbres* (1801; system of invertebrate animals) presented a systematic basis for the classification of the lower animals. His *Hydrogéologie* (1802; *Hydrogeology*, 1964) interpreted the history of the earth as a series of inundations, each resulting in organic deposits that built up the continents. The book was especially noteworthy for its recognition of the vastness of geologic time.

Lamarck was not the first to propose a theory of biological evolution, but his theory was more systematic and coherent than previous versions. He gave the clearest explanation for his theory in *Philosophie zoologique* (1809; *Zoological Philosophy*, 1873), presenting a two-part process. First, a change in the environment forced organisms to change their behavior. If particular organs were used, they would increase in size and strength; in contrast, disuse or disease would weaken and shrink organs. Second, Larmark argued that such changes would be inherited, so that the characteristics of a species would change gradually over many generations.

Lamarck's scientific work culminated in an exhaustive study, *Histoire naturelle des animaux sans vertèbres* (1815-1822; natural history of invertebrate animals).

Charles Darwin acknowledged the great contribution of Lamarck's work, and Darwin's own theory of natural selection never entirely rejected the possibility that some acquired traits might be inherited. With advancements in the science of heredity during the twentieth century, the concept of Lamarckian inheritance has been largely abandoned. Late in the twentieth century, nevertheless, Edward J. Steele and other biologists found evidence that the acquired immunities of organisms might be passed on to their offspring.

Brandon, Robert N. *Concepts and Methods in Evolutionary Biology*. New York: Cambridge University Press, 1996. A collection of essays spanning two decades, addressing problems in the philosophy of biology, particularly the conception of relative adaptedness and the principle of natural selection.

Darwin, Charles R. *On the Origin of Species by Means of Natural Selection: Or, the Preservation of the Favoured Races in the Struggle for Life*. London: John Murray, 1859. This is the original edition, still worth reading. It is better than the more widely reprinted sixth edition, in which Darwin's more forceful statements were toned down as a response to criticism that is no longer greatly valued by biologists. Some knowledge of zoology, geology, and geography would definitely increase any reader's understanding and appreciation of this book. Darwin provided no bibliography, but some modern editors have supplied one.

Dobzhansky, Theodosius G. *Genetics of the Evolutionary Process*. New York: Columbia University Press, 1970. Although somewhat technical in places, this book is extremely well written, and a careful reader should be able to understand it all without any formal background. It is an excellent (and very detailed) outline of the evolutionary process in terms of genetic changes. It contains much information about the genus *Drosophila* (fruit flies), on which Dobzhansky was an expert. Very comprehensive bibliography.

Gould, Stephen J. *Ever Since Darwin*. Reprint. New York: W. W. Norton, 1992.

_______. *The Flamingo's Smile*. New York: W. W. Norton, 1985.

_______. *The Panda's Thumb*. Reprint. New York: W. W. Norton, 1992. These three books all consist of essays reprinted (and occasionally updated) from *Natural History* magazine. All are well written and directed to a general audience; no previous background is assumed. Although Gould has occasionally supported unorthodox viewpoints, most of the views represented here have become accepted into the mainstream with the passage of time. Gould's easy, familiar style makes for lively reading and he uses esoteric cases and seemingly inconsequential details to make important points about evolution in general. The bibliographies are wide-ranging but are confined to the topics of the individual essays.

Grant, Verne. *The Evolutionary Process: A Critical Study of Evolutionary Theory*. 2d ed. New York: Columbia University Press, 1991. A comprehesive and critical review of modern evolutionary theory. Focuses on whole organisms and general principles rather than molecular changes and mathematical models.

Rose, Michael A. *Darwin's Spectre: Evolutionary Biology in the Modern World*. Princeton, N.J.: Princeton University Press, 1998. Written for the general reader. Outlines the fundamental ideas of evolutionary biology and its influence in other fields such as agriculture, medicine, and eugenics.

EXOSKELETONS

Type of animal science: Anatomy
Field of study: Invertebrate biology

The exoskeleton is one of the distinctive primary features of members of the phylum Arthropoda. The evolution of the exoskeleton cuticle is thought to have been important in this group's successful adaptation to many diverse environments. The exoskeleton's intricate structure has provided advantages enabling the arthropods to thrive for hundreds of millions of years.

Principal Terms

CHITIN: a cellulose-like, crystalline material that makes up 25 percent to 60 percent of the dry weight of the cuticle

CUTICLE: the outer arthropod exoskeleton consisting of several layers of secreted organic matter, primarily nonliving chitin

ENDOCUTICLE: usually the thickest layer of the cuticle, found just outside the living epidermal cell layer and made of untanned proteins and chitin

EPICUTICLE: the outermost and thinnest layer of the arthropod cuticle, composed mainly of the hardened protein cuticulin

EPIDERMIS: a living cellular layer that secretes the greater part of the cuticle and is responsible for dissolving and absorbing the cuticle during molting (also termed the hypodermis)

EXOCUTICLE: a thick middle layer in the cuticle made up of both chitin and rigid, tanned proteins termed sclerotin

INTEGUMENTARY PROCESSES: surface outgrowths from the cuticle, primarily rigid nonarticulated processes or movable articulated processes

SCLEROTIN: a hard, horny protein constituent of the exocuticle found in arthropods such as insects; it is superficially similar to vertebrate horn or keratin

The evolution of invertebrate animals possessing rigid, hard exoskeletons represented a great advance for members of the phylum Arthropoda. The development of such exoskeletons—in comparison with less solid structures, such as the hydrostatic skeleton of coelenterates—gave arthropods several distinct evolutionary advantages over other invertebrate phyla. Hydrostatic skeletons, such as those possessed by sea anemones, operate by the animal's musculature being arranged in a pattern that surrounds an enclosed volume of fluid. Contraction of any one section of the muscular system creates a fluid pressure in the central cavity that is consequently transmitted in an omnidirectional manner to the rest of the body. Arthropodic exoskeletons, on the other hand, are consistently rigid and much harder because they are composed to some extent of crystalline substances. Flexibility of movement is attained by multiple jointings in the limb system and in other appendages in the body such as feeding and sensory apparatuses.

Exoskeletons and Arthropod Success

As a consequence of two distinctive features—a hard, rigid exoskeleton and jointed appendages and other body parts—arthropods have become one of the most successful of all animal groups; indeed, it is by these two features that they are taxonomically defined. Biologists sometimes term the enhancement of the annelid (worm) body plan of segmentation by arthropod improvement "arthropodization." Because of it, the ancestors of the present immense spectrum of arthropod species successfully adapted to myriad ecological niches in the sea, on land, and in the air. Arthropod species account for more than three quarters of all known animal species. In fact, the class Insecta, one of a number of classes within the arthropod phylum, numbers at least 700,000 known species, with new species being discovered yearly, mostly in the tropics.

The immense success of arthropods is, to a great extent, the result of the advantages provided by the composition and structure of the seemingly simple surface architecture that is the arthropod exoskeleton. This exoskeleton not only provides a substantial chemical and physical barrier between the animal and the external environment, protecting the internal organs and fluids, but also allows a degree of temperature and osmotic regulation. In addition, the exoskeleton helps deter predation, provides a solid base of attachment for an internal muscular system, and offers a good site for the location of various sense organs. One of the most noteworthy evolutionary advantages of the exoskeleton is its service as a solid base of muscle attachment. The arthropod limbs act as a system of mechanical levers that is a much more efficient locomotive system than that of evolutionarily older and less sophisticated invertebrate locomotive systems such as that of the annelids. Because of exoskeletons and the structurally strong, jointed appendages that exoskeletons permit, arthropods possess an internal, muscular body wall broken down into separate muscles having an arrangement allowing contractions that are more localized in time and space than annelid or coelenterate muscle behavior. This more modular approach to the musculature allows arthropods to react to their environments to use energy more efficiently and with greater precision of movement and response. In fact, the inner surface of the exoskeleton acts as a limited type of endoskeleton, or inner skeleton, in that it provides good anchoring sites for muscle attachment, thus further increasing the leverage power of arthropod limbs and appendages.

The Parts of the Exoskeleton

The exoskeleton itself can be divided into several distinct units based on function and composition. These are composed of consecutive layers that surround the animal in an arrangement similar to a medieval knight's suit of armor. Like the armor suit, the outermost exoskeleton is, in a typical arthropod, very rigid and hard; movement is possible only because both protective systems are composed of plates or body-contoured segments that incorporate narrow, flexible jointings allowing motion. The motion is usually narrowly defined in extent and direction, and it is this quality that gives both armored humans and many arthropods their often distinctively awkward and ungainly mode of movement. The larger terrestrial beetles and marine forms such as crabs and lobsters are ready examples of this. Some arthropods are nevertheless adroit and delicate in their movements, as shown by various arthropod aerialists such as the dragonflies and butterflies.

Insects can, in many ways, be considered typical arthropods and are therefore useful as models for a discussion of the exoskeleton as found among all arthropods. All the various layers of the exoskeleton, both living and nonliving, are as a whole variously termed the integument or cuticle. These layers are the skin or surface of the animal. The innermost layer of the exoskeleton is termed the epidermis, or hypodermis, and is made of living cells. The epidermis is immediately external to a basement membrane that separates the epidermis from the inner body, with its organs and fluids. The epidermis is responsible for secreting the layers external to it, which are organic but actually nonliving material. From the epidermis outward, these layers in insects consist of the endocuticle, the exocuticle, and the epicuticle. (Some biologists use the term procuticle to describe the endocuticle and use epicuticle to mean both the epicuticle and the exocuticle.) Whatever precise terms may be employed, the general concept is that layers of material closer to the epidermis are more flexible and less chemically hardened than layers that are found closer to the actual exterior of the animal. The endocuticle is usually the thickest cuticle layer and is constituted of protein mixed with a material called chitin. Chitin is a cellulose-like, crystalline material that makes up anywhere from 25 percent to 60 percent of the dry weight of the cuticle. It has many useful properties, such as resistance to concentrated alkalies and acids. In chemical composition, chitin is a nitrogenous polysaccharide. Chitin itself can be a relatively soft and flexible material that gains hardness in the outermost arthropod exoskeleton in several ways. One way is by using the presence of a material termed sclerotin. The process of hardening through the agency of sclerotin is called sclerotinization and involves a molecular change in the organization of the protein part of the cuticle. The outermost chitin found in the exocuticle of insects, for example, is thoroughly sclerotinized, which characteristically results in a darkening of the chitin. The other method by which chitin hardens is the deposition of calcium carbonate, primarily in the form of calcite. This is the process found among marine arthropods such as the Crustacea: crabs, lobsters, and shrimp, for example. This process, called calcification, occurs among Crustacea, starting in their epicuticle, or outermost exoskeletal layer, and works inward to the exocuticle and finally the endocuticle.

Besides the darkening caused by sclerotinization, coloration of the cuticle is effected in two basic ways. One is simple pigmentation caused by the presence of colored compounds found within the cuticle itself. The other is through the presence of extremely fine parallel ridges found on the epicuticle. These ridges break normal white light into its constituent wavelengths by prismatic diffraction in the same way that raindrops create rainbows. It is by this means that the effect of spectacularly iridescent rainbow hues found on many insects' wings and bodies is achieved.

Adding to the complexity of the cuticle are great numbers of sensory organs that project from or extend through the various exoskeletal layers. Prominent among these sensory structures are tactile hairs, bristles, and spines found all over the general body surface and on limb surfaces. These sensory structures, or setae, are movable and are set into thin, flexible disks on the cuticle surface itself. When one of these projections is moved, its base mechanically stimulates one or more sensory cells, setting off stimuli to which the arthropod can respond.

The Drawbacks of Exoskeletons

While the exoskeleton has evolved wonderfully to protect the arthropod and to enhance its locomotive and sensory abilities, its overall rigid structure presents some inherent drawbacks. Perhaps chief among these is the fact that its formidable rigidity and solidity are limitations to an individual's physical growth throughout its lifetime. Growth, in fact, is probably an arthropod's single most difficult physiological problem. This is true because once formed and hardened, an exoskeleton cannot be enlarged as the animal within enlarges with time. The physiologic solution among arthropods is the process termed ecdysis, or molting.

This process is intrinsically dangerous to the arthropod, as it leaves each individual extremely vulnerable to predation during, and immediately following, molting. It has been estimated that as much as 80 to 90 percent of arthropod mortality occurs during ecdysis. The process takes place in stages. Prior to the shedding of the old exoskeleton, a new, soft cuticle is formed beneath the old one. The new cuticle has not started along either the sclerotinization or calcification process and therefore is still soft and pliable. As the new cuticle is forming, the lower section of the old cuticle is partially dissolved by corrosive fluids secreted by cutaneous glands situated below the new cuticle. Immediately prior to the shedding, also termed casting, of the old exoskeletal cuticle, the arthropod stops feeding and absorbs more than the usual amount of water and oxygen. Its body begins to swell, and the animal makes spasmodic movements to shake off the old cuticle, most of the base of which has been removed by the corrosive process. Eventually, the old exoskeleton is effectively disconnected from the arthropod's body, and the animal extricates itself from the remains. At this point, its new exoskeleton is soft and very pliable, and its movements are limited. Conse-

Image Not Available

quently, the individual is extremely vulnerable to both predation and serious damage from tearing through abrasive or sharp-edged materials in its environment. It takes some time before the animal's cuticle has hardened and thickened enough for it to resume its normal activities. In the meantime, the exoskeleton—which normally provides a great degree of protection and mobility—acts as a hindrance and danger to the arthropod.

Studying Exoskeletons

The two main approaches used to study the arthropod exoskeleton are the same types of study used by researchers in nearly all branches of the life sciences: field studies and laboratory studies. In the field approach, living arthropods are observed in nature. The specific techniques employed include both still and motion photography in various light—normal, infrared, and ultraviolet. It is important to combine the observational database with later structural analyses of specific arthropod body parts, such as exoskeletons, to ascertain how the anatomical components actually function in the natural setting. Actual physical collections are necessary for study by laboratory workers, who subject the specimens to a range of tests to determine their qualities and features in comparison with similar species and with the normal parameters that are known for previously collected members of the same species.

Specimens are often dissected—or in some cases, vivisected (disassembled while alive)—in order to record useful data such as chemical composition of exoskeletons, metabolic rates, and the estimated age of the sample. In the case of specimens raised in captivity, more precise data can be gained, as the precise age, food type, and daily or hourly intake are known with great precision.

A wide range of techniques are employed in the laboratory to analyze the structural components of exoskeletons. Among them, optical microscopy has traditionally been the primary approach. Working with dissected parts, frequently cut and chemically stained to facilitate viewing or bring out certain features selectively, researchers have used powerful microscopes capable of magnifying by a factor of many hundreds to see tiny subcomponent structures found within exoskeletal tissue. Optical microscopes have also been used to take a close look at associated cellular and noncellular organic matter, such as chitin and sclerotin. An exponential increase in magnification for study, however, has arrived with the advent of scanning electron microscopes (SEMs). These are instruments that use a beam of focused electrons to scan an object and form a three-dimensional image on a cathode-ray tube. The SEM reads both the pattern of electrons scattered by the object and the secondary electrons produced by it. This greatly enhanced ability to see smaller objects with great clarity allows scientists to see very small target sections of exoskeletal tissue, measured in microns (millionths of a meter) in circumference. Researchers can examine in minute detail the structures and interrelationships of the various layers of the arthropod cuticle.

Exoskeletons in the Fossil Record

Because the hard arthropod exoskeleton fossilizes more readily than the remains of many other animals, the evolutionary history of the phylum Arthropoda is abundantly represented in the fossil record. Much more is known about this phylum than other invertebrate phyla because of this phenomenon. Entire classes of arthropods that have left no modern descendants are known today because their substantial body armor appears in various marine strata. Examples of this are well documented in the remains of the extinct marine groups of the trilobites (similar to modern horseshoe crabs) and the eurypterids (giant "water scorpions"). In the case of the trilobites, many fossils are actually the result of cast-off exoskeletal moltings rather than the carcasses of the dead animals. This illustrates the fact that, for hundreds of millions of years, arthropods have maintained a lifestyle and evolutionary approach to physiological problems that are similar to those of modern forms. X-ray photography has been employed successfully to penetrate the hard, mineralized fossils of extinct and ancestral forms of modern arthropods, showing in good detail the internal structures of exoskeletons and other tissues. Radiographic images produced by this technique demonstrate the continuity of structure and life shared by members of this extremely successful phylum for a period extending beyond the early Cambrian period (500 million years before the present).

The exoskeleton is an evolutionary advantage shared by all arthropods. This advantage, along with their body and limb segmentation, has allowed them to move into myriad ecological niches, first in the sea and later on land, in freshwater, and finally in the air. As a phylum, arthropods are arguably the most successful of all metazoan animal phyla; they exceed all others combined in terms of the number of species, diversity, and the number of individual organisms. This ubiquity in all biomes and climates and in virtually every conceivable niche in every ecosystem makes them a force that has a constant influence on human life.

Bibliography

Anderson, D. T. *Atlas of Invertebrate Anatomy*. Sydney, Australia: Univerity of New South Wales Press, 1996. Biological drawings illustrate the internal and external anatomy of eighty species frequently studied in zoology and marine biology class labs. Includes notes on classification, life cycle, and habitat. Indexed by taxonomy and anatomical feature.

Boardman, Richard S., Alan H. Cheetham, and Albert J. Rowell, eds. *Fossil Invertebrates*. Palo Alto, Calif.: Blackwell Scientific Publications, 1987. An extremely thorough and exhaustively detailed treatment of all known types of fossil invertebrates, with an emphasis on metazoans. The chapter on the phylum Arthropoda is of prime interest because it includes a comprehensive description of exoskeletons and what is known of their evolution from the fossil record in extinct and extant taxonomic classes. Features numerous expert drawings, diagrams, and black-and-white photographs. It is suitable for readers who have a solid foundation in natural history.

Clarkson, E. N. K. *Invertebrate Palaeontology and Evolution*. 4th ed. Boston: Allen & Unwin, 1998. Intended as a college-level textbook for introductory courses in invertebrate paleontology, this book nevertheless is a very useful source of information on exoskeletons for all readers having a serious interest in the subject. Chapter 11, "Arthropods," is the main focus of useful information, with subsection 11.2, "Classification and General Morphology," treating the subject in the greatest detail.

Ruppert, Edward E., and Robert D. Barnes. *Invertebrate Zoology*. 6th ed. Fort Worth, Tex.: Saunders College Publications, 1994. A college-level textbook, emphasizing the correlations of structure and function in living invertebrates. Illustrations, glossary.

Savazzi, Enrico, ed. *Functional Morphology of the Invertebrate Skeleton*. New York: John Wiley & Sons, 1999. A wide-ranging collection of essays by an international roster of experts, covering the current understanding of the functional morphology of the invertebrate skeleton.

Stachowitsch, Michael. *The Invertebrates: An Illustrated Glossary*. Illustrated by Sylvie Proidl. New York: Wiley-Liss, 1992. Covers seventy-seven living invertebrate taxa, with full descriptions of major anatomical features. Intended as a guide to identification and description. Illustrated.

EXTINCTION

Type of animal science: Evolutionary science
Fields of study: Conservation biology, evolutionary science, genetics, population biology

Extinction is the total disappearance (by dying out) of all members of a species. Two types of extinction are recognized by scientists: background extinction, in which a single species disappears for one or more reasons, and mass extinction, which occurs when many different species disappear in a relatively short period of time.

Principal Terms

CATASTROPHISM: a scientific theory which postulates that the geological features of the earth and life thereon have been drastically affected by natural disasters of huge proportions in past ages

FOSSIL: a remnant, impression, or trace of an animal or plant of a past geological age that has been preserved in the earth's crust

GENE: an element of the germ plasm that controls transmission of a hereditary characteristic by specifying the structure of a particular protein or by controlling the function of other genetic material

GENE POOL: the whole body of genes in an interbreeding population that includes each gene at a certain frequency in relation to other genes

SPECIES: a category of biological classification ranking immediately below the genus or subgenus, comprising related organisms or populations potentially capable of interbreeding

UNIFORMITARIANISM: a scientific theory that all processes which have affected the earth and living creatures thereon in the past are presently at work and observable by scientists

In 1796, a French naturalist, Georges Cuvier, demonstrated incontrovertibly that many species of once-living plants and animals had completely disappeared from the earth. Cuvier was also the first to recognize that many of the extinct species he identified had disappeared at approximately the same time—a mass extinction. He and his successors attributed extinctions to catastrophic events, such as the biblical Flood. The catastrophists held the field of scientific opinion concerning extinction until the publication of Charles Lyell's *Principles of Geology* (1830-1833), which proclaimed the doctrine of uniformitarianism. Lyell maintained that no processes have affected the earth (including its flora and fauna) that are not presently observable. He denied that any spectacular cataclysms had occurred.

Climate, Evolution, and Extinctions

Lyell's arguments convinced geologists, but the problem of extinctions remained: What could cause a species to die out? In 1859, Charles Darwin offered a biological explanation for extinctions that seemed to answer all questions. In *On the Origin of Species*, Darwin suggested that all life-forms engage in a perpetual struggle for survival. The best-adapted species, therefore, survive and perpetuate themselves. The less-adapted species are outcompeted and disappear. Darwin's ideas seemed to fit well with the doctrine of uniformitarianism, but the problem of mass extinctions remained. He suggested no reasons why great numbers of very different species should disappear at approximately the same time.

Although his ideas were not accepted for many years after Darwin, another scientist proposed a

Coelacanths

Bony fishes are divided into two lineages, the Actinopterygii, or ray-finned fishes, which are by far the dominant group today, and the Sarcopterygii, or lobe-finned fishes, which are now very rare although they were a much more significant group in the past. The sarcopterygians include the modern lungfish and coelacanths, as well as the extinct rhipidistians, which gave rise to the tetrapods or land animals in the Devonian period (350 million years ago). All sarcopterygians are characterized by the presence of a muscular fin base that contains a stout bony skeleton, and it is this structure that became the limbs in land animals.

Coelacanths are known from the Early Devonian era (410 million years ago) but have not been found in sediments younger than the end of the Cretaceous era (70 million years ago). They are fairly large fish, up to five feet long, with deep bodies covered by large, rough scales, paired fins that are conspicuously lobed, and symmetrical tails with small central lobes. As they were thought to be extinct, it was a great surprise when a specimen was caught off the southeast coast of South Africa in 1938. It was recognized as a coelacanth by Marjorie Courtenay-Latimer, who brought it to the attention of the ichthyologist J. L. B. Smith. He named it the following year as *Latimeria chalumnae*, after its discoverer and the Chalumna River, near the estuary of which the specimen had been caught. The next specimen was not discovered until 1952, this time almost one thousand miles farther north, in the Comoro Islands, which lie between East Africa and the northern tip of Madagascar. Since then, numerous specimens have been caught around the two main Comoro islands, and it is clear that a breeding population of these fish lives around the islands at a depth of between one hundred and five hundred meters. Because *Latimeria* lives at depth, it does not survive being caught on a line and pulled rapidly to the surface. However, in 1987, it was filmed swimming free in its natural environment by Dr. Hans Fricke, using a submersible. His film shows them moving slowly and hovering above the bottom, using the paired lobe fins in a regularly alternating pattern to scull themselves along. Although no film has been taken of *Latimeria* feeding, it is clear from stomach contents that it feeds on small fish, and its body shape indicates that it is a fast swimmer over a short distance, suggesting that it is probably an ambush predator.

No additional populations were discovered until 1997, when a specimen was recognized in a fish market in North Sulawesi, Indonesia, by Dr. Mark Erdmann. North Sulawesi is about eight thousand miles from the Comoros, with no apparent water current interactions. That this was a separate population was subsequently confirmed when a second specimen was caught, and the fish was then named *Latimeria menadoensis*. This discovery raises the hope that other populations may exist, and that although still a "living fossil," the coelacanth may be more widely distributed than previously thought.

—*David K. Elliott*

possible solution to the puzzle of mass extinctions as early as 1837. Louis Agassiz produced evidence that the earth has periodically undergone periods of extreme cold, with much of its surface covered by glaciers. Agassiz's glaciers are presently in existence, move very slowly, and thus fit well with the uniformitarian view. His glaciers might also explain mass extinction in evolutionary terms, since plants and animals that could not adapt to changing climate would be outcompeted by other species that could adapt, and, thus, the less-flexible species would disappear.

Uniformitarian views about extinction received a further boost in the twentieth century with the proposal of the theory of continental drift, which has evolved into the modern theory of plate tectonics. Scientists have demonstrated that the landmasses of the earth are in constant motion relative to one another and to the poles of the planet. Over millions of years, the present landmasses have occupied very different positions on the earth's surface, often drifting quite near the polar regions, causing massive climatic changes. In addition, scientists have demonstrated that landmasses have subsided to be covered by the seas and have risen to create dry land from ocean floors. These massive changes would also have a profound effect on flora and fauna, creating constant competition and struggle for survival.

Genetic Factors in Extinctions

Many contemporary biologists believe that background extinctions may be the result of genetic rather than strictly climatic factors. In simple terms, extinction results from an excess of deaths over births in a given species. This excess represents, in biological terms, a reduction in the characteristics of a species that allow it to adapt to its environment. Those characteristics, biologists argue, are brought about through natural selection, a process that favors the genes that give the organism an advantage in the struggle for survival. Since natural selection has produced not only the species itself but its ancestors as well, any change in environment must work against the existing organisms. In the new process of changed environment, new gene combinations will result that will produce an organism better adapted to the changed environment. If, however, these genetic changes do not occur rapidly enough, adaptation will not take place and the species will become extinct.

Another possibility results if an organism is too well adapted to its environment. The gene pool of a species usually combines those genes that work well with one another to produce a well-adapted individual. Some biologists have observed a tendency within the gene pools of some species to resist genetic adaptation when environmental changes occur. Thus, genetic changes that could impart greater chances for survival of the individual in times of environmental turbulence do not occur. This effect also occurs when groups of genes are linked together (usually by a chromosomal inversion) in such a way as to prevent new gene combinations that might impart the ability to adjust to changed environmental conditions. This phenomenon actually retards the ability of a species to survive and may lead to extinctions.

Genetics may also explain mass extinctions. One biologist has theorized that species which live in environments that change very little over long periods of time probably have low genetic variability (a gene pool in which nonutilitarian genes have disappeared). Conversely, species in

Image Not Available

changeable environments should have much more genetic diversity, allowing them to cope with rapidly altering living conditions. If that is true, then mass extinctions might result from a rapid environmental change after a very long period of stability. When the change came, the theory goes, widespread extinctions of many species resulted. Most geneticists, however, reject this theory of mass extinctions. The species in unstable environments may actually have less genetic variability than those in stable environments. Biologists therefore have not been able to advance a plausible genetic explanation for mass extinctions.

Mass Extinctions

Geologists have identified a number of what they call "mass extinction events." The first such event known to paleontologists occurred 440 million years ago at the end of the Ordovician period, during which more than 22 percent of all families and 57 percent of all genera disappeared. Another mass extinction occurred during the Devonian period, 370 million years ago, during which more than 20 percent of all marine families disappeared. The greatest of all mass extinctions occurred 248 million years ago, at the end of the Permian period. During that event, 52 percent of all marine families, 83 percent of all genera, and a frightening 95 percent of all species became extinct. During this event, land animals and plants vanished, along with marine flora and fauna. Yet another "great dying" took place during the Triassic period, approximately 215 million years ago, when 20 percent of all marine families and 48 percent of all genera disappeared.

The mass extinction known most widely outside the scientific community occurred at the end of the Cretaceous period, about 65 million years ago. During this event, the dinosaurs vanished, along with 50 percent of all marine genera. A number of less-spectacular mass extinctions have taken place in the earth's long history, including a relatively recent one at the end of the Pleistocene epoch, which included among its victims such well-known extinct animals as the woolly mammoth and the so-called saber-toothed tiger.

Some paleobiologists and archaeologists are convinced that many of the Pleistocene extinctions were caused by the activities of human beings. They point out that the extinction of most of the large North American land mammals coincided with one theoretical date for the appearance of humans in the Western Hemisphere, approximately 11,500 years ago. According to these scientists, especially efficient human hunters were responsible for those extinctions; however, this theory seems unlikely as an explanation for all the Pleistocene extinctions. Many species in areas other than North America disappeared at the same time, most of which would have had little or no value as game. In addition, there are huge "boneyards" containing fossils of the extinct species in areas as far separated as Alaska and Florida that apparently died at the same time from causes that seem to be related to some great natural cataclysm.

Asteroids as Agents of Mass Extinctions

The species that disappeared in each of these mass extinctions apparently died at approximately the same time, and scientists were at a loss to explain them until 1980. In that year, a scientific team led by Nobel laureate Luis Alvarez presented what seems to be irrefutable evidence that the extinction of the dinosaurs coincided with the collision of a huge asteroid or comet with the earth. The evidence is based on a layer of clay that separates the rock formations associated with the dinosaurs from the overlying formations, which contain fossils from the era of mammals. The clay contains large amounts of iridium and other elements that are scarce in the crust of the earth but common in asteroids and comets.

Many scientists now contend that the collision between the earth and a large extraterrestrial body would have thrown enormous quantities of dust into the atmosphere, sufficient to block out the sun's radiation for an extended period of time. The resulting subzero weather would have had devastating effects on flora and fauna, including the seemingly invincible dinosaurs. Shortly after the evidence for the collision appeared, other scientists presented evidence for an even more frightening phenomenon—periodicity of extinction events.

A scientist charting the occurrence of mass extinction events showed that they seem to occur at regularly spaced intervals, approximately every 26 to 30 million years. Almost immediately after the presentation of the evidence for periodicity, new scientific studies demonstrated more evidence that several mass extinctions other than the one during which the dinosaurs disappeared are also associated with unusually high concentrations of iridium. Taken together, these data seem to indicate that most, perhaps all, mass extinctions are caused by extraterrestrial agents and recur on a regular basis. If that is indeed the case, the implications for all the sciences, including evolutionary biology, are profound.

An Interdisciplinary Study

Scientists from several different disciplines are currently studying extinctions, including mass extinctions, in a variety of ways. Many biologists believe that the most effective way to understand background extinctions is to examine those that have taken place in historic times. Geologists and paleontologists are subjecting the fossil record to a new and rigorous examination, armed with new, supersensitive techniques for ascertaining the ages of the rocks in which fossils occur in an attempt to understand mass extinctions better. These new techniques are the products of research in nuclear physics. Ecologists are particularly examining currently endangered flora and fauna, which may soon disappear. Even some astronomers are actively engaged in research into mass extinctions, scanning the heavens with powerful telescopes in search of an extraterrestrial agent that might explain the apparent periodicity of mass extinction events.

Biologists studying recent background extinctions conclude that virtually all of them are the results of the activities of humankind. The great auk, the last known specimens of which were killed by Icelandic fishermen in 1844; the Tasmanian tiger cat, the last known specimen of which died in captivity in 1934; and many other species are examples of human-caused extinctions. These studies lend validity to the theory that at least some of the many extinctions during the Pleistocene resulted from the hunting activities of prehistoric peoples. More disturbing are studies which show that such modern phenomena as acid rain and ozone depletion, both results of industrialization, may be doing irreparable damage to the environment, which could result in another mass extinction event in the very near future. Indeed, some biologists and ecologists believe that such an event has already begun.

A number of geologists and paleontologists, using new dating techniques based on the rate of radioactive decay in rocks, are reassessing the ages traditionally assigned to fossils by less sophisticated techniques in the past. These studies should eventually reveal whether the mass extinction events of the remote past occurred in a very short or over a relatively longer period of time. Other geologists are searching for impact craters, to lend further credence to the theory that at least some and perhaps all mass extinctions resulted from periodic collisions between the earth and large celestial bodies.

A team of physicists (including astrophysicists), engaged in an ongoing search for a hypothetical dark companion to our sun, has postulated that the orbit of this presently undiscovered body may periodically disrupt the comet cluster on the outer fringes of the solar system, resulting in many comets being diverted into an intersection with the earth's orbit. If their search is successful, it will provide powerful substantiating evidence for the collision theory, with sobering implications. Some physicists have even proposed ways to prevent future collisions between the earth and large heavenly bodies.

The implications of background and mass extinctions are profound. If, as an overwhelming mass of evidence seems to indicate, the activities of humankind are a major cause of recent background extinctions, then those activities may soon lead to an ecological disaster of gigantic proportions. At present rates of disappearance, as many as two million species currently in existence will disappear by the middle of the twenty-first century. Unless immediate steps are taken, plant extinctions on the scale envisioned by many botanists may also cause massive climatic changes. Some ecologists and geophysicists warn that if the tropical forests disappear, the result will be the greenhouse effect. Of less immediate, but nevertheless great, concern is the theory that mass extinction events in the fossil record have resulted from collisions between the earth and asteroids or comets. The implications of the collision theory for evolutionary biology, however, are far-reaching. If the theory is correct, then the struggle for survival is not the most important feature of evolution. No matter how well adapted to its environment a species may be, survival of a collision would be largely a matter of chance. If the theory proves to be correct, biologists will need to rewrite the textbooks on evolution.

Donovan, Stephen K., ed. *Mass Extinctions: Processes and Evidence*. London: Belhaven Press, 1989. A series of chapters authored by specialists covers all the major mass extinctions and speculates on their causes. The first two chapters, on the historical aspects of studies of extinctions and their recognition, are particularly useful. Extensive bibliography.

Leakey, Richard E., and Roger Lewin. *The Sixth Extinction: Patterns of Life and the Future of Humankind*. New York: Doubleday, 1995. Argues that human activity is creating the sixth great extinction of life on earth, which is now under way.

McGhee, George R. *The Late Devonian Mass Extinction*. New York: Columbia University Press, 1996. An excellent synthesis of one of the less-studied mass extinctions in the history of life on earth. Argues that the disappearance of 22 percent of all families of marine animals, which occurred 365 million years ago, was caused by an asteroid impact that set off a chain of events that lasted close to three million years.

Martin, Paul S., and Richard G. Klein, eds. *Quaternary Extinctions: A Prehistoric Revolution*. Tucson: University of Arizona Press, 1984. Thirty-eight articles analyzing the most recent mass extinction event from many perspectives. Various articles examine the influence of humankind on extinctions in many parts of the world, the influence of climatic changes, and the influence of seafloor rising/land subsidence. The articles demonstrate the complexity of the problem of extinctions and the lack of a scientific consensus on their causes.

Muller, Richard. *Nemesis: The Death Star*. New York: Weidenfeld & Nicolson, 1988. Muller provides a fascinating account of the origin and evolution of the currently controversial theory that the dinosaurs became extinct because of the collision of the earth with an asteroid or comet. He then details the development of the theory that our sun has a presently undiscovered dark companion (he has named it Nemesis) that causes the disruption of either the asteroids or (more likely) the comet cluster every twenty-six million to thirty million years. This disruption results in periodic collisions between the celestial objects and the earth, causing mass extinctions of terrestrial life.

Raup, David M. *Extinction: Bad Genes or Bad Luck?* New York: W. W. Norton, 1991. A text that deals with the reasons for extinction events in an informative and readable style. Suitable for high school and college students as well as the general reader.

Stanley, Steven M. *Extinction*. New York: Scientific American Library, 1987. An excellent account of extinctions in general and major mass extinctions in particular. Stanley makes a strong case for gradual climatic changes being the primary agent in extinctions but acknowledges that catastrophic events and the activities of humankind may have played significant roles in some extinction events.

Stearns, Beverly Petersen, and Stephen C. Stearns. *Watching, from the Edge of Extinction*. New Haven, Conn.: Yale University Press, 1999. Offers accounts of eleven endangered species from the perspectives of scientists and others who work with them. Written for ecologists, conservation biologists, and wildlife biologists, but useful for everyone concerned with the threat of species extinction.

EXTINCTIONS AND EVOLUTIONARY EXPLOSIONS

Type of animal science: Evolution
Fields of study: Environmental science, evolutionary science, paleontology, zoology

The history of life has been punctuated by episodes of great change, some marked by the loss of large numbers of organisms, others by explosive development. Explanations proposed for these fluctuations have a bearing on current extinction levels and the extent to which they can be controlled.

Principal Terms

ADAPTIVE RADIATION: the rapid production of a new species following invasion of a new geographic region or exploitation of a new ecological opportunity

BOLIDE: an extraterrestrial object (for example, a meteorite) that hits the earth

DIVERSITY: the number of fossil taxa (classification groups) associated with a particular place and time

LAZARUS TAXA: groups that apparently disappear during a mass extinction only to appear again later

MASS EXTINCTION: an event in which a large number of organisms in many different taxa are eliminated

PERIODICITY HYPOTHESIS: the proposal that mass extinctions have occurred approximately every 26 million years over the past 250 million years

PHANEROZOIC: an era of geologic time beginning approximately 544 million years ago at the start of the Cambrian period, when animals with mineralized skeletons became common

REGRESSION: the migration of the shoreline and associated environments toward the sea

Extinction of species is a continuous process, and evidence of its occurrence abounds in the fossil record. It has been estimated that marine species persist for about four million years, which translates into an overall loss of about two or three species each year. This is the "background" extinction rate, and it is balanced by speciation events that result in the development of new species. Mass extinctions are events during which the rate of extinction rises dramatically above this background rate, and a number of these have been recognized in the Phanerozoic era. In each of these events, at least 40 percent of the genera of shallow marine organisms were eliminated. Using statistical methods, it has been estimated that at least 65 percent of species became extinct at each of these events, with 77 percent being eliminated at the event at the end of the Cretaceous period and 95 percent at the event at the end of the Permian period. These mass extinctions were balanced by periods of explosive development that often followed, as organisms moved into vacant adaptive zones during periods of adaptive radiation. The most important of these was at the base of the Cambrian period, 544 million years ago, when all the major groups in existence originated, but other radiations occurred in the Early Triassic period and at the start of the Tertiary period.

Causes of Mass Extinctions

Attempts to explain the causes of mass extinctions have centered on terrestrial phenomena such as sea level changes, climatic changes, or volcanic activity. The sea level has shown regular fluctuations on a global level during the Phanerozoic era, and these appear to be related to the melting or formation of polar ice caps or to major tectonic events such as continental splits or the collision and uplift or subsidence of ocean ridges. Extinction events appear to be correlated mostly with periods of marine regression. During such a regression, the withdrawal of the ocean leaves a much smaller habitat for shallow marine organisms. This leads to increased crowding and competition and ultimately to an increased extinction rate. Reduction of large terrestrial vertebrates during these regressions, as happened during the events at the end of the Permian and Cretaceous periods, may be related to increased seasonality caused by the loss of the ameliorating influence of the shallow epicontinental seas.

It has also been shown that some extinctions are related to transgressive events (the spread of the sea over land areas), possibly resulting from the spread of anoxic (oxygen-poor) waters across epicontinental areas. Climatic changes seem to be correlated with eustatic events (worldwide changes in sea level), and the evidence implicating temperature as the main cause of extinctions seems weak. For example, the most important extinction event at the end of the Permian period occurred at a time of climatic amelioration marked by the disappearance of the Gondwanaland ice sheet. Volcanic activity has been presented as a possible cause of the extinctions that occurred at the end of the Cretaceous period. The Deccan Traps of northern India were erupting at that time and would have produced large quantities of volatile emissions that could have resulted in global cooling, ozone-layer depletion, and changes in ocean chemistry. However, no evidence exists as yet for the involvement of volcanic activity in other extinction events.

Although various extraterrestrial causes for mass extinction events have been suggested in the past, these ideas have gained greater credence since the publication in the early 1980's of work by Luis and Walter Alvarez, who ascribe the end-Cretaceous extinction event to the effects of the impact of a large bolide, or extraterrestrial object, perhaps ten kilometers in diameter. The impact of such a large object would have resulted in some months of darkness because of the global dust clouds generated, and this would have halted photosynthesis and resulted in the collapse of both terrestrial and marine food chains. Although cold would initially have accompanied the darkness, greenhouse effects and global warming would have followed as atmospheric gases and water vapor trapped infrared energy radiating from the earth. Physical evidence for an impact rests on the presence in the period boundary layers of high concentrations of iridium and other elements generally rare at the earth's surface but abundant in asteroids. In addition, these layers often contain shocked quartz grains, otherwise found only in impact craters and at nuclear test sites, and microtectites, glassy droplets formed by impact. Although the evidence for extraterrestrial impacts having caused the other major extinction events is slight, this causal factor has been linked with the apparently regular 26-million-year periodicity exhibited by extinctions. Scientists suggest that the regular passage of an unidentified planetary body by the Oort Cloud of comets and the subsequent perturbation could result in increased asteroid impacts and extinction events on earth.

Historical Mass Extinctions

The first mass extinction event that can be recognized in the fossil record occurred in the Middle Vendian period, about 650 million years ago, when microorganisms underwent a severe decline. This event has been linked to climatic cooling related to glaciation. The extinction in the Late Ordovician period was a major event in which 22 percent of marine families became extinct. As there were two main pulses of extinction and no iridium anomaly was found, an extraterrestrial cause seems unlikely. However, sea level and temperature changes have been cited as likely causes. In addition, biologically toxic bottom waters might have been brought to the surface during periods of climatic change. The event at the end of the

Devonian period had a devastating effect on brachiopods, which lost about 86 percent of genera, and on reef-building organisms such as corals. Shallow-water faunas were most severely affected; only 4 percent of species survived, although 40 percent of deeper-water species did, and cool-water faunas also survived better. This event has been linked to a significant drop in global temperatures of unknown cause.

The mass extinction event at the end of the Permian period was the most severe of the Phanerozoic era and resulted in the extinction of up to 95 percent of all marine invertebrate species. On land, amphibians and mammal-like reptiles were both badly affected, and plant diversity fell by 50 percent. No iridium anomaly was found, and the most likely explanation is climatic instability caused by continental amalgamation and the simultaneous occurrence of marine regressions. These occurrences would have disrupted food webs on a major scale. The event that occurred at the end of the Triassic period was much less severe but still involved extensive reductions in marine invertebrates and reptiles. On land, a major faunal turnover took place. Primitive amphibians, early reptile groups, and mammal-like reptiles died out and were replaced by advanced reptiles and mammals. No evidence of an impact event has been found, and the extinctions are generally correlated with widespread marine regressions.

The extinction that took place at the end of the Cretaceous period has become the most hotly debated, in large part because of the bolide impact hypothesis. Although the broad pattern of extinction among marine organisms is known, the detailed picture only encompasses microorganisms such as planktonic foraminifera and calcareous nannoplankton. Study of the ranges of these microorganisms shows that the extinctions occurred over an extended period, starting well before and finishing well after the boundary. Although much has been made of the extinction of ammonites at the end of the Cretaceous period, there are too few ammonite-bearing sections to show whether it was gradual or abrupt. On land, evidence of an increase in the population of ferns just above the boundary suggests the presence of wildfires, as ferns are usually the first plants to recolonize an area devastated by fire. However, in many sections, a return of the Cretaceous vegetation is seen above the fern increase, indicating little extinction.

Post-Extinction Recoveries

Among the vertebrates, a picture of gradual change is seen for mammals, with drastic reductions occurring only in the marsupials. The boundary also does not seem to have been a barrier for turtles, crocodiles, lizards, and snakes, all of which came through virtually unscathed. The dinosaurs did become extinct, and much argument has centered on whether this was abrupt or occurred after a slow decline. In this context, it must be noted that there is only one area where a dinosaur-bearing sedimentary transition across the boundary can be seen, and that is in Alberta, Canada, and the northwestern United States. Records of dinosaurs in this area during the upper part of the Cretaceous period show a gradual decline in diversity, with a drop from thirty to seven genera over the last eight million years. Although explanations of the extinction of dinosaurs have ranged from mammals eating their eggs to terminal allergies caused by the rise of flowering plants to the current ideas about bolide impacts, the answer may be climate related. A major regression of the oceans occurred at this point, resulting in a drop in mean annual temperatures and an increase in seasonality. The bolide impact may have served as the death blow to taxa (animals in classification groups) that were already declining.

The main period of evolutionary expansion in the Phanerozoic era is at the base of the Cambrian period, 544 million years ago. Termed the “Cambrian explosion,” it marks the development of all the modern phyla of organisms, and as many as one hundred phyla may have existed during the Cambrian period. This period seems to have lasted only about 5 million years, and the subsequent history of animal life consists mainly of variations on the anatomical themes developed during this short period of intense creativity. This period is represented in the fossil record by the remarkably well-preserved Burgess Shale fauna of British Columbia, which has been extensively described, and faunas of similar age from China and Greenland. Why the Cambrian explosion could establish all major anatomical designs so quickly is not clear. Some scientists believe that the lack of complex organisms before the explosion had left large areas of ecological space open, and when experimentation took place, particularly with the advent of hard skeletons, any novelty could find a niche. Also, the earliest multicellular organisms may have maintained a genetic flexibility that became greatly reduced as organisms became locked into stable and successful designs. Why some of the innovations were successful in the long term and others were not is unknown, as no recognized traits unite the successful taxa. It has even been suggested that success may be due to no more than the luck of the draw.

In contrast, the recoveries after the major extinctions at the end of the Permian and Cretaceous periods did not result in the development of new phyla. The earliest Triassic ecosystems were more vacant than at any time since the Cambrian period, yet no new phyla or classes appear in the Triassic period. This suggests that despite the overwhelming nature of the extinctions, the pattern was insufficient to permit major morphological innovations, in part probably because no adaptive zone was entirely vacant. Hence, despite the fact that the mass extinction at the end of the Permian period triggered an explosion in marine diversity described as the Mesozoic marine revolution, persisting species may have limited the success of broad evolutionary jumps.

Reading the Fossil Records

All understanding of extinction events or of evolutionary explosions depends on the fossil record. The study of the diversity of organisms through time—the number of different types of organisms that occur at a particular time and place—is therefore very important. The basic data consist of compilations of extinctions of taxa plotted against similar compilations of originations of taxa. Periods when either extinction or origination was unusually high show as peaks or troughs on a graph. Unfortunately, biases in the preservation, collection, and study of fossils have conspired to obscure patterns of change in diversity.

Geological history of patterns of diversity is obscured by a variety of filters, many of which are sampling biases that cause the observed fossil record to differ from the actual history of the biosphere. The most severe bias is the loss of sedimentary rock volume and area as the age of the record increases because the volume and area correlate strongly with the diversity of organisms described from a stratigraphic interval. The quality of the record also tends to fall with increasing age because the rocks are exposed to changes that may destroy the fossils they contain. The differences in levels of representation among the paleoenvironments in the stratigraphic record also influence the composition of the fossil record; for example, shallow-marine faunas are much better represented than are terrestrial faunas.

Diversity patterns are studied at a variety of levels, from the species upward, that vary in their quality and inclusiveness. A basic problem is that many of the processes that are of interest occur at the species level or even below it, but the biases of the fossil record mean that data are best at higher levels. Diversity of shallow-marine organisms for the Phanerozoic era cannot be read directly at the species level because the record is too fragmentary. The record at the family level is much more complete because the preservation of one species in a family allows the family to be recorded. For this reason, paleodiversity studies are often conducted at the family level. However, higher taxon diversity is a poor predictor of species diversity. For example, an analysis of the mass extinction at the end of the Permian period indicates that the 17 percent reduction in marine orders and 52 percent reduction in marine families probably represent a 95 percent reduction in the number of species. Another problem with the study of fossils is that soft-bodied and poorly skeletonized groups may leave little or no record. It has generally been assumed that the ratio of heavily skeletonized to

Georges Cuvier

Born: August 23, 1769; Montbéliard, France
Died: May 13, 1832; Paris, France
Fields of study: Anatomy, paleontology, zoology
Contribution: Cuvier, the founder of functional anatomy and the father of paleontology, was the first to devise a systematic natural classification of the animal kingdom and to document extinctions of ancient animals.

George Cuvier studied at the Académie Caroline in Stuttgart from 1784 to 1788. In 1795, he was invited to Paris by Étienne Geoffroy Saint-Hilaire, where he was appointed as a professor of animal anatomy at the French National Museum of Natural History.

After dissecting and studying many large animals, Cuvier concluded that organisms are functional wholes, in which the form and function of each part is integrated into the entire body. Each part of an organism bears signs of the entire organism. Thus, any change in an organism's anatomy would render it unable to survive. Consequently, Cuvier did not believe in organic evolution.

Based on rational principles and his knowledge of the comparative anatomy of living organisms, Cuvier reconstructed a number of organisms from fragmentary fossils. His studies led him to believe that any similarities between organisms were due to common functions, not to common ancestry. Paradoxically, some of his findings were later used to help support the theory of evolution.

During Cuvier's lifetime, some scientists interpreted fossils as remains of living species. Others thought that the unusual organisms known as fossils must still survive in unexplored parts of the world. Many could not believe that God would allow any species to become extinct. Cuvier published detailed studies about elephant anatomy showing that the African and Indian elephants were distinct species and that the fossil mammoths of Europe and Siberia were different from any living elephant species. He also published documentation of the past existence of large mammals, including the ground sloth, the Irish elk, and the American mastodon, that resembled no living species. Through these studies, Cuvier established the fact that some animal species had become extinct. The results of his studies, such as his *Discours sur les révolutions de la surface du globe* (1825; discourse on the revolutions of the globe), launched the field of modern vertebrate paleontology.

Georges Cuvier was the first scientist to document the existence of extinctions of animal life. (National Archives)

Cuvier believed that the Earth was very old and that periodic upheavals, rather than the inability of a species to adapt, had annihilated a number of species. He viewed the upheavals as catastrophic events produced by natural causes that were linked to geological conditions, including the periodic rise and fall of sea level. As a result, Cuvier inferred that extinctions of species documented by the fossil record were the result of abrupt changes that caused the strata of the continents to be dislocated and folded.

Eventually, the theory of catastrophism was supplanted in favor of uniformitarianism. However, in addition to the slower natural processes suggested by uniformitarianism, the Earth has also been shaped by occasional catastrophic events, which appear to be the source of major extinctions of animal species.

—Alvin K. Benson

non-skeletonized species has remained approximately constant through the Phanerozoic era; however, there are no data to support this and there is some evidence that skeletons have become more robust through time in response to newly evolving predators. The net result of these biases is severe. Only 10 percent of the skeletonized marine species of the geologic past and far fewer of the soft-bodied species are known.

Despite these problems, it has been possible to show that diversity of organisms has varied in a number of ways during the Phanerozoic era. Tabulations of classes, orders, and families have been used to show that there were significant periods of increased extinction or increased evolutionary rates. One of the most important uses of these data has been the tabulation at the family level that appears to show a regular periodicity of about 26 million years for extinction events and that has been used to support ideas about periodic extraterrestrial events. However, although fluctuations occurred, it has also been possible to show that the number of marine orders increased rapidly to the Late Ordovician period and has remained approximately constant since then.

The Ebb and Flow of Life on Earth

Mass extinctions and evolutionary explosions are the opposite faces of the pattern of diversity of organisms through time. During periods of mass extinction, the diversity of organisms on earth has dropped drastically, and in some cases entire lineages have been wiped out. Evolutionary explosions, on the other hand, resulted in enormous innovation, particularly at the beginning of the Cambrian period, and the development of new variations on established morphotypes (animal and plant forms and structures) later in the geologic record. Understanding the processes that caused these events is of major importance because people have reached the point where they are capable of influencing their environment in drastic ways.

Studies of extinction events have shown that they have a variety of causes, some of which appear to be environmental changes brought about by natural processes while others may be the result of extraterrestrial forces. The most severe of these extinction events occurred at the end of the Permian period, 245 million years ago, and resulted in the loss of up to 95 percent of marine invertebrate species. The cause of this extinction appears to be primarily that continents were amalgamating and oceans were retreating, which resulted in a major reduction in the habitat of shallow-marine organisms. Terrestrial habitats were also affected as the increase in continental area and loss of the ameliorating effect of extensive areas of shallow ocean brought about climatic changes. Although climatic changes are thought to be the main culprit in the majority of extinction events, some scientists believe that large bolides, or extraterrestrial bodies, struck the earth with such force as to create major changes in the environment that significantly reduced diversity. This theory has enjoyed the most popularity as the explanation for the event at the end of the Cretaceous period, during which the dinosaurs became extinct, but evidence for an extraterrestrial body's involvement in any of the other events is slight.

Whatever the cause, environmental change that results in habitat reduction is the main reason for species decline. As humans have risen to dominance over other species, the extinction rate has accelerated, and in the last half-century, this rate has climbed considerably above natural attrition as populations have increased and habitats have been altered. Although the levels of extinction have not yet reached those recorded during major extinction events of the past, some scientists believe people may be facing an ecological disaster. A better understanding of the processes surrounding past extinction events and the rebounds that followed them will help people prepare for and deal with the future.

Written by a paleontologist and an astronomer, who argue that simple life, such as bacteria, may be common throughout the universe, but that complex life, such as has evolved on earth, is rare. Outlines the special features of earth that make the evolution of life possible, and the consequent tragedy of species extinction.

EYES

Type of animal science: Anatomy
Fields of study: Anatomy, biochemistry, cell biology, neurobiology, physiology

The eyes are the sensory organs that allow animals to visualize the world around them. Many different types of eyes have evolved, from very simple light-gathering eye spots to the complex compound eyes of insects. Each type of eye is used to convert a light signal into a useful piece of information for the animal.

Principal Terms

BINOCULAR VISION: the ability to utilize image information from both eyes to form a single image with depth information

CHROMOPHORE: the molecule which interacts with opsin; absorption of light changes the interaction and starts the phototransduction cascade

OMMATIDIUM: individual unit of the multifaceted compound eye

OPSIN: a membrane-bound protein, or pigment, which absorbs light

OPTIC NERVE: the main nerve taking information from the eyes to higher processing areas

PHOTORECEPTOR: cell containing membranes which house light-sensitive pigments

RETINA: the light-sensitive membrane at the back of the eye

There are many different kinds of eyes in the animal kingdom, each type with its own set of benefits for a particular species. The most basic function of the eye is to act as a light-sensitive organ, to detect the presence or absence of light. In addition to this, elaborations are often made, such as the ability to form an actual image on a retina, or the ability to control the amount of light entering the eye; each elaboration is made to provide the visual needs of individual species. The animal kingdom comprises eyes from the very rudimentary to exceptionally complex. The two basic types of eye are the simple eye and the compound eye. The simple eye is made up of a single light-sensitive region, whereas the compound eye comprises several such elements.

Simple Eyes

The most elementary simple eye consists of a photosensitive membrane, or eye spot. Light should enter the membrane from only one direction, and so eyes have a pigmented backing to stop entry of light from the wrong side. In order to give the light entering a sense of directionality, the photosensitive membrane is often shaped like a cup; this basic eye type is called a pigmented cup eye. An example of an animal which possesses a simple eye of this nature is the cephalopod, *Nautilus pompilius*, which is known as a living fossil as it is thought to exemplify the behavior and physiology of ancient organisms. *Nautilus* has a pinhole eye with a pigmented backing; the pinhole aperture is a primitive method to restrict the amount of light entering the eye. This eye has no other formal optics. An elaboration of this type of eye would be to add a spherical lens; this would allow the light entering to be focused and to form an image on the photosensitive membrane. In many animals, the lens can change shape (become thinner or fatter) using surrounding musculature, in order to properly focus the image on the retina; this ability is called accommodation. The lens changes the angle at which light bends, and hence the focal length of the eye. The focal length of the eye is the distance from the eye to the part of the retina on

Optimization of Eyes

In order to adapt to the particular needs of individual species over evolutionary time, simple eyes have had to change and become optimized to deal with unique circumstances. Two major aspects of superior vision are resolution and sensitivity. Resolution, or spatial acuity, refers the ability to tell that two points are separate, and not just one point. Thus, better resolution is beneficial to an animal that needs to resolve images at a distance. To increase resolution, one can build more receptors per retina. However, there is a limit to this; to fit in more photoreceptors, they would have to become smaller (thinner) and at some point they would be too small to trap photons efficiently. This can be counteracted by making the receptors longer to catch more photons of light. Also, with too many receptors the nervous system becomes overloaded; for this reason, throughout most of the retina, many photoreceptors converge onto a single ganglion. Nevertheless, there are regions of high resolution at which each photoreceptor has its own ganglion; this region of the retina is called the fovea and is best described in vertebrate eyes. Increasing the eye size also increases the resolution, since it increases the amount of light getting to each receptor. Some species need to maximize sensitivity of their eyes, for example, animals who are active at night. To do this, the aperture needs to be large. This allows for maximum light entry into the eye. To the same end, the receptors could be made bigger, as could the entire eye. Thus, nocturnal animals, such as the opossum, have much larger eyes and apertures than diurnal animals, such as primates, which use a smaller eye and a smaller lens to give better optics.

which the image is focused. Other animals actually move the entire lens forward or backward in order to accommodate. One drawback that comes along with spherical lenses is that the entire image is rarely totally focused on the retina because, as a result of the spherical shape of the lens, the light rays become focused over several focal lengths (this is called spherical aberration). To correct this, many lenses have a refractive index gradient across their length; basically, the density of the lens is different across its length, which causes the light rays to bend differently and corrects for spherical aberration, allowing proper focusing of the entire image on the retina. In spiders, a different kind of optics is found; instead of a lens, these creatures focus light rays with their corneas. The structure, unlike the lens, is fixed and does not change shape to accommodate.

Compound Eyes

Compound eyes are the most abundant type of eye in the animal kingdom, and can be thought of as being derived from the simple pigmented-cup type of eyes. The simplest compound eye consists of several pigmented-cup-type units, each of which samples a different angle of visual space. Found only in invertebrates, such as certain types of worm, this kind of eye gives very poor quality images, but does give the animal a sense of the direction from which light is coming. A more complicated version of this eye is the apposition compound eye, found in many insects, where each cup has its own optics. Each individual unit is called an ommatidium, comprising the rhabdom (containing the light-sensitive cells), directly contacting a light-focusing apparatus (either a lens or a cornea). In order to fit as many ommatidia into the eye as possible, the facets are hexagonal. Another elaboration is the superposition compound eye; this eye has a space between the cornea (or lens) and the rhabdom of each ommatidia. As such, this allows light from many corneal facets to converge onto each rhabdom. This increases the sensitivity as compared to the apposition eye. Several mechanisms are used to bend the light from each ommatidium; the simplest is the reflecting superposition eye, found in shrimp, which uses a series of mirrors along the edge of each facet to reflect the light onto the rhabdoms.

Photoreceptors

The photoreceptive element common to all eyes differs from species to species, from the cup-shaped retinas of simple eyes to the complex rhabdom structures of compound eyes. In simple eyes, the light-sensitive element is platelike, with projections containing flat layers or discs of membranes. In vertebrates, the two photoreceptor types are the cones (cone-shaped projections), which have layers of photosensitive membrane, and the rods (rod-shaped projections), which contain free-floating discs. Compound eyes have rhabdomeric microvillar photoreceptors; the microvilli are fingerlike structures that project from the rhabdomeres and are light-sensitive. Within each of these structures lies the actual light-sensitive pigment, a membrane-bound protein known as opsin. In the rhabdoms, the orientation of the opsin molecule is parallel to the axis of the microvilli; this fact aids in the perception of polarized light. There are many types of opsin protein, and they can be categorized according to which wavelength of the light spectrum they preferentially absorb. The opsin protein interacts with a Vitamin A-derived molecule called the chromophore. Its chemical name is 11-cis retinal. The absorption of a photon of light changes the chemical interaction between the opsin and the chromophore, and it is this chemical change which initiates the cascade of events that leads to a nerve signal, known as phototransduction.

The actual biochemistry of phototransduction is very complex, but involves the amplification of the signal of reception of light, and its transformation into a nerve impulse. The passage of the information through the nervous system is also very complicated and details are different in different species, but in general, the receptors converge onto axons and the nerve impulse travels through the optic nerve for higher processing. Of the two types of photoreceptor existing in vertebrates, rods are very light-sensitive and are used in situations where light is limited (scotopic conditions). Cones are less sensitive and are used in situations where light is abundant (photopic conditions). The vertebrate retina almost always possesses both rods and cones, although some nocturnal animals or animals living in an environment where light is scarce, for example deep-dwelling fishes, have all-rod retinas. Mammals have rod-dominated retinas, which are probably remnants of the time millions of years ago when mammals were nocturnal. There are several kinds of cones, which are characterized according to which opsins they carry within the membrane layers; this dictates which wavelengths of light the cone preferentially absorbs. Absorption of light by combinations of at least

Other Features of Photoreceptors: Pigments and Oil Droplets

Some vertebrate and invertebrate photoreceptors have been found to possess filtering mechanisms. The classic example of this is oil droplets in the cones of bird eyes. The cone possesses a droplet of oil positioned just behind the outer nuclear layer of the retina, where the photoreceptor layer containing the opsin molecules is located. The droplet is carotenoid in nature and as such can be colored blue, yellow, orange, or red. As light travels through this droplet, it is filtered in intensity and in wavelength. Thus, the droplet acts as a selective spectral filter, only allowing certain wavelengths of light to get through the pigment to be absorbed at the photoreceptor level. It therefore increases the spectral sensitivity of individual receptors, and could enhance the color vision of such animals. Since most of the carotenoid oil droplets block out the shorter wavelengths of light, it is thought that they could also be a mechanism for protecting the receptors from the damage of ultraviolet light. In invertebrates, a similar filtering system has been found, although it is not in the form of an oil droplet but in the form of pigmented vesicle bundles. In the same way, these vesicles filter the incoming light, narrowing the absorbance spectrum of the photoreceptor layer above them.

The placement of the eyes in the head, so that each eye captures a slightly different angle on the same visual field, creates binocular vision and depth perception. (Digital Stock)

two different cone types will allow a species color vision, given the cognitive ability to process such information.

Another important feature of eyes is their position on the head relative to each other. Most vertebrates and some invertebrates have two eyes, allowing them a certain amount of binocular vision depending on the angle between them. In fact, both eyes project a slightly different image onto each retina, but the brain is able to compute this as a single image. This results in a larger field of view and also a sense of depth; these are definite advantages, for example for a hunting animal, which needs to know how far it is from the prey target.

FAUNA: AFRICA

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology, zoology

Africa is renowned for the richness of its wildlife, having a greater variety of large ungulates (some ninety species) and freshwater fish (two thousand species) than any other continent. However, many of these animals are being hunted to near extinction or endangered due to habitat loss.

Principal Terms

ARTIODACTYLS: mammals with an even number of toes

PREDATOR: a carnivorous animal that obtains food by hunting

UNGULATE: a hoofed mammal

Known for the enormous diversity and richness of its wildlife, Africa has a greater variety of large ungulates, or hoofed mammals (some ninety species), and freshwater fish (two thousand species) than any other continent. However, probably no group of animals is more identified with Africa than its flesh-eating carnivore mammals, of which there are more than sixty species. In addition to the better-known big cats, such as lions, leopards, and cheetahs, there are wild dogs, hyenas, servals (long-limbed cats), wildcats, jackals, foxes, weasels, civets, and mongoose.

The African Enigma

There are many theories as to why Africa has such an abundance of wildlife, and large wildlife at that. While early North American human societies drove mammoths, giant beaver, and sabertooth tigers to extinction, early Europeans wiped out lions and rhinos, and Asians domesticated their landscapes, Africans lived in relative accord with creatures that were no less grand or ferocious. Some African folklore places animals on the same footing with people.

Another theory is that the tsetse fly, by spreading the sleeping sickness, made much of tropical Africa uninhabitable by humans and protected the wilderness and wildlife from human depredation. Still another possibility may have been the constancy and small size of the African population in comparison with European and Asian numbers—too few people to either overhunt large mammals or exhaust their habitat. One more possibility is that the savannas of Africa—grassy plains with scattered tree cover—provide good habitat for so many ungulates. Humans cannot hunt ungulates easily under these conditions because the humans can be seen and outrun easily. At the same time, a large population of ungulates supports an appreciable population of predators such as lions and scavengers such as hyenas.

At one time, most African fauna was believed to have originated in the Palearctic regions, that is, Europe, northwest Africa, and much of Asia. There is no doubt that as recently as fifteen thousand years ago, a milder Saharan climate allowed typically Ethiopian forms, such as clariid catfish, to reach the river systems of North Africa. Similarly, northern animal life and vegetation seem to have extended far south into the Sahara. The white rhinoceros evidently coexisted with elklike deer.

The spread of forests during the wetter epochs created separate northern and southern wooded grasslands. This led to the evolution of such closely related northern and southern species of antelope as the kob and puku, the Nile and common lechwe, and the northern and southern forms of white rhinoceros. In earlier periods, the animal life was even more remarkable than in modern times. Fossil deposits have revealed sheep as big as present-day buffalo, huge hippopotamuses, giant baboons, and other types similar to existing species. These "megafauna" probably lived in wetter periods and died out as the climate became drier.

Effects of Human Population Growth

The fine conditions for Africa's fauna in the mid- to late nineteenth century started to come to an end when European settlers arrived in many parts of Africa. Technologies, in the form of Western

Habitats and Selected Vertebrates of Africa and Madagascar

medicine and sanitation, sparked a demographic revolution. In places such as Rhodesia (now Zimbabwe), the human population exploded twenty-fold during the ninety-year reign of white settlers.

Since 1940, the combined pressures of hunting and habitat destruction have cut wildlife numbers greatly. The antelope known as the Zambian black lechwe, believed to have numbered one million in 1900, had been reduced to less than eight thousand by the late twentieth century. The population of African elephants declined from two million in the early 1970's to 600,000 by 1990, largely because of poaching for the ivory trade.

Since the 1960's, poaching has caused a 95 percent decline in the world's black rhino population to fewer than 2,600 in 1997. The African white rhinoceros reached the verge of extinction in 1980. In West Africa, the continual southward advance of the Sahara desert has amplified the twin pressures of habitat destruction and human population. The larger fauna that lived there, caught between the desert and the burgeoning population, are largely gone now.

In Kenya, farmers have long since cleared most of the central part of the country that was once a densely forested region inhabited by wild animals. Some people have invaded national parks for commercial purposes such as logging and cattle grazing, thus forcing wildlife out of their preserved habitats. Some animals have had no alternative but to fight with humans for food and water. Along the Kenyan coast, many people have been attacked and killed by charging hippopotamuses and crocodiles in search of food and space. Similar cases have been common in the highlands, where Kenyans have lost their lives to charging elephants or to leopards and buffalo.

In recent years, human-elephant conflicts in Cameroon have become a major issue. Such conflicts are more acute in the savanna ecosystem, due to the loss of the elephant's range and habitat following the conversion of natural vegetation to farmland and the logging of large tracts of forests. Cameroon still has a relatively large herd of elephants, estimated at about twenty thousand in 1997. Approximately 75 percent of these elephants live in the dense equatorial forest.

Another issue in Cameroon in 1999 was a 652-mile (1,050-kilometer) pipeline proposed to traverse tropical rain forests and link oil fields in landlocked Chad to an export facility in Kribi, Cameroon. The original route of the pipeline was changed to go through two less-fragile ecosystems, but the new route was still designed to cut through tropical areas and provide easier human access to endangered species such as gorillas, chimpanzees, and elephants.

African Mammals

The main group of herbivores is the African antelope, which belong to four subfamilies of the ox family. The first subfamily is further subdivided into the African buffalo and the twist-horned antelope, including the eland (the largest of all antelope), kudu, nyala, and bushbuck. The second subfamily is the duiker, a small primitive antelope that lives in the thickets, bush, and forests. Other well-known large African herbivores include the

Endangered Chimpanzees Source of HIV

A type of chimpanzee that is feared to be headed for extinction by the year 2010 carries a unique genetic blend of human immunodeficiency virus (HIV) and simian immunodeficiency virus (SIV). Scientists have stated that, in the genetic family tree of all known HIVs and SIVs, this virus appears to be the strain that could be the source of all HIVs. Once the strain known as SIVcpz made its way into the human species, probably in the 1950's, it mutated into the existing human strain, adapting naturally to its new host.

The chimpanzees are being driven from their homes by loggers in the rain forests of the Congo River basin. They also are being slaughtered for their meat. However, scientists consider it is crucial that this species of chimpanzee remain in existence so they may study them for critical HIV research.

zebra, giraffe, hippopotamus, rhinoceros, and African elephant.

Africa's large number of endemic or native mammal species is second only to that of South America. These include several families of the ungulate order Artiodactyla (mammals with an even number of toes), such as the giraffe and hippopotamus. Some carnivores—such as civets, their smaller relations, the genets, and hyenas—are chiefly African. The rodent family of jumping hares is endemic, and one order, the aardvark, is exclusively African. The Malagasy Republic (Madagascar) has a remarkable insect-eating family. These are the tenrecs, animals with long, pointed snouts. Some tenrecs are spiny and tailless.

The primates include about forty-five species of Old World monkeys and two of the world's great apes: the chimpanzee and the world's largest ape, the gorilla. The gorilla is present in two subspecies: the lowland gorilla of Central and West Africa and the mountain gorilla of East Africa. The rare mountain gorillas live only in the upland forest on the borders of Uganda, Rwanda, and Congo-Kinshasa (Zaire). There are two populations of roughly equal size. One is in Uganda's Bwindi Impenetrable Forest National Park, where a 1998 census counted 292 gorillas. The second is in the Virunga Mountains, on the borders of the three countries. The last census there, completed in 1989, estimated 324 gorillas in the Virungas, but war has prevented a recount.

Presimian primates include pottos or African lemurs and galagos, bush babies, or small arboreal lemurs. These and other African lemurs tend to be small and nocturnal. In the Malagasy Republic, where there are no true monkeys, the lemurs have occupied all ecological niches, both diurnal and nocturnal, that the monkeys would have taken. Accordingly, the world's most diverse collection of presimian lemurs survives in Madagascar.

African Reptiles, Birds, and Insects

Most African reptiles have their origins elsewhere—mainly in Asia. These include lizards of the agamid family, skinks, crocodiles, and tortoises. Endemic reptiles include girdle-tailed and plated lizards. Large vipers are common and diverse. Certain species have extremely toxic venom, but they are rarely encountered. One of the most noted is the black mamba. Amphibians also belong mainly to Old World groups. Salamanders and toothed tree frogs are confined to the Palearctic northwest Africa. Abundant and more common frogs and toads include such oddities as the so-called hairy frog of Cameroon, whose hairs are auxiliary respiratory organs.

The birdlife south of the Sahara includes almost fifteen hundred resident species. An additional 275 species either reside in northwestern Africa or are winter migrants from Europe. Once there may have been as many as two billion individual migrants, but their numbers have been reduced considerably by severe droughts and by human land use and predation. The few endemic bird species include the ostrich, shoebill, hammerkop, and secretary bird. The many predators of land mammals include eagles, hawks, and owls. Many more, such as storks, waders, and a few species of kingfishers, prey on fish. Even more feed on insects.

Insects include large butterflies, stick insects, mantises, grasshoppers, safari ants, termites, and dung beetles. Spiders abound throughout the continent, and scorpions and locusts can be plentiful locally. Huge swarms of locusts periodically spread over wide areas, causing enormous destruction to vegetation. Mosquitoes that carry malaria are present wherever there is a body of water. Female blackflies transmit the nematode *Onchocera volvulus*, a parasitic filarial or threadlike worm. This organism eventually collects in many parts of the body, including the head near the eye. Nematode clusters around the eyes cause a blindness known as "river blindness." This disease has prevented any significant human habitation in many of Africa's river valleys.

Tsetse flies carry the parasite that causes African sleeping sickness in humans and nagana in livestock. These flies are found in all tropical portions of sub-Saharan Africa. The controversial chemical pesticide, dichloro-diphenyl-trichloro-

Tsetse Fly: Winged Guardian of Wilderness

The tsetse fly acts as a carrier for trypanosomiasis, a parasite that causes sleeping sickness, which is a wasting disease. When sleeping sickness is acute, the symptoms are high temperature, anemia, fitful appetite, and swollen limbs. The victim eventually sinks into an irritable haze, then slips into a coma and dies.

Sleeping sickness has had a long history in Africa. One subspecies of the trypanosomiasis parasite lives amicably in the bloodstream of wild animals such as antelope. However, when it gets into a cow, it makes the animal waste away and die. As a consequence, raising livestock has been difficult or impossible in much of sub-Saharan Africa. More than three million square miles (eight million square kilometers) of that region are off-limits to cattle, and in places where they are raised, three million cows die of the disease each year. The tsetse fly is cheered by conservationists because it makes so much of Africa largely uninhabitable for humans and cattle, thus preserving wildlife. However, it is estimated that the sleeping sickness spread by the tsetse fly threatens fifty million Africans.

ethane (DDT), which is banned in the West, is being used in Zimbabwe and other countries to eliminate the tsetse fly. DDT has adversely affected birds and fish there and has even been found in nursing mothers' breast milk.

Changing Human Attitudes Toward Conservation

If people can benefit from wildlife, their attitudes and actions toward wildlife will improve. Starting in Namibia in 1967 and extending to Zimbabwe in 1975, lawmakers put the idea into action. Large landowners were allotted ownership rights to wildlife, an idea totally alien to the European and the United States' tradition of exclusive state ownership. Landowners, for the first time since the imposition of colonial rule, were free to make economically informed—and, as it turned out, ecologically desirable—market decisions on how best to use their land. By 1990, 75 percent of Zimbabwean ranchers in areas too dry to support crop production had shifted partly or entirely to wildlife ranching. That change was due to the nearly quadruple net profit per acre advantage held by wildlife over cattle.

Rinderpest, a highly contagious bovine plague that has killed millions of Africa's cattle, buffalo, and wildlife in the past century, is finally being brought under control. The disease has been eradicated in West and Central Africa, and is contained in most of East Africa. Rinderpest, caused by morbillivirus, attacks ungulates such as cows, sheep, buffalo, and giraffe and is almost always fatal. It is easily transmitted through direct contact and by drinking water contaminated with the dung of sick animals. It is believed to persist in the Sudan and possibly Somalia, and about four other places in the world.

In Swaziland, pastoralists known as Shewula are breaking with tradition by giving more than 7,400 acres (3,000 hectares) of land used for grazing cattle to a large new game reserve. It will be part of a new transnational reserve with neighboring South Africa and Mozambique. In return, donors have provided funds to build tourism facilities on the land and to train the community in conservation, management, and marketing skills. The goal is to develop the reserve's tourism potential to benefit the rural villagers who have chosen wildlife over cattle.

Similar arrangements have been made between an international hotel chain and a village community outside Tanzania's Serengeti National Park. The agreement involved more than 25,000 acres (10,000 hectares) of land in the Loliondo buffer zone between the Serengeti and the Masai Mara of neighboring Kenya. The Loliondo corridor is used by thousands of stampeding wildebeest during their famed migrations between the Serengeti and the Mara.

Progress has been made in efforts to increase the elephant population. In East Africa, the numbers of elephants are slowly increasing after the poaching rampages of the 1980's. The areas around Tsavo National Park in Kenya and in neighboring Tanzania have reported a count of eighty-one hundred elephants, as opposed to about six thousand elephants in the late 1980's. In 1972, however, there were about twenty-five thousand elephants in the greater Tsavo area. The elephant conservation record of Namibia, Botswana, and Zimbabwe has been impressive. As of the summer of 1999, they had an estimated 200,000 elephants.

FAUNA: ANTARCTICA

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, evolutionary science, wildlife ecology, zoology

Antarctica, the name meaning "opposite to the Arctic," is the coldest and windiest continent on earth. It is also one of the driest, despite being covered in ice sheets up to four kilometers thick. The faunas of the Antarctic display indistinguishable diversity. Many species of fauna are rare and/or endemic, particularly the invertebrates.

Principal Terms

Antarctica: the continent surrounding the South Pole, almost entirely covered by an ice sheet
collembola: primitive, wingless insects
higher insects: generally larger insects with increasing levels of morphological complexity
pack ice: floating islands of ice that form flows measuring from a few feet wide to ice islands miles across
sub-Antarctic: Antarctic landmasses of lesser southern latitude exhibiting more moderate climatic conditions

The history of life in the Antarctic is a fascinating one, largely because, in geologic terms, Antarctica has been very different from the way it is today. For much of Antarctic history, the continent was fully vegetated and carried all the animal life that depends on plants for a living. This is very different from today. Antarctica's gradual glaciations and long isolation from other continental landmasses has impeded the establishment and development of land-based flora and fauna. Other significant factors that have hampered terrestrial biotic evolution on Antarctica include the harsh climate, the ice cover, and the limited number of ice-free land areas. Consequently, the terrestrial flora and fauna of Antarctica are few.

The Antarctic is an extreme environment for any organism to survive in, yet both marine and terrestrial habitats of the Antarctic contain fauna that have adapted to the extreme conditions in order to effectively utilize available resources. Generally speaking, Antarctic regions are devoid of a wide array of faunal diversity due to lack of habitat. The sub-Antarctic and cool temperate islands have much greater diversity, including shrubs and trees. With this higher plant life comes a correspondingly complex array of animal life. The sub-Antarctic and cool temperate islands also possess high levels of endemism as a consequence of their long-standing geographical and ecological isolation from each other and the surrounding continental landmasses.

Antarctic Fauna

The terrestrial fauna consists of a few invertebrate species of protozoans, rotifers, nematodes, tardigrades, collembola, and a species of mite. These life forms are restricted mainly to moist beds of moss. The diversity of marine mammals and birds in the coastal areas and associated pack ice is dependent on marine food chains in the adjacent seas. Because of the vast ice, the continent supports only a primitive indigenous population of cold-adapted land plants and animals. The surrounding sea is as rich in life as the land is barren.

The resource of Antarctic and sub-Antarctic waters supports vast numbers of a variety of seabirds, which play an important role in the marine ecosystem. Nesting grounds are limited, being confined to the scattered sub-Antarctic islands and ice-free localities during the summer on the Antarctic continent and Antarctic Peninsula.

Few terrestrial vertebrates are resident in Antarctica, and those that do occur are limited to sub-Antarctic islands. There are no naturally occurring mammals, reptiles, or amphibians, although humans have deliberately or accidentally introduced a range of animals such as rats, mice, fish, chickens, rabbits, cats, pigs, sheep, cattle, and reindeer to the sub-Antarctic, many impacting native species. Terrestrial animals of the sub- and maritime Antarctic include arthropods, earthworms, and mollusks. Higher insects include spiders, beetles, and flies, most of which are confined to the less severe areas. Microinvertebrate groups such as nematodes, tardigrades, and rotifers are also numerically well represented. The terrestrial fauna of the severe areas of the Antarctic continent are even more simplified. No higher insects are present; the smallest arthropods are restricted to limited areas of vegetation. Instead, groups such as nematodes become dominant. In the most extreme continental cold deserts, simple food webs consist of as few as one to three nematode species, only one of which may be predatory.

Threats to the Antarctic

Much of the Antarctic bears the distinctive imprint of human modification, particularly through the deliberate introduction of animal pests and predators. Of particular concern are the introduced mammals, notably rodents, cats, rabbits, sheep, cattle, and reindeer. In recent years, there have been several cases of successful eradication of alien mammals from islands, and such efforts are continuing. This is important, since islands are vital breeding and resting grounds for seabirds.

FAUNA: ARCTIC

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, evolutionary science, wildlife ecology, zoology

The Arctic, the name derived from the Greek arktos, *meaning, "bear," may appear to be desolate and lifeless, but it is far from these things. Plants exhibit surprising richness even though generally limited to a few inches in height and sparse distribution. The shallow, often sterile soil, abrasively high winds, low soil temperatures, and frequent freezing and thawing fluctuations have forced the development of a wide variety of fauna that have adapted to these harsh conditions.*

Principal Terms

ADAPTATION: the processes of change in a living organism that enable it to adjust to the conditions of the environment in which it lives

ARCTIC: the surface of earth lying above 66.5 degrees North latitude, including the Arctic Ocean between North America and Russia

PERMAFROST: any soil in the arctic regions in which temperatures below freezing have existed continuously for a long time

TUNDRA: a treeless, level or gently rolling plain of the arctic region; characterized by a marshy surface from which mosses, lichens, and low shrubs grow

The Arctic is the northernmost region of the earth, centered on the North Pole. The arctic landscape is mainly tundra. This frozen ground lies above tree line and is covered with hearty plants such as moss and lichen, from which caribou and musk ox feed. Arctic temperatures average 10 degrees to 20 degrees Fahrenheit on an annual basis. Due to its extreme northern latitude, the Arctic gets varying amounts of sunlight at different times of year. Precipitation is very low, with average annual rainfall of only seven inches.

Besides extreme fluctuations between summer and winter temperatures, the arctic landscape contains permanent snow and ice in the high country; grasses, sedges, and low shrubs in the lowlands; and permafrost in almost all locations. The permafrost limits drainage and retains moisture for plant growth within the active layer. This can result in wetland formation, as occurs in level areas of the coastal plains of the Arctic. Here, extensive wetlands are home to aquatic vegetation, invertebrate fauna, waterfowl, and shorebirds. The plant growth season is usually less than one hundred days. However, plants do take advantage of constant sunlight in summer months, which enables them to optimize photosynthesis without the usual nighttime cost of respiration.

Arctic Fauna

Arctic ecosystems lack the diversity and richness of species that characterize temperate or tropical ecosystems. Animal as well as plant species decline in number with increasing latitude. Vertebrate species of the Arctic are limited to approximately twenty species of mammals and more than one hundred species of birds. Most are closely related species, such as the caribou of North America and the reindeer of Eurasia. This similarity in arctic mammalian fauna is a result of the lower sea levels of the Pleistocene glaciations, when a broad land connection, known as the Bering Land Bridge, connected present-day Alaska and Siberia. Some arctic mammalian fauna, primarily herbivores and carnivores, rarely occur outside the Arctic and have adapted to life in this environment. Other fauna, such as species of ground squirrels, voles, shrews, red fox, ermine, wolverine, wolf, and brown bear, are common to other ecosystems but are distributed widely throughout the Arctic.

Wet sedge meadows often associated with lake margins, estuaries, and seacoasts are favored nesting habitats for millions of migrating waterfowl and shore birds during the summer months in arctic regions. In addition to shorebirds and waterfowl, finches, buntings, and sparrows are the most abundant species nesting in the Arctic. Terrestrial avian fauna of the Arctic include only a few resident species, among them the ptarmigan, snowy owl, gyrfalcon, and raven. Nonresident species include raptorial birds that commonly nest in the Arctic, such as the peregrine falcon, rough-legged hawk, short-eared owl, the golden eagle, and the white-tailed eagle. These remaining species are present in the Arctic only in summer to breed and rear young, migrating to southern latitudes during winter.

A wide range of marine mammals and fish live in the severe conditions of the Arctic Ocean. Whales, dolphins, walruses, and seven species of seals all make their home in this northern polar region, which is covered by ice most of the year.

Threats to the Arctic

Human activity has exercised a strong influence on the wildlife of arctic regions. Polar bear, walrus, musk ox, and caribou all have been greatly reduced in numbers through hunting alone. This danger was recognized in 1973 when protective legislation was approved for the polar bear. Still, species diversity continues to decrease at an alarming rate, and measures to protect the wildlife of the Arctic must be taken.

FAUNA: ASIA

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology, zoology

Asia is a huge continent with widely varying climate and geography. As might be expected, its animal life is equally diverse. Since Asia has areas of some of the most dense human population on earth, pressure on animal species from habitat loss is particularly dangerous.

Principal Terms

GRAZER: an animal that eats grass; some are wild, but many grazers have also been domesticated

HERBIVORE: an animal that only eats plants

NOCTURNAL: active at night and dormant or asleep during the day

PREDATOR: an animal that obtains food by hunting other animals

TAIGA: a moist, subarctic forest, primarily coniferous

TUNDRA: a rolling arctic or subarctic plain, located too far north for trees to grow

Asia is a vast and diverse continent with many different types of climate, temperature extremes, and large and small human populations. Many portions of Asia, such as Siberia, are almost empty of people. Some areas are quite densely populated, such as Java in Indonesia, Japan, India, and much of China. Unfortunately for the fauna of Asia, in those areas where the human population is thin, the extremes of climate do not allow for an abundance of wildlife. Many species are near extinction, endangered, or at risk because those areas of Asia that have a climate good for fauna are also densely populated. Some species, however, may have become too specialized for survival. The giant panda eats only bamboo and has an inefficient digestive system. This requires a giant panda to eat large quantities of bamboo. The panda also reproduces slowly. This characteristic may have evolved because the panda has few or no natural enemies—except humans. This type of adaptation can prove to be fatal for a species when factors such as climate, habitat, and predators change.

Much of Asian fauna is under pressure as a result of loss of habitat and overhunting. Most primates worldwide live only in tropical rain forests. The tropical rain forest is being rapidly cleared for timber, firewood, and land for agriculture. Species such as the rhinoceros are disappearing because they are hunted down just for their horns, which have been used for dagger handles in Yemen and for medicinal purposes. Many animals of all species are slaughtered because they are considered to be pests or just in the way of the ever-growing human population.

The Tundra, Taiga, and Steppes

Northern Siberia can be characterized as tundra. Because the tundra is partly free from snow only during the short summer, conditions for life are poor. The principal animals of the tundra are the reindeer, arctic hare, arctic fox, wolf, and lemming. With the exception of the lemming, they live in the tundra in the summer only and migrate in autumn. Birds can be found in the tundra, but with the exceptions of the willow grouse and ptarmigan, they also desert the tundra in winter. Many species of waders, the gray plover, and several kinds of sandpipers migrate to the tundra and breed there in the summer. The snow bunting and the Lapland bunting are also found there. Gyrfalcons (a type of large arctic falcon), buzzards, and skuas feed on these smaller birds and lemmings.

The taiga takes in much of the rest of Siberia and is forested mostly by pine trees. Fauna are richer and more diverse in the taiga than in the tundra, because the greater degree of vegetation provides more food and cover. Mammals found there include the brown bear, wolf, glutton (a kind of wolverine), otter, ermine, sable, lynx, elk, and forest reindeer. The rivers of northern Asia have many species of freshwater fish and several types of sturgeon.

The steppes are the southern edges of Siberia, portions of Kazakhstan, western China, and northern Tibet. Those areas are relatively treeless and similar to the northern Plains states of the United States. The steppes were the place of origin of the northern cattle, the horse, and the Bactrian (two-humped) camel. The animal life of the steppes includes burrowing rodents, jerboas, marmots, and piping hares, and larger animals such as diverse types of antelope. Wild sheep and goats live in the mountains and the plateau areas north of the Himalayas. Tibet is the home of the wild yak, which is an endangered species.

East and Southwest Asia

Northeastern and eastern China, Korea, and Japan have several native species of deer. The giant

Habitats and Selected Vertebrates of Asia

panda lives in the lower mountain area of China near Tibet. The lesser panda, a member of the raccoon family or perhaps its own distinct family, is native to the Himalayas. A rare animal in East Asia is the Siberian tiger, which feeds on elk and inhabits a corner of the Russian Far East and possibly small portions of China and North Korea.

As of 1997, there were estimated to be 360 to 406 wild Siberian tigers. Their numbers are declining, evidently due to overhunting of their main food source, the elk. Another endangered animal is China's true dragon, the Chinese alligator. The remaining populations of these timid reptiles, fewer than 150 in the wild, are limited to just a few village ponds in heavily populated southeastern Anhui Province. One of just two alligator species in the world, Chinese alligators are believed to have diverged from their American counterparts at least twenty million years ago. They reach lengths of about six feet (two meters), which is only half the size of American alligators.

The great rivers of China have a rich variety of fish. In the Yangtze and Huang Ho Rivers, the paddlefish is found. Its only close relative is the paddlefish of North America. The giant salamander, which can grow to a length of 4 feet (1.2 meters) or more, is found in Japanese waters. Most members of the carp family are in Southeast Asia and southern China.

Japan's fauna include the bear, wild boar, fox, deer, and antelope. Some of these species are very different from those on the Asian mainland. The Japanese macaque inhabits many areas. Those at the northern tip of Honshu form the northern limit of monkey habitat in the world. There are eagles, hawks, falcons, pheasant, and more than 150 species of songbirds. Waterbirds include gulls, auks, grebes, and albatrosses. Reptiles include sea turtles, freshwater tortoises, sea snakes, and two species of poisonous snakes.

The Philippines has about 220 species of mammals, including as many as fifty-six species of bats. There are more than five hundred species of birds, including jungle fowl (related to the chicken). The rare and endangered monkey-eating eagle is found in a few locales on Mindanao and Luzon. Fossils show that elephants once existed in the Philippines. It is possible that the climate of the Philippines was much drier in the somewhat distant past. If so, there may have been savanna-like grassland that would have favored elephants. As the climate subsequently became wetter, tropical rain forest grew, which would have reduced the elephants' habitat and thus their population.

Fashion Victim: The Tibetan Antelope

Known by its elegant, lyrate horns and the striking black markings on its face and legs, the male Tibetan antelope, or chiru, is considered one of the world's most beautiful mammals. It inhabits the windswept Tibetan steppe. At the end of the twentieth century, the population of the chiru was down to perhaps seventy-five thousand animals, from an estimated several million earlier in the century. The chiru's wool, called shatoosh, is considered to be the finest in the world and a growing status symbol in Western fashion. Tibetan antelope must be slaughtered to harvest the wool, and it takes an average of three to four antelope to make a single scarf. Ironically, sale of shatoosh has been illegal under the Convention on International Trade in Endangered Species since 1975. Nonetheless, despite the CITES ban, as late as 1998 fashion magazines touted the virtues of shatoosh scarves, priced in the thousands of dollars.

West Asia

Fauna in Iran include the leopard, bear, hyena, wild boar, ibex, and gazelle that inhabit the forested mountains. Seagulls, ducks, and geese line the shores of the Caspian Sea and the Persian Gulf. Buzzards nest in the desert. Deer, hedgehogs, foxes, and more than twenty species of rodents live in the semidesert high-altitude regions. Palm squirrels, Asiatic black bears, and perhaps a few lions inhabit Baluchistan in the southeast. Amphibians and reptiles include frogs, salamanders, boas, racers, rat snakes, cat snakes, and vipers. More than two hundred varieties of fish are found in the Persian Gulf, along with shrimp, lobsters, and turtles. Sturgeon is one of thirty species found in the Caspian Sea.

Arabia has camels, both wild and domesticated, sheep, goats, and Arabian horses (now rare there). Gazelles, oryx, and ibex are becoming rare. Other wild animals are the hyena, wolf, and jackal. The baboon, fox, ratel, rabbit, hedgehog, and jerboa are among the smaller animals. Reptiles include the horned viper, a species of cobra; striped sea snakes; and the large desert monitor. Common birds include eagles, vultures, owls, and the lesser bustard. Flamingos, pelicans, and egrets live on the coasts.

Common insects include locusts, which can descend on fields like a biblical plague. Turkey has the wolf, fox, boar, wildcat, beaver, marten, jackal, hyena, bear, deer, gazelle, and mountain goat. Game birds are the partridge, wild goose, quail, and bustard. The rest of Southwest Asia—Israel, Syria, Lebanon, Jordan, and Iraq—have fauna that are a mix of those found in Arabia and Turkey.

The Oriental Region

The oriental region includes India and extends eastward from India over the mainland and much of insular Southeast Asia. A major portion of the oriental region is tropical. That climate supports malaria-bearing mosquitoes and water-borne flukes carrying the schistosomiasis-causing parasite. These two problems are present in much of tropical Asia as well as in Africa.

In tropical rain forest areas, monkeys are common. Larger primates are found only in tropical rain forests because the kind of cover and food supply that they seem to need exists only there. Gibbons are found in Assam in northeast India; Myanmar (formerly Burma); the Indochinese peninsula—Thailand, Laos, Cambodia, and Vietnam; and the Greater Sunda Islands—Java, Sumatra, and Borneo. The orangutan is found only in Sumatra and Borneo. Indonesia is home to the world's two most endangered rhinoceros species, the Javan and Sumatran. The largest group of Javan rhinoceros is in Ujung Kulon National Park in West Java, but the number of rhinoceros there was fewer than seventy in the late 1990's. The only known wild population of Javan rhinos outside Indonesia, a small group of fewer than fifteen animals, is found in Cat Loc Nature Reserve in Vietnam.

India is an important part of the Oriental zoogeographic region. Almost all orders of mammals are found in India. The primates there include diverse types of monkeys, including the rhesus monkey and the Hanuman langur. Wild herds of Indian elephants can be found in several areas such as the Periyar Lake National Park in Kerala and Bandipur National Park in Karnataka. The Indian rhinoceros is protected at Kaziranga National Park and Manas Wildlife Sanctuary in Assam. There are also four species of large cats: the leopard, snow leopard, Bengal tiger, and lion. The Asian lion, once ranging into West Asia including the Levant, is now found only in the Gir Forest Lion Sanctuary in the Kathiawar Peninsula of Gujarat. Tigers are found in the forests of the Tarai region of Uttar Pradesh, Bihar, and Assam; the Ganges delta in West Bengal; the Eastern Ghats; Madhya Pradesh; and, eastern Rajasthan. The snow leopard is found only in the Himalayan regions.

More than twelve hundred species and perhaps two thousand subspecies of birds are found in India. Herons, storks, ibises, and flamingos are well represented, and many of these are found in the Keoladeo Ghana National Park in Rajasthan. The Rann of Kach forms the nesting ground for one of the world's largest breeding colonies of flamingos.

Crocodiles are found in India's rivers, swamps, and lakes. The estuarine crocodile, which can grow as large as thirty feet (nine meters), feeds on the fish, birds, and crabs of muddy delta areas. The long-snouted gavial or gharial, which is similar to the crocodile, is found in several large rivers, including the Ganges and Brahmaputra. There are almost four hundred species of snakes. One-fifth of these are poisonous, including kraits and cobras. The Indian python inhabits marshy areas and grasslands. More than two thousand species of fish are found in India, 20 percent of which are freshwater species. Commercially valuable insects include the silkworm, bees, and the lac insect. The lac insect secretes a sticky, resinous material called "lac," from which shellac and a red dye are made.

Southeast Asia is located where two important divisions of the world's fauna come together. It constitutes the eastern half of the Oriental zoogeographic region. Bordering on the south and east is the Australian zoogeographic region. The eastern part of the Southeast Asian islands—Sulawesi (Celebes), the Moluccas, and the Lesser Sunda Islands (Bali, Sumba, Flores, and Timor)—forms an area of transition between these two faunal regions. Southeast Asia thus has a considerable diversity of wildlife throughout the region. The region has placental mammals as opposed to the marsupials of Australia, but has hybrid species such as the bandicoot of eastern Indonesia. Small mammals such as monkeys and shrews are the most common. Larger mammals have been pushed into remote areas and national preserves.

Indonesia is located in the transitional zone between the Oriental and Australian faunal regions. The so-called boundary between these two zones is known as Wallace's Line. The line runs between Borneo and Sulawesi in the north and Bali and Lombok in the south. A unique species of proboscis monkey lives only in Kalimantan (southern Borneo). The babirusa (a hoglike animal with curved tusks) and anoa (a small, wild ox with straight horns) are found only in Sulawesi. A giant lizard, the Komodo dragon, occurs only on two small islands, Rinca and Komodo. Insect life in Indonesia includes giant walkingsticks that attain 8 inches (3.2 centimeters) in length, walkingsticks, large atlas beetles, luna moths, and bird-wing swallowtails.

Mammals in Vietnam include elephants, tapirs, tigers, leopards, rhinoceros, wild oxen such as gaurs and koupreys, black bears, sun bears, and several species of deer such as the small musk deer and barking deer. In Cambodia, small populations of elephants, wild oxen, rhinoceros, and several deer species can still be found, along with tigers, leopards, and bears. Snakes abound, with the four most dangerous species being the Indian cobra, the king cobra, the banded krait, and Russell's viper. The fauna of Myanmar and Thailand is similar to that found in Cambodia.

FAUNA: AUSTRALIA

Types of animal science: Anatomy, classification, ecology, reproduction
Fields of study: Anatomy, ecology, evolutionary science, wildlife ecology, zoology

The animals of the island continent of Australia are diverse and in a number of instances bizarre and strange in appearance and behavior. A large number of mammals are marsupials; native placental mammals are rare.

Principal Terms

ABORIGINE: European name for the Native Australians

MARSUPIAL: a type of mammal where the females possess an external abdominal pouch in which the young are suckled and protected

MONOTREME: a primitive mammal that lays eggs, such as the duck-bill platypus

PLACENTAL: a mammal in which the developing young are nurtured via a blood-rich tissue (the placenta) within the mother's body.

The European exploration of Australia and discovery of its rich but strange animal life was late in coming. The British naval officer, Captain James Cook, sailed around Australia and charted the east coast of Australia, named it New South Wales, and claimed it for England between 1768 and 1771. In 1788, the first Europeans were transported to what is now Sydney. They were prisoners who had been sentenced by the British courts and incarcerated in prisons in Australia.

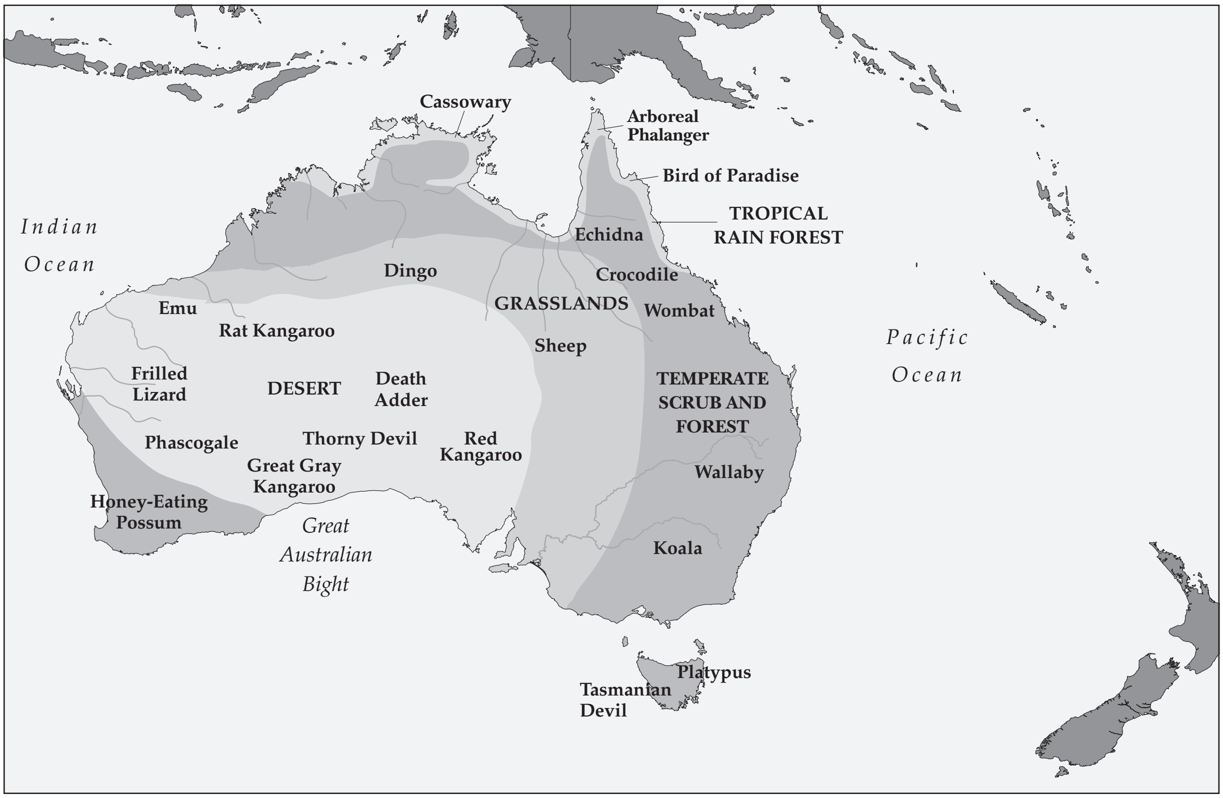
Mammals

The groups of large hopping animals that the aborigines called kangaroo became a favorite source of meat to the prisoners. Like all the other native mammals, the kangaroos are marsupials. Several other marsupials are also hopping animals. They range from the slightly smaller wallaby (which resembles the great gray kangaroo) to the tiny, flat-headed marsupial mouse, which weighs a mere sixth of an ounce. The koala is a well-recognized marsupial, although it is commonly called a bear because of its resemblance to a child's teddy bear. Mainly a tree dweller, its favorite food is the highly fragrant leaves of eucalyptus trees.

In addition to the diverse marsupial mammals, the fauna of Australia includes several species of placental mammals, the majority brought to the island continent by humans. The aborigines, who came to Australia about forty thousand years before the present, were foragers or hunter-gatherers. They brought no animals with them. About eight to ten thousand years ago, fishermen from the islands of Indonesia regularly plied the waters off the north coast of Australia in search of sea cucumbers, a large, marine, wormlike animal. These were dried on board the ship and returned to the home islands as food. These ships apparently also carried the companion of humans through the centuries, the rat. The rats, inadvertently, were among the first placental mammals other than humans to find a foothold in Australia, and quickly established themselves wherever there was food and water. These fishermen also were responsible for taking dogs with them, probably as food. Some of the dogs escaped, becoming the dingoes or wild dogs of Australia.

Other placental mammals were introduced by Europeans for hunting, such as the rabbit and the red fox. Both soon escaped into the wild and became serious pests, especially the rabbit. With no predators to attack them, the rabbits reproduced prodigiously, overwhelming control efforts. The fox had been introduced to serve as quarry for hunters riding to hounds, but it never reached the pest status of the rabbit. Visitors to Australia also

Habitats and Selected Vertebrates of Australia



are often startled to see camels, apparently wild, striding over the sandy wastes of the Outback and other desert areas. These animals, now wild, are the descendants of domestic dromedary camels that had been used to carry freight across the deserts. A few domestic animals, principally dogs and cats, have escaped and established a feral existence. No doubt some cats were easily and swiftly caught and eaten by dingoes, crocodiles, and feral dogs. The dogs formed packs and preyed on a variety of small marsupials. They are a particular predator of the koala. Some feral dogs were preyed on by dingoes but also joined dingo packs, interbred with them, and quickly became part of the predatory fauna of Australia.

The Life Cycle of Marsupials

Marsupials, as mammals, have milk-producing glands and suckle their young. They reproduce similarly to nearly all other mammals: One or more eggs, produced internally by the female, are fertilized internally by the male and develop within the female's body. After a period of developmental stages lasting weeks or months, the fertilized egg becomes an embryo, then a fetus, and finally is ready to be born. Marsupials differ because after only a short development period, the young fetus leaves the female's uterus and painstakingly crawls over her abdomen to enter the brood pouch (marsupium). Here the fetus continues its development until it is a fully formed and viable organism ready to take up an external existence.

The female has prepared the way for the fetal animal to move over her abdomen by vigorously licking the surface hairs from birth canal to pouch. Observers had long believed the licking laid down a scent trail of saliva for the fetus to follow to the entrance of the marsupium. Recent studies suggest the licking is performed primarily to cleanse the path to be followed by the fetus.

The marsupium is endowed with nipples or teats—the number varies according to the species from one or two to a dozen or more—which the fetus takes into its mouth. This action causes the teat to swell, thus effectively sealing it into the fetus's mouth. The quality of the mother's milk varies during the development of the young; the milk fat increases with time to enhance the nutrition available to the developing young.

Kangaroos, Wallabies, Wombats, and Koalas

The most familiar and readily recognized Australian marsupial are the kangaroos. They range in size from the seven-foot-tall red kangaroo, which weighs up to 200 pounds, to the slightly smaller gray kangaroo, which weighs up to 165 pounds and may be as much as six feet tall. In both species, the heavy, muscular tail is nearly as long as the body. It serves as a prop when the animal is sitting and helps to balance it when it is fleeing. The kangaroo moves forward by a series of powerful hops at speeds of up to thirty miles per hour. The small front legs are used primarily in holding objects.

Wallabies are medium-sized members of the kangaroo family. For the most part, they feed in open grasslands at night. The body size, from nose to root of the tail, is eighteen to forty-one inches. The tail ranges from thirteen to thirty inches long. Because of their smaller size, wallabies are preyed on to a greater extent by dingoes, feral dogs, and, in years past, the Tasmanian tiger.

Before Europeans colonized Australia and introduced sheep and beef cattle, wombats and kangaroos were the major grazers in the grasslands of the island continent. Although it is a marsupial, the wombat looks nothing like any of the other marsupials. It has been described as resembling a fur-covered barrel with four legs. An adult may weigh up to one hundred pounds and measure four feet in length. It is a burrower, tunneling passageways one hundred feet long, six feet under the earth's surface.

The tunnels help the wombat conserve energy and water, and thus reduce its need for food. Its chief foods include grasses, generally of poorer quality than required by sheep. Thus, wombats are able to survive in areas where sheep do not thrive, but if there is better quality forage available, the wombat becomes a competitor with the sheep. As a result, sheep ranchers do not like wombats. They also do not like the cylindrical, muscular animals because they burrow under fences, damaging the fence lines and opening routes for rabbits.

The rotund wombat is not a very swift animal and many fall easy prey to dingoes and large, feral dogs. The most serious threat to the animals, however, is the automobile. Many wombats are killed on the highways as they amble across the pavement at night in search of water or new grazing.

Along with the kangaroo, the most readily recognized Australian animal is the koala, another marsupial. The koala produces one young at a time. When it is able to spend time out of the pouch, it clings to the female's fur and is carried along with the mother on her foraging expeditions. Much of the adult's time is spent high in the treetops, especially eucalyptus, whose leaves are a favorite food of the animal.

The average koala male weighs from fifteen to thirty pounds and is about two feet long. The fur is thick and soft

Comparison of Ecological Functions Between Placental Mammals of North America and Marsupial Mammals of Australia

Ecological Function	*North America*	*Australia*
Large grazer	American bison	gray kangaroo
Small grazer	cottontail	wallaby
Tree dweller	porcupine	koala
Burrowing grazer	woodchuck	wombat
Glider	flying squirrel	sugar glider
Large carnivore	gray wolf	Tasmanian wolf
Small carnivore	wolverine	Tasmanian devil

and the animals were hunted in the fur trade. The last fur season occurred in 1927, when six thousand koalas were slaughtered. They were part of the aborigine diet and undoubtedly had a strong eucalyptus flavor as a result of their diet of eucalyptus leaves.

Although there is no longer an open season on koalas, the mortality rate is high. Loss of habitat in land clearing is a major cause of its decline. In addition, many are killed by automobiles while crossing roadways. Dingoes and domestic dogs kill many of them and a significant number drown in backyard swimming pools. Pool owners often suspend a rope in the water so that koalas that fall in can climb out.

Tasmanian Tigers and Devils

Most of the marsupials in Australia have maintained a somewhat shaky coexistence with the European settlers. Two, however, have not. The Tasmanian tiger (more commonly called the thylacine) was the largest living carnivorous marsupial known. It resembled a large, long dog with a long, stiff tail, and brown fur marked with thirteen to twenty dark brown to black stripes on the rear portion of the body. It was active mostly at night and preyed on small animals and birds. The thylacine also occasionally killed and ate sheep and chickens kept by European settlers. It was a fearsome-looking animal, but it was shy and secretive, avoiding contact with humans.

Thylacine females had a back-opening pouch with three to four young in a litter. Pouch life is presumed to have been about four months. The Europeans feared the thylacine, probably because of its bizarre appearance, its nocturnal habits, and its presumed attacks on domestic animals. A bounty was placed on the animal and it was trapped, poisoned, and shot. The last known thylacine died in an Australian zoo in September, 1936. Occasional sighting of thylacines have been reported, but in 1986 the species was declared extinct.

The Tasmanian devil, although it is a relative of the thylacine, differs in a number of ways. Devils are smaller, about two feet long with a tail about one foot long. They weigh up to twenty-six pounds and are heavily built, with a broad head and a short, thick tail. The devil's powerful jaws and strong teeth help it to completely devour its food, bones, fur, and all. It is mainly a scavenger and will eat whatever is available. Wallabies, small mammals, and birds are included in its diet, either captured alive or scavenged as a carcass. It has been suggested that the Tasmanian devil helps maintain countryside sanitation by cleaning up carcasses.

The female devil has a back-opening pouch with four nipples. Since more than four young are born in a litter, the extra young die. On average, about two or three young survive in the pouch.

It is the coloration and behavior of the devil that have given it a fearsome reputation. The fur is black, sometimes marked with white patches, and it makes eerie screeches as it ambles about at night in search of food. At one time the Tasmanian devil was widely distributed on mainland Australia, but in modern times it is restricted to the island of Tasmania, off the southeast coast of the mainland. It is believed that the dingo ousted the devil from the mainland. The Tasmanian devil's population, under government management, appears to be stable.

Reptiles

Australian reptiles consist of a number of species of snakes—some poisonous—several monitor lizards (related to the Komodo dragon), and the most feared reptile, the crocodile. The largest monitor lizard, the giant goanna, reaches a length of 8.5 feet. It lives in rock crevices in desert regions, feeding on any animals that come within reach.

The estuarine or saltwater crocodile is the largest and probably most dangerous Australian reptile. Specimens thirty feet long have been captured, and there may be a few larger than that in some isolated coastal marshes. It can live in freshwater billabongs, brackish coastal estuaries, and has been observed swimming 150 miles out at sea. Its diet consists of any animals that come to waterways to bathe or drink, and it will attack and eat humans. Indeed, many Australian rivers, especially those in the Northern Territory, are marked with signs that warn visitors to beware of crocodiles in the water. The animals once were actively hunted for their hides, to be made into expensive shoes and bags. Prehunting populations were estimated at more than 150,000 crocodiles from Western Australia to Queensland. Hunting pressure reduced their numbers to about seven thousand individuals, but it rebounded to more than seventy thousand after hunting was banned. Today, the crocodile population is closely monitored and a limited number can be taken for their hides and meat.

Birds

The best known of Australian birds are the parrots. Many species of parrots are collected for the pet trade, the most popular being the small budgerigar, or parakeet. They are aptly called "love birds" because of the apparent kissing that goes on between pairs of the "budgies." Some of them can be taught to mimic human speech. Some Australian birds are not as well known as the diminutive (6.5 inch) budgerigar. Bowerbirds build elaborate structures of branches, grasses, and bits of bone or shell to attract females for mating. The kookaburra, though not often seen, is aptly named the "laughing jackass bird" because of its loud and very distinctive call.

Australia's birds also include two large, flightless species—the cassowary and the emu. Cassowaries are about fifty-two to sixty-five inches tall and weigh up to 140 pounds. The skin of the head and neck, in both males and females, is bare of feathers, with bright red, yellow, blue, and purple skin. The top of the head bears a bony structure called a casque. Cassowaries inhabit the tropical rain forests of the Australian northeast coastal region. They are well-muscled and dangerous; they can kill a human by leaping feet first and raking the intruder with sharp claws.

Like the cassowary, the emu is a large, flightless bird. At five to six feet in height, it is topped only by the African ostrich. Emus are found throughout Australia feeding on fruits, seeds, roots, and occasionally insects. They are pests in farming country because of their liking for cereal grains. They are eaten by aborigines and Europeans in the Outback. Attempts to farm them for the American market as a novelty food have not proved to be very successful.

Placental Mammals

Prior to the arrival of humans, especially Europeans, the Australian mammalian fauna consisted almost entirely of marsupials. One major exception was the flying fox, the large fruit bat. Undoubtedly the earliest bats flew, or were blown by storm winds, from the Asian mainland. With few natural enemies, the bats thrived in the tropical and subtropical forests. They continue to be abundant today. Almost all other placental mammals, such as the dingo, were introduced to Australia with the arrival of humans.

Fossil remains indicate the dingo has been a feature of the outback for about four thousand years. Contrary to earlier beliefs, it probably did not arrive with the aborigines forty thousand years ago but is a relative newcomer. Research by Dr. Laurie Corbett, a scientist with the Australian Commonwealth Scientific and Industrial Research Organization (CSIRO) in Darwin, suggests the dingo ancestors were transported, perhaps as food, aboard Malaysian fishing boats. Once in the wild, they soon found a good supply of game in the populations of ground-dwelling marsupials. When Europeans began to raise sheep and beef cattle, the dingo quickly found them a ready source of food. Research on dingo behavior revealed the animals often simply scatter the flocks or, at worse, ravage the animals without eating the carcasses.

To control the dingo, the Australian government has erected a wire mesh fence six feet high, extending nearly four thousand miles across the country. Many ranchers attempt to control the dingo by any means, including poison, traps, and guns. Dr. Corbett reports that the animal, as a separate species, may be naturally sliding toward extinction by being absorbed into the domestic dog population through interbreeding.

The interior sections of Australia, well away from the moist climate of the coastal regions, resemble what most people think of as desert. Vast wastelands of sand and gravel are interspersed with billabongs and other water courses. To complete the desert picture, groups of wild camels troop across as they seek favorable grazing and water. The camels are not native, but were introduced in the nineteenth century to serve as beasts of burden. The trails they followed served as lifelines for most of inland Australia. The animals brought food and other supplies to the settlements, mines, and sheep stations.

The settlers chose the one-humped dromedary, or Arabian camel, rather than the two-humped Bactrian camel. The Bactrian is an animal of the cold Eurasian steppes, whereas the dromedary is common in the hot deserts of Africa and thus better able to survive in the conditions of Australia. Their cloven hooves have cushioned pads underneath that spread with each step and provide good traction in the loose sand and gravel. The hump stores energy-rich fat and the animals conserve water by minimizing perspiration and recycling moisture exhaled through the nostrils.

At their peak there were between ten thousand and twenty thousand dromedaries on the desert trails of Australia. However, when road improvements and motor trucks came along, the camels were no longer needed. The camel owners slaughtered some for food and their hides, the rest were driven into the Outback and set free. Here they thrived and multiplied. Modern estimates of their numbers place the population of feral camels as high as four hundred thousand animals.

The now-wild camels are a nuisance to sheep and cattle station owners. The camels, ambling along, knock down fences, releasing the livestock and also providing entry ways for predatory dingoes. The resourceful Australians are turning a nuisance to a profit. Many of the feral camels are being harvested for food, wool, and leather. In visitor centers, such as Alice Springs, Uluru (Ayer's Rock) National Park, and Ratatjuta, camels are available for rides, either as "picture opportunities" or for guided tours through the Outback.

While the camel and dingo may be considered nuisances, the European rabbit turned out to be an obnoxious pest. In 1859, a homesick Australian stock grazer imported two dozen European rabbits from England and released them on his land. The rabbits bred prodigiously, and six years later he killed twenty thousand on the ranch. In 1895, twenty million rabbits were killed, and still they increased. Five rabbits eat as much grass as one sheep. The rabbits spread over the countryside like a plague. Rabbit-proof fences were erected, but usually the rabbits had already gotten through. By 1953, over a billion rabbits were inhabiting 1.2 million square miles of Australian grassland.

After years of fruitless efforts to control the rabbits, scientists introduced a disease organism, myxoma, a virus, and within one year, 95 percent of the rabbits were dead. However, in the long run, the control agent was not completely successful. A few rabbits were naturally immune to the disease, and others developed immunity and continued to reproduce. Unfortunately, the virus has evolved to an avirulent form. Thus, the biological control of the rabbit is no longer as effective as it once was.

FAUNA: CARIBBEAN

Types of animal science: Ecology, evolution, geography
Fields of study: Conservation biology, ecology, evolutionary science

Biologists have exploited the tremendous diversity and phenomenally high population densities of some West Indian animals to better understand evolutionary, ecological, and biogeographic principles.

Principal Terms

ECOLOGICAL NICHE: the sum of environmental conditions necessary for the survival of a population of any species, including food, shelter, habitat, and all other essential resources

ECOMORPH: species of different phyletic origins (at most distantly related) with similar structural and behavioral adaptations to similar niches

ENDEMISM: the condition of a species that has evolved in a given area, adapted to local conditions, and is found nowhere else in the world

SPECIATION: an increase in the number of species, usually resulting from descendants of a common ancestor adapting to different environmental conditions in different geographic areas

WEST INDIES: a body of islands including the Greater Antilles (Cuba, Jamaica, Hispaniola, Puerto Rico), the Lesser Antilles (an island arc extending from east of the Virgin Islands to the north of Trinidad and Tobago), associated smaller island banks, the Bahamas, and sometimes the islands of the western Caribbean east of Nicaragua, but not the continental islands of Central and South America

The Caribbean Sea is bordered to the west and south by Central and South America, respectively, to the east by the Lesser Antillean island arc, and to the north by the Greater Antilles. When used in a biogeographic context, however, the Caribbean Region is usually defined as the islands that have been called the West Indies since the days of Christopher Columbus. These islands vary greatly in size and age. The oldest islands sit on the Caribbean Plate, which first emerged in what is now the eastern Pacific Ocean, drifted between ancient North and South America before the Isthmus of Panama had formed, and eventually collided with the Bahama Platform and the Atlantic Plate. Throughout this passage, rising and falling sea levels repeatedly inundated entire low-lying islands and at least the lower elevations of the higher ones. In addition, to the east, a subduction zone creates a band of intense and often explosive volcanic activity, which has been responsible for the creation of many Lesser Antillean islands that constitute the newest additions to the archipelago. Islands vary in size from barely emergent rocks to Cuba (over 110,000 square kilometers) and Hispaniola (over 75,000 square kilometers), but sizes have varied as rising sea levels during interglacial periods have fragmented island banks and inundated smaller landmasses.

The island fauna has, like that of any region, been defined by a combination of historical events and current realities. Although transient contact with Central America may have occurred at one time, the vast majority of these islands have never been connected to a continent. Because seas are generally effective barriers to dispersal, relatively few terrestrial animals successfully reached the islands, and even fewer became established. Another factor limiting the number of species is the small number of ecological niches available on relatively small islands. Generally speaking, larger islands with greater elevations are more ecologically complex and contain more niches than smaller islands with less topographical relief, but even the largest islands pale in comparison with the ecological diversity of continents. However, when the region is considered as a whole, the fragmentation and isolation of the islands results in a phenomenally high species richness (of at least some animals) and a very high degree of endemism.

A Fauna Dominated by Reptiles and Amphibians

Studies of West Indian invertebrates are largely limited to those of specific sites or groups, and an overview would be cursory at best. As for terrestrial vertebrates, the quantity of mammalian fauna is relatively impoverished and most birds are migratory; consequently, amphibians and reptiles dominate the fauna in terms of both diversity and numbers. On islands with limited resources, the greater energetic needs of birds and mammals limit population sizes. In contrast, amphibians and reptiles do not require large amounts of energy to sustain stable body temperatures and, as a result, phenomenally high population densities are possible.

Over fifty species of bats and over one hundred species of other nonmarine mammals are known from the region. However, the vast majority of the ninety-four species of nonflying species, all endemic, are extinct, victims of habitat destruction, competition with introduced exotics, or exploitation by humans. Consequently, the mammalian fauna is currently dominated by bats and introduced species. Most of the over 550 West Indian species of birds are migrants, and another large number are sea birds with broad distributions throughout the world. Of the endemic groups, as many as a dozen appear to be relicts of genera that were formerly widespread on adjacent continents. Consequently, the avifauna merely mirrors the greater mainland diversity.

In contrast, almost seven hundred frogs (but no salamanders or caecilians), turtles, crocodilians, and squamate reptiles (lizards and snakes) are known from the region. The vast majority is endemic. Population densities include the highest reported for any vertebrate anywhere in the world (approaching 70,000 per hectare for at least two species of dwarf geckos).

Evolutionary and Ecological Studies

The diversity and population densities of amphibians and reptiles have provided biologists with many opportunities to investigate evolutionary, ecological, and biogeographic questions. In particular, the most diverse groups have demonstrated repeatedly the remarkable abilities of animals to speciate by adapting to varying local conditions on isolated islands or disjunct habitats created by topographic relief on larger islands. West Indian lizards in the genus *Anolis* have provided the best insights into the principle of ecomorphology. Structurally and behaviorally similar species on different islands are more closely related to very different species on the same islands than to their ecological counterparts elsewhere. This phenomenon provided evidence for evolutionary adaptations to local conditions and divergence from relatives that adapted to other available habitats. Many fundamental biogeographic principles have also been developed or supported by studies on West Indian animals. Over-water dispersal of large terrestrial vertebrates, long a staple of biogeographic hypotheses, was first demonstrated in 1995 when green iguanas were transported over hundreds of kilometers of open ocean from Guadeloupe to Anguilla on a floating mass of debris. Other important biogeographic concepts emerging from West Indian studies include positive relationships between biodiversity and area, habitat heterogeneity, and proximity to the nearest large body of land—and between habitat fragmentation and extirpation or extinction.

Conservation Concerns

Studies of habitat fragmentation, unfortunately, also provide many examples of the negative impact humans have had on the survival of the other species on the planet. Although Amerindians began the process, and may have been responsible for the extinction of the few large land mammals known to have lived in the islands, the most harm has resulted from humans of European and African descent, to whom the islands have been subjected longer than any other area in the Western Hemisphere. In addition, human population growth is rapid and island areas are limited. Finally, economic development, often related to tourism, is accelerating to accommodate the growing needs of humans living in a region with few natural resources.

Many West Indian animals have small ranges and are extremely vulnerable to habitat alteration and the impact of introduced exotics. A large percentage of frogs and some lizards are restricted to forests that are disappearing rapidly. Other species, notably the critically endangered iguanas of the genus *Cyclura*, the most endangered reptiles in the world, and hutias, large endemic rodents, have suffered from exploitation by humans for food. Many species in both groups are extinct, and all populations are threatened or endangered. Introduced predators, notably feral cats and the mongoose, which was introduced to control rats in sugar cane fields, have eliminated populations of ground-dwelling snakes and lizards on many islands. Goats denude vegetation on which native species depend. The outlook is grim for many species, but hard lessons learned in the West Indies might lead to more enlightened policies elsewhere.

FAUNA: CENTRAL AMERICA

Type of animal science: Geography
Fields of study: Ecology, environmental science, zoology

Central America is host to a tremendous diversity of animal life, a fauna quite different from other parts of the world. Central America is a land bridge that connects North America and South America, and it has fauna with similarities to both of these continents, as well as endemic species that have evolved within its own borders.

Principal Terms

ENDEMIC: confined and indigenous to a particular region or locality

HABITAT: the physical and chemical factors of the environment

MARSUPIAL: a pouched mammal that gives birth to embryonic young that complete development in a pouch, attached to the mother's nipples

NEOTROPICAL FAUNA: the geographic faunal region that includes Central and South America

OMNIVOROUS: a diet that consists of both plants and animals

PLACENTAL: a mammal whose young develop in the uterus and are nourished through the mother's blood vessels in the placenta

Central America, according to geographers, is the region that commences at the narrow Isthmus of Tehuantepec, in southern Mexico, and extends all the way down to the Atrato River valley, just east of the Panama border in Colombia, South America. Situated in the Western Hemisphere, it is a tapering isthmus, often called the land bridge that joins the two continents of North and South America. By definition, Central America is part of North America, and it includes the countries of Costa Rica, Panama, Belize, Honduras, Guatemala, Nicaragua, and El Salvador.

The world has been divided into six biogeographic regions based on the characteristics of the different types of animals that reside there. The Neotropical area begins at the southern border of the Mexican desert, and continues through Central America to the sub-Antarctic zone of South America to the south, and the West Indies to the east. There is significant mixing and influence from the northern continent, as well as endemic species that evolved in western Panama, eastern Costa Rica, and the highlands of Guatemala, Honduras, and northern Nicaragua.

The marsupials are the older indigenous mammals. After the land bridge was created, there was an influx of North American mammals into the once isolated ecosystem of Central and South America. This explains why many creatures of the Central American regions seem to have close ties to North American animals. The more recent arrivals (about three million years ago) are the rodents, including guinea pigs, and porcupines, tapirs, bats, deer, and guanaco, as well as carnivores such as the margay and jaguarundi. These are the more efficient placental mammals that have adapted and survived in the evolutionary and predatory struggle.

Warm-Blooded Vertebrates

The forests of Central America have a relatively meager population of mammals compared to reptiles, and it hosts widely varying species of birds and insects. The isthmus is the natural habitat of the jaguarundi, margay, jaguar, and ocelot. These species are excellent examples of the adaptation process of North American mammals that migrated south, eventually evolving into unique and well-situated species. The jaguarundi is a small, unspotted cat found only in the New World. It is also called the otter-cat because of its otterlike countenance and swimming ability. It lives in the forested and brushy regions near water and is very rare north of Mexico. Similarly, the coati or coatimundi is an animal like a raccoon (family Procyonidae), with a body that is slimmer, has a longer tail, and an elongated flexible snout. Like an anteater, this animal uses its snout to find insects in the ground, yet it can also climb trees to acquire birds and eggs, with a preference for fruits and berries. The Central American species is classified as *Nasua narica*. Other animals that have migrated to the central region but have not changed much from their North American counterparts are the coyote, gray fox, and puma.

Habitats and Selected Vertebrates of Central America

Howler Monkeys: Voices to Be Heard

Howler monkeys (primates of the family Cebidae) are among the most fascinating animals of Central America. These heavy-bodied monkeys are the largest primates of the New World tropical rain forests, with a combined head and body length of over 550 millimeters and a prehensile tail that may be even longer. They spend virtually their entire lives in the treetops, where they find food and water and may come down to drink only during the dry season. The fur is long, soft, and luxurious, and the animal almost looks as though it is wearing a cape. Both sexes have a beard, but it is much more developed in males. Color of the fur may range from a dark, glossy black to a dark reddish brown to a light ochre.

As impressive as howler monkeys look, it is not their appearance that makes them so distinctive. Males produce vocalizations which are so strong and loud that the reverberations can be heard up to several miles. If the source of the sound were not known, one would think that a much larger animal, such as a jaguar, was producing it. When making this extraordinary sound, the howler monkey's tongue is dilated and forms a gobletlike chamber. The chorus may begin with an old male, perhaps the leader of the band. The sound builds up, and there does not appear to be any pause. Other males may join in to create a loud cacophony.

Unfortunately, as is true of many animals in the tropical rain forests of Central America, loss of habitat is threatening the species.

On the other hand, some South American animals used the isthmus as a conduit to the northern continent. Some examples of these northbound animals are the armadillo, marley, opossum, anteater, and kinkajou. This north-south migration is why the Central American region has a mixture of Neartic (northern) and Neotropical (southern) animals. Armadillos are mammals that are related to the sloth and anteater, and inhabit open areas as well as forests. These animals have an armor plating on their bodies as a shield against predators. Although most anteaters are arboreal, with a prehensile tail, the giant anteater is not a climber. The opossum is an arboreal marsupial with an ability to swim. The kinkajou is a relative of the raccoon but behaves like a primate. In fact, for a long time scientists mistakenly grouped them with lemurs. Kinkajous are carnivores with a prehensile tail and are both arboreal and good swimmers. The giant tree sloth, a slow-moving arboreal mammal, makes Panama its home.

Primates of Central America are another group of interesting mammals. The New World monkeys are typified by their prehensile tails. They reside in forested areas. Honduras is home to the howler, spider, and capuchin monkeys. The red-backed squirrel money is found in Panama and Costa Rica. This monkey is valued by the biomedical industry.

Other unusual mammals found in this region are the manatee and the river otter. The spectacled bear is found in Panama. Bats are diverse and plentiful. The bloodsucking vampire bat is an endemic species of this area.

South America is called the bird continent. It is no surprise that the avian population of Central America harbors an enormous number of bird species. They are a unique mixture of birds found in both the northern and southern continents, as the isthmus serves as a migratory path between the two. Hummingbirds and parrots are perfect examples of this mixing.

The resplendent quetzal is a type of trogon with iridescent feathers. It is the national emblem of Guatemala, where the monetary unit is also called a quetzal. Brilliantly colored toucans and macaws are also characteristic of this region. Among the predatory birds, the giant harpy is the most powerful of all eagles. It hunts macaws, sloths, and monkeys. The crested eagle of El Salvador is becoming more rare due to extensive logging and the loss of its natural habitat.

Cold-Blooded Vertebrates

The fish life is prolific in Central America. The majority of fish belong to the following groups: catfish, characins, the pacus, the air-breathing eel, and the cichlids. Catfish make up about half of the total fish fauna, the characins are noted for containing the flesh-eating piranha, eel stun their prey with electric shocks, and the cichlids are similar to North American sunfish. One of the more interesting freshwater fish is the landlocked shark, found in Lake Nicaragua. The lowlands of Belize, with their mangroves and swamps, are the prime environment for the lungfish, which breathe through their lungs instead of gills.

Central America flourishes with a multitude of reptiles and amphibians. The effects of solitary evolution and divergent speciation are very noticeable among these animals. In Costa Rica alone, there are about 130 species of frogs. The golden tree frog is native to Panama. From voracious mammal-eating frogs to beautiful but deadly venomous ones, Central America is host to all. Some of the largest snakes in the world, such as the boas and the anacondas, make the tropical forest their home. Some of these constrictors can devour caimans and mammals. There are also colubrids or coral snakes, green snakes that have adapted to living in trees, the ground, the water, and in burrows. Crocodiles, caimans, lizards, iguanas, salamanders, geckos, turtles, and tortoises are all part of this ecosystem. The crested basilisk lizard, a type of iguana, lives on stream banks. This lizard is known in Spanish as Jesus Cristo, because it appears to have the ability to walk on water, which it does by skimming over the surface very fast.

Indiscriminate hunting and logging have caused many of these animals to become rare or endangered. Many Central American nations have passed or are in the process of passing legislation that will prohibit hunting and protect forested areas. It will take concentrated, unified, and consistent effort by these national governments and others to save the unique species of Central America.

FAUNA: EUROPE

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology, zoology

Millennia of urban life and intensive agriculture have made European wildlife especially endangered. Large mammals are at the greatest risk, with many historical species already extinct. Since the 1990's, increasing efforts have been made to restore endangered populations through breeding programs and advanced reproductive technologies.

Principal Terms

ENDANGERED SPECIES: a species of animal or plant that is threatened with extinction

STEPPE: arid, loess-rich land, usually experiencing extremes of temperature

TUNDRA: a rolling arctic or subarctic plain, located too far north for trees to grow

UPPER PALEOLITHIC: the era from 30,000 B.C.E. to 3500 B.C.E., when humans first began to affect European wildlife populations

The number of wildlife species in decline across Europe increased during the second half of the 1990's. Eleven of Europe's twelve most urgent environmental problems, including waste, climate change, and stratospheric ozone depletion, remained static or worsened over the latter half of the 1990's. The threat to Europe's wildlife continues to be severe, with more than a third of bird species in decline, most severely in northwestern and central Europe. Up to half the known vertebrate species were under threat in many countries.

In the countries of the European Union (EU), intensive and subsidized agriculture has devastated the wildlife. Italy is a good example. The extent of animal life in Italy has been reduced greatly by the long presence of human beings. The primary locales in Italy where wildlife survive are the Italian Alps, the Abruzzi (east central Italy on the Adriatic Sea), and Sardinia. Only in those areas can one find the Alpine ibex, brown bear, wolves, foxes, fallow deer, mouflon (wild sheep), and wild boar.

Portugal and Spain are somewhat different from the rest of Europe in that their wildlife is a mixture of European and North African species. In Portugal, about two-thirds of the wildlife overall is Mediterranean, but the farther south one is in Portugal, the more North African the fauna becomes. Birdlife is rich in both countries of Iberia because the peninsula lies on the winter migration route of western and central European species. Nevertheless, major species in Portugal and Spain are endangered.

Despite its reputation for pollution, the eastern portion of Europe is the stronghold of Europe's wildlife. Agriculture in Eastern Europe is starting to intensify, however. One notable exception to the situation of Europe's fauna is Latvia. Although a small country, Latvia contains a number of species and ecosystems rare in other European nations. As many as four thousand Eurasian otters can still be found in Latvian rivers.

Less fortunate European countries struggle to re-establish their beavers, but Latvia has a population of forty-five to fifty thousand beavers, which were reintroduced in 1952 from Russia. There are two hundred to four hundred wolves, as well as three hundred to four hundred lynx. Latvia has more than two hundred breeding species of birds, some of which are rare elsewhere. These include the white-backed woodpecker, lesser-spotted eagle, and black stork. Estonia, which borders on

Habitats of Selected Vertebrates of Europe

Latvia, is similar in some respects. The moose is the largest animal, along with roe deer and red deer. In the forests of northeast Estonia, bears and lynx are found. Along the riverbanks, mink and nutria are common.

The Effects of Humans

Wild animals have been in retreat since Upper Paleolithic times (30,000 B.C.E. to 3500 B.C.E.), when small human groups held their own against such big game as aurochs, a type of bison, and mammoths, now extinct. In more recent centuries, settlers won the land for crops and domesticated animals. As the population increased in industrializing Europe, humans inevitably destroyed, or changed drastically, the wild vegetation cover and the animal life. With difficulty, and largely due to human tolerance, animals have nevertheless survived.

In January, 2000, a dike holding millions of gallons of cyanide-laced wastewater gave way at a gold-extraction operation in northwestern Romania. The collapse of the dike sent a deadly waterborne plume across the Hungarian border and down the nation's second-largest river. Two hundred tons of dead fish floated to the surface of the blighted waters or washed up on the Tisza River's banks. The toxic brew also killed legions of microbes and threatened endangered otters and eagles that ate the tainted fish.

Wildlife Preserves

Even when there are parks and preserves, human activities endanger the fauna and environment. Doñana National Park, an area of wetlands and sand dunes on the Guadalquivir River delta in southern Spain, is one of the most important wildlife sanctuaries in Western Europe. More than 250 bird species, over half of Europe's total, are found there. It is also home to the rare Iberian lynx. The park covers 190,830 acres (77,260 hectares) and is a World Heritage Site. In the 1990's, the park was threatened by falling water levels caused by thirty dams along the Guadalquivir River.

In 1998, the park was further threatened by a flood of toxic waste from a breached dam that was holding back a reservoir used for dumping mining waste. The waste was successfully diverted, but not before wetlands surrounding the park were contaminated by heavy metals. Those heavy metals may yet poison many of the birds that fly there to feed. The aquifer that supplies the park was contaminated, and thousands of fish and amphibians died. These had to be removed to prevent carrion-eating birds from being poisoned.

Mammals

Larger mammals are mostly gone from Western Europe, with the possible exceptions of Spain and Portugal. In the tundra of European Russia and of Lapland in Finland, Norway, and Sweden, caribou or reindeer thrive. In the short summer of the tundra, arctic fox, bear, ermine, and the wolverine

Efforts to Save Europe's Large Carnivores

Habitat destruction and the loss of prey species have contributed to the decline of large carnivores in Europe. In the year 2000, large carnivores occupied fragmented landscapes dominated by humans. The Iberian lynx population is confined to about ten isolated pockets of Spain and Portugal and numbers less than eight hundred. Elsewhere, relic brown bear populations are dangerously small and highly fragmented in southern, central, and western Europe. Like wolves, brown bears face a hostile reception whenever they move into new areas. Wolverines have been reduced to a few hundred in remote areas of Scandinavia. The Eurasian lynx has disappeared from much of its original habitat; where populations are starting to recover, conflict with humans remains a major stumbling block.

The World Wildlife Fund's (WWF) Campaign for Europe's Carnivores aims to challenge ancient prejudices and to help fund projects supporting peaceful coexistence between people and predators. Wolves are beginning to return to old haunts in France, Switzerland, and even Germany. This fact, along with continuing human conflicts with the wolverine, lynx, and brown bear in other areas, emphasizes the need to secure public support for carnivores. WWF's strong European network is working across international boundaries to help secure pan-European cooperation for carnivore populations and to gain public acceptance of their important place in Europe's natural heritage.

may appear. In the deep forests of Poland, Belarus, and European Russia, one still finds the moose, reindeer, roebuck, and brown bear. The brown bear no longer inhabits Scandinavian forests, but the moose is common in Norway, Sweden, and Finland.

Finland is the home of the only species of freshwater seal in the world—an animal depicted on one of the country's coins. The lynx is mostly gone, but wolves, fox, marten, badgers, polecats, and white weasels survive. The sable, which is much hunted for its valuable fur, only just survives in the northeastern forests of European Russia. In Romania, there can still be found bears, wolves, wild goats, and even the European bison.

In much of the rest of Europe, wild fauna are limited to foxes, squirrels, marmots, and other rodents. In higher elevations in France, Italy, and Austria, one can still find the chamois and ibex. Italy's renowned Gran Paradiso National Park in the Valle d'Aosta saved the alpine ibex from extinction. Alpine marmots and chamois can be seen in the Bavarian Alps near Berchtesgaden, Germany. In the steppes of the Ukraine and European Russia, large wildlife is gone except in the semidesert areas north and northwest of the Caspian Sea. There one can still find two types of antelope, the saiga and the jaran, along with rodent sand marmots, desert jerboas, and the sand badger.

Wildlife Drowning Under the High Seas

Some of Great Britain's best-known nature reserves are expected to be covered by the sea before the middle of the twenty-first century. The British government forecast that the sea level around southeast England would rise by two feet (sixty centimeters) by mid-century. A wildlife-rich chain of low-lying grazing marshes, reedbeds, and lagoons behind the shingle beaches of Suffolk and Norfolk in southeast England are at risk. In February, 1996, a combination of storms and exceptionally high tides flooded the freshwater Cley and Salthouse Marshes in Norfolk with saltwater to a depth of six feet (two meters) along a two-mile (three-kilometer) stretch of coast. The marshes there are one of the few British haunts of the bittern, a large heronlike bird that is one of the most critically endangered species in Britain. No bitterns bred there in 1996 because the salt stunted the reeds that give the bitterns cover and killed the freshwater fish they eat.

Reptiles, Amphibians, and Fish

Europe's reptiles are most common in Mediterranean and semidesert areas. In the coastal Mediterranean, vipers and similar snakes, lizards, and turtles are found frequently. In the semidesert areas north and northwest of the Caspian, cobras and steppe boas are found, along with lizards and tortoises.

In Italian waters, freshwater fish are the brown trout, sturgeon, and the eel. Off the coast of Italy, one finds the white shark, bluefin tuna, and swordfish. There is an abundance of red coral and commercial sponge on the rocks of the warm southern seas. Spanish waters contain a diversity of fish and shellfish, especially in the southeast where Atlantic and Mediterranean waters mix. Species include red mullet, mackerel, tuna, octopus, swordfish, pilchard, and anchovy. Bottom-dwelling species include hake and whiting. The striped dolphin and the long-finned whale are found off southeastern Spain, and the bottlenosed dolphin off the delta of the Ebro River. In Scandinavian waters, salmon trout, and the much-esteemed *siika* (whitefish) are relatively abundant in the northern rivers. Baltic herring and cod are the most common sea fish.

Birds

In the short summer of the tundra, seabirds and immigrant birds such as swans, ducks, and snipes can be found. In the great forests of Eastern Europe, black grouse, snipe, hazel hen, white partridge, owls, and blackbirds are common. The steppes have a more abundant selection of fowl. There are eagles, falcons, hawks, and kites and water and marsh birds such as the crane, bittern, and heron.

Insects

Different kinds of locusts and beetles are common in the steppes of the Ukraine and European Russia. In the summer months of 2000, much of the Eurasian steppes was hit by a plague of locusts, devastating Russia's vital grain crops. In Mediterranean and semidesert areas, scorpions, the karakurt spiders, and the palangid are insects dangerous to humans.

Conservation Efforts

In a remote part of northwestern Greece, the lakes of Mikri Prespa and Megali Prespa combine to form rich wetlands. The area has more than fifteen hundred plant species, forty mammals, including the brown bear, otter, and wolf, eleven species of amphibians, twenty-two species of reptiles, and seventeen fish species. Since 1974, Prespa has been a national park, but there was no management plan. In 1991, the World Wildlife Fund (WWF) helped to establish the Society for the Protection of Prespa (SPP) to intervene at a local level and develop the necessary strategies to maintain the area.

Scientists trying to save the Iberian lynx, the most endangered cat in the world, from extinction are using the latest deoxyribonucleic acid (DNA) technology to track the cat by its droppings. The scientists want to put several healthy cats in a captive-breeding center in the Doñana National Park. Once the population is located, DNA testing will reveal whether inbreeding is further endangering the dwindling species by producing unhealthy offspring. The idea is to capture several cats from different regions and bring them to the breeding grounds. In 2000, there was no stock to breed. There are no more than six hundred lynx in Spain and fifty in Portugal. If the rate of decline continues at the current trend, the animal could be extinct by 2010.

The Mediterranean monk seal is one of the ten most endangered species in the world. At the beginning of the twentieth century, it was prevalent throughout the Mediterranean. It is now a rare sight, although still spotted, particularly in the eastern Mediterranean and out in the Atlantic off the Madeira Islands of Portugal. The monk seal is a shy animal with low reproduction rates. It is thus highly sensitive to changes in its habitat and external disturbances. Increasing pollution from industrial waste, plastics, insecticides, and heavy metals have also affected its habitat, food, and most probably its mating ability. More important, since the seals are perceived by commercial fishermen to be in competition for limited fish stocks, they have been deliberately killed.

The WWF began a project in 1993 in the eastern Mediterranean to monitor the presence of the seal and to determine its interaction with the local population. The WWF has mounted information campaigns and government lobbying in Greece, Turkey, and Cyprus in order to pass protective measures to achieve a balance between increasing human use of decreasing marine resources and the basic survival needs of the monk seal.

FAUNA: GALÁPAGOS ISLANDS

Types of animal science: Classification, ecology, evolution, geography
Fields of study: Ecology, evolutionary science, herpetology, ornithology, wildlife ecology, zoology

The Galápagos Islands, clustered around the equator six hundred miles west of the coast of Ecuador, are renowned for their remarkable fauna, including the giant Galápagos tortoise, the world's only marine iguana, and Darwin's finches, whose variety and ecological diversity inspired Charles Darwin's revolutionary theory of evolution.

Principal Terms

CARAPACE: hard case covering the back of an animal

DISHARMONIC: ecologically unbalanced

ENDEMIC: belonging to or native to a particular place

NOCTURNAL: active at night and dormant or asleep during the day

VESTIGIAL: less developed or degenerated from an original useful form

The Galápagos are oceanic islands, created by submarine volcanoes that emerged from the ocean devoid of life. Because of the great distance between an oceanic island and the nearest continent, only animals and plants that can disperse easily through the air or water are likely to reach such an island. Even fewer will survive its particular environmental conditions and thrive. For this reason, oceanic islands tend to be disharmonic.

For animals to reach the Galápagos before humans arrived, there were only three options: by sea, whether by swimming, floating, or drifting on natural rafts of logs or other vegetation; by air, either by flying or drifting in wind currents; or by hitching a ride on or in the body of another animal. As a result of such limited, haphazard possibilities, freshwater fishes and amphibians are totally absent from the islands, and endemic mammals are few. Only birds and reptiles well represent the vertebrates, and only beetles and butterflies the invertebrates.

Reptiles

Reptiles dominate the Galápagos. Seventeen out of twenty-seven species are endemic. They include geckos, snakes, lava lizards, iguanas, and giant tortoises. Geckos are small, mostly nocturnal lizards. The one endemic snake is a small constrictor. Lava lizards are so named for their habit of basking on lava rocks, and range in size up to twenty-five centimeters (almost ten inches).

The islands have both land and marine species of iguanas. Land iguanas grow up to 1.2 meters (almost four feet) long, have a large dorsal crest, and can live up to seventy years. They prefer fruits, flowers, cactus pads, and other vegetarian fare but also consume insects and carrion. The marine iguana is the only sea-going iguana in the world and can drink seawater, utilizing special salt glands to excrete the excess salt. It spends most of the day basking but dives to depths of twenty meters (over sixty feet) to feed almost exclusively on marine algae. It can reach a length of 1.5 meters (five feet) and live up to thirty years.

The most famous reptile on the islands is the Galápagos tortoise, *Geochelone elephantopus*. Males can weigh up to 250 kilograms (550 pounds); females are considerably smaller. They drink from pools at any opportunity and browse on plants, but they can survive a year or more without eating or drinking and can live 170 years or more. There are two distinct types of tortoise with one intermediate type. One type has a dome-shaped carapace and lives in moist, lush areas where vegetation is abundant and easy to reach. The other inhabits more arid regions and has a saddle-shaped carapace, allowing extension of its long neck to reach leaves and cactus pads high overhead. It is this tortoise's distinctive shell that gave the islands their name: "Galápago" refers to a light saddle or sidesaddle in Spanish.

Birds

Although sea birds are abundant on the islands, most are nonnative migrants. Only a quarter of sea birds species are endemic: the lava and swallowtail gulls, the waved albatross, the flightless cormorant, and the Galápagos penguin. The Galápagos penguin is the northernmost penguin species and one of the smallest, standing forty centimeters (sixteen inches) tall. The flightless cormorant has a strong, hooked beak and vestigial wings. Like the penguin, it swims underwater to catch fish, propelled by its webbed feet.

Twenty-two out of twenty-nine land birds are endemic. There are four species of mockingbird, one dove, one flycatcher, one hawk, one martin, one rail, and thirteen species of Darwin's finches. Darwin's finches all originated from a species native to the Caribbean, *Melanospiza richardsonii*, evolving over time into thirteen species, with different bill sizes and shapes and varying habits.

Mammals

Not including the sea lions that gather in colonies on the beaches, only eight species of mammals are endemic to the Galápagos, six species of omnivorous rice rats and two species of bats. Unfortunately, many nonnative mammals, feral and domestic, have moved in and decimated many native populations of both flora and fauna. Lush vegetation has been converted to grazing land for goats, cattle, and horses. Donkeys trample tortoise nests while pigs root up and devour the eggs of giant tortoises, sea turtles, and birds. Dogs, cats, and nonnative rats prey on any reptile or bird they can catch.

Arthropods

About one thousand insect species inhabit the Galápagos. Because of the arid environment, most are nocturnal. Although there are relatively few species, insects are plentiful, particularly during the rainy season.

Of the arachnids, two endemic species of scorpions are found on the islands. Although there are over fifty spider species, only a few are endemic. The least popular animal on the island is an endemic centipede that can grow as long as thirty centimeters (approximately one foot) and administers a very painful bite.

FAUNA: MADAGASCAR

Types of animal science: Classification, evolution
Fields of study: Conservation biology, population biology, wildlife ecology, zoology

Madagascar is home to a rich variety of unique and remarkable animal species, most of which are found nowhere else in the world. These animals have evolved in isolation after the island split off from mainland Africa over 120 million years ago.

Principal Terms

ARBOREAL: living in or among trees
CAMOUFLAGE: to blend in with one's surroundings
ENDANGERED: at risk of becoming extinct
ENDEMIC: existing only in a particular locality
NOCTURNAL: active at night
OMNIVOROUS: feeds on both plants and animals
PROSIMIANS: a group of primates that retain some primitive characteristics absent in higher primates

Madagascar is a large island located in the Indian Ocean about 250 miles east of the African continent. Its varied geography and the resulting differences in temperature and rainfall have led to the identification of five distinct climatic regions, each having its own specialized floras and faunas. Because of the island's isolation, up to 90 percent of its estimated 200,000 evolved animal species so far identified are endemic. Biologists are discovering additional species every year. This unique biodiversity makes it a source of fascination for amateur and professional naturalists alike, as well as a hotspot for bioconservation efforts.

Mammals

There are relatively few mammal species on Madagascar. The ancestors of these unusual, diminutive creatures first arrived on the island by floating across the water on mats of vegetation or by hopping on temporary landmasses. Large mammals are thus conspicuously absent. Excluding bats, Madagascar's native mammals are 100 percent endemic.

Lemurs (order Primates, infraorder Lemuriformes) are Madagascar's trademark animals. These curious prosimians occupy a singular place in primate evolution. Lacking some of the characteristics of the higher primates, such as monkeys and apes, they are nevertheless intelligent and display social organization. Lemurs have excellent night vision, an acute sense of smell, distinctive bright eyes, pointed snouts, long tails, and are about the size of a cat. Most are arboreal and have the ability to jump great distances from tree to tree. They are primarily vegetarians, although some species also eat insects. There are thirty-three living species in five families. Of the true lemurs (family Lemuridae), the ringtail lemur is best known, the most sociable, and the only species that spends most of its time on the ground. Others species include the bamboo, mongoose, brown, black, and ruffed lemurs. The indri (family Indriidae) is the largest lemur, growing up to three feet tall and weighing up to fifteen pounds. It is famous for its loud, wailing, territorial call that can be heard at great distances. Woolly and sifaka lemurs are also in this family. The nocturnal mouse and dwarf lemurs (family Cheirogaleidae) are the smallest primates in the world, travel on all fours, and are the most numerous group on Madagascar. The aye-aye (family Daubentoniidae) is a single species that is quite different from all others. This solitary lemur has scruffy black fur, huge ears, rodentlike teeth, a thick tail, and a long, skeletal middle finger. It hunts for insects by listening for sounds underneath bark, then gnaws a hole and inserts its long finger into the hole to scoop out its prey. Lepilemurs (family Megaladapidae) are medium-sized, nocturnal lemurs.

Madagascan carnivores consist of civets (family Viverridae) and mongooses (family Herpestidae). The fossa is the largest civet and predator on the island, with a body length of about 2.5 feet. It is a catlike creature, with powerful legs and a long tail, and is an agile tree climber. It preys on reptiles, birds, and mammals, including lemurs. Other civets are smaller and more foxlike. The five species of mongoose are even smaller.

Tenrecs (order Insectivora, family Tenrecidae) are among the most primitive of all living mammals and were probably the first to arrive on the island. These small creatures resemble hedgehogs or shrews. Tenrecs feed primarily on insects, but many are omnivorous.

There are twenty-nine species of bats. Only 60 percent are endemic, due to their ability to migrate off the island. The flying fox, a fruit bat, is the largest.

Only eleven species of rodents exist on Madagascar. The giant jumping rat is the largest, about the size of a rabbit and weighing about 2.5 pounds.

Reptiles and Amphibians

Madagascar's amphibian population consists of about 150 species of frogs. The true frogs (family Ranidae) are most abundant, followed by the narrow-mouthed frogs (family Microphyidae) and just a few species of the Hyperoliidae and Rhacophoridae families. Most are arboreal forest dwellers.

The reptiles are better represented, with approximately 260 species identified. The lizards (subclass Lepidosauria, order Squamata, suborder Sauria) comprise the largest diversity, and include Madagascar's famous chameleons, whose color-changing ability, multidirectional vision, sharpshooting tongues, and V-shaped feet make them fascinating subjects. Madagascar is home to the majority of the world's chameleon species. Fifty-four species inhabit the island. The parsonii are the world's largest chameleons, and the pardalis is the most common. They eat insects as well as small birds and lizards. The sixty-three species of geckos include those with perfect camouflage as well as brightly colored ones. Iguanas inhabit only the dry regions. Skinks and girdle-tailed lizards are widespread.

There are no venomous snakes on Madagascar. The largest group are harmless snakes from the family Colubridae, the giant hog-nosed snake being the most common. The rest are blind snakes (family Typhlopidae) and boas (family Boidae). Madagascar is also home to a few species of sea turtles and tortoises. The endangered radiated tortoise is one of the rarest animals on earth. The Nile crocodile is also rare on Madagascar.

Birds

Madagascar has a relative paucity of bird species. Only 250 species have been recorded, and they are generally less colorful than those in other tropical areas. Of these, 106 species are endemic, and in fact there are five endemic families: the mesites, ground-rollers, cuckoo-rollers, asities, and vangas. The couas, a subfamily of the cuckoo, are among the most attractive, as are the kingfishers, flycatchers, sunbirds, weavers, lovebirds, and red fody. Of the sixteen species of birds of prey, eleven are endemic, and include kestrels, fish-eagles, and owls. There are nine species of partridges, quails, and grouse. Most of Madagascar's seabirds and wading birds are also found elsewhere in the world.

Invertebrates

A huge variety of invertebrates exist on Madagascar, due to the abundance of different ecological niches. The largest group is the insects, and most are endemic, many even to a particular locality. These include dragonflies and damselflies, grasshoppers, termites, flies, ants, fifty-two species of praying mantis, and over one hundred species of hissing cockroach. The more than eighty species of stick insects are amazing masters of camouflage. There are over one thousand species of true bugs, many strikingly colored. These include stinkbugs, water bugs, cotton-stainer bugs, and assassin bugs. At least twenty thousand species of beetles exist. These are colorful and varied in appearance, with descriptive names such as jewel-beetles, longhorn beetles, tiger beetles, darkling beetles, scarabs, and the bizarre giraffe-necked weevils. Madagascar has hundreds of moth and butterfly species, including many varieties of swallowtails and the attractive pansy butterflies. Hundreds of species of wasps and bees live in Madagascar, and several have bright metallic green coloring. Of the remaining invertebrates, there are many worms, leeches, and flatworms, and a huge variety of endemic land snails. There are about 430 species of spiders, 12 species of scorpions (only two have a painful sting), 64 species of centipedes, and also many millipedes, some reaching giant sizes of six inches or more.

Conservation

Humans arrived on Madagascar about two thousand years ago, and since then wildlife populations have been steadily decreasing due to hunting and habitat destruction. Several large species have already become extinct. The elephant bird, which stood about ten feet tall and weighed about one thousand pounds, died out about five hundred years ago, and its huge eggs are still found. Several species of the lemur, one the size of a gorilla, have also become extinct, as well as the giant tortoise and pigmy hippopotamus. The Malagasy people of Madagascar use the tavy method of slash and burn rice farming, which destroys the forests and erodes the soil. Only about 10 percent of the original forest cover remains. Cattle grazing, the production of charcoal, and the growing human population add to the problem. Many of Madagascar's unique animal species are severely threatened.

There are now a number of national parks and special reserves throughout the island, created to protect ecosystems and their endangered plant and animal species. A program of education to teach the Malagasy about the importance of their environment and wildlife is also under way.

FAUNA: NORTH AMERICA

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology, zoology

North America, stretching from the Arctic Circle in Canada to the tropics of southern Mexico, encompasses every type of climate and habitat, and as a result has a correspondingly diverse animal population.

Principal Terms

GRAZING SPECIES: animals that eat grass; some are wild, but many grazers have also been domesticated
HERBIVORE: an animal that only eats plants
MIGRATORY SPECIES: a species of animal that lives part of the year in one habitat and then moves to another habitat for another part of the year
PREDATOR: an animal that obtains food by hunting other animals

The wildlife of North America can be grouped within two large regions: the Nearctic realm, which covers most of North America from the Arctic to northern Mexico; and the Neotropical realm, which covers southern Mexico and all of Central America. Species in the Nearctic region are similar to those of Eurasia and North Africa, and originally reached North America from Eurasia by passing over the Bering Strait land bridge that once connected Siberia and Alaska, about 60 million years ago. Species in the Neotropical zone are distinctly different from Nearctic wildlife, and reached Central America and Mexico by gradual movement up the isthmus of Panama from South America.

North America's fauna also can be grouped by regions that reflect such climatic influences as latitude, the position of mountain ranges and oceans, and the plants and trees that grow in that area (grasslands, desert, forest, or tundra). Generally, arctic animals are found to the far north, and on the highest slopes of mountains. As one goes farther south, or farther down the sides of mountains, the animals to be found will be those of the forest, grasslands, or desert environments.

Arctic Tundra

Animals of the far north are similar to those found in Eurasia and are well adapted to their cold, treeless environment. Many of these animals evolved from Ice Age species as the glaciers that once covered North America slowly retreated northward. They are large in size and thickly furred, allowing them to maximize conservation of body heat. Large herbivores such as musk oxen and caribou graze on grasses, lichens, and mosses and are, in turn, a food source for polar bears and arctic wolves. Smaller predators such as the arctic white fox feed on arctic hares and small rodents such as voles, lemmings, or the arctic ground squirrels that subsist upon the small shrubs, berries, and grass seeds of the tundra.

Seals and whales proliferate in the Arctic seas. Birdlife in the Arctic tundra is nearly absent in the winter months, with the exception of willow ptarmigans and snowy owls. In the three to four months of summer, several bird species use the region as a breeding ground where young can be hatched and fed with the abundant insect life that emerges during the long and warmer days of summer. Among these migratory species are many varieties of waterfowl, including Canada geese, snow geese, whooping swans, trumpeter swans, phalaropes, plovers, and arctic terns.

Forests

Farther south, below the tree line, coniferous northern forests of fir, spruce, cedar, hemlock, and pine provide shelter and food for the moose, mule

Habitats and Selected Vertebrates of North America

deer, and snowshoe hares that browse on the needles of these trees. Squirrels, chipmunks, and porcupines also thrive in the forests of the far north. Predators of this region include martens, fishers, lynx, wolves, weasels, red foxes, and wolverines. Ponds, rivers, marshes, and swamps are common in this habitat, and provide homes for beavers, muskrats, river otters, mink, and such common fish species as whitefish, perch, pickerel, and pike.

Bird species native to the boreal forest include jays (Canada, blue, and gray), thrushes, finches, nuthatches, loons, osprey, ravens, and crows. A wide variety of songbirds (warblers) and some hummingbirds nest in the boreal woods in the summer months.

The eastern half of North America, from southern Canada to Florida, was once thickly covered by deciduous forests of maple, oak, beech, ash, sycamore, hickory, and other trees that shed their leaves in the winter. Where this forest remains, it provides food for a wide variety of mammals, including black bears, red foxes, raccoons, red and gray squirrels, mink, muskrats, jackrabbits, cottontail rabbits, groundhogs, chipmunks, mice, moles, bobcats, skunks, ermine, opossums, and porcupines. Fish species common to the rivers of eastern and southeastern North America include catfish, suckers, and gar. Several species of salamanders and turtles live in the marshes, streams, and rivers of the deciduous forests, especially in the Appalachians. Waterfowl such as kingfishers, herons, ducks, and grebes also live along the waterways of the hardwood forest region.

Adapting to Extremes

The extremes of climate in North America have caused many animals to adapt in interesting ways. In the far north, animals such as polar bears, musk oxen, and caribou tend to be large in size, so that their external skin area is minimized in relation to their internal portions, allowing the least possible heat loss to the cold air. Many arctic animals have both inner and outer layers of fur, trapping their body heat in the insulating layer. The feet of arctic animals are thickly furred and quite broad, allowing the animals to move over snow without sinking into it.

Animals of the southern deserts have equally effective ways of adapting to the extreme dryness and heat of their environment. They collect and store food when it is abundant after a rare rainfall and then survive long periods of drought on the surplus. They obtain water from the vegetation they eat, rather than from lakes or streams. Many desert animals are pale in color, reflecting back the heat of the sun and blending in with the surrounding landscape. Desert animals are largely nocturnal, moving about only in the cool of the night, after the moist dew falls.

Grasslands

The prairies in the center of North America provide abundant grasses and other herbaceous plants for many small mammals and grazing animals. Jackrabbits, badgers, prairie chickens, and small rodents such as pocket gophers, prairie dogs, and Richardson's ground squirrels, feed on grass and roots, as do such larger herbivores as pronghorn antelope and the American bison. The numerous small rodents and the openness of the grasslands provides optimal habitat conditions for such raptors as owls, hawks, and falcons. Waterfowl nest in the many seasonal watering holes (sloughs) that dot the prairies, although farm drainage and extended periods of drought have greatly reduced this habitat. Seeds and insects are plentiful in the grasslands, supporting such bird species as grouse, quail, partridge, and finches.

Rocky Mountains

The high mountains that run along the western side of North America are inhabited by a number of unique species. Bighorn sheep, Rocky mountain goats, mule deer, and elk graze on the grasses of the foothills and slopes of the mountains. Kodiak bears, grizzly bears, and mountain lions prey upon the grazing animals, and bald and golden eagles subsist upon the ground squirrels, marmots, voles, shrews, and pikas that live in the grasses and scattered forests of the lower mountain slopes. Dipper birds feed from the fast-running mountain streams and are found nowhere else on the continent.

Southwestern Deserts

A large number of animals have adapted to the lack of vegetation and water that exists in much of the southwestern United States and Mexico. Kangaroo rats, pocket mice, jackrabbits, armadillos, peccaries, ring-tailed cats, and ground squirrels all survive in that hostile environment. Predators include bobcats, desert foxes, badgers, and coyotes.

The most prolific forms of wildlife in the arid deserts of southernmost North America are the reptiles, including many different species of lizards, rattlesnakes, toads, and iguanas. Because they can only be active when the outside air temperature provides warmth for basic body functions, reptiles and amphibians are quite rare in the most northern parts of the continent but thrive in the arid and hot southern parts of North America. Roadrunners are a major bird predator of these reptiles, along with eagles and hawks.

Neotropical Forests

The tropical rain forests of Central America and southern Mexico have an astonishing variety of wildlife. The forest canopy has abundant bird life in the form of macaws, parrots, turkey vultures, and flycatchers. Monkeys of many varieties (spider, howler, squirrel, and capuchin) as well as sloths and tamarinds also live in the canopy, feeding on the many fruiting trees. On the floor of the forest, many varieties of ants, spiders, beetles, and chiggers provide food for smaller predators such as anteaters and various species of bats. A number of animals indigenous to South America have adapted to and thrive in Central America, including tapirs, capybaras, pacas, jaguars, ocelots, and agoutis.

Coastal Regions

The beaches, shores, lagoons, and marshes that line the North American continent are home to many kinds of animals that feed upon the ocean life or the intertidal plants and animals that live in the midzone between fresh and salt water. Many different kinds of migratory waterfowl exploit the small crustaceans and mollusks that live at the water's edge, including sandpipers, stilts, curlews, and flamingos. Seals, sea otters, and walruses are found on both coasts in the north of the continent, while Steller's sea lions and California sea lions are found only on the Pacific coast. The lagoons of the southern Atlantic coast and the Gulf of Mexico are home to alligators, pelicans, egrets, and spoonbills.

FAUNA: PACIFIC ISLANDS

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology, zoology

The thousands of islands that dot the Pacific Ocean contain a wide variety of animal species. The restricted conditions of island life result in interesting examples of fauna that have developed in relative isolation, but also increased threat to species that have nowhere to go to escape human encroachment on their habitats.

Principal Terms

ENDEMIC: native to a specific environment and found nowhere else on earth

EXOTICS: nonnative species introduced into an ecosystem

FERAL: an animal, formerly domesticated, which is now living wild

MARSUPIAL: animal with a pouch in which immature young complete their fetal development

The vast region of the Pacific, collectively called Oceania, comprises thousands of islands. Oceania spreads across the Pacific Ocean from 20 degrees north latitude to 50 degrees south latitude and from longitude 125 degrees east to 130 degrees west. The major groupings are Melanesia, Micronesia, Polynesia, and New Zealand. Melanesia ("black islands") is a group of large islands immediately north and east of Australia, from New Guinea to New Caledonia. Micronesia ("little islands") is made up of hundreds of tiny atolls in the western Pacific. Polynesia ("many islands") covers a huge region in the central Pacific. New Zealand lies east and south of Australia. Climates range from tropical to sub-Antarctic, dry to very rainy. Types include volcanic (Fiji, Guam, and Hawaii), tectonic (New Zealand and New Guinea), and low coral atolls (nearly all of Micronesia's islands).

Organisms have a hard time reaching the islands across the broad expanses of the Pacific Ocean. This isolation leads to trends in the number of species found on any given island: Bigger islands have more species; those farthest from continents have fewer species. To reach the islands, animals must fly (birds and bats), float on logs, or be carried in by humans. Birds are usually the first visitors, bringing with them hitchhiking insects. Bats are the only mammals to reach many islands without human help.

Island plants and animals evolve together, affected by difficult conditions; soil is often poor and food limited. Harsh environments and isolation contribute to the formation of new and unique species; some of the strangest creatures on earth are endemic to particular islands. Most of the world's flightless birds developed on islands, where there originally were no large land predators. Island ecosystems are sensitive to disturbances, whether from natural causes such as severe storms, or human activities such as construction, agriculture, logging, and introduced species.

Introduced species (exotics), both accidental and deliberate, are a serious problem. Rats and feral animals can devastate island ecologies. Pigs, cats, rats, and goats are particularly devastating—goats devour vegetation, cats eat birds and small animals, and rats and pigs eat anything.

Exotics also bring diseases to which native animals have no resistance. Humans have tried to deal with exotics, with mixed results. For example, the mongoose was intentionally brought to Fiji to control accidentally introduced rats. No one considered that rats are active at night and mongooses during the day. The mongoose did not control the rats, but they did eat seven native Fijian bird species to extinction.

Another strange example occurred in Hawaii. A Hawaiian bee crawls headfirst into native, barrel-shaped flowers, gathers the nectar, and then backs out. A plant that was introduced by landscapers attracted bees, but the flowers were smaller than the native plants. Once a bee crawled in, it became stuck like a cork in a bottle. There are thousands of these plants, each with hundreds of flowers stoppered with dead bees.

Many tropical and temperate islands have coastal wetlands and mangrove swamps growing at the edge of the sea. Mangroves are low-growing, salt-tolerant trees that form dense tangles that are virtually impenetrable to humans. Wetlands and mangrove swamps are important breeding grounds for many types of fish and crabs, and also trap sediment, stabilize shorelines, and protect coastlines from storms. Humans often fill in the wetlands and cut down the mangroves, causing coastal erosion and the loss of food fish.

Easter Island

Easter Island (Rapa Nui) lies in the South Pacific 2,400 miles (3,862 kilometers) from Chile, South America. It is best known for its huge, mysterious stone statues. Archaeological evidence proves that Easter Island once was densely forested and supported many animal and bird species. The inhabitants burned or cut down the forests before Europeans discovered the island in the eighteenth century. The only plants now living on the island are sparse grasses, a few shrubs, and two species of trees. There are almost no land animals larger than insects. The few thousand people who still live on the island must import nearly all of their food. The devastation of Easter Island is an extreme example of what can happen to island ecologies when human development exceeds natural capacity.

Fiji

The Fiji Islands are mostly volcanic in origin and lie in the South Pacific Ocean about 1,300 miles (2,100 km.) north of Auckland, New Zealand. Some parts of the islands receive up to 13 feet (4 meters) of rain per year, while other parts remain dry. A range of volcanic peaks divides the islands; the highest, Mount Tomanivi (formerly Mount Victoria), is 1,322 meters (4,341 feet). These differences in weather and elevation create a variety of habitats—dense rain forests, grassy savanna, and mangrove swamps—and a large diversity of species.

Human disruption on Fiji has been moderate. About half the total area is still forested, and less than 25 percent of the land is suitable for agriculture. Endemic animals include birds such as lorikeets (parrots that eat flowers or nectar), the Fiji goshawk, spectacularly colored pigeons and parrots, and a pigeon that barks like a dog. The Vanikoro broadbill, which holds its mossy nest together with spider webs, is one of the few native birds that has adapted to forest clearing. It is commonly seen in town gardens and suburbs.

Other creatures native to Fiji are snakes, including a rare, tiny cobra, two species of frog, and several species of geckos and skinks (small lizards). The crested iguana was not discovered until 1978 and lives only on the island of Yaduataba. Yaduataba is now a preserve, and the crested iguana is more likely to survive since feral goats were removed from the island.

There are twelve reserve areas in the Fijian islands, but several are being logged and provide little sanctuary to native plants and animals. The University of the South Pacific is located in Fiji and is a source of serious research into South Pacific species. Tourism is important to Fiji's economy and, with management, could be a source of income to Fijians while still preserving native wildlife.

New Guinea

The world's largest tropical island, New Guinea is located north of Australia and just south of the equator. It is tectonic in origin, with large changes in elevation and many different habitats. Because of its size and varied terrain, New Guinea has a greater variety of habitats than any similar-sized land area in the world. In fact, New Guinea is so rugged that it is one of the least explored or developed places on earth. It provides the best remaining example of the types of organisms that can develop in island isolation.

New Guinea habitats include cold tundra, tropical rain forests, grassy savannas, coastal zones, montane rain forests, cloud forests, and bogs. There are at least twenty thousand species of flowering plants, including more than twenty-five hundred species of orchids, and hundreds of birds and animals. Many New Guinea species are unusual.

Native birds range from the beautiful to the bizarre. There are several species of birds of paradise, some of the most beautiful birds in the world. They have brilliant colors or long, wiry feathers with metallic-looking feather disks that they wave and tremble to attract mates. The bower bird builds large, complicated structures and decorates them with colorful flowers, feathers, or trash, and even uses berry juice as paint. The megapode tunnels into the earth near volcanic hot springs with huge, powerful feet. It lays its eggs in the warm tunnel so that it does not have to sit on them.

New Guinea has several parrots, including the endangered Pesquet's parrot, whose face is completely bald so it can stick its head into fruit without getting sticky feathers. Lorikeets are colorful, nectar-eating parrots. New Guinea is also home to the flightless cassowary, a large bird up to 6.6 feet (2 meters) tall and weighing up to 130 pounds (60 kilograms). Other bird species include feathery crowned pigeons, kingfishers (twenty-two species), ducks, herons, hawks, and egrets.

As in Australia, primates and large mammals never arrived in New Guinea. Marsupials took their ecological places. There are several species of tree-living kangaroos. The basic kangaroo shape is modified in the tree species; they have larger forearms and smaller hind legs. Other marsupials include striped and feather-tailed possums, ringtails, and land wallabies that look like small, dainty kangaroos.

Other odd New Guinea animals are the echidnas, perhaps the most primitive mammal in the world. Echidnas lay eggs and are related to the duck-billed platypus. There are several echidna species; the largest is the giant spiny anteater, which has long spines, dense fur, thick claws, and a long, slender snout. Despite its name, it eats mostly earthworms, which it reels into its mouth using spines on its tongue.

New Guinea has many types of fruit bat. One large species, the flying fox, roosts in colonies. The largest roost is in a tree directly in front of the main police station in the town of Madang. Thousands of bats roosting overhead cause significant problems in street cleaning and for pedestrians without hats.

Reptiles and amphibians on New Guinea consist of snakes, lizards, frogs, and toads. The Salvadori monitor lizard is the longest in the world, growing up to sixteen feet (five meters) long, most of which is tail. Crocodiles live in many rivers and are endangered from hunting and demand for their hides. Some locals have begun crocodile ranches, where they breed and raise the crocodiles for meat and hides without damaging

Biological Mass Murder

The brown tree snake vividly illustrates the dangers of introducing an exotic species to an island ecosystem. The brown tree snake, a native of Australia, was accidentally introduced to Guam after World War II. It reproduced in incredible numbers and reached the highest density of any snake population on Earth, with up to sixteen to twenty thousand snakes per square mile. In the late 1970's, biologists noticed that birds were disappearing from Guam. Of the fourteen bird species endemic to the island, at least nine had become extinct by the 1990's. Many small animal species, as well as chickens raised by the island's inhabitants, also disappeared. The snakes harm humans as well; they bite viciously and cause frequent power outages by climbing on power lines. Millions of dollars have been spent on unsuccessful attempts to control the brown tree snake.

wild populations. Snakes include adders and pythons (eight species), and the deadly taipan and Papuan black snakes. There are many species of frogs, including several odd rain forest species that no longer have a tadpole stage.

New Guinea's insects include the largest moth in the world and the largest butterfly, the Queen Alexandra's birdwing. This species is endangered due to collecting and loss of habitat, but some New Guineans run butterfly ranches. They raise the insects, sell them to collectors and museums, and still preserve the species. There are also giant millipedes, stick insects twelve inches (thirty centimeters) long, and a fly with its eyes on stalks. Several species of flies have antlers on their heads, which they use to fight in defense of egg-laying territory.

Many forests host "ant-plants," warty looking epiphytes that have hollow mazes inside their tissues. Ants live in the maze, safe from predators. The ants provide nutrition for the plant in the form of droppings, scraps of food, and dead ants.

Even though New Guinea is rugged and isolated, human impact is increasing. It has proven difficult to develop New Guinea economically without destroying the unique life of the island. It is hoped that lessons learned on other islands, such as Guam and New Zealand, may be applied to New Guinea. The government has tried incentives to keep wild areas wild, such as encouraging ecologically friendly businesses like crocodile and butterfly farms and ecotourism. The National Park reserve that includes Mount Jaya is the only place in the world where it is possible to visit a glacier and a coral reef in the same park.

New Zealand

Located off the eastern edge of Australia, New Zealand has a fairly moderate climate that comes from conflicting warm, humid Pacific and colder Antarctic weather. It is similar to New Guinea, with rugged terrain, high mountains, and habitats from grassy open plains to dense forests, wet areas to near-deserts. Unlike New Guinea, however, New Zealand has been occupied and developed by humans for hundreds of years. Before large-scale agriculture, about half of New Zealand was covered with forests and one-third with grassland communities. Now, half is pasture for grazing and a quarter is forest, mostly introduced species. Much of the remaining native forest is maintained as national parks and reserves. Pasture land usually consists of a single species of grass and does not support the wide variety of bird and animal life of the original grassland communities.

It is sometimes said that the dominant mammal in New Zealand is the sheep. Sheep are vital to the economy but have caused problems for native animals; more than six hundred native species are threatened and several are extinct, including 43 percent of New Zealand's frogs and more than 40 percent of its native birds.

Like New Guinea and Australia, New Zealand did not originally have any large mammals or carnivores. Fourteen flightless or weak-flying birds developed there. The native Maori people hunted the large, flightless moa to extinction before the Europeans arrived, one of the rare instances in recent history when humans not from a Western culture were responsible for a species' extinction.

Flightless birds that still survive in New Zealand are the kiwi and the kakapo parrot. The introduction of cats, dogs, rats, and pigs has severely endangered both species, and at the end of the twentieth century, there were fewer than seventy kakapo left. All had been moved to predator-free, offshore islands. The kiwi is New Zealand's state bird, and efforts are being made to save it as well. Two species of another flightless bird, the penguin, breed on the south and east coasts. There are more than two hundred species of flying birds, at least forty of them introduced, including tropic birds, gulls, hawks, harriers, skuas, spoonbills, and pheasant.

The only original endemic mammals were two species of bats. In the last two hundred years, many exotic marsupials and mammals have appeared, including rabbits, rats, mice, weasels, otters, cats, pigs, cattle, deer, goats, and sheep. Domestic cattle, sheep, and pigs are economically important.

Amphibians and reptiles are interesting but not numerous. Among them is a frog that retains its tail as an adult and one that bypasses the tadpole stage. Some frog species have been introduced but have had little impact. Reptiles include geckos, skinks, and the extremely primitive, lizardlike tuatara.

Invertebrate species include such oddities as a giant carnivorous land snail. There are more than four thousand species of beetles, two thousand species of flies, and fifteen hundred species of butterflies and moths. In a reversal of the usual ecological concerns, some native insects are destroying introduced pasture grasses.

Micronesia

The Federated States of Micronesia consists mainly of small atolls. Coral atolls are found only in tropical latitudes because coral (small, colonial animals) grows only in warm water. Coral reefs support a tremendous variety of fish, crabs, and mollusks. Atolls tend to have porous, infertile soil and to be very low in elevation; the inhabited state of Tokelau, comprising three small islands, has a maximum elevation of sixteen feet (five meters). Fauna usually consists of lizards, rodents, crabs, and other small creatures. Pigs, ducks, and chickens are raised for food, and dogs and cats are kept as pets.

Human disturbances on coral atolls often have been particularly violent; several nuclear test bombs were exploded on Bikini Atoll and other islands in the 1940's and 1950's. Kwajalein, the largest atoll in the world, is used by the U.S. military for intercontinental ballistic missile target practice. Johnston Atoll, about 820 miles (1,320 km.) southwest of Honolulu, Hawaii, is a U.S. military base and storage facility for radioactive and toxic substances. It is also designated as a protected area and bird-breeding ground.

The Prospect for Island Ecologies

Island ecologies are unique and fragile. Some, like those in Guam and New Zealand, can never be returned to their original state, but with extensive wildlife management, many native species can be saved from extinction. Ironically, people in the developed world who visit zoos see more native Pacific island species than those who live on those islands. Some endemic species have been wiped out or had their habitat destroyed, so zoos are the last refuge for many creatures.

New Guinea, Fiji, and many smaller islands are in earlier stages of modern development and wildlife destruction can still be controlled. Conservationists sometimes do not realize that islands are not small, geographical zoos; people live there and want to improve their lives. Development cannot be stopped, but it can be managed so that the humans can improve their standard of living as they wish, and the original, amazing island dwellers can still survive.

FAUNA: SOUTH AMERICA

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science, wildlife ecology, zoology

South America, stretching from the tropics of southern Mexico and Central America to the Antarctic, encompasses every type of climate and habitat, and as a result has a correspondingly diverse animal population.

Principal Terms

GRAZER: an animal that eats grass; some are wild, but many grazers have also been domesticated

HERBIVORE: an animal that only eats plants

NOCTURNAL: active at night and dormant or asleep during the day

PREDATOR: an animal that obtains food by hunting other animals

A wide range of animals, both ordinary and exotic, inhabit the continent of South America. The types of animals found in any geographical area are determined by the climate and the terrain. In the Andes, animals such as the llama have adapted to the terrain and climate of the high, steep mountains. North of Antarctica, in the archipelago known as Tierra del Fuego, there are many penguins, whose layers of feathers help them to survive the frigid sea waters in that area.

Camelids of the Andes

Four members of the camel family live in the Andes Mountains of Peru, Bolivia, Ecuador, and Chile: alpacas, vicuñas, guanacos, and llamas. These camelids all have commercial value in the Andes, as pack animals and for their meat and fur. Many people of the Andes also raise sheep on the mountains for both wool and meat.

More than four thousand years ago, alpacas, which are raised for meat and for their fine cashmere fur, were reserved for the exclusive use of the Incas, who prized their coats. Alpacas live from fifteen to twenty-five years. The average adult is about three feet (one meter) high at the shoulder and weighs up to 180 pounds. In 1999, there were approximately three million alpacas in South America, mostly in Bolivia, Chile, and Peru.

Closely related to the alpaca is the llama, domesticated as a work animal more than three thousand years ago. Llamas, used primarily in Peru and Bolivia, have historically been the beasts of burden in the Andes Mountains. A single animal can carry about two hundred pounds (ninety kilograms) for twelve hours a day. However, they cannot be ridden, and when they tire, they often simply lie down and refuse to move. They even spit at their drivers when they no longer want to work. Reaching heights of nearly 4.5 feet (1.5 meters) llamas are generally larger than alpacas. A llama's fur is usually white with black and brown, but some are pure white and others pure black. Although llamas are used for work, they are also kept as pets in many homes of South America.

Vicuña fur has historical importance in South America. It was used by Incas to make cloth, and only members of Inca royalty could wear clothing made from this cloth. Anyone else found with such clothing was executed. By 1979, only four thousand vicuñas were left in South America. They had been hunted for their fleeces by poachers who killed the animals. Representatives of the governments of Bolivia, Chile, Ecuador, and Peru signed a treaty for protection of the vicuña. Twenty years later, there had been a resurgence of vicuñas in Peru, Chile, and Argentina: in 1999, there were 103,000 in Peru, 30,000 in Argentina, 16,000 in Chile, and a small transplanted herd in Ecuador. Even though *el chacu*, the communal hunting of vicuña, continued after 1979, laws lim-

Habitats and Selected Vertebrates of South America

ited these hunts to local people. Those local hunters sold the fiber from the animals as an important source of income for their families.

Vicuñas weigh ninety pounds and are a little less than three feet (one meter) in height at the shoulder. They have long necks, slender legs, padded cloven feet, large round eyes, and a fine, dense, tawny coat. Aside from their economic value, the vicuña is valuable for scientific study. They are highly communicative animals, signaling each other with body postures and ear and tail positions. They emit soft humming sounds as symbols of bonding and greeting.

The fourth member of the camel family found in South America is the guanaco. The guanaco is more adaptable than the other three camelids. It is found throughout the Andes, in the dry Atacama Desert of Chile, and in Tierra del Fuego, where it rains year-round. This animal, from which the llama was domesticated, began life in the semiarid desert and has developed physiological mechanisms for coping with both heat and dehydration. It is similar in structure to the other camelids, but is the largest member of the camel family living in South America.

Other Andean Mammals

Throughout the Andes, from Argentina to Colombia, and on into Central America, pumas roam. This reddish brown feline can reach lengths of about 6.5 feet (2 meters), not including its long tail. In some areas of South America, the puma is endangered. It is a carnivore whose natural prey are elk, deer, and small wild animals; however, it also eats sheep and cattle. Thus, ranchers have retaliated by killing the predators. Another member of the cat family is the elusive Andean mountain cat. Rarely sighted by humans, it is the least-known New World cat. The Andean wild cat is considered sacred by the native people of the *altiplano* of Bolivia, the Aymara.

In the forests of the Andes lives the spectacled bear. Its range extends as far north as Ecuador. This bear, which is endangered because of overhunting and destruction of its environment, has a shaggy brown coat with yellow facial markings and a cream-colored muzzle, throat, and chest.

Several rodents are native to the Andes. Chinchillas were found living in crevices in the mountains when early Spanish explorers first arrived there. Living off berries and fruits in Peru, Chile, and Argentina, these rodents belonged to Inca royalty, who used their fur to make chinchilla stoles. In the latter part of the twentieth century, they were nearly extinct in the wild but existed in captivity. Related to the chinchilla is the viscacha, which is prey for such animals as the Andean mountain cat. Mountain viscachas have long, rabbitlike ears, and long, squirrel-like tails. East of the mountains lives the plains viscacha, which has shorter ears and a blunter head. The cavy, the South American guinea pig, lives in the crevices of the Andes.

Andean Birds

Various exotic birds also live in the Andes, many of which also are found in the Amazon Basin to the east. Among these birds are the Andean cock-of-the-rock, the scarlet macaw, the quetzal, the Andean condor, and the James flamingo. The cock-of-the-rock is a huge dancing bird found in the mountain forests. The scarlet macaw, a brilliantly plumed member of the parrot family, is an endangered species. The quetzal had religious significance to early Andeans; even at the beginning of the twentieth-first century, it is regarded as a symbol of the Andes Mountains. The Andean condor is found in the high plains area of Bolivia and Chile. With a wingspan of twelve feet (four meters), it is the largest flying bird in the world. It can soar to a distance of 26,000 feet (7,925 meters) above sea level.

In the southern Andes lives the rhea, a flightless bird related to the ostrich, which often is called the South American ostrich. The rhea is much smaller than an ostrich and has three toes on each foot, whereas an ostrich has two toes on each. Rheas live in flocks of twenty to thirty in Brazil's southern plains and in Argentina, Paraguay, and Uruguay.

Animals of the Amazon Basin

Representatives of almost one-fourth of all known varieties of animals live in South America, mostly in the Amazon Basin. The basin includes the rain forests, plateaus, rivers, and swamps southeast of the Andes Mountains.

The tapir, found in the Andes and in the forests east of the Andes, is South America's largest animal. With its short, hairy body, it resembles a pig, but is actually related to the horse and the rhinoceros. The number of tapirs in South America lessened over the twentieth century because they were hunted for their flesh and their thick hides, and also because the cutting of forest has reduced the land available for their habitat.

The tapir's natural enemy, the jaguar, also is found in the eastern Andes and in the forests east of the high mountains. This feline, which was worshiped by pre-Columbian civilizations as a god, lives in the area between the southern United States and northern Argentina and is especially prevalent in Brazil. Strong swimmers, jaguars like to live near rivers and other streams. At the end of the twentieth century, they were on the list of threatened animals in South America. They were threatened because farmers were farming lands that previously were their natural habitat, and also because farmers, claiming that the cats killed their cattle and sheep, were killing the jaguars.

Several types of foxes are indigenous to the Amazon Basin and roam through lower mountain areas to the east and the west of the Amazon. Among them are the gray fox and the crab-eating zorro. The gray fox roams over the plains, the Pampas, the desert, and the low mountains, but its number is decreasing because farmers are cultivating lands that previously were its habitat. In Argentina, where it has been hunted for its skin, the gray fox has been placed on the endangered species list. In Chile it is protected by law, but enforcement of the law has been lax. The crab-eating zorro is found in Colombia, Venezuela, Suriname, eastern Peru, Bolivia, Paraguay, Uruguay, Brazil, and northern Argentina. An omnivore, it eats not only crabs but also insects, rodents, fruit, reptiles, and birds.

Also living within the Amazon Basin are the giant anteater, the sloth, and the peba. The giant anteater has value to the environment and to farmers because it consumes up to thirty thousand insects per day. The peba, a nine-banded armadillo found widely throughout South America, also contributes to agriculture by consuming insects and worms. This nocturnal animal is protected from its predators by a horn and bony plates covering its body. The sloth is the world's slowest-moving large mammal.

Within the Amazon Basin lives one of the world's most interesting rodents, the huge capybara. It generally is as large as a big dog, but can reach 4 feet (1.2 meters) in length and can weigh as much as one hundred pounds (forty-five kilograms). Humans have little to fear from the amphibious capybara, however, since it is a vegetarian.

The coatimundi inhabits areas from Arizona to northern Argentina. A member of the raccoon family, it is brown or rust-colored. It eats snails, fish, berries, insects, spiders, lizards, birds, eggs, and mice, and is often kept as a pet by South Americans.

The rain forest is also inhabited by many bats, squirrels, and parrots, which eat the fruits and nuts of the upper and lower canopies. In the lower canopy live lemurs, flying squirrels, and marmosets, small monkeys found mostly in eastern Brazil. These animals use their sweat glands for communication. Animals of the lower canopy eat the fruits, nuts, and insects that are found there. Within the rain forests also live vampire bats; these fascinating animals have to have two tablespoons of blood per day in order to survive.

Other residents of the Amazon Basin include the yapok, a member of the opossum family that has webbed feet for swamp travel; the sapajou monkey, a small New World primate; and the octodont, an eight-toothed rodent also known as a spiny rat or a spiny hedgehog because of the sharp spines embedded in its fur.

Birds and Reptiles of the Amazon

Many types of birds live in the Amazon Basin, some deep within the rain forest, others closer to the mountains. Among the birds in the basin are hummingbirds, parrots, ospreys, macaws, boat-billed herons, great egrets, white-necked herons, least bitterns, and blue and yellow macaws. Tou-

The Anaconda

Another name for the anaconda is the water boa, an appropriate name for a snake that is almost always found near water. Anacondas live in the Amazon and Orinoco basins of tropical South America, and their habitat extends to Trinidad. Like the crocodile, the anaconda has nostrils high on its snout so that it can swim with its head above water to breathe. The anaconda lies near the shore, waiting for its prey. When a deer, bird, or other prey comes to the water to drink, the anaconda quickly strikes, dragging its victim underwater to drown it. The anaconda then eats the unfortunate animal whole. A good meal can last an anaconda for several weeks, during which it will lie in the water, digesting its food.

cans, which also live at high elevations up to 10,000 feet (3,050 meters), can be found deep within the Amazon rain forest.

Both the land iguana and the lava lizard live in the Amazon Basin. Land iguanas can live up to twenty-five years and weigh up to 15 pounds (6.8 kilograms). They eat low-growing plants, shrubs, fallen fruits, and cactus tree pads. The lava lizard, about 1 foot (30.5 centimeters) long, is smaller than the land iguana. Lava lizards are beneficial to agriculture because they eat beetles, spiders, and ants.

The boa constrictor also lives in the jungles of this basin. This snake, which is usually six to nine feet (two to three meters) in length, but can reach thirteen feet (four meters), kills its prey by squeezing it to death, using its body coils to suffocate its victims. After killing its meal, the boa constrictor stretches its jaws wide apart and pulls the entire victim into its mouth. Using this method of killing, a boa is able to eat animals that are much larger than its head.

Another large snake native to the Amazon Basin is the anaconda. Most anacondas weigh several hundred pounds (100 kilograms) but can reach weights of 550 pounds (250 kilograms) and can reach thirty-six feet (eleven meters) in length. The anaconda is found in the Guyanas and throughout tropical South America, east of the Andes. With eyes high on its head, the anaconda can submerge its body in water and watch for the approach of unsuspecting prey.

River Animals

Many animals spend all or part of their lives within the Amazon. The black caiman, an alligator that is nearly extinct, is one such animal. It can weigh as much as a ton. It will eat all vertebrates, including humans, if that is the only food available.

The semiaquatic brown water lizard also is found in the jungle area around the Amazon. Within the Amazon are manatees as well as Boto River dolphins, also known as an Amazon River dolphin. This endangered animal is the only dolphin to have a neck. Giant otters live in the waters of the Amazon as do many types of fish, including piranhas, which, with their sharp teeth, can quickly strip the flesh from their prey.

Animals of the Eastern Highlands

The Eastern Highlands of South America host many unique animals, including the bush dog, woolly tree porcupine, maned wolf, peccary, bushmaster, and coypu rat, and many birds such as flamingos.

The bush dog is a wild dog, but, with its webbed feet, it resembles an otter more than a dog. Bush dogs live in packs and hunt small deer and rodents. Bush dogs can be found from the rain forests into the grasslands, in Colombia, Venezuela, the Guyanas, Brazil, Paraguay, northeastern Argentina, eastern Bolivia, and eastern Peru.

The maned wolf is one of South America's most beautiful and revered animals. Weighing on average one hundred pounds (forty-five kilograms), it is South America's largest canid. It is found mostly in Argentina and Brazil and has no natural enemies. An omnivore, it will eat nearly anything, including fruits, insects, and small vertebrates. At the end of the twentieth century, the Smithsonian Institution estimated that fewer than ten thousand maned wolves existed in the wild, living mostly in Argentina and Brazil. Because of its beautiful red and gold fur, the maned wolf is a tourist attraction. Many South Americans regard it as an important part of their cultural heritage. The rural people of the Sierra de Canastra of Brazil believe that the maned wolf has medicinal and supernatural powers.

The peccary and the bushmaster are also found in the Eastern Highlands. The peccary resembles the tapir, but is much smaller. It has a big head, sharp teeth, and prickly fur. It eats smaller animals and plants such as cactus flowers. The bushmaster, the largest poisonous snake in the Americas, is a type of pit viper related to the rattlesnake. Like the rattlesnake, it shakes its tail before striking, but it has no rattles. Gray and brown with a diamond pattern, it averages 8 to 12 feet (2.5 to 5.5 meters) in length.

The coypu rat is also known as a swamp beaver. This relative of the muskrat is found in southern Brazil, Bolivia, and Colombia. The agouti, a rodent nearly two feet (sixty centimeters) long,

Baron Alexander von Humboldt

Born: September 14, 1769; Berlin, Germany
Died: May 6, 1859; Berlin, Germany
Fields of study: Environmental science, wildlife ecology, zoology
Contribution: Von Humboldt was a great German naturalist and explorer who founded the field of physical geography. He also studied the relationship between regional geography and its flora and fauna.

Alexander von Humboldt was born in Berlin, Germany, the son of an army officer. After his father's death in 1779, his mother raised him in the family castle at Potsdam. Von Humboldt was privately tutored to prepare him for a life in public service. He began studying economics at the University of Frankfurt, then switched to engineering. At that time, von Humboldt became interested in botany.

Study at the University of Göttingen turned von Humboldt's interest to geology, and he studied at the Frieberg School of Mines for two years. This led to an appointment to the Prussian Department of Mining. In this position, he reorganized numerous mines and supervised mining activities. In 1797, von Humboldt resigned this post to study meteorology and geomagnetism. He obtained permission from Spain to visit its Central and South American colonies.

In 1799, his self-financed expedition set off in a small ship, the *Pizarro*. He was accompanied by botanist Aimé Bonpland. Over the next five years, the expedition thoroughly explored Central and South America. First, it proved that the Casiquiare River connected the Amazon and Orinoco rivers. Next came exploration of the Andes, including von Humboldt's climb to near the top of Mount Chimborazo, a world record that stood for many years.

In 1803, the *Pizarro* sailed to Mexico for a study of that country. Then it returned to France with a huge collection of plants and data on physical geography. From 1804 to 1827, von Humboldt processed the data. In Paris, he published thirty volumes of findings. Meteorological data included weather maps which helped to found comparative climatology, studies of the relationship between regional geography and its flora and fauna, and proof that the earth's surface was not formed by sedimentation from the liquid state.

In 1827, von Humboldt returned to Berlin and the royal court, where he tutored the crown prince, was on the privy council, and was court chamberlain. In 1829, he was invited to Russia to examine gold mines and advise on mining techniques. This experience produced important geographical, geological, and meteorological observations on Central Asia. Von Humboldt, also hugely interested in fluctuations of Earth's geomagnetic field (magnetic storms), saw that a world net of observatories was needed to identify their origin. In 1836, he convinced the British Royal Society to establish such stations. Data obtained proved that the storms were due to sunspot activity.

Amid these other activities, over twenty-five years von Humboldt wrote four volumes of *Kosmos*, a work which gave a clear account of the structure of the known universe. A great success, it was translated into every European language. At age eighty-nine, while working on the fifth volume, von Humboldt died in Berlin.

—Sanford S. Singer

also lives in the Eastern Highlands. Farmers detest the agouti because it eats sugar and banana plants. A cousin of the jaguar, the ocelot, also makes its home in this area. This slender cat is camouflaged in the forests and deserts of the highlands.

Birds that live in the Eastern Highlands include the James flamingo, which lives on Bolivia's frigid salt lakes, and the giant antshrike, more than a foot (30 centimeters) in length.

Animals of Tierra del Fuego

In the islands that make up Tierra del Fuego, many unusual animals are found, including penguins and many other types of birds. Penguins cannot fly; they use their wings for swimming in the icy waters near their home. Penguins are insulated from the frigid ocean waters by three layers of short feathers and an underlying layer of fat. Other birds common to Tierra del Fuego are Magellanic cormorants, imperial cormorants, albatrosses, and various petrels. Sea lions also live on these islands.

FEATHERS

Types of animal science: Anatomy, evolution
Fields of study: Anatomy, archaeology, ornithology

Feathers are a unique physical characteristic of birds. There are many types of feathers serving a variety of purposes, including flight, insulation, communication, breeding, and camouflage.

Principal Terms

KERATIN: fibrous proteins that are the chemical basis for feathers
MOLT: the process of replacing feathers
PIGMENTS: a variety of colored substances which impart color to feathers
SHAFT: long, central spine of the feather
VANE: flat, broad web emerging from opposing sides of the feather shaft

In 1860, a quarryman from southern Germany discovered a fossil preserved in limestone revealing a single, 2.5-inch-long feather. This feather was asymmetric, with the vane on one side of the quill being twice the width of the vane on the other side, and similar to the flight feathers of modern birds. A year later, a fossil was discovered in a nearby quarry which demonstrated a feathered creature named *Archaeopteryx*, which means "ancient wing." *Archaeopteryx* is generally regarded as the first bird because of its feathers, and it flew 150 million years ago.

Structure and Color of Feathers

Feathers continue to define birds. They are the only animals that have feathers, and all birds have some type of feathers. Feathers result from a modification of the outer layer of the bird's skin, the epidermis, and probably evolved from scales as found on reptiles, such as snakes and lizards. Feathers are composed largely of keratin, an inert substance that is light, strong, and long-lasting. The developing bird inside the egg is covered with bumps called papillae, and the epidermis folds inward around each of the papillae to form follicles. From these structures feathers are grown and regrown. The number of feathers on birds varies greatly, from less than 1,000 on a ruby-throated hummingbird to over 25,000 on a tundra swan.

A typical feather has a central shaft with two vanes arising from opposite sides. On flight feathers, the vane from the leading edge of the feather is narrower and more rigid, thereby maintaining the wing structure and producing the lift necessary for flight. Amazingly, this basic feather structure has remained unchanged since *Archaeopteryx* flew above the dinosaurs of the late Jurassic period. The portion of the feather shaft within the follicle and beneath the skin is called the calamus. The portion of the shaft above the skin is called the rachis, from which extend numerous opposing parallel branches, called barbs, that collectively form the vanes. Hooked structures called barbules join the barbs together, producing a smooth, sheetlike surface.

Color is imparted to feathers by colored substances called pigments and by variations in feather structure, which alter the manner in which light is reflected. There are three types of pigments. The most common pigment is melanin, which produces black, a spectrum of brownish shades, and light yellow. Examples include the black of a crow or yellow of a baby chicken. Birds synthesize melanin from dietary proteins. Carotenoids are produced by plants and are ingested by birds. They produce red, orange, and yellow feathers, such as the red of the northern cardinal. Porphyrins are metabolic breakdown products produced by birds from hemoglobin, the oxygen-carrying component of red blood cells, when red blood cells become old and are broken down by the liver. Porphyrins produce a variety of colors, including red, brown, green, or pink. Porphyrins produce the brown feathers of many owls. Structural properties of the feathers, such as layers, often containing pigments, and microscopic air bubbles, produce iridescent colors, such as the colored throats of hummingbirds, or noniridescent colors, such as the blue of a bluejay. Often the multiple colors of a bird's feathers result from some combination of both pigment and structure.

Functions of Feathers and Molting

While flight is certainly the most outstanding function of feathers, they serve many important functions, enabling birds to exist and thrive in environments all over the globe. Feathers provide insulation by trapping air and thereby helping to control body temperature. The color and form of feathers help birds communicate and signal breeding, as well as keep them camouflaged from predators. Adults sitting on a nest or fledgling birds often depend greatly on their feather coats to make them less visible against the background of the environment. Feathers also help birds remain waterproof while swimming or diving. Some feathers help birds remain clean, and others help the birds to support themselves, as can be seen when the stiff tail feathers of a woodpecker act as a strut against the trunk of a tree. Specially modified feathers serve as sense organs able to detect feather position and movement essential for the complexities of flying.

A fully developed feather is a dead structure and when it becomes worn or broken it must be replaced, as repair is not possible. Molting is the process of replacing all (complete molt) or a portion (partial molt) of the feather coat. This process varies widely among birds in timing as well as completeness and annual number. However, most adult birds undergo a partial molt prior to breeding season. This partial molt frequently yields bright colorful feathers and is called the alternate plumage. A good example is the bright yellow and black of the American goldfinch, seen in the spring. A complete molt occurs after the breeding season and results in the basic plumage. The basic plumage of the American goldfinch is a drab olive. This complete molt provides some migrating birds with new feathers for the long flights to their home territories. Other birds get new feathers to help insulate them from the winter cold.

The beauty of feathers and the wonder of flight have attracted the attention of humans throughout history. Feathers have adorned priests and warriors as well as the hats of fashionable women. In 1905, Guy Bradley, a warden hired to patrol wading-bird rookeries in southern Florida, was shot and killed by plume hunters. He is buried in Everglades National Park and his death resulted, in 1913, in stricter laws to protect birds in the United States and a change in public opinion that abolished the use of feathers in hats sold in America. It is currently illegal to possess wild bird feathers in the United States.

FERTILIZATION

Types of animal science: Development, reproduction
Fields of study: Cell biology, developmental biology, embryology, reproduction science

Fertilization occurs when the genetic information in a haploid sperm combines with the genetic information of the haploid ovum to form the diploid zygote.

Principal Terms

CORONA RADIATA: the layers of follicle cells that still surround the mammalian egg after ovulation
VITELLINE ENVELOPE: the protective layers that form around the egg while it is still in the ovary
ZONA PELLUCIDA: mammalian protective layer analogous to the vitelline envelope

For fertilization to occur, several things must happen: Sperm and eggs must be in close proximity, the gametes need to be compatible, the sperm must be able to penetrate the egg, and the haploid egg nucleus must combine with the haploid sperm nucleus. If any one of these is missing, fertilization will not occur.

Assuring Eggs and Sperm Are in Proximity

Animals have many mechanisms to ensure that sperm and eggs are in close proximity. This can be a major concern for aquatic organisms with external fertilization, and many release gametes in the millions or even billions to assure that at least some sperm reach the appropriate eggs. To increase the chances of a meeting between same-species gametes, animals often have specialized mating behaviors. Corals are among those animals that release their gametes into the water and depend on currents to bring egg and sperm together. This is not, however, as random as it may seem. As the first coral releases its gametes, it also releases hormones that induce nearby corals of the same species to release their gametes. These also release the same chemicals with their gametes, and soon there are clouds of eggs and sperm, and the chances of a proper meeting are increased dramatically. One species of polychaete annelid, *Eunice viridis*, or the palolo worm, has another method of assuring male and female gametes are in the same place. In this species, sexually mature worms called epitokes swarm together at the ocean's surface in response to the lunar cycle. Females then secrete a hormone that induces males to release sperm, and the sperm induce the females to shed eggs. Many fish go through elaborate courtship rituals, during which males and females release gametes at a specific point, thus assuring that egg and sperm are together. Other fish build nests where females lay eggs and males deposit sperm. Frogs and toads usually breed in the water, but the female will only release her eggs when the male is clasped to her back in amplexus. Thus, sperm are deposited on the eggs as they are being laid.

Males of other species place sperm directly in the female's reproductive tract. The male octopus has a special tentacle that is used to place one of his sperm packets in the mantle cavity of the female. Some salamander males deposit their sperm packets on the substrate during a squat dance courtship ritual. Females also do the squat dance and pick up the packet with the lips of their cloacae. In some species of water mites, females mount a special saddle-shaped extension of the males' abdomen. The male squats to deposit a sperm packet, moves ahead slightly and then squats again when the opening of the female's reproductive system is over the packet, forcing the packet into her reproductive system. Another interesting way to assure fertilization is seen in the sea horse. In these animals, a female deposits her eggs into a pouch on the male's abdomen and the male releases sperm into the pouch at the same time. The most common way to introduce sperm into a female's reproductive tract is through copulation, where the male ejaculates sperm directly into the female's reproductive tract. The motile sperm then travel to the egg. For a sperm to gain full motility, it usually must undergo a little-understood process called capacitation.

Penetration

Once eggs and sperm are in close proximity, the sperm must begin to penetrate the egg's protective layers. All eggs have at least one protective layer outside the cell membrane. Called the vitelline envelope in most organisms, it is synthesized in the ovary and composed primarily of polysaccharides and glycoproteins. The oviducts and uterus often secrete other protective layers around the egg. In some instances, the sperm must also penetrate these layers, for example, the jelly layers that surround sea urchin and frog eggs. In other instances, the egg is fertilized before these layers are added, as is the case with the many protective layers that surround bird and reptile eggs. A protective layer made up of cells is seen in most mammals, since the egg is released by the ovary with cells of the cumulus oophorus still attached. For the sperm to penetrate these layers, its acrosome must contain the appropriate enzymes to lyse (disintegrate) the chemicals that block its way. The acrosomal reaction must also take place in order to expose the digestive enzymes of the acrosome. This reaction depends on changes in membrane permeability to ions and subsequent changes in pH.

Once through the protective layers, the sperm makes contact with the egg's plasma membrane. If the sperm and egg are of the same species, sperm receptor molecules on the egg membrane attach to complementary molecules, called bindins, on the sperm membrane and the two membranes fuse. If the bindins on the sperm do not complement the receptors on the egg, there is no fusion and fertilization does not continue, thus preventing most interspecies crosses. However, closely related species often have bindins and receptors sufficiently alike to allow some fertilization to proceed. The products of these interspecific matings are hybrids, such as the mule.

Once the first sperm fuses with the egg, mechanisms to prevent polyspermy, the fertilization of an egg by more than one sperm, are put into place. The first block to polyspermy is common to most animals studied: a very quick and only temporary depolarization of the plasma membrane. In sea urchins, the resting membrane potential of the egg plasma membrane is approximately –70 millivolts, the inside being more negative than the outside. Fusion of the sperm plasma membrane with the egg cell membrane causes a rapid influx of sodium ions. The positive charges neutralize negative charges in the egg until the membrane potential is raised to +10 millivolts. All this happens in less than five seconds, and lasts for about one minute before the egg cell has actively transported enough sodium out of the cell to repolarize it. While the cell is depolarized, no further sperm membranes can fuse with the egg membrane. This is often referred to as the fast or temporary block to polyspermy and seems to occur in all animals thus far studied. The fast block also sets into motion the slow or permanent block to polyspermy. The changed membrane potential of the fast block and the release of nitrous oxide by the sperm allows cells to release calcium ions from storage. The initial calcium ion release causes the egg to release nitrous oxide, which then increases the egg's release of calcium ions. The release of calcium ions induces the cortical reaction by which cortical granules move to the surface of the cell, fuse with the cell membrane, and empty their contents into the space between the cell membrane and the vitelline envelope. In sea urchins, the first acrosomal enzymes released break the bonds between the cell membrane and the vitelline envelope. In the presence of water, other chemicals released by the cortical granules swell, lifting the vitelline envelope away from the cell membrane. Finally, other enzymes released by the cortical granules alter the vitelline envelope, knocking off any attached sperm and causing the release of peroxide ions, which harden the envelope, making it impermeable to sperm. This impermeable barrier is renamed the fertilization membrane. The released peroxide may also provide another benefit. Any sperm that had penetrated the vitelline envelope before it hardened would be killed by the peroxide and would thus not lead to polyspermy. In other animals studied, although cortical granules do empty their contents into the perivitelline space, the permanent block to polyspermy does not seem to involve the same extensive changes to the vitelline envelope (or *zona pellucida* in mammals) that are seen in the sea urchin. In large, yolky eggs, some polyspermy does occur, but the extra sperm remain in the yolk and never reach the egg nucleus for fusion.

Cell Metabolism and Meiosis

Concomitant with the cortical reactions is an increase of metabolism in the egg, which will be necessary for nuclear fusion and cleavage. In species where the egg has not completed meiosis, it does so at this time. Which parts of the sperm enter the egg is dependent on the species. In many mammals, the entire sperm enters, while all but the tail enters in echinoderms. In other organisms, the head with the nucleus and centrioles seem to be the only things that enter. There is no evidence that any parts of the sperm other than the nucleus and centrioles are used by the zygote, and other parts that enter most probably degenerate and their components are recycled.

Studies on the mitochondria of sperm indicate that soon after entering the egg, the sperm's mitochondria are tagged by ubiquitin, the first step in breakdown and recycling. After entry, the sperm nucleus imbibes water and is converted into the male pronucleus. At the same time, the egg nucleus becomes the female pronucleus. In most animals, the male pronucleus and the female pronucleus fuse to form the diploid zygote nucleus. In some nematodes, mollusks, and annelids, however, the pronuclei remain separate until after the first cleavage division. In a few others, like the copepod *Cyclops*, the pronuclei divide separately for several cleavage divisions.

The fusion of the sperm with the egg nucleus affects many other cellular processes. One of the most interesting is the displacement of some cytoplasmic constituents. These constituents of the egg determine the fate of cells derived from the parts of the egg in which they were located and probably determine the plane of bilateral symmetry. Sperm attachment and entry often causes shifts in the position of the viscous cortical and subcortical cytoplasm, where many of the fate-determining chemicals are located.

—Richard W. Cheney, Jr.

In Vitro Fertilization of Endangered Species

Techniques of in vitro fertilization were first developed to aid couples who had not been able to conceive through normal sexual relations. In this technique, eggs were surgically removed from the mother and mixed with the father's sperm in the laboratory. If fertilization took place, one or more embryos were introduced into the mother's uterus in the hope that an embryo would implant and develop into a full-term infant. Almost immediately, these techniques were used in other animals, especially endangered species. It offered many advantages over natural reproduction. In pairs that showed little sexual interest in each other, eggs and sperm could be extracted, mixed in the laboratory, and viable embryos could be introduced into the female's uterus. Also, if there was little genetic diversity in a zoo population, sperm from a donor at another location could be sent and used. By the end of the twentieth century, in vitro fertilization was being coupled with surrogate motherhood. Here, after the embryos are formed, they are introduced into the uteri of females of similar, but not endangered, species. This increases the number of uteri available for the endangered species' reproduction.

FINS AND FLIPPERS

Type of animal science: Anatomy
Fields of study: Anatomy, behavior

Vertebrate animals first evolved in an aquatic environment. The necessity to move in a stable and directed manner resulted in the evolution of fins, which impart both stability and lift while swimming. As fishes have evolved, fins and their related structures have become more complex and may play a direct role in starting, stopping, and turning. When certain fish groups moved from an aquatic to a terrestrial environment, the paired fins of fishes eventually gave rise to forelimbs and hindlimbs. When, much later, certain mammalian groups (including whales and dolphins) returned to the oceans, their forelimbs evolved into finlike structures called flippers, which retained the internal bone structure of the limbs from which they are derived.

Principal Terms

FIN-FOLD THEORY: theory that fins initially evolved as long folds of tissue extending around the body

FLIPPER: finlike structures of marine mammals that have evolved from the forelimbs of their terrestrial ancestors

FOUR-FIN SYSTEM: the combined activity of paired fins in some bony fishes that makes them highly maneuverable

HETEROCERCAL: a tail in which the spine extends into the upper lobe, giving a distinctly sharklike impression

HOMOCERCAL: a type of tail at which the spine ends at the base of the tail, which consists of two equal lobes

LEPIDOTRICHIA: modified scales that form the supporting rays of the fins of bony fishes

PECTORAL AND PELVIC GIRDLES: skeletal structures that form a structural base for attachment of the paired fins in fishes, connecting them to the rest of the body's skeleton

One of the characteristic features of aquatic vertebrate animals is the presence of single and paired appendages used for locomotion. In fishes these structures are known as fins and in marine mammals they are known as flippers or flukes (on the tail). Although these structures bear superficial resemblances to each other, there are significant differences in their anatomies, attesting their different evolutionary histories. However, at a deeper level, they are related structures, having evolved from the same basic structures found in the earliest vertebrates. This is a classic example of evolutionary parallelism: Finlike structures have evolved independently in both fishes and marine mammals from a common ancestral structure.

The Evolution of Fins

The earliest vertebrates were elongated aquatic animals, and locomotion in these animals was probably accomplished by an eel-like undulation of the body. The efficiency of this form of locomotion is decreased by unwanted motion resulting in an up-and-down (pitch) or side-to-side (yaw) seesawing and rolling around the long axis of the body. Fins first evolved as stabilizers to resist these motions and increase swimming efficiency. Since their appearance, however, they have also evolved other functions.

There are two theories as to how fins first evolved. The fin-fold theory suggests that the early vertebrates had two paired folds of tissue extending along the side of the body. These folds fused just behind the anus to form a single fin which extended around the tail and up onto the midline of the upper body (dorsal) surface. The theory states that several regions of these fin folds have persisted, resulting in the paired and unpaired fins in modern fishes, whereas the rest of the early fin folds have been lost. As evidence for this theory, the sand launce, *Brachiostoma* (amphioxus) is used as an example. Amphioxus is an animal that is closely related to the vertebrates, and the earliest protovertebrates are believed to have resembled it. It has extensive folds that closely resemble the theoretical fin-folds of the earliest vertebrates. A different theory, the body-spine theory, states that the earliest vertebrates possessed two or more pairs of spines extending from both sides of the lower portion of the body. Fins were then formed when membranes extended from the tip of the spine to the side of the body, rather like a sail extending from the mast of a boat. Internal support structures within the fin (the endoskeleton) developed at a later date. At the current time there is no evidence to conclusively support one theory or the other.

The Uses of Fins

Fins in fishes are either paired, meaning there are equivalent fins on either side of the body trunk, or unpaired, meaning that there is a single fin located on the midline of the upper or lower body. The paired fins are the pectoral fins, generally located just behind the gills, and the pelvic fins, which are located behind and below the pectoral fins. The unpaired fins comprise one or more dorsal fins, located on the midline of the back, the anal fin, located on the midline of the bottom (ventral) surface of the body, behind the anus, and the caudal fin, or tail.

Dorsal fins, as on this killer whale, help maintain stability and straightforward movement while swimming through the water. (Digital Stock)

Other Uses of Fins

Although the principal roles of fins are in locomotion, there are numerous other ways in which they are employed. Many fishes possess fins with stout or serrated spines that serve in defense; often such spines are associated with venom glands. In the elasmobranch fishes (sharks and rays) and the related ratfishes, the pelvic fins of males are modified into claspers, the male organs of reproduction. In the common aquarium swordtail (platy), the unpaired anal fin performs a similar role.

The dorsal fin of the deep-sea anglerfishes has an elongated fin ray that possesses a fleshy lobe at its tip. A fish pursuing this "lure" soon finds itself engulfed in the sharp-toothed maw of the anglerfish.

The remoras and sharksuckers are well known for attaching themselves to larger fishes such as sharks and tunas. Despite their name, these fishes do not attach themselves to larger fishes by "sucking" with their mouths, but rather via a modified first dorsal fin. This fin has been modified into a series of flattened plates that can be retracted by the remora, creating a suction that leaves the fish attached to its host.

The deep-sea tripodfishes (family Bathyperidae) have pelvic fins with extremely long fin rays, set well forward on the body, and long fin rays on the lower lobe of the caudal fin. When extended, these form a three-point landing gear, upon which the fish rests above the oozy surface of the ocean floor.

Finally, the first three pectoral fin rays of the sea robin are covered with taste buds and can be moved independently. As this fish "walks" across the bottom, it is actually tasting the substrate, searching for food.

In fishes, the tail, or caudal fin, provides a large portion of the forward thrust required for moving through the water and has evolved as a specialized portion of the rearward end of the body trunk and spine. The spine itself is composed of repeating skeletal structures, the vertebrae, which together form a flexible column extending through the long axis of the animal. Sharks, sturgeon, and paddlefish possess a heterocercal tail, in which the vertebral column extends into the upper portion, or lobe, of the tail, giving it a distinctly asymmetric and sharklike appearance. The majority of bony fishes possess a homocercal tail, in which the spine ends at the base of the tail and in which the tail is composed of equal-sized upper and lower lobes. A few extinct species of fishes possessed hypocercal tails, in which the spine extended into the ventral lobe of the tail. These animals therefore possessed caudal fins in which the lower lobe was larger than the upper, the opposite of what is seen today in sharks.

The paired and unpaired fins of sharks are solid, broad-based, and relatively inflexible. Like all fins they possess an internal skeleton, which provides structural support as well as attachment for muscles that allow the fin to be moved. These consist of a series of cartilages, known as basals and radials, located in the base of the fins. Long rods of cartilage called ceratotrichia extend from the radials out to the edges of the fin, providing support. The principal role of these fins is to resist the yawing, pitching, and rolling motions generated during swimming. Because of the asymmetric heterocercal tail, the thrust generated in forward swimming extends downward from the upper lobe of the tail through the shark's center of gravity, pushing the animal downward. An important function of the large pectoral fins in sharks is to generate lift, in much the same manner as an airplane's wing. The lift generated by the pectoral fins counters the downward thrust and moves the animal forward through the water. The pelvic fins are specialized in male sharks and rays to form claspers, which serve as the male organs of reproduction in internal fertilization.

The fins of bony fishes are distinctly different from those seen in sharks, although the endoskeleton of the fins also consists of basal and radial bones. The fins of the majority of bony fishes, particularly the paired fins, are much narrower at their base, more flexible, and may play a more direct role in locomotion in addition to stabilizing the fish during swimming. The radials of the endoskeleton are reduced to very small structures located within the muscles at the base of the fin. These articulate with modified scales called lepidotrichia, or fin rays, which extend out to form the main structural elements of the fin. Membranous connective tissue extends between the fin rays, giving them their typical weblike appearance. The vast majority of bony fishes possess this type of fin structure, and they are known collectively as the ray-finned fishes, or Actinopterygii.

The Fins of Bony Fishes

A key development in the evolution of bony fishes was the appearance of a swim bladder, a gas-filled sac in the abdominal cavity that counters the fish's tendency to sink in the water and thus provides it with neutral buoyancy. With the evolution of this structure, it was no longer necessary for the pectoral fins to generate lift, and they could then be employed as brakes to stop forward motion. The pectoral fins of most bony fishes have a large surface area and a narrow base that is inserted into the body wall almost vertically, as opposed to horizontally in sharks. They are therefore admirably suited to act as brakes both singly and together, and greatly increase the ability of the fish to stop or change direction rapidly. The pelvic fins act to counterbalance any pitching or rolling motion generated by the pectorals. The combined activity of the paired pectoral and pelvic fins, often called the four fin system, provides enhanced maneuverability and control. This system is best observed in many types of coral reef butterfly fishes (Chaetodontidae), in which the pelvic fins are inserted almost directly below the pectoral fins. These fishes are highly maneuverable, able to move, turn, and stop quickly and accurately within the complex and constrained multidimensional environment of the coral reef.

A relatively small group of bony fishes possesses paired fins of a different sort. This group of fish, which includes the lungfishes and the coelacanth, is characterized by pelvic and pectoral fins that possess fleshy lobes at their base. The lobes contain muscles and skeletal elements; however, only a single basal bone articulates with the rest of the skeleton of the fish. These lobe-finned fishes (the Crossopterygii) are important because they represent descendants of the lineage that moved from the aquatic environment onto land. The pectoral and pelvic fins of these fishes gave rise to the forelimbs and hindlimbs of terrestrial vertebrates, and the single bone articulating with the body skeleton is the forebear of the humerus, the bone of the upper arm.

In all fishes, the paired fins are connected to the rest of the body's support framework, the skeleton, via structures known as the pectoral and pelvic girdles. The pectoral girdle in sharks is relatively simple and consists of a large bar of cartilage that extends across between the two pectoral fins, known as the coracoid bar. Scapular processes extend above the base of the pectoral fin and connect the pectoral girdle to the skeleton. The pelvic girdle of sharks has fused into a single bar of cartilage, the puboischiac bar.

The pectoral girdle of bony fishes contains a large number of small bones including the cleithrum, supracleithrum, and the clavicle. A posttemporal bone attaches the pectoral girdle to the rear of the skull. The pelvic girdle in most bony fishes is composed of a pair of bones that act as extensions of the basal bones of the fins.

Flippers

During the Tertiary period (approximately thirty-five to fifty-seven million years ago) several groups of land-dwelling mammals returned partly or completely to the aquatic environment. The best known of these are the cetaceans (whales and dolphins), but other groups include the Sirenidae (manatees) and the pinnipeds (seals and sea lions). These animals faced the same problems of locomotion in water as did their fish ancestors, and in the course of evolution they have evolved finlike structures called flippers and flukes. These perform the same stabilizing functions as in fishes, and bear a superficial resemblance to fins. However, closer examination of whales and dolphins demonstrates that the pectoral flippers of cetaceans are in fact modified mammalian forelimbs and contain the same bones present in the forelimbs (arms) of terrestrial mammals. Thus, the bones of the pectoral fins, which gave rise to the forelimbs of terrestrial vertebrates, have evolved back into finlike structures in these mammals as an adaptation to an aquatic lifestyle. The hindlimbs, along with their bones and supporting pelvic girdle (the hip bones in land mammals) have been lost in modern dolphins and whales, although they are still present in fossil forms such as the extinct fossil whale *Basilosaurus*. These mammals also possess fleshy dorsal fins to help stabilize them during swimming and large horizontal flukes on the tail, which provide the main forward propulsive thrust to these animals as they move through the water.

FISH

Type of animal science: Systematics (taxonomy)
Fields of study: Anatomy, liminology, marine biology, oceanography, zoology

Bony fishes constitute one of the seven living classes of vertebrates. There are approximately twenty thousand recognized living species, nearly as many as all other vertebrates combined.

Principal Terms

CTENOID SCALES: thin, flat, bony scales with tiny spines on the exposed rear edge, found on sunfish, perch, sea bass, and other advanced teleosts

CYCLOID SCALES: thin, flat bony scales with a smooth surface; rounded in shape, found on herrings, minnows, trout, and other primitive teleosts

GANOID SCALES: thick, diamond-shaped, bony scales that are covered with ganoine, a hard inorganic substance; found on bichirs, gars, and other primitive bony fishes

OSTEICHTHYES: the taxonomic class in which the bony fishes are placed; contains species related to the ancestors of higher vertebrates

PECTORAL FINS: paired fins found near the head end of the fish body; related to the forelimbs of higher vertebrates

PELVIC FINS: paired fins found either near the tail end of the fish body or below the pectoral fins; related to the hindlimbs of higher vertebrates

SWIM BLADDER: the hydrostatic (buoyancy) organ of teleost fishes derived from the lung of more primitive bony fishes

TELEOSTS: members of the infraclass Teleostei, the most advanced of the ray-finned fishes; they compose the vast majority of living bony fish species

The Osteichthyes, or bony fishes, constitute the largest and most diverse of the classes of vertebrates. Like the jawless and cartilaginous fishes, they are characterized by gills, fins, and a dependence on water as a medium in which to live. Unlike those fishes, however, they typically possess a skeleton made of bone. Additional features characteristic of most bony fishes include a lateral line system, scales, osmoregulation (salt balance) by means of salt retention or secretion, and a bony operculum (gill cover) over the gill openings.

The fossil record of bony fishes begins nearly 400 million years ago in the early Devonian geological period, mostly in freshwater deposits. Thus there is reason to believe that bony fishes originated in freshwater habitats. Living bony fish species inhabit both freshwater habitats (58 percent of species) and marine habitats (41 percent), and some (1 percent) move between the two environments on a regular basis. This distribution does not reflect the relative proportions of these environments, since 97 percent of the earth's water is in the oceans and only 0.001 percent is in freshwater lakes, rivers, and streams (the rest is ice, groundwater, and atmospheric water). Rather, the high diversity of freshwater species is a reflection of the ease with which freshwater populations become isolated and evolve into new species.

Fish Subclasses

There are four subclasses of bony fishes: Dipneusti (or Dipnoi), Crossopterygii, Brachiopterygii, and Actinopterygii. The first three of these include a total of only eighteen primitive living species.

Subclass Actinopterygii includes all the rest. The Dipneusti, or lungfish, are named for their possession of lungs, an ancestral characteristic suggesting that the earliest steps of bony fish evolution took place in tropical freshwaters subject to stagnation. Modern lungfishes (six species) are able to cope with such conditions by swallowing air and exchanging respiratory gases (oxygen and carbon dioxide) in the lung. Once considered closely related to terrestrial vertebrates, they are now believed to share certain similarities merely because of convergence (independent evolution of characteristics that appear similar).

The Crossopterygii, or fringe-finned fishes, were the dominant freshwater predators of the Devonian period. One fossil subgroup, the rhipidistians, had many features intermediate between fishes and ancestral amphibians, including tooth structure, lobed fins, and a jaw connected directly to the skull. Therefore, they are believed to represent a link between fishes and higher vertebrates. The other subgroup, the coelacanths, was also believed to be extinct (for 70 million years) until a coelacanth was taken from deep water off South Africa in 1938. This species, *Latimeria chalumnae*, is the only known living crossopterygian fish, and is of great interest as a kind of "living fossil."

The Brachiopterygii, or bichirs, include eleven living species known from swamps and rivers in tropical Africa. Though they share some characteristics with the other bony fish subclasses, they have some distinct features that warrant placing them in a separate subclass. One such feature is a dorsal fin consisting of many separate finlets, each supported by a single spine.

The Actinopterygii, or ray-finned fishes, comprise three major infraclasses: the Chondrostei, Holostei, and Teleostei. Chondrosteans, which have reverted to a largely cartilaginous skeleton, include the sturgeons (twenty-three species) and paddlefishes (two species). One species, the beluga sturgeon (*Huso huso*), source of the famous Russian caviar, may be the largest living Osteichthyes species. It is known to achieve a length of 8.5 meters and a weight of nearly 1,300 kilograms.

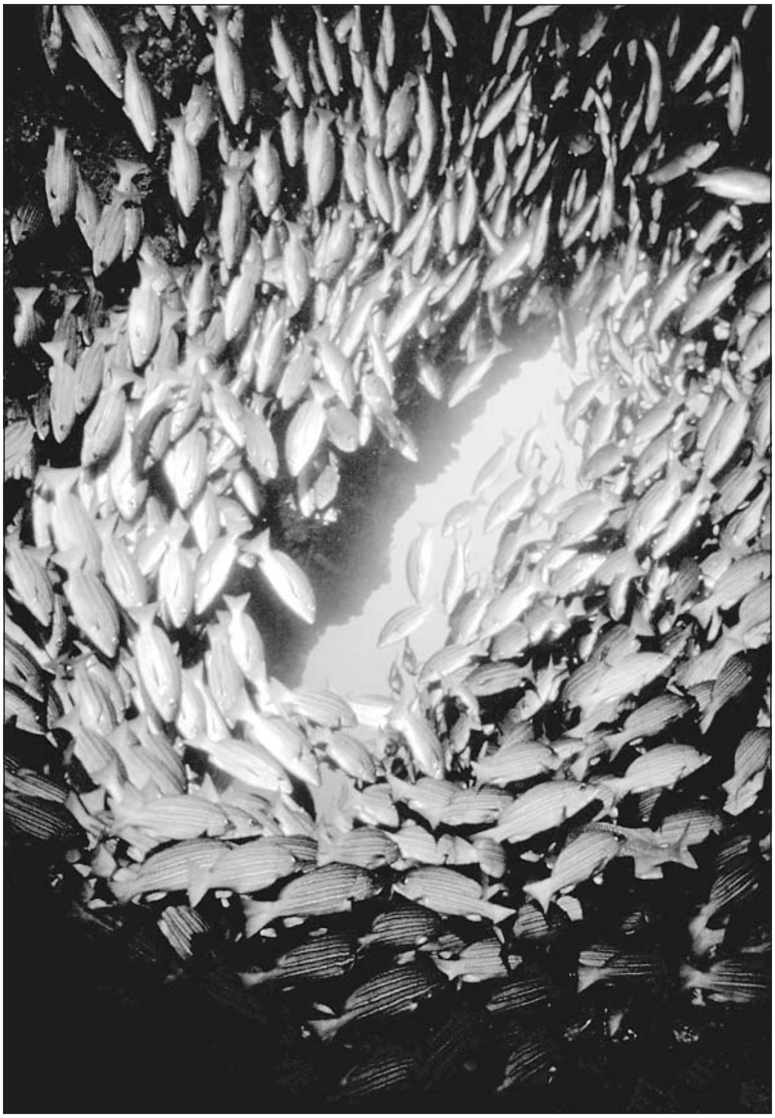
Holosteans include eight species: seven gar and one bowfin species, all known from North America. These freshwater piscivors (fish predators) are characterized by a skeleton made entirely of bone, but they do have certain other features in common with their more primitive ancestors, such as the ability to breathe air (with the swim bladder) and ganoid scales (also found in sturgeons).

The vast majority of ray-finned fishes, hence, of bony fishes—and indeed nearly half of all living vertebrates—belong to the infraclass Teleostei. It includes nineteen to twenty thousand living species. Among the features characteristic of teleosts are cycloid or stenoid scales (though some are scaleless), a swim bladder (lost in many bottom fishes), highly maneuverable fins, and a homocercal tail (meaning that its upper and lower lobes are symmetrical). Teleosts are represented by an amazing range of body sizes and shapes. A large number of species are quite small, enabling them to occupy niches (ways of living) unavailable to other fishes. The smallest known fish, in fact the smallest vertebrate of any kind, is a goby from the Indian Ocean, *Trimmatom nanus*, which matures at 8 to 10 millimeters in length.

Fish Shapes and Habits

There are several common body shape categories among teleosts which relate strongly to the fishes' habits. "Rover-predators" have the fusiform (streamlined) body shape that is perhaps most typically fishlike. Fins are distributed evenly around the body, and the mouth is terminal (at the end of the snout). This category includes minnows, basses, tunas, and others that typically are constantly moving—searching for and pursuing prey. "Lie-in-wait predators" tend to be more elongated, with the unpaired fins far back on the body, favoring a sudden lunge for their prey. The pike, barracuda, and needlefish typify this category.

"Bottom fishes" include a wide variety of shapes. Some are flattened for lying in close contact with the bottom (as are flatfishes such as flounder), some have flattened heads and sensory barbels (filaments with taste buds) near the mouth (as do catfishes), and some have fleshy lips for



Many species of marine fish live in large schools, such as these four-line snappers. (Digital Stock)

sucking food from the bottom sediment (as do suckers). A number of bottom-fish species have structures, usually modified pelvic fins, that enable them to cling to the bottom in areas with strong currents (sculpins and clingfishes have these).

"Surface-oriented fishes" tend to be small, with upward-pointing mouths, heads flattened from top to bottom, and large eyes. The mosquitofish, killifish, and flying fish belong to this category. "Deep-bodied fishes" are laterally flattened and have pectoral fins high on the body, with pelvic fins immediately below. This arrangement favors maneuverability in tight quarters such as coral reefs, thick plant beds, or dense schools of their own species. Examples include angelfishes, surgeonfishes, and freshwater sunfishes. "Eel-like fishes" have highly elongated bodies, tapering or rounded tails, and small, embedded scales (or no scales at all). They are adapted for maneuvering through crevices and holes in reefs and rocks and for burrowing in sediments. Eels, loaches, and gunnels typify this category.

Teleosts occupy habitats ranging from torrential streams high in the Himalayas to the bottom of the deepest oceanic trenches. They are found in the world's highest large lake (Lake Titicaca) and deepest lake (Lake Baikal). Some blind species live in the total darkness of underground caves. One *Tilapia* species lives in hot soda lakes in Africa at 44 degrees Celsius, while the Antarctic icefish *Trematomus* lives at –2 degrees Celsius.

The vast majority of teleost fishes, both marine and freshwater, are tropical. Southeast Asia contains the greatest number of freshwater fish species, but the Amazon and its tributaries contain almost as many (and perhaps many hundreds more, still undiscovered). Marine teleosts are most diverse in the Indo-Pacific region, especially in the area from New Guinea to Queensland, Australia. A single collection made in the Great Barrier Reef off northeastern Australia may contain one hundred or more species. Some marine teleost species have a nearly worldwide distribution, while certain freshwater species have highly restricted ranges. The Devil's Hole pupfish (*Cyprinodon diabolis*), for example, is found only in one small spring in Nevada.

Many teleosts have highly specialized associations, called symbioses, with other organisms. Some live among the stinging tentacles of sea anemones (the clownfish *Amphiprion*), within the gut of sea cucumbers (the pearlfish *Carapus*), within the mantle cavity of giant snails (the conchfish *Astrapogon*), or among the stinging tentacles of the Portuguese man-of-war jellyfish (the man-of-war fish *Nomeus*).

Reproduction

Reproduction among teleosts is incredibly varied. Most species are egg-layers, often producing an enormous number of eggs. The female ocean sunfish *Mola mola* may produce up to 300 million eggs, making it the most fecund vertebrate of all. Some species are livebearers, such as the platyfishes, swordtails, and surfperches. Some species are oral brooders, incubating the eggs in the mouth of the male (as in many cardinal fishes) or of the female (as in many cichlids). In one South American cichlid species, *Symphysodon discus*, the female "nurses" its young with a whitish milklike substance secreted by the skin.

Many teleost species are hermaphroditic. A few of these are synchronous hermaphrodites (functioning as male and female at the same time), such as the hamlet *Hypoplectrus*, but many more are sequential hermaphrodites (first one sex, then the other), such as the sea bass *Serranus*. In some coral reef fishes in the wrasse family, a dominant male mates with a harem of females. If this male is removed, the largest female becomes male and takes over the missing male's behavioral and reproductive function.

In a few species, all individuals are female, as in the Amazon molly *Poecilia formosa*. It has been shown that this species is a "sexual parasite" of two related "host" species. Sperm from host males are required to activate development of Amazon molly eggs, but male and female chromosomes (genetic material) do not join, and the offspring are all genetically uniform females.

Ichthyology

The scientific study of bony fishes dates back to Aristotle, who was the first to note, for example, that the sea bass is hermaphroditic. The "father of ichthyology" in more recent times was Peter Artedi (1705-1735), whose classification system was used by Carolus Linnaeus (1707-1778) in his *Systema Naturae*, which became the basis for all future classification systems.

Bony fish classification depends on the study of taxonomic features, or characters, which vary from one species, or group of species, to another. Useful characters include countable features (meristic characters), such as the number of fin supports (rays) or the number of scales in the lateral line, and measurable features (morphometric characters), such as the relative lengths of body parts. Such studies are typically done on museum specimens that are preserved in alcohol solution after fixation in formaldehyde solution. Dissecting tools, microscopes, and even X-ray machines are used for revealing meristic and morphometric characters. For studying bones, dry skeletons are sometimes prepared, or (especially for small species) specimens are "cleared and stained." This latter technique involves clearing the flesh with potassium hydroxide and staining the bones with Alizarin red stain.

Other techniques use samples of living tissue for finding taxonomic characters. Karyotyping (analysis of the chromosomes) and enzyme electrophoresis (using an electric field to separate similar proteins) are also important sources of taxonomic information.

Specimens for taxonomic studies are collected by means of netting, trapping, catching with hook and line, and spearing. Specialized techniques include electrofishing (use of an electric shocking device) for stream fishes, and ichthyocide (fish poison such as rotenone) for coral reef fishes.

Understanding the evolutionary history and classification of the Osteichthyes also depends on paleontological studies (the study of fossils). Bony fishes are well represented in the fossil record because of the superior fossilizing nature of their bony skeletons. Many fish biologists are concerned with matters other than taxonomy. Because of the economic importance of both marine and freshwater bony fishes, the science of fisheries biology (concerned with the management and exploitation of fish populations) is of great significance. Fish populations are often studied with "age and growth" techniques. Age (determined by scale analysis), length, and weight data can be used to calculate growth and mortality rates, age at maturity, and life span. Other techniques for studying fish populations involve tagging individuals (useful for making estimates of population size) and even using tiny radio transmitters that can be followed by aircraft (useful for studying fish migrations).

Ecologists and ethologists (behavioral biologists) are also active in fish studies, particularly since the invention of scuba diving, which allows direct observation of fishes in their natural habitat. An example of an important discovery made possible by scuba diving is cleaning symbiosis, common in coral reef areas. This symbiosis (an association involving members of two different species) involves a "cleaner" species (often a goby or wrasse), which feeds on the external parasites and diseased tissue of a host ("cleanee") species, which visits the cleaner for this service.

Questions Still to Be Answered

Bony fishes are by far the most numerous of all vertebrates. They are also arguably the most diverse in terms of body form, reproductive habits, symbiotic relationships, and other characteristics. Yet much remains to be learned. Virtually every ichthyological expedition into the Amazon region, for example, returns with specimens of previously unknown species. Some ichthyologists estimate that perhaps five or ten thousand undiscovered teleosts remain in unexplored streams and remote coral reefs.

Many biological mysteries remain about even some of the most familiar species. A good example is the American eel, *Anguilla rostrata*. This predatory species spends most of its life in the rivers, streams, and lakes of eastern North America, where it is often one of the dominant species. After six to twelve years in these habitats, the adult eels swim to the ocean and apparently migrate more than five thousand kilometers to spawn in deep water in the Sargasso Sea (an area in the western Atlantic south of Bermuda).

This general location of eel spawning has been inferred from the appearance there of the tiniest eel larvae (called leptocephali, these were once considered a separate species). The larvae become larger and larger as they drift in the Gulf Stream toward the North American coast. This much has been known since 1922. The adult migration has never actually been followed, however, and no one knows exactly where, at what depth, or how they mate and spawn, nor is it known what then happens to the adults.

Despite many advances in scientific knowledge, much remains to be learned about the interrelationships, ecology, behavior, and fishery potential of the world's bony fish species.

Bibliography

Bond, C. E. *Biology of Fishes*. 2d ed. Philadelphia: W. B. Saunders, 1996. Intended as an introduction to the study of fishes for the general reader and for the college student. Includes a concise summary of bony fish diversity, and ten chapters on general topics in fish ecology, behavior, and physiology. Illustrated with black and white drawings. Each chapter has a reference list.

Cailliet, G. M., M. S. Love, and A. W. Ebeling. *Fishes: A Field and Laboratory Manual on Their Structure, Identification, and Natural History*. Belmont, Calif.: Wadsworth, 1986.

This manual, used in college-level ichthyology courses, is the best source of information on the techniques used in the field and laboratory study of fishes. Concise, well illustrated, and thoroughly referenced. Spells out, in step-by-step detail, the actual methods used by modern ichthyologists.

Chiasson, Robert B. *Laboratory Anatomy of the Perch*. 4th ed. Boston: McGraw-Hill, 1991. The North American yellow perch *Perca fluviatilis* has long served as a "typical bony fish" for college zoology classes. In fact, anatomical structure is highly similar throughout the six or seven thousand perchlike species in the teleost order Perciformes. This short (67-page) dissection guide is an excellent introduction to any of them, and to fish anatomy in general.

McClane, A. J. *McClane's Field Guide to Freshwater Fishes of North America*. New York: Henry Holt, 1978. Probably the best angler's guide to North American freshwater gamefishes available. "Tackle-box-size," nontechnical, and packed with the kind of information sport fishermen would find most interesting and useful. Arranged by family, with accurate full-color illustrations and useful glossary.

_______. *McClane's Field Guide to Saltwater Fishes of North America*. New York: Henry Holt, 1978. Companion edition to McClane's freshwater fish guide, and contains similar features. A handy, popular guide to the saltwater gamefishes of North American coastal waters. Arranged taxonomically, with color illustrations and a glossary. Highly recommended for the saltwater sport fisherman.

Mills, D., and G. Vevers. *The Golden Encyclopedia of Freshwater Tropical Aquarium Fishes*. New York: Golden Press, 1982. An attractive popular introduction to tropical freshwater aquarium fishes in two parts. Part 1 is a practical guide to starting and maintaining an aquarium, illustrated with full color drawings and photographs. Part 2 is a detailed guide to two hundred of the most popular and attractive species, illustrated with stunning photographs.

Moyle, P. B., and J. J. Cech. *Fishes: An Introduction to Ichthyology*. 4th ed. Englewood Cliffs, N.J.: Prentice Hall, 2000. One of the best college-level textbooks of general ichthyology available. Covers all aspects of fish biology and surveys the diversity of bony fishes in eight detailed chapters (16 to 23). Large, exhaustive bibliography.

Paxton, John R., and William N. Eschmeyer. *Encyclopedia of Fishes*. 2d ed. San Diego, Calif.: Academic Press, 1998. Beautifully illustrated encyclopedia, with information on levels of extinction threat. Covers twenty-four thousand fish species, including habitats and adaptations and behavior. Photographs, illustrations, diagrams, and maps.

Pough, F. H., J. B. Heiser, and W. N. McFarland. *Vertebrate Life*. 5th ed. Upper Saddle River, N.J.: Prentice Hall, 1999. This large college text, a superlative introduction to vertebrate biology, is revised to incorporate changes in the philosophy and methodology of vertebrate taxonomy. Chapters 1 to 5 provide an excellent general background to vertebrate evolution, and chapter 8 covers the bony fishes in detail.

FLAMINGOS

Types of animal science: Anatomy, classification
Fields of study: Anatomy, ornithology, zoology

Eight flamingo types exist, all beautiful red, pink, or white water birds. Hunted to near extinction in the United States, they inhabit Europe, Africa, Asia, South America, and the West Indies. A great threat to flamingos everywhere is pollution and destruction of their habitats

Principal Terms

GASTRONOMIC: pertaining to the art of fine dining
MANDIBLES: the beaks of birds
PLUMAGE: the feathers of birds

Eight kinds of flamingos make up the avian family Phoenicopteridae. Flamingos are beautiful water birds with long legs and luxuriant deep red, light red, pink, or white plumage. They inhabit Europe, Africa, Asia, South America and the West Indies. European flamingos migrate to Africa in the winter.

The birds usually live in tropical and temperate regions along oceans and lakes or in marshes. Flamingos are also found in the Andes mountains. It is thought that flamingos are pink to red because they eat varied amounts of blue-green algae and other organisms, which contain the substances that make carrots orange and tomatoes red. Flamingos also eat diatoms, shrimp, and small mollusks.

There are four flamingo (Phoenicoparrus) species: the American and Caribbean, the Andean, the James', and the lesser flamingos. Several Phoenicoparrus species have subspecies. For example, American and Caribbean flamingos (*Phoenicopterus ruber*) have three subspecies: greater (*P. ruber roseus*), Chilean (*P. ruber chilensis*), Galápagos (*P. ruber ruber*) flamingos. Regrettably, few of these birds are seen in the United States, as feather hunters made them almost extinct. A Chilean flamingo is a bit smaller than a greater flamingo. It is pink, with red streaks on its back, and nests in Andean mountain lakes and southern South American lowlands. Two smaller species, are the Andean (*Phoenicoparrus andinus*) and James' flamingo (*Phoenicoparrus jamesi*). The smallest, most abundant species, numbering in the millions, is the lesser flamingo (*Phoeniconaias minor*) of Africa and India. It has a subspecies (*Phoeniconaias minor jamesi*).

Physical Characteristics of Flamingos

All flamingos have very long legs, webbed feet, and long, flexible necks. The long legs and webbed feet allow them to wade into fairly deep waters and stir up the muddy bottoms of lagoons and lakes, causing food to rise up closer to them. Their bills bend sharply about halfway from their ends. The upper mandible (beak half) is narrow and, when closed, fits tightly into the lower mandible. To feed, flamingos dip their heads into water upside down and scoop backward, taking in food-containing water. Then they press their mandibles together and push their tongues upward. As mandible edges have small ridges, the tongue pressure pushes water out and the strainerlike action retains the small animals and vegetation they feed on.

Different species and subspecies are colored differently and have different sizes. Overall, adult flamingos attain heights and weights of 2.5 to 5.5 feet and weigh four to seven pounds, depending on species. Females are usually shorter and weigh less than males. Flamingo plumage is white, various pinks, or crimson red. Their legs, webbed feet, bills, and faces are red, pink, orange, or yellow.

The Flamingo Life Cycle

Most flamingos live in colonies which number tens to hundreds of thousands. The colonies are usually located in or around lagoons and lakes. A well-known, very populous example is Kenya's Lake Nakuru, where millions of flamingos congregate. During breeding season, a male and female mate. It is believed that once mated, pairs of flamingos are monogamous.

The female lays one 3.5-ounce white egg in a depression atop a nest which is a conical mound of mud, one foot tall, built by the breeding pair. The pair then incubate the egg for about a month, until it hatches. On hatching, the baby flamingo stays in the nest for about three months. At first, it has gray, downy feathers and its legs and bill are pink. Its feathers turn pink and its bill curves into the adult shape as it grows. Both parents feed the young bird. It is given regurgitated food for as long as it remains in the nest, though it can feed itself thirty days after hatching. In the wild, flamingos may live for forty to fifty years.

Flamingo Conservation

Flamingos live in isolated habitats and have few natural predators except for humans. In the distant past, the ancient Romans hunted flamingos for their tasty tongues, thought to be a gastronomic delicacy. Regrettably, the American greater flamingo (*P. ruber roseus*), once common in the South, is now seen only rarely in the United States. They were hunted for their beautiful plumage faster than they could reproduce. This is unfortunate, because few sights are more beautiful than a flock of pink, rose, or scarlet flamingos standing

Flamingos are wading birds, living at the edges of lakes or oceans, or in marshes. (PhotoDisc)

Flamingo Facts

Classification:
Kingdom: Animalia
Phylum: Chordata
Subphylum: Vertebrata
Class: Aves
Order: Ciconiiformes
Family: Phoenicopteridae (flamingos, three genera, seven species)
Geographical location: Europe, Africa, Asia, South America, the West Indies
Habitat: Lagoons, lakes, and marshes
Gestational period: One month of incubation
Life span: Forty to fifty years in the wild
Special anatomy: Long, storklike legs; bills that strain shellfish and other food out of water

together or flying in the sun of the United States tropics. They are still plentiful in the West Indies and South America.

It might be thought advantageous to restock the wild with zoo-bred flamingos. However, this has not been possible because flamingos captured for zoos often die in transit, and those in zoos rarely breed successfully. It is hoped that with time and with the cessation of feather hunting, flamingos will reestablish themselves in the United States. A great threat to this prospect, and to flamingos elsewhere, is pollution and destruction of their habitats

FLATWORMS

Type of animal science: Classification
Fields of study: Anatomy, invertebrate biology, physiology

Flatworms are wormlike animals with a single major opening to the gut. Many are parasitic for at least part of their life cycle.

Principal Terms

DEFINITIVE HOST: the host in which a symbiont (the organism living within the host) matures and reproduces

ECTOPARASITE: a parasitic organism that attaches to the host on the exterior of the body

ENDOPARASITE: a parasitic organism that attaches to an interior portion of the host's body

FREE-LIVING: an organism that does not have to spend a portion of its life cycle attached to another organism

HERMAPHRODITIC: a situation in which both functional ovaries and testes are present in the same organism

PROGLOTTID: a body segment of a tapeworm that contains a set of reproductive organs, usually both ovaries and testes

SNAILING: the process in which the free-swimming larva (miracidium) of the flukes utilizes the tissue of a snail as an intermediate host

The flatworms or Platyhelminthes are wormlike animals with a single major opening to the gut. This opening functions as both a mouth and an anus. Between the gastrodermis (lining of the gut) and the epidermis, the body is filled with tissues, including layers of muscle, connective tissue, and reproductive organs. Included in the flatworms are free-living forms (class Turbellaria), and two major groups of animal parasites (class Trematoda—flukes—and class Cestoda—tapeworms). Most tubellarians are bottom dwellers in marine water or freshwater or live in moist terrestrial environments, but a few species are symbiotic or parasitic. The majority of the larger species are found on the underside of rocks or other hard objects in freshwater streams or in the littoral zones of the ocean. All of the cestodes and trematodes exist as endoparasites and most exhibit indirect life cycles with more than one host. The initial host is usually an invertebrate, and the final host is most often a vertebrate. A number of species utilize humans as a final host.

General Characteristics of Flatworms

The free-living flatworms generally range in size from five to fifty millimeters. The epidermis is covered with cilia, and locomotion is achieved through a combination of ciliary movements and the contraction and relaxation of layer of circular muscles that go around the body, and a layer of longitudinal muscles that extent down the length of the body. The most commonly studied turbellarians are the planarians. The digestive system consists of a mouth on the ventral surface, a pharynx, and an intestine. Planarians are mostly carnivorous, feeding mainly on nematodes, rotifers, and insects. In contrast to the parasitic species, the turbellarians have simple life cycle. Some can reproduce by asexual fission, but most reproduce sexually. While the turbellarians are hermaphroditic, they generally crossbreed. Planarians demonstrate a remarkable ability to regenerate. If a section is excised from the middle of the worm, it will regenerate both a new tail and a new head.

Flukes primarily differ from the turbellarians in their adaptions for parasitism, including organs

Flatworm Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Platyhelminthes
Classes: Turbellaria (free-living), Monogenea (ectoparasitic flukes with a one-host life cycle), Trematoda (endoparasitic flukes), Cestoda (tapeworms)
Subclasses: Cestoda—Cestodaria (body not segmented), Eucestoda (body segmented into proglottids)
Orders: Turbellaria—Acoela (no gut cavity), Rhabdocoela (simple tubular gut), Alloeocoela (gut with one main branch and small side branches), Tricladia (gut with three branches), Polycladia (gut with many main branches); Trematoda—Aspidogastrea (endoparasitic with a one-host life cycle), Digenea (endoparasitic with at least a two-host life cycle); Eucestoda—Bothriocephaloidea (fish tapeworms), Taenioidea (pig and beef tapeworms)
Geographical location: All over the world
Habitat: Turbellaria—generally found in ponds, lakes, streams, and oceans; Monogenea, Trematoda, and Cestoda—larvae may be found in streams, but adults live within the body of a host
Gestational period: Varies among species, but most species lay eggs within a few days after fertilization; eggs usually hatch within a few days to a few weeks after being deposited
Life span: Varies among species; can be as short as a year in some turbellarians and up to thirty years in some flukes
Special anatomy: Elongated, bilateral invertebrates without appendages, have neither a true body cavity nor a circulatory system; parasitic species have specially adapted mouth parts for attaching to the tissues of the host

for adhesion such as suckers or hooks and an increased reproductive capacity. They are generally leaf-shaped, varying in size from ten to twenty millimeters. Most flukes, such as those in the class Digenea, have complex life cycles. The eggs produced by the mature fluke pass from the definitive host and hatch in water to form free-swimming larvae called miracidia. The miracidium enters the tissue of an intermediate host, snails, and transforms into a sporocyst, which reproduces asexually to form rediae. The rediae reproduce asexually to form cercariae, which leave the snail and penetrate a second intermediate host, such as fish, or encyst on vegetation, where they become metacercariae, juvenile flukes. When the metacercariae are eaten by the definitive host, they develop into mature flukes.

Tapeworms are also keenly adapted for parasitism, but unlike the flukes, they have long, slender bodies that can reach lengths of several meters and lack a digestive system. They obtain digested nutrients directly from the gut of the host. The tapeworm body consists of a linear series of proglottids. The tapeworm grows lengthwise by adding new proglottids. Mature proglottids contain fertilized eggs and break off the end of the tapeworm to be excreted out of the host. Almost all cestodes require at least two hosts, and the adult is a parasite in the digestive tract of vertebrates. One of the intermediate hosts is usually an invertebrate. Almost all species of vertebrates are subject to tapeworm infection.

FLIES

Types of animal science: Anatomy, classification, reproduction
Fields of study: Anatomy, entomology

Flies are members of the order Diptera, two-winged insects, of which there are 95,000 species. Flies are related to the other dipterans, the mosquitoes.

Principal Terms

IRIDESCENT: showing the colors of the rainbow depending on light reflection
MOLT: shed an insect shell
SYMBIOSIS: beneficial relationship between two organisms

Flies belong to the fourth largest animal order, Diptera, which comprises 95,000 species of two-winged insects. The Diptera evolved from four-winged insects, and their vestigial rear wings are stalks that act as gyroscope balance organs, enabling the forewings to move the fly forward without causing nose dives, and keeps it on a steady course.

Dipterans occur worldwide, including Antarctica, but are most plentiful in moist, warm climates. The main dipteran suborders are Nematocera, Brachycera, and Cyclorrapha. Nematocera are mosquitoes, slender, with long antennae. The other orders have stout bodies and short antennae; among them are houseflies and tsetse flies.

Physical Characteristics of Flies

A fly body has three parts: a head, thorax or middle part that holds six legs, and an abdomen or rear end. Two compound eyes containing up to four thousand facets cover most of the head. The eyes see light changes and sudden movement from many different directions at once. This is why flies are hard to catch

Atop a fly's head, paired antennae provide the senses of touch and smell. Dipterans have a mouth part called a proboscis. It is funnel-shaped, with its wide part at the bottom. The proboscis is like a straw, sucking up fluid via a pump in the head. The proboscis of a housefly is soft, so it cannot bite. Bee flies have a long proboscis that enters flowers for nectar. Biting flies, such as horseflies, have hard, sharp proboscises that pierce the skin of their victim.

Each foot on a fly is tipped by claws that grip rough surfaces. Under the claws are pads called pulvilli. On smooth surfaces, they flatten and grip tightly, allowing a fly to walk upside down on ceilings without falling. Flies breathe through openings called spiracles, located on each side of thorax and abdomen.

Fly Life

The life of a fly begins when a female lays hundreds to thousands of eggs in manure, garbage, vegetable waste, fruit, plant stems, or stagnant water. Houseflies have telescoping ovipositors that place eggs in soft matter. Other species have stiff ovipositors that penetrate plant stems or fruit. Flies, like mosquitoes, also lay eggs on water.

The heat given off in these environments incubates the eggs. In one or two days they hatch as white, legless larvae (maggots), which eat the material surrounding them. Maggots rapidly grow too large for their skins, which split and allow molting. After molting twice, the larvae find sheltered places to form upariums, where they molt a final time and become pupae, and then become winged flies. The process usually takes four to ten days. Adult flies emerge from the pupae full-sized. Most live for thirty days. In winter most die,

Image Not Available

but larvae and pupae live to become adults in the spring. The development of a fly from egg, to larva, to pupa, to adult is called metamorphosis.

Tsetse Flies, Horseflies, and Blowflies

Tsetse flies are twenty species of genus *Glossina*. Five of these species carry sleeping sickness. They live in grasslands, forests, and river and lake shores in Africa, between the Sahara and Kalahari deserts. Tsetse flies suck blood with their sharp proboscises; the blood is digested with the assistance of a membrane that is secreted around the blood meal in the foregut. Tsetse flies mate year round. Females have one offspring per mating. After fertilization, an egg hatches in the mother and is later born as a full-sized maggot, which burrows into the soil, pupates, and becomes adult in a month. The flies carry trypanosomes that can infect people with sleeping sickness. When the tsetse fly bites a victim, the trypanosomes enter, multiply, make them very tired, and quickly kill them.

The 3,500 Brachycera species of horseflies occur worldwide, most in tropical and temperate fields and forest areas near water. They have inch-long, stout bodies, large heads, short antennae, and iridescent compound eyes. Their mouths pierce the surfaces of plants and animals to suck fluids. Males eat nectar and plant juices, while females suck blood. The time of mating varies according to species and climate. Females must eat blood before laying eggs or the eggs do not develop. A female lays one thousand eggs in damp sites such as rotten wood. Larvae hatch in two to three weeks, although some hibernate all winter. Before becoming adults, larvae pupate for about three weeks. Adults live for six weeks before mating and dying. Horsefly bites are painful and may cause anthrax or tularemia.

Fly Facts

Classification:
Kingdom: Animalia
Subkingdom: Bilateria
Phylum: Arthopoda
Subphylum: Uniramia
Class: Insecta
Order: Diptera
Suborder: Brachycera, thirty-five families
Geographical location: Every continent
Habitat: Grasslands, forests, near rivers and lakes
Gestational period: Eggs hatch in two to seven days; adulthood occurs in one to six weeks
Life span: One to six months
Special anatomy: Six legs; compound eyes; one pair of wings, antennae, proboscises; pulvilli

Blowflies are metallic blue-green and are larger than houseflies. Females lay eggs on meat or in the open wounds of animals. Eggs or larvae that are in food swallowed by animals and humans cause pain and sickness when the maggots eat into the wound or tissue where they were laid. When the larvae enter an animal's skin, puss-filled sores form. The screwworm, a blowfly larva, harms livestock. If screwworms are not controlled, animals die.

Flies and Disease

A housefly can carry pathogenic bacteria disease because it lives in manure and garbage. Thousands of related species transmit germs to whatever surface they land on, spreading disease. Often it is best to kill flies and stop their reproduction. Flies destroy crops; parasitize animals; and carry typhoid and cholera.

However, flies are also useful. Some flies, such as hoverflies, pollinate plants. Larvae also eat aphids, which kill crops. Flies speed the decomposition of animal carcasses and manure. In addition, flies consume other harmful insects, controlling their numbers. Finally, flies are the food source for numerous insectivores higher up the food chain.

FLIGHT

Types of animal science: Anatomy, evolution
Fields of study: Anatomy, biophysics, evolutionary science, invertebrate biology, ornithology, paleontology, zoology

Flight has evolved in a number of groups of organisms. Seed pods, insects, pterosaurs, birds, and bats are all familiar examples of organisms that have evolved some flight capability. Depending on the definition of flight, certain organisms inhabiting the oceans and freshwater realms, such as fish, ocean turtles, penguins, sea snakes, and even crocodiles can fly underwater.

Principal Terms

DRAG: a force that acts in the opposite direction of the movement of a body through a fluid medium; sources of drag vary but include friction and pressure suction

FLUID: a substance, either liquid or gas, that flows or conforms to the outline of its container

INERTIA: the property of an object with kinetic energy to move in a straight line unless acted upon by an outside force

LIFT: an aerodynamic force created through differential flow above and below a structure

REYNOLDS NUMBERS: the results of a formula that takes into account the velocity of an object, its characteristic length divided by the dynamic viscosity of the fluid

TURBULENCE: flow that is chaotic and may create stall conditions through the loss of lift

VISCOSITY: the stickiness of a fluid created by internal forces as molecular attractions

There are two types of movement through a fluid environment: rowing and flying. Organisms that row use the viscosity (stickiness) of the fluid to propel themselves along. These organisms generally have limbs used as oars with which to row; these oars push up against the fluid (usually water) and the fluid exerts a force back onto the oars that drives the animal forward. Organisms that fly use the inertial qualities of the fluid (usually air); essentially, they will use differential flow rates over the body surfaces to create thrust and lift. Flying is necessary when animals are large, and the drag on the body becomes too high for rowing to be effective. The choice between rowing and flying has to do with the organism's Reynolds number, which is a ratio between length and inertial viscosity forces. Viscosity dominates at low Reynolds numbers, whereas inertial forces dominate at high Reynolds numbers. Drag can be defined as any force that tends to retard the forward movement of an object in a fluid environment. Drag can be due to friction on the body surface; pressure drag is due to the fluid not adhering to the shape of the object and peeling away as a wake. The size of an organism capable of achieving airborne flight by means of rowing is quite small (hypothesized for insects such as mymarid wasps, which are smaller than fruit flies). In aquatic environments, larger forms can row due to the greater viscosity of water.

How Flight Works

Regardless of the organism, flow must take on different velocities above and below the body or wing, according to Bernoulli's principle, whereby flow is understood in terms of conservation of energy. What this means is that in an ideal fluid where there is no friction (that is, no viscosity), if the fluid accelerates, its pressure goes down. Conversely, when the velocity is reduced, the pressure goes up. While this may be counterintuitive, it nonetheless provides a basis for understanding flight. Thus, wings are not necessary to fly, but rather an organism needs to create a surface that is longer on top than it is on the bottom. A concave body form might possibly provide lift by its shape alone in an air streamline. Wings can assume such a shape by twisting themselves, as in insect wings, or creating a curvature with feathers, as in birds. In this situation, air flows faster above than below the structure, and lift is produced perpendicular to the upper surface.

This only works because fluids follow the law of continuity: if a streamline of air is split by an airfoil, the streamline will flow both over and under the structure. Both the upper and lower streamline must theoretically meet at the end of the structure. Thus, a curved structure or a structure that is inclined at an angle to the oncoming flow will create a longer upper surface than lower surface, hence the differential velocity as the streamlines race to the rear edge of the structure. If the aerodynamic structure is inclined downward, the lifting force can now be separated into a force that drives the structure forward and upward.

This picture of flow is very basic, and it is more complicated in practice. The flow over wings circulates around the wing in circles. Bernoulli's principle may still be applied to the circulating flow to understand how lift is generated. This circulation is shed off the wings at the tips in particular patterns based on the movements of the

The feathers on bird wings create sufficient curvature to produce lift and allow the bird to fly. (Corbis)

From Dinosaurs to Birds

Paleontologists have suggested that ground-dwelling bipedal dinosaurs gave rise to birds, and thus avian flight developed from the ground up. This viewpoint is flawed, since the dinosaurian proavis would have had to overcome gravity by running, which would not be energy-efficient. Moreover, bipedal dinosaurs, by virtue of their well-developed hindlimbs, had their center of mass in the pelvis, a situation which would create an unbalanced torque that would flip the animal attempting to fly. Any lift generation in the chest would act vertically at the forelimb area. The pelvic center of mass would act as a downward force in the rear of the animal, resulting in a rotation of the body. Flying birds have their center of mass and center of lift in roughly the same place, and thus rotations of this kind do not occur. It is likely that birds originated from arboreal reptilian ancestors that were quadrupeds. Jumping or falling from a tree would create a cost-free air flow about the body surface to create lift and thus extend a glide between trees. Quadrupeds have a center of mass close to the pectoral area, unlike bipeds, and thus have less problems with unbalanced rotational forces, such as torques. In fact, those land vertebrates that glide today are all quadrupeds.

wing or (in the case of most fishes) the tail. This circulation of fluid around the wing must be generated for lift and thrust to be generated. These circulating rings of fluid are shed off the wings or oscillating tail as vortex rings. This why aircraft are spaced apart during landings, as these vortex rings may cause such turbulence that the aircraft flying behind may experience loss of lift.

Laminar flow is a flow whose constituent pattern is in one direction, an even flow. Turbulent flow occurs when areas within a flow become chaotic, causing heat production and a loss of velocity. Worse than this is a condition when the turbulence becomes so great that the flow no longer adheres to the aerodynamic surface and departs from the structure, causing a loss of lift. This can happen for a variety of reasons. If the angle of attack of a wing becomes too steep, the flow may become turbulent and separate off the structure. If there is no circulation on the wing, there is no lift, a stall develops, and gravity takes over, with dire consequences. In addition, if the velocity is too great, the flow will become turbulent and unable to stay on the surface.

Shape also may contribute to the production of turbulence. Surface roughness may cause turbulence to occur through collisions with the streamlines. In addition, convexities and concavities can cause turbulence to form and prevent the adherence of the fluid on the surface of the object. While this has practical applications in design, it points to the fact that aerodynamic structures are streamlined, having tapered ends that preclude the necessity of fluids having to adhere to abrupt curvatures and creating potentially turbulent flows.

What has been described here is large-scale turbulence, where separation of flow from the object's surface occurs. Small-scale turbulence can actually benefit the lift on the aerodynamic structure, since the longer the flow adheres to the airfoil, the more lift and thrust the structure can generate. Small-scale turbulence may actually maintain the flow on a surface, and thus the lift produced far outweighs the drag force produced by the turbulence.

Flight in Animals

The evolution of flight in birds is centered mainly on the evolution of feathers. Feathers are complex epidermal structures that may have been derived via a developmental program alteration of scales. Feathers are the most complex epidermal structure found in vertebrates. They have a central strut, called a rachis, and a series of barbs emanating from both sides of the rachis in pinnate fashion to form the feather vane. These barbs are hooked together by a series of hooklets that act very much like Velcro. Feathers form the major aerodynamic surface in a bird. They are lightweight, but very strong. Contour feathers maintain a uniform surface for the bird so that there are no abrupt curvatures that may create turbulence. The long flight feathers, known as primaries, secondaries, and tertiaries, form the wing. Long, narrow wings, termed high aspect-ratio wings, consume less power when flapped than broad or low aspect-ratio wings. The bird wing is cambered and so creates lift in an airflow. Shore birds, such as gulls, are seen lifting out of the water just by holding out their wings in a breeze without the need of flapping. Flapping the wings faster than the velocity of the air increases the lift and thrust imparted to the air. Birds are able to fly because they can generate more lift than their body weight, and it has taken them considerable evolutionary time to perfect the weight reduction necessary for flapping flight. Penguins use their wings to fly underwater. They are extremely maneuverable and use their agility and speed to catch fish. The wing beat does not proceed through the same distance as aerial flying birds because of the greater viscosity of water.

Bats are also evolved from a quadrupedal ancestor. In their case, a skin membrane is stretched between the elongated fingers. In this way the camber and aspect ratio of the wing can change quickly. Many bats retain a membrane between the legs, the uropatgium, that increases the lifting surface of the body. Bats are agile and rapid flyers and, equipped with ultrasonic pulses, can locate a variety of prey from insects to frogs. Mammals have evolved gliding forms in much the same way across other taxa. A wing membrane is stretched between the fore and hindlimbs in marsupials such as sugar gliders, and among placental mammals such as flying squirrels (rodents) and the so-called flying lemur (*Cynocephalus*).

Pterosaurs also used a skin membrane stretched between the elongated fourth digit and the hindlimb. This design worked well for over a hundred million years, but a tear in the membrane would destroy the lift-generating ability of the wing. While most pterosaurs were small, some giant forms evolved with wing spans of over forty feet. Lizards have never evolved powered flight, but have generated gliders and parachutists. In the Triassic and Cretaceous periods as well as in the present day, lizards evolved a flight membrane supported by the ribs. The ribs can be folded against the body when the lizard is climbing among the branches in search of insect prey. Other lizards, such as geckos, have evolved body fringes of skin and the ability to flatten themselves to create an aerodynamic surface. Some species of snakes launch themselves into the air, and some frogs use their expanded webbed hands and feet for gliding.

Although fishes essentially fly with the tail, and many flap the pectoral fins like bird wings, some fish have taken to the air. Flying fish will gain speed underwater using their tail and then leap out of the water spreading their large pectoral fins. These fishes can glide for some distance before reentering the water. The flight strategy is associated with escape behavior from predaceous fish.

There is controversy surrounding the origin of insect flight. Some postulate that insect wings developed for temperature control, as wing beating would heat the organism. Moreover, wings could be used to collect or dissipate heat depending upon exposure to the sun or wind. Others contend that insect wings evolved from lateral extensions of the exoskeletal tergites to aid in the stabilization of jumps. However it began, insects are the only invertebrate to evolve aerial powered flight. Normally insects have two pairs of wings, the first pair essentially acting as covers for the posterior wings involved in lift and thrust generation. Some insects have two functional pairs of wings, such as dragonflies. The wings are operated by muscles that have short contraction lengths to obtain rapid wing movements. As is the case in birds, small insects have the highest wing beat frequencies, reaching over one thousand beats per second. Muscles attach either directly to the wing bases, or indirectly to a specialized part of the dorsal carapace termed the notum. The deflection of the notum moves joints that connect to the wings, allowing them to beat in a twisted fashion and create the aerodynamically shaped surfaces.

FOOD CHAINS AND FOOD WEBS

Types of animal science: Behavior, ecology, geography, physiology, scientific methods
Fields of study: Ecology, environmental science, marine biology, physiology, population biology, wildlife ecology

In the biosphere—the portion of earth that sustains life—organisms including plants, animals, and microbes interact and interconnect with one another through organized and complex networks. Understanding this network, also referred to as a food chain or food web, is vital to the study of many subjects in biology.

Principal Terms

BIOLOGICAL MAGNIFICATION: the increasing accumulation of a toxic substance in progressively higher feeding levels

CONSUMER: an organism that eats other organisms

DECOMPOSERS: microbes such as fungi and bacteria that digest food outside their bodies by secreting digestive enzymes into the environment

DETRITUS FEEDERS: an array of small and often unnoticed animals and protists that live off the refuse of other living beings

ENERGY PYRAMID: a graphical representation of the energy contained in succeeding trophic levels, with maximum energy at the base (producers) and steadily diminishing amounts at higher levels

NUTRIENT CYCLE: a description of the pathways of a specific nutrient (such as carbon, nitrogen, or water) through the living and nonliving portions of an ecosystem

PRODUCERS: organisms that produce food for themselves as well as for nearly all other forms of life, including plants, plantlike protists, and cyanobacteria

TROPHIC LEVEL: the categories of organisms in a community, and the position of an organism in a food chain, defined by the organism's source of energy

All activities of life are powered, whether directly or indirectly, by a single source of energy: sunlight. The energy enters the biosphere through primary producers, which trap and convert solar energy into chemical energy, first in form of sugars and ultimately in other complex organic molecules. Energy in its chemical form is then passed along from one type of organism to another through a complex feeding relationship. Two fundamental laws underlie this function: Energy moves through ecosystems in a one-way street, while nutrients cycle and recycle. Each time the energy is used, some of it is lost as heat. Energy needs constant replenishment from an outside source, the sun. In contrast to energy, nutrients constantly cycle and recycle in a circular flow. Nutrients enter the system from soil or water or atmosphere through primary producers (plants), and pass along to herbivores, then to carnivores. The wastes and dead bodies or body parts degraded by detritus feeders return nutrients to the ecosystem.

Feeding Relationships Within a Community

Feeding relationships in a community are often defined or described through food chains and food webs. A linear feeding relationship spanning all trophic levels is called a food chain, whereas many interconnecting food chains in a community make up the food web. Obviously, different ecosystems have drastically different food chains. To illustrate who feeds on whom in a community, it is better first to examine some basic laws and structures that govern a community in general. Energy and nutrients are two common elements that sustain all communities and ecosystems. Energy enters communities through the process of photosynthesis, by which plants and other photosynthetic organisms trap a small portion of sunlight and convert it into sugars. Photosynthetic organisms, from the mighty sequoia to the zucchini and tomato plants in a garden to single-celled diatoms in the ocean, are called autotrophs or producers, because they produce food for themselves. They also produce food for nearly all other organisms, called heterotrophs or consumers.

The amount of life a community can support is determined by how much energy the producers within it can capture. Within the community, energy flows from producers, occupying the first trophic level, through several levels of consumers. The consumers that feed directly and exclusively on producers are herbivores, ranging from caterpillars to buffaloes to wheat aphids. These herbivores, also called primary consumers, form the second trophic level. Carnivores, such as the spider, eagle, fox, and birds that eat caterpillars, are meat eaters, feeding primarily on primary consumers. Carnivores are secondary consumers that form the third or higher trophic level. Some consumers, such as the black bear that eats both blueberries and salmon, occupy more than one trophic level.

A food web, however, represents many interconnecting food chains in a community, describing the actual, complex feeding relationships within a given community. A food web also reflects the feeding nature of organisms that occupy more than one trophic level. Animals such as raccoons, bears, rats, and a variety of birds are omnivores, eating at different consumer levels at different times. In addition to producers and consumers, a functional ecosystem also consists of detritus feeders and decomposers that release nutrients for reuse. The extremely diverse network of detritus feeders is made up of earthworms, mites, protists, centepedes, nematodes, worms, some crustaceans and insects, and even a few verte-

Dodos and Bats: Cases of Disrupted Ecosystems

Within complex ecosystems, animals and plants interact with each other in very intricate and dynamic ways. Plants provide animal species with nutritious fruits. In return, animals help to disperse their seeds. These mutually beneficial relationships sustain both plant and animal populations, and ultimately the ecosystem itself.

A pair of organisms, the dodo bird and the tambalacoque tree, coexisted on the island of Mauritius in the Indian Ocean for a long time. When humans arrived at the island, the slow dodos were easy prey. By 1681, humans had hunted the dodo to extinction. The damage, however, reached far beyond just dodos. It turned out that dodos helped disperse the seeds and promote the germination of the tambalacoque trees of Mauritius. Dodos ate the tambalacoque fruit before it had a chance to rot, thoroughly cleaning the seeds and thereby protecting them from infections by destructive fungi. Dodos also dispersed the seeds all over the island, ensuring that some of them reached fertile soil for germination. With the dodos gone, the fruit rapidly rots, the seeds are destroyed by fungi, and the tambalacoque trees are seriously threatened.

In tropical forests, bats serve as the most important agents for seed dispersal. Bats may eat up to twice their weight in fruit in a day. They also fly more than twenty miles per night, defecating the seeds in flight. After passing through bats' digestive tract, seeds have more than a 95 percent germination rate, as compared to 10 percent in seeds planted directly from fruit. As bat populations (and those of other fruit-eating animals) decline dramatically, seed dispersal has stopped or been significantly reduced. Tropical fruits are rotting on the forest floor or sending up doomed sprouts under the shade of their parents and other canopies. Some types of tropical forests may not survive.

brates such as vultures. Except for vultures, these organisms thrive in the garden, and compost by extracting energy stored within dead organic matter, in turn releasing it in a further decomposed state. The excretory products released serve as food for other detritus feeders and decomposers, which are primarily fungi or bacteria. Fungi and bacteria digest food outside their bodies by releasing digestive enzymes into the environment. They then absorb the nutrients they need, and leave the remaining nutrients for recycling. Without detritus feeders and decomposers, nutrients would soon be locked into organic matters, and the ecosystem will cease to be functional.

Energy Transfer and the Nutrient Cycle

One important principle that governs the flow of energy through the ecosystem is that the energy transfer from one trophic level to the next is never efficient. The net transfer of energy between two trophic levels is roughly 10 percent. During the transfer, 90 percent of the energy is lost as heat or in other forms. Of one thousand calories stored in the producer (plants), the caterpillars that consume all plant tissues will obtain one hundred calories, a bird that eats caterpillars will extract ten calories, and when a hawk catches the bird, that portion of the energy is reduced to a mere one calorie. This inefficient energy transfer between trophic levels is called the 10 percent law, or an energy pyramid. This 10 percent law has profound impacts within an ecosystem. Plants have the most energy available to them; the most abundant animals will be those directly feeding on plants, and carnivores will always be relatively rare, especially those of large size that occupy a higher trophic level.

However, when toxic substances pass through trophic levels, the exact opposite is true. While energy diminishes in the process of flowing from lower to higher trophic levels, toxic substances progressively increase in concentration along the food chain. This phenomenon, called biological magnification, was discovered through the study of the use of the pesticide dichloro-diphenyl-trichloroethane (DDT). Tests of water samples following the use of this pesticide showed a trace amount of DDT. Tissue analyses of predatory birds in the same aquatic ecosystem, however, revealed a DDT concentration a million times greater than that in the water. Fish caught from the same waters also contained much higher DDT levels than the water, but substantially lower levels than that of the birds that consumed those fish. DDT has since been confirmed as the cause for population declines of several predatory birds, especially fisheaters such as bald eagles, brown pelicans, and cormorants. Understanding biological magnification is crucial to the prevention of widespread loss of wildlife.

Unlike energy, no mechanism or source exists to allow a constant replenishment of nutrients. The same pool of nutrients has been supporting life from the beginning. Nutrients are elements and small molecules that form all the building blocks of life. Macronutrients are those acquired by organisms in large quantities, including water, carbon, hydrogen, oxygen, nitrogen, phosphorus, sulfur, and calcium. Micronutrients, including zinc, molybdenum, iron, selenium, and iodine, are acquired in trace quantities. Nutrients cycle from producer, to consumer, to detritus feeder and decomposer, and eventually back to producer. The major reservoirs of nutrients are in the nonliving environment, such as soil, rock, water, and atmosphere. In an undisrupted ecosystem, nutrients have cycled and recycled in a sustainable manner for thousands of years. However, human intervention, either through industry or agriculture, has created enormous problems for sustainable nutrient cycling. One example is the nitrogen cycle. Although plants may obtain nitrogen from soil, the primary source of nitrogen is the atmosphere. Nitrogen gas (mainly N) makes up over 70 percent of the air. N may be extracted by some plants or converted by lightning into useable forms that drop as rainfall. Through industrial production and use of nitrogen fertilizers in agriculture, humans have overcharged the nitrogen cycle, causing acid rains and surface water and groundwater contamination, which pose a serious threat to natural ecosystems.

Why Preserve Biodiversity?

Biodiversity is defined as the total number of species within an ecosystem, and also as the resulting complexity of interactions among them. It measures the "richness" of an ecological community. Among an estimated eight to ten million unique and irreplaceable species existing on Earth, fewer than 1.6 million have been named. A tiny fraction of this number has been studied. Over thousands of years, organisms in a community have been molded by forces of natural selection exerted by other living species, as well as by the nonliving environment that surrounds them. The result is a highly complex web of interdependent species whose interactions sustain one another and provide the basis for the very existence of human life as well. Thus, it is easy to see why biodiversity should be preserved.

Loss of biodiversity poses a serious challenge to the sustenance of many communities and ecosystems. For example, the destruction of tropical rain forests by clearcut logging produces high rates of extinction of many species. Most of these species have never been named, and many never even discovered. As species are eliminated, the communities of which they were a part may change and become unstable and more vulnerable to damage by diseases or adverse environmental conditions. Aside from disrupting the natural food webs, potential sources of medicine, food, and raw materials for industry are also lost. As Harvard professor Edward O. Wilson once said, "The loss of species is the folly our descendants are least likely to forgive us."

Food Chains and Food Webs in a Terrestrial Ecosystem

Since different ecosystems have drastically different food chains and food webs, they can be better illustrated using examples of different communities. The first example is a land community, to provide an overview of terrestrial food chains and food webs. Plants such as maple trees and squash are the producers that occupy the first trophic level. Aphids, caterpillars, grasshoppers, and other animals that forage directly plants or plant tissues are primary consumers that occupy the second trophic level. Birds, spiders, and other insects that feed on primary consumers are secondary consumers occupying the third trophic level. Large birds, such as eagles, owls, and hawks, that eat secondary consumers are tertiary consumers making up the fourth trophic level. This food chain can go on to even higher trophic levels.

However, natural communities rarely contain well-defined groups of primary, secondary, and tertiary consumers in a linear pattern. In reality, a food web showing many interconnecting food chains in a community describes much more accurately the actual feeding relationships within a given land community. This is in part due to the omnivorous, or "eating all" nature of some animals. These animals include but are not limited to bears, rats, and raccoons. They act as primary, secondary, and even tertiary consumers at different times. Many carnivores will eat either herbivores or other carnivores, thus acting as secondary or tertiary consumers, respectively. An owl, for instance, is a secondary consumer when it eats a mouse, which feeds on plants, but a tertiary consumer when it eats a shrew, which feeds on insects. Once a shrew eats carnivorous insects, it is by itself a tertiary consumer, making the owl that feeds on the shrew a quaternary consumer that occupies the fifth trophic level. Since organisms are interlocked in such complex yet organized networks, disruption at any particular point of the food web (damage to one group of organisms) might have far-reaching effects on a whole community or ecosystem.

Food Chains and Food Webs in a Marine Ecosystem

Coral reefs will be used as an example for marine ecosystem. Reefs are created by concerted efforts of producers—algae—and consumers—corals. In warm tropical waters, with just the right combination of bottom depth, wave action, and nutrients, specialized algae and corals build reefs from their own calcium carbonate skeletons. The reef-building corals grow best at depths of less than forty meters, where light can penetrate and allow their algal partners to photosynthesize. Algae and corals are involved in a mutualistic relationship, where algae benefit from the high nitrogen, phosphorus, and carbon dioxide levels in the coral tissues. In return, algae provide food for the coral and help produce calcium carbonate, which forms the coral skeleton.

Coral reefs provide an anchoring place for many other algae, a home for bottom-dwelling animals, and shelter and food for the most diverse collection of invertebrates and fish in the oceans. In essence, algae is the producer that occupies the first trophic level. Corals that feed on algae are primary consumers sitting at the second trophic level. Many fish (such as blue tang) that feed on corals are secondary consumers occupying the third trophic level. Larger fish, such as sharks that eat small

Ecosystem Energetics

The diverse forms of life in all ecosystems are powered by a single energy source, sunlight, which enters the biosphere through a process called photosynthesis. Organisms such as plants and algae capture a small fraction of sunlight's energy, storing it as chemical energy in sugar or other complex organic molecules. The energy then passes through an ecosystem via different feeding (trophic) levels. Each time the energy is passed on, a portion of it is lost as heat. Thus, energy needs constant replenishment from the original source, the Sun.

How does energy flow through communities? It flows through ecosystem energetics. Of the energy that reaches Earth, much is either reflected or absorbed as heat by the atmosphere and Earth's surface, leaving only about 1 percent to power all life. Of this 1 percent, green plants capture 3 percent or less. All life on this planet is therefore supported by less than 0.03 percent of the energy reaching Earth from the Sun. Photosynthetic organisms are called autotrophs, or producers, because they produce food for themselves. Directly or indirectly, they produce food for nearly all other forms of life as well. Organisms that cannot photosynthesize are called heterotrophs, or consumers, because they must acquire energy prepackaged in the molecules of the bodies of other organisms.

There are three basic principles that govern ecosystem energetics. First, the amount of life an ecosystem can support is defined by the energy captured by the producers. This energy, made available to consumers over a given period, is called net primary productivity. It is usually measured in units of energy stored per unit area in a given period, or measured as biomass, the dry weight of the total organic material added to the ecosystem per unit area in a given time span. The net primary productivity is influenced by a variety of environmental factors, including the amount of sunlight, the availability of water, the amount of nutrients available to producers, and the temperature. Among all environmental variables, the most limiting variable is the one that determines net primary productivity, for instance, water in the desert or light in the deep ocean.

Second, within the community, energy is passed from one feeding level to another. Energy flow moves from producers to primary consumers to secondary and tertiary consumers. Primary consumers are normally herbivores that directly consume producers. Secondary and tertiary consumers are typically carnivores that eat meat of other consumers. Certain consumers may occupy more than one feeding level. As energy is passed through feeding levels via food chains or food webs, the transfer is never efficient. This is the third basic principle of ecosystem energetics. Each time the energy is transferred to the next feeding level, the bulk of it is lost as heat. On average, only 10 percent of the energy is transferred from one feeding level to the next. In other words, the higher the feeding level an organism occupies, the less energy is available to it. This so-called 10 percent law or energy pyramid puts a cap on how much life a particular ecosystem can sustain.

—Ming Y. Zheng

fishes, are tertiary consumers at the fourth trophic level. A vast array of zooplanktons, invertebrates such as sponges, the poisonous blue-ringed octopus, and so on, also live in coral reef ecosystems to make extremely complex marine food webs. For example, the Great Barrier Reef in Australia is home to more than two hundred species of coral, and a single reef may harbor three thousand species of fish, invertebrates, and algae.

Similar to terrestrial ecosystems, aquatic ecosystems are also prone to human disturbance. Of all aquatic or marine ecosystems, coral reefs are probably most sensitive to certain types of disturbance, especially silt caused by soil eroding from nearby land. As silt clouds the water, light is diminished and photosynthesis reduced, hampering the growth of the corals. Furthermore, as mud accumulates, reefs may eventually become buried and the entire magnificent community of diverse organisms destroyed. Another hazard is sewage and runoff from agriculture. The dramatic rise in fertilizer in near-shore water causes eutrophication, by which excessive growth of algae blocks sunlight from the corals, deprives corals of nutrients, and suffocates corals and other organisms. A third threat to coral reefs, overfishing, is also strictly a result of human interference. It is estimated that in over eighty countries, an array of species, including mollusks, turtles, fish, crustaceans, and even corals, are being harvested much faster than they can replace themselves. Collectively, these human activities had destroyed over 30 percent of coral reefs worldwide by year 2000. Assuming no effective measure is taken to preserve or restore coral reef ecosystems, another 50 percent of reefs will disappear by year 2030. The message is clear: Once humans disturb an ecosystem, through damaging one or more species in an intricately networked food web, balance and sustainability within the whole system is affected. The price for such disruption is high and far-reaching.

FORESTS, CONIFEROUS

Types of animal science: Ecology, geography
Fields of study: Conservation biology, ecology, environmental science

Coniferous forests are those in which the predominant species of trees carry their seeds in cones. Although conifers are often associated with cooler climates, they have wide global distribution. Conifers form the plant phylum Pinophyta and include such well-known species as sequoias, spruces, and cedars.

Principal Terms

CONIFER: member of the phylum Pinophyta, characterized by carrying seeds in cones and often having needlelike foliage

DECIDUOUS: trees which lose their leaves annually, such as maples and elms

GYMNOSPERM: a plant whose seeds are borne on seed scales arranged in cones

NAVAL STORES: conifers used for production of turpentine, pitch, and other materials once considered necessary for maintenance of navy vessels

TOLERANCE: ability of a tree to grow in the shade of other trees

Forests in which the dominant species of tree are members of the plant phylum Pinophyta are referred to as coniferous forests. Coniferous forests are often associated with cooler climates, such as the boreal forest stretching across northern Europe, Asia, and North America, but conifers are actually found in a wide range of climates and locations. Conifers are sometimes referred to as evergreens, meaning that the trees seemingly never lose their leaves, but not all conifers are evergreen, nor are all evergreens conifers.

Conifers do, in fact, lose their leaves, but with the exception of the larches (also known as tamaracks), which change color uniformly and shed their leaves seasonally, needle drop is a gradual process. Depending on the species, leaves will remain green and on the tree for many years rather than being replaced annually. The new growth replaces the dropped needles gradually enough that often only the thick mulch of dead needles at the base of pines, spruces, and other conifers provide definitive evidence that needle drop occurs. In some coniferous forests, the thick carpeting of needles on the woodland floor chokes out shade-tolerant species of vegetation, while the evergreen canopy blocking the sun discourages intolerant species from sprouting. Over time a pure stand of conifers may emerge, in which few other species of trees grow and even smaller trees of the same species are crowded out. Many conifers are highly shade intolerant, so a coniferous forest will thin itself naturally. The spreading branches of the taller trees will block the light needed by smaller ones. A mature stand of red pine, for example, will eventually be composed of so many trees of similar size and even spacing that natural red pine forests can be mistaken for artificially planted commercial stands.

Physical Characteristics of Conifers

Conifers take their name from the fact that their seeds are carried in cones and from the observation that many of the most widely recognized coniferous trees, such as spruces and pines, present a rather conical appearance, broad-based at the bottom and tapering symmetrically to a pointed top. The trunks of conifers rarely fork, but instead form a straight central trunk with branches radiating from it. In the event a conifer loses its tip, or leader, a branch near the break may shift its orientation to grow upward to replace the lost leader, while other branches will continue to radiate out horizontally. Not all conifers form such a neat appearance, however. The bristlecone pine is noted for its twisted, gnarled appearance, and many junipers and yews tend to sprawl rather than grow upright. The narrow, needlelike leaves of many conifers are another easily identifiable characteristic, although some conifers, such as the cedars, have leaves that are small and scalelike rather than needle-shaped.

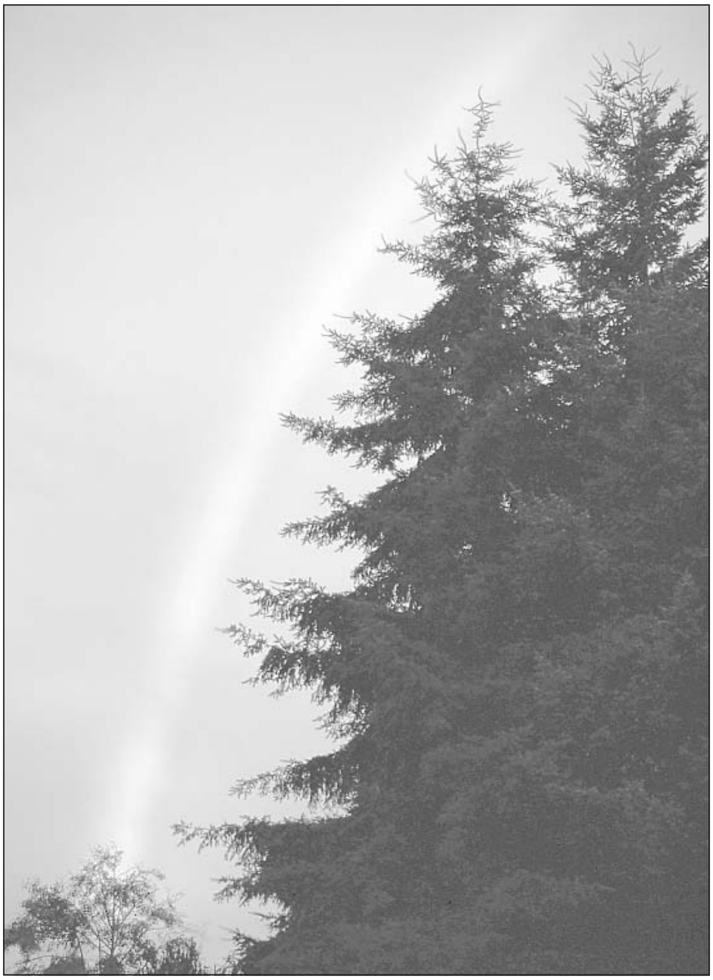
The long, straight trunk of many conifers has contributed to the trees being valued as a source of building materials. During past centuries, millions of acres of white pine forest in North America were cut, first for use as masts on sailing ships, and later for lumber for general construction. Species such as western red cedar, redwoods, and bald cypress continue to be prized for their natural resistance to rot and water damage, while Douglas fir and white spruce are important sources of construction lumber.

In addition to being cut for lumber, conifers are harvested for pulp and the production of chemicals. Prior to the introduction of petroleum products, sailing ships required huge quantities of pine tar. Governments would set aside forest reserves as naval stores, which meant that the trees were not to be cut for lumber. The conifers were instead reserved as a source for turpentine and pine tar, which were produced from the sap of conifers such as pitch pine. The bark of the trees were slashed to allow sap to run into pans for collection. The sap was then distilled into turpentine and pine tar.

Conifer Range

Although coniferous forests dominate the cooler regions of the globe, conifers are also found in tropical and desert regions. Cypress trees thrive in warm, swampy areas, such as the bayous of Louisiana, while piñons and other pines constitute the dominant species on the desert plateaus of the American southwest. The thin, waxy needles of conifers conserve moisture while allowing photosynthesis to occur year-round, an adaptation that serves conifers equally well in the harsh conditions of a subalpine mountain slope or during long Canadian winters.

Some mature conifers are also noted for their extremely thick bark, which reduces their vulnerability to fire. As recently as the 1990's, foresters continued to use fire routinely as a management tool in plantations of loblolly and southern yellow



Coniferous forests are composed of very tall trees with relatively little undergrowth. (Corbis) pines. Controlled burns removed the undesirable broadleaf species, such as rhododendrons, from the understory, while leaving the taller, thick-barked pines unharmed. Other species have evolved so that natural fire is a necessary part of the reproductive cycle. Until humanity began suppressing forest fires, fires triggered by lightning strikes were a common occurrence in many coniferous forests. The litter of dead needles and fallen branches on the ground rarely built up to catastrophic levels, and low intensity fires remained on the ground where they did little long-term harm to the forest. Lodgepole pine, for example, bears seed cones that will remain tightly closed for many years, until exposed to extreme heat. When fire sweeps through an area, it both clears the ground of competing species and opens the lodgepole pine cones, allowing for a new generation of trees to sprout.

Conifer Size and Age

Species of trees found in coniferous forests range from the stunted-looking spruces growing in the arctic taiga, where the boreal forest merges into the tundra, to the giant sequoias (*Sequoiadendron giganteum*) in the mountains of southern California. In far northern regions, spruce trees hundreds of years old may stand barely ten feet tall and be only a few inches in diameter. Sequoias, in contrast, are the most massive trees on earth, as they attain heights of 275 feet and diameters as large as 30 feet. Young sequoias present a pleasing symmetrical appearance, the typical cone shape of many conifers, but as the trees mature they often lose their tops to lightning strikes and become rather ragged and uneven looking. The largest sequoia on record measured 293 feet in height, with a diameter of 37 feet. Once widespread throughout North America, giant sequoias are now found only in isolated groves high in the mountains of California. A closely related species, the redwood (*Sequoia sempervirens*) is the dominant species in the forests along the Pacific coast in northern California and Oregon. Although redwoods grow as tall as sequoias, they do not achieve as a large a diameter, nor are they as long-lived. Redwoods are considered mature at 400 years and may live to 1,500. No sequoia is known to have died of old age, although mature trees have been killed by lightning strikes and fire.

The oldest known living examples of conifers, however, are not the mammoth redwoods and sequoias, but bristlecone pines found in the mountains of the North American West. Scientists have identified individual bristlecone trees over four thousand years old. Unlike the sequoias and the bristlecone pines, which may live for millennia, other conifers, such as balsam fir, are relatively short-lived, reaching maturity in only a few decades and dying off while less than a century old.

Based on the fossil record, scientists believe conifers have existed on earth much longer than the broad-leaved species of trees. Botanists speculate that conifers evolved from the giant fern trees common during the days when dinosaurs roamed the earth. Broad leaf trees, such as maples, are angiosperms, or plants whose flowers contain both male and female parts. Angiosperms are the most common plants on earth, with hundreds of thousands of different species growing in a wide range of environments. Angiosperms encase seeds within fruits, such as acorns, that both protect the seed and provide food for the embryonic plant. In contrast, the flowers of gymnosperms will be either male or female, never both at once, and seeds are set on scales arranged in cones. Although the flowers of gymnosperms are less complex than angiosperms, gymnosperms may have both male and female flowers on the same plant. Just as the needles of many conifers may remain on the tree for five or more years, so too do the cones of some species cling to the tree through many seasons. Sequoias, for example, will hold cones for as long as twenty years, with the cones remaining green and seemingly recently formed the entire time they are on the tree. Gymnosperms such as the conifers number fewer than one thousand species globally and are more limited in range than angiosperms.

Conifers as Habitat

All forests provide wildlife habitat on multiple levels, with some animals living on or under the forest floor, others taking advantage of resources available in the lower sections of the trees, and still others living in the canopy. Coniferous forests are no exception. Small rodents, such as chipmunks and mice, live in underground burrows, subsisting on seeds gathered from fallen cones. While the needles on conifers may not appear palatable to humans, deer, elk, and moose depend on conifers for winter browse. Moose, in particular, rely on conifers such as balsam fir as a primary food. Squirrels often thrive in dense spruce and balsam stands, building their nests high in the trees and rarely setting foot on the ground. A wide variety of small birds and mammals often dwell in coniferous forests, as the evergreen canopy provides a protective cover from large birds of prey such as eagles. Kirtland's warbler, the marbled murrelet, and the spotted owl are only a few examples of birds that call coniferous forests home.

FORESTS, DECIDUOUS

Types of animal science: Classification, ecology, reproduction
Fields of study: Anatomy, ecology, zoology

Deciduous forests contain trees that shed their leaves. Temperate deciduous forests shed their leaves in autumn, and monsoon or tropical deciduous forests do so in the dry season. They hold many animal species, including predators, omnivores, and herbivores.

Principal Terms

CARNIVORE: animal that eats other animals
DECIDUOUS: shedding or losing leaves at the end of a growing season
GESTATION: the term of pregnancy
HERBIVORE: animal that eats plants
OMNIVORE: animal that eats plants and animals

A forest is an aggregate of vegetation, mostly trees and other woody plants, on land that may encompass many square miles. Forests exist relatively unchanged over very long time periods, having in them lasting populations of specific trees, shrubs, grasses, and animals. The interactions of these creatures with each other and with the forest helps to maintain the status quo. The climate, soil, and geography of the region where a forest occurs determine the main tree types it contains and their locations in the aggregate. Within any section of a forest, dominant trees help to control the specific shrubs, herbs, and grasses that are present.

Forests are divided into ten types on the basis of tree leaf types and ambient climate. Two are deciduous temperate and deciduous monsoon or tropical forests. Deciduous temperate forests are exemplified by the typical forest of the eastern and midwestern United States, Balkan forests, and Scandinavian forests such as the ones in Norway. Deciduous temperate forests hold trees which lose their leaves in autumn, when the weather turns cold. Deciduous monsoon or tropical forests include those of Southeast Asia, western coastal Mexico, and Central America. The climate in those areas varies between long periods of heavy daily rainfall and dry periods during which trees shed their leaves.

Temperate Deciduous Forests

Typical temperate deciduous forests are those occurring in the mountains of southeastern Europe's Balkan Peninsula. These mountains begin at the western Romanian border and run south to the Bulgarian border. In Bulgaria, they turn east and run toward the Black Sea. The Balkans contain deciduous forests whose trees are mostly oak, ash, beech, birch, hazel, and maple. Elk, deer, foxes, wolves, badgers, weasels, martens, wild boar, lynx, bear, and roe deer are among larger animals found in them.

In the United States, over 40 percent of Wisconsin's land is forest. The southern part of the state has huge deciduous forests composed largely of maple, basswood, oak, elm, and hickory trees. Many animals inhabit the forests, including white-tailed deer, black bears, badgers, foxes, hares, porcupines, woodchucks, coyotes, skunks, mink, beavers, muskrats, wolves, martens, copperhead snakes, rattlesnakes, and lynx. In addition, wild birds include pheasant, ruffed grouse, partridges, robins, wrens, swallows, owls, chickadees, and eagles.

Forests also cover about one third of Norway. Scandinavian deciduous forests occur near the south and southwest coasts. The main trees in the forests are oak, ash, birch, hazel, elm, and maple. Elk, deer, foxes, otters, wolves, martens, pit vipers, other reptiles, and many birds inhabit the forests.

Fauna of Temperate Deciduous Forests
Among the interesting organisms in temperate deciduous forests are carnivores, including the weasel family (mustelids). These furry mammals weigh from a few ounces to one hundred pounds. They include weasels, martens, otters, skunks, and badgers. All have short legs and paws with five toes and sharp claws for grasping prey and burrowing. Beautiful mustelid fur is used in expensive fur garments. Mustelids have glands that make musks, which produce odors to mark territory or enable self-defense. Mustelid musk is most offensive in skunks, who use it in self-defense. Male and female mustelids live alone, except when mating. Mating seasons, gestation (two to nine months), and litter size (up to ten young) depend upon species. Life spans of those mustelids that reach old age are up to twenty-five years.

Lynx, also carnivores, are cats. They have very long legs and large paws, are found all through temperate and subarctic regions of the northern hemisphere, and can grow to three feet long. Most have hair tufts at each ear tip and are agile climbers, spending much of their time on the limbs of trees, waiting to ambush passing prey. Lynx live in caves and hollow trees. Their litters contain two to four offspring. The lynx of Europe, the United States, and Canada are different species.

Wolves belong to the dog family. The two wolf species are the gray (timber) wolves of Europe, Asia, and the New World and the red wolves of Texas and Louisiana. An adult timber wolf has a maximum body length of 6.5 feet and a weight of 185 pounds. These wolves are usually reddish-yellow to yellowish-gray, with white underbodies. Red wolves are smaller and darker colored. All wolves have powerful teeth and bushy tails. They live on prairies, in forests, and on mountains. In winter, their packs seek small animals, birds, and large mammals as prey. Wolves den in caves, hollow trees, or holes they dig. Breeding season is the spring, and a female has three to nine cubs, which stay with parents until the following winter.

Monsoon or Tropical Deciduous Forests
Deciduous monsoon or tropical forests, with their broadleaf trees, occur in southern Brazil and along highland slopes of the Andes, South America, Central America, and the lowlands of Mexico, a neotropical region. Its animals are quite varied and differ from those of all other continents, including North America north of Mexico's plateau region.

Deer and Elk

Deer and elk inhabit all temperate forests. The name deer denotes hoofed, artiodactyl mammals of the family Cervidae, whose males have bony, branching antlers that are shed and regrown annually. There are forty cervid species in the Americas, Asia, Europe, and North Africa. Most inhabit forests, especially deciduous forests. Deer species range in size from moose, seven feet tall at shoulder height, to tiny species only a foot tall.

Deer and elk eat the twigs, leaves, bark, and buds of bushes and trees, as well as grasses. They feed mostly at twilight. Does (or female moose) birth one or three offspring each year, after six- to ten-month gestations. In the United States, the most common deer is the white-tailed deer, known for a tail with a white underside. The American elk, or wapiti, is called the red deer in Europe. Moose—the largest deer in the world—found throughout the United States, are known as elk in Europe.

Dear and elk have compact bodies and long, powerful legs suited for woodland terrain. They are also fine swimmers. They are herbivorous ruminants (cud chewers). Also, their solid and bony antlers, unlike the hollow, permanent horns of other ruminants, form only in males. The antlers are used to make territorial markings and threaten or combat other males. Male moose have the largest antlers, which can be six feet wide and weigh fifty pounds.

Deciduous forests are usually composed of a wide variety of trees of different sizes, with a lot of undergrowth. (PhotoDisc)

Found throughout tropical deciduous forests, as well as in rainforests, are mammals confined to the neotropical region, such as monkeys different from those seen elsewhere. Ruminants such as cameloid llamas and alpacas graze forest meadows and carnivorous puma or jaguar eat them. Many neotropical birds such as tanagers, macaws, hawks, and condors also live in or seek prey in the deciduous forests and their open meadows. Reptiles include boas, bushmasters, fer-de-lance, and other poisonous snakes. Also present in these forests are peccaries, tapirs, capybaras, and agoutis.

Jaguars are the largest, most powerful American big cats. Found in Mexico and throughout Central and South America, they are most abundant in Central America and Brazil. Jaguars are the only big cats absent in Africa and Asia. They inhabit forests, swamps, and grasslands. Mature jaguars have lengths of seven feet, shoulder heights of two feet, and weights of 275 pounds. Their yellow coats are spotted with black rosettes, each a circle of spots around a central spot. Adept climbers and swimmers, jaguars eat a wide range of animals, such as peccaries, deer, tapirs, monkeys, agoutis, capybaras, birds, fish, and rodents.

Jaguars of either sex live alone except when mating, each maintaining a hunting territory. They have no set breeding season and gestation is about 3.5 months. Mothers give birth to two to four babies. They mate at age two years and have life spans up to twenty-two years. Jaguars are close to the top of the food chain in their environment.

Among the interesting animals that are prey for jaguars and pumas are tapirs. Brazilian tapirs have stocky bodies, short necks, and sturdy legs built to push through forests. They have short trunks with flexible "fingers" at the trunk tips. Trunk fingers bring leaves to their mouths. Nocturnal animals, Brazilian tapirs have short, stiff neck manes which provide some protection from predators. Tapirs have thick brown skins, and can attain lengths of 6 feet, heights of 2.5 feet, and weights of five hundred pounds. These herbivores eat grass, aquatic plants, leaves, buds, twigs, and fruit. They are solitary except when mating or nursing young. Mating occurs year round and gestation is 12.5 months. A mother births one offspring, which cannot mate until age two to three. Tapirs can live for over thirty years.

Peccaries, forest-dwelling pigs, are also prey for big cats. They inhabit high-altitude forests from Mexico to South America. These artiodactyls reach lengths of four feet, heights of two feet, and weights of one hundred pounds. They are gray-black to brown, have slender legs, and can run quite fast. Omnivorous, peccaries eat roots, seeds, fruits, and insects. They have tusks, which they use to dig and cut roots. Peccaries live in herds of up to one hundred. After mating, gestation is six months and produces two or three young, dependent on their mother for six months. Peccaries can mate at a year old and can live for up to ten years in the wild or twenty years in captivity.

Damaging Deciduous Forests

A deciduous forest is a self-sustaining ecosystem. In it, interactions of trees, shrubs, and grasses help to maintain viability and forest identity. Added to this, appropriate interaction of plants and resident herbivores help to assure that plant species do not overgrow and damage the balance or severely change the status quo that gives the forest its identity. In addition, predation by forest carnivores adds to the picture by assuring that herbivores do not become so plentiful that they overgraze the forest and alter its identity.
