that is often treatable nonetheless. In light of this a palliative approach is often the mainstay of therapy, with several important exceptions that will be addressed in the discussion that follows. For patients with relatively small effusions that do not cause a high degree of dyspnea or impairment of functional status, consideration of systemic therapy of the malignancy, usually chemotherapy, is indicated. If, on the other hand, dyspnea is a primary concern, immediate management of the effusion is necessary. Unfortunately, for many patients with advanced disease, chemotherapy might not be able to provide rapid enough resolution of dyspnea or other symptoms, and thus one must use mechanical means of reducing the effusion. First and foremost, the clinician should consider the individual patient's situation, with particular attention to overall prognosis, prior therapies (if any), age, and performance status. The physician must also weigh the likelihood of progression of other systemic disease during the time required for resolution of an effusion. For patients with large effusions who are in the terminal stage of their disease, supplemental oxygen with hospice referral might be the only appropriate intervention.

Systemic Therapy in Specific Malignancies

Many advanced solid tumors do not respond well to chemotherapy, so primary management of the effusion is often required. There are notable exceptions. Small cell lung cancer is unlikely to be curable, but effusions from this cause respond well to chemotherapy.[54,55] Testicular and other germ cell neoplasms are not only responsive but also very curable, even at an advanced state, and thus early systemic treatment should be used if at all possible.[56] Even patients with advanced germ cell tumors have good responses and should be considered for aggressive systemic therapy. Breast cancer might respond well to hormonal therapy or chemotherapy, particularly among patients who have not received prior systemic therapy. Mesothelioma is a unique tumor that arises directly from pleural or peritoneal surfaces. Effusions are often associated with the tumor and are not included in the staging system. Patients amenable for aggressive local therapy, even with an effusion, should be considered for such therapy. Effusions from hematologic malignancies, such as lymphoma, are often highly responsive to systemic chemotherapy. Treatment of effusions related to hematologic malignancies are generally focused on treatment of the disease as a whole rather than treatment directed at the effusion directly. Because patients with solid-organ tumors and advanced disease have relatively poor responses to chemotherapy overall, early direct management of the effusion among patients with dyspnea should be considered at the outset for patients who are unlikely to achieve rapid responses to chemotherapy.

SYSTEMIC CHEMOTHERAPY AND EFFUSIONS. It should be remembered that the pharmacokinetics of drugs in the presence of effusions are poorly understood, because drug might accumulate in effusions and only slowly redistribute throughout the body. Methotrexate is a classic example of this phenomenon. Methotrexate is slowly released from all of the "third spaces," and those of large volumes (ascites, pleural effusions, or anasarca) might dramatically prolong the terminal half-life and lead to potential increased toxicity.[57] There are no direct guidelines for the use of methotrexate or other chemotherapies when large effusions exist, but the clinician should consider drainage of the effusion before the use of methotrexate, or the use of alternative therapies. Patients with pleural effusions receiving new chemotherapy agents should be monitored closely for treatment-induced toxicity.

Effusion-Targeted Therapy

THERAPEUTIC THORACENTESIS. Therapeutic thoracentesis might serve as the main or sole therapy for management of an effusion in many patients. Thoracentesis, unlike other procedures, might permit rapid relief of symptoms without need of hospitalization. If systemic disease is a significant concern, thoracentesis might allow for a window of opportunity in which to gain control over a patient's symptoms before systemic chemotherapy is given. Similarly, it might also allow for palliation of symptoms for those patients with far advanced disease.

Therapeutic thoracenteses are performed similarly to diagnostic procedures. Although a pneumothorax usually occurs when air leaks into the pleural space through the needle, it can also occur if the visceral pleura is lacerated with the needle. The latter complication may be avoided if a plastic catheter is threaded through the needle, directed inferiorly, and the needle is then removed; this procedure minimizes the chances that a pneumothorax will occur via perforation when the visceral and parietal surfaces become opposed after fluid removal. If a pneumothorax occurs the leak usually seals itself quickly, but closure can be hastened by having the patient lie on the affected side, which decreases the pressure gradient between the alveoli and the pleural space.[58] The volume of pleural fluid that can be removed safely is unknown. One study by Light and coworkers demonstrated that pleural fluid removal could be considered safe as long as pleural fluid pressure does not decrease below −20 cm H_2O.[28] Because most clinicians do not measure pleural pressure, current recommendations are that no more than 1.0 to 1.5 L of fluid be removed at any one time, and that amount only if there are no signs of any adverse events such as dyspnea, pleural pain, or cough, which are indications of the rapid restoration of a strong negative pleural pressure. Patients with contralateral mediastinal shift can have larger amounts of fluid removed safely, because these adverse events are unlikely to occur. Rapid reexpansion might bring on the phenomenon of reexpansion pulmonary edema, which is due to the rapid restoration of capillary permeability through unknown mechanisms; this can occur when air or fluid is removed from the pleural space.[58] Patients with ipsilateral mediastinal shift are unlikely to obtain significant relief from thoracentesis, because this condition indicates a large amount of either trapped lung or mainstem bronchial occlusion.[46]

There have been no randomized or comparison trials examining the use of repeated thoracentesis compared with the use of other procedures. It is also difficult to predict the length of time within which an effusion might recur; some patients have rapid recurrence (within days), whereas others might have recurrence over a period of weeks. Most oncologists and pulmonologists often make an initial attempt at a therapeutic thoracentesis to allow immediate symptomatic relief and time for systemic therapy to take effect, as well as to gauge the extent to which a pleural effusion causes dyspnea. For patients whose effusions recur rapidly, more invasive procedures might be required; those whose effusions recur more slowly might be managed solely with repeat thoracentesis.

RADIATION THERAPY. In general, radiation of the hemithorax, as a means of controlling an effusion, is contraindicated in most patients with malignant pleural effusions. This is because of the high incidence of radiation pneumonitis that is likely when a sufficient dose of radiation is given to large areas potentially involved with malignant effusions.[59] Certain situations, such as lymphatic obstruction from focal areas of lymphadenopathy (which may arise in lymphoma or in lung cancer), might benefit from radiation applied to these specific areas. Radiation doses are dependent on the nature of the malignancy.

CHEMICAL PLEURODESIS. Pleurodesis is intended to achieve a "symphysis between the parietal and visceral pleura, in order to prevent accumulation of either air (pneumothorax) or fluid (pleural effusion) in the pleural space,"[60] and malignant pleural effusions are the largest indications for pleurodesis.[60,61] The mechanism by which this symphysis occurs is poorly understood, but in general it depends on pleural irritation to cause a cycle of inflammation, activation of the pleural coagulation cascade, fibrin placement and fibroblast recruitment, and, finally, collagen deposition that ultimately results in the fusion of both pleural surfaces.[60,62,63] Nevertheless, the exact

mechanisms and factors that influence pleural sclerosis and effect pleurodesis are not well known and require further research. Many agents have been used in the past with various success rates reported; much of this information is based on personal and anecdotal experiences. These agents include, as a minimum list

- Talc
- Tetracycline
- Minocycline
- Doxycycline
- Quinacrine
- Mepacrine
- Bleomycin
- Mitomycin
- Thiotepa
- Nitrogen mustard
- 50% glucose and water
- Interferon-α
- Interferon-γ
- Iodopovidone
- Radioactive colloidal gold
- Autologous blood
- Fibrin glue
- Bacille Calmette-Guérin
- Silver nitrate
- Killed *Corynebacterium parvum*[60]

The exact mechanism by which these agents effect pleurodesis probably differs slightly from one agent to another, but all lead to a final common pathway that activates the pleural coagulation cascade and the appearance of a fibrin network that yields a symphysis between the two surfaces.[61–63] The various agents have different properties and methods of administration.

METHOD OF PLEURODESIS. It should be recalled that patients must demonstrate that symptoms (usually dyspnea) respond to drainage of the pleural fluid, because patients with malignancy often have numerous reasons for dyspnea—pulmonary metastases, anemia, pulmonary embolus, trapped lung, or poor gas exchange—and might be unlikely to benefit from a resolution of the effusion. Thus, it is important for patients to undergo a trial of therapeutic thoracentesis initially rather than proceed directly to chest tube drainage. At the time that pleurodesis is performed, the effusion must be drained. For successful sclerosis, there should be evidence of complete lung reexpansion after initial drainage. Traditionally one gauged the optimal time for sclerosis when there was minimal pleural fluid drainage (<150 mL per day), but this seems to be less relevant for success in sclerosis than does the confirmation of complete radiologic lung reexpansion.[64]

Traditionally chest tube drainage has been performed with a standard-size (24–32 Fr) chest tube. Tubes in this size range are associated with a great deal of pain and discomfort. More recent work has supported the use of smaller bore (8–16 Fr) catheters. A prospective, randomized study of 18 patients found improved comfort and no difference in success or complication rates when small-bore catheters were used.[65] Small-bore tube placement is an emerging standard of care.[66]

Sclerosing Agents

TETRACYCLINE/DOXYCYCLINE. Tetracycline was the most widely used sclerosing agent until it was discontinued by the manufacturer in 1992, although it might still be available in some countries.[67,68] Doxycycline has been recommended as a replacement, but there are no direct studies comparing the two agents. Historical comparisons demonstrate similar success rates with doxycycline compared with tetracycline, both on the order of 80% to 85%.[69,70] Most studies and investigators have used 500 mg of doxycycline mixed in 50 to 100 mL of sterile saline, and the primary complication is pain related to the doxycycline, requiring either narcotics or conscious sedation.[45,69,70]

TALC. Talc is currently the most widely used, the best studied, and probably the most controversial sclerosing agent. A major advantage of talc is the cost; the average wholesale price for the amount of talc typically used for pleurodesis procedures is less than $1.00. Sterilization of the talc raises the cost to between $5 and $20, dependent on the methods used, and it remains sterile for at least a year on pharmacy shelves.[71] The cost of talc is therefore significantly less than for any of the other agents used. Talc may be introduced via slurry (i.e., mixed with saline) in the chest tube used to drain the effusion, or insufflated (poudrage) with a bulb syringe or atomizer at the time of a thoracoscopic drainage procedure. (Thoracoscopy will be discussed shortly.)

In 1994 Kennedy and Sahn reviewed all the published series using talc as a pleurodesis agent and found a 91% success rate (659 of 723 patients) for pleurodesis, with success judged by various clinical and radiologic findings.[72] Doses of talc ranged widely, from 1 to 14 g per procedure. There was no difference between poudrage and slurry. Animal studies suggest that concomitant use of steroids can decrease the efficacy of talc pleurodesis, and a small study in humans demonstrated a small, not statistically significant decreased response to talc slurry when steroids were used.[73,74] Although these studies are not conclusive, steroids should be discontinued or the dose reduced as much as possible before pleurodesis procedures when talc or any pleurodesis agent is used.

Adverse effects from talc are variable. Pain ranging from nonexistent to severe is not uncommon; there is an overall reported incidence of 7%.[75] Fever, up to 102°F, occurs within the first 12 hours and can last up to 72 hours.[16,75] Empyema is an occasional complication, more often with talc slurry than with poudrage. Cardiovascular complications (e.g., arrhythmia, chest pain) have been noted, but it is difficult to assess whether these are a result of the talc pleurodesis procedure itself or the patients' comorbidities.[72,74]

Pulmonary complications constitute the largest and most significant group of complications associated with talc pleurodesis. Acute respiratory distress syndrome (ARDS), pneumonitis, and respiratory failure all have been reported after pleurodesis with talc.[75,76] The mechanisms by which talc might produce acute lung injury are unclear. One hypothesis is that the pneumonitis is related to the systemic absorption of talc; this is supported by the findings of Rinaldo and colleagues[77] and others who were able to demonstrate talc particles both in bronchoalveolar lavage fluid after talc pleurodesis and in virtually every organ at autopsy of one patient.[76–79] One of the most concerning studies comes from Rehse and associates,[80] who found that in a series of 78 patients, 33% developed respiratory complications or death after talc pleurodesis, and 9% developed ARDS rates that are significantly higher than those previously reported. Some investigators feel that the incidence of pulmonary complications is related to the dose of talc used for pleurodesis. Talc pleurodesis is still commonly used, however, and the relative merits of this in comparison to other methods are fiercely debated among experts and will be discussed later in this chapter.[78,81]

BLEOMYCIN. Bleomycin has been studied since the 1970s for its use as a sclerosing agent.[82,83] The recommended dose for intrapleural administation is 60 U or 1 U/kg body weight, and is often reduced to 40 U/kg in the elderly.[84] Administration and its side effects are similar to those with talc pleurodesis, with pleuritic pain, rigors, fever, and mild nausea as the main concerns.[84] Although it also is used commonly as a chemotherapeutic agent, only 40% is systemically absorbed from the pleural cavity, and bleomycin is not myelosuppressive when used in pleurodesis.[82] Several studies report mixed results for bleomycin compared with other agents. A large meta-analysis (1168 patients) from Walker-Renard and coworkers[85] demonstrated a 54% success rate with bleomycin versus a 67% success

rate with tetracycline and its derivatives (doxycycline, minocycline) and a 93% success rate with talc. Zimmer and colleagues,[86] in a subsequent prospective randomized trial, did not demonstrate a statistically significant difference in efficacy between talc (90% successful) and bleomycin (79% successful, $P = 0.388$). Patz and associates[84] directly compared bleomycin and doxycycline with a small-bore catheter and likewise did not find any statistically significant difference between the two agents. It is important to note that there are large cost differences between the different agents. In the aforementioned study by Zimmer and coworkers, the cost of the bleomycin was $955 per patient, compared with only $12 per patient for talc.[86]

PLEURODESIS WITHOUT THE USE OF AGENTS. Interestingly, two studies demonstrated that one could obtain relatively effective pleurodesis with thoracoscopy and chest tube placement for several days without instillation of a pleurodesis agent; these studies demonstrate a combined 62% success rate among 61 total patients.[87,88] Talc insufflation at the time of thoracoscopy does indeed increase the success rate to more than 90% of patients, however.[72] The fact that one can achieve decent pleurodesis and modest success rates without the use of any pleurodesis agent highlights our relatively poor understanding of the mechanism of pleurodesis and suggests that irritation of any sort can in fact lead to sclerosis and symphysis of the two pleural membranes. One potentially superior alternative to simple chest tube placement is to perform mechanical abrasion of the pleura. There are, however, no large series evaluating mechanical abrasion at the time of thoracoscopy for effectiveness, nor any comparing mechanical abrasion with any other techniques.[78,79] Mechanical abrasion can be performed with a thoracoscope (usually VATS) or via an open procedure. Pleural abrasion, in conjunction with bleb stapling, has been shown to be effective in preventing recurrent pneumothorax as a method of sclerosis in this nonmalignant entity.[89]

PREDICTING THE EFFECTIVENESS OF PLEURODESIS. It has been stated that low pleural fluid pH can identify patients who might experience a low likelihood of success with pleurodesis.[61] Low pH is thought to be a marker of increased metabolic activity of intrapleural tumor, and as such it represents a larger tumor burden.[36] Large tumor burdens might prevent apposition of the pleural membranes. Heffner and colleagues[90] reanalyzed individual patient data from both published and unpublished studies in 2000. Their analysis of 433 patients demonstrated that pleural fluid pH was the only independent predictor of pleurodesis failure, with an odds ratio of 4.46 when pleural fluid pH was lower than 7.28. A pH value of 7.15 or lower had a positive predictive value of 45.7% for pleurodesis failure. Although pH certainly helps predict pleurodesis failure, it is only of modest benefit in predicting outcome in individual patients, in that even those patients with a low pH in the analyzed studies had a greater than 50% success rate with pleurodesis. Because of these limitations, fluid pH should only be considered as an additional piece of information, not as a means to totally rule out pleurodesis.

Surgical Options Including Shunts

There are several surgical procedures—parietal pleurectomy, decortication, and pleuropneumonectomy—that may be attempted for management of a malignant pleural effusion. These procedures carry with them major morbidities, and they have proven to be no better than pleurodesis alone.[91] Surgical palliation might, however, be an option for some patients, particularly those who fail chemical pleurodesis, patients with loculated effusions, or those with large tumor rinds on the pleural surface. VATS permits direct visualization of the entire pleural surface, the potential for mechanical abrasion of the pleural surface, and removal of some adhesions and loculations. Talc poudrage via insufflation may be performed, and a pleuroperitoneal shunt may be inserted as well.[92] Surgical intervention should also be considered if lung reexpansion does not occur promptly after removal of an effusion via chest tube drainage; failure to reexpand suggests a rind of malignant tissue surrounding the lung, which may be further confirmed by a radiograph demonstrating a large effusion without mediastinal shift.[91] If such a cortex is seen at the time of VATS, it may be removed by conversion of the VATS to an open thoracotomy. This procedure might make pleurodesis and the restoration of a trapped lung possible. There is, however, a perioperative mortality of 12% associated with open procedures for decortication in these situations; therefore, this choice of procedure must be limited to an appropriate patient population.[91] Pleuroperitoneal shunts have a complication rate of approximately 12%, which is manifested mainly by shunt occlusion requiring replacement.[93] Peritoneal seeding of intrathoracic malignancy is a potential hazard but has not been definitively studied.[91]

Intrapleural Therapy

The rationale of intrapleural therapy is very appealing: Agents given directly into the pleural space can be directly toxic to tumor cells or are stimulants of the immune system that would ultimately be cytotoxic to tumor cells, thereby causing resolution of an associated malignant effusion. It should be noted that it is difficult to separate the cytotoxic effects of intrapleural therapy from pleural irritation to determine whether resolution of an effusion is due to cytotoxicity or pleurodesis. Bleomycin is a classic example of this phenomenon in that it is used as a sclerotic agent but also posseses antineoplastic activity. Intrapleural therapy, particularly chemotherapy, offers hope for patients who have a malignancy confined to the pleural space (e.g., mesothelioma) or for patients who have a higher disease burden in this location compared with other sites. A similar approach of locally directed chemotherapy has been used with particular success in the abdominal cavity, in cases of intraperitoneal chemotherapy for ovarian cancer.

Most agents that have been tried over the years have had limited success, and thus the idea of intrapleural therapy is still highly experimental. In terms of cytotoxic chemotherapy, many agents have been tried, including intrapleural 5-fluorouracil (5-FU), mitomycin, cisplatin, cytarabine, doxorubicin, and etoposide.[85] Shoji and associates[94] recently reported their phase II results using repeated intrapleural chemotherapy with an implantable access system (an infuse-a-port, similar to that used for subcutaneous venous access), placed by a VATS procedure. Patients received biweekly 5-FU and cisplatin. Such a system was used previously for the administration of interferon-γ in the treatment of malignant mesothelioma by Driesen and coworkers[95] and allows for repeated, easy administration of intrapleural drugs with minimal catheter-related toxicity. There was virtually no systemic toxicity, not even of the type that is usually associated with systemic therapy of these drugs, although the doses (5-FU 250 mg, cisplatin 10 mg) were far less than those typically used intravenously. Because of this observation, such a system warrants further testing as a method of both pleurodesis and treatment (neither of which was an endpoint in this dose-finding trial), particularly for tumors sensitive to agents that can be given intrapleurally.

As described in virtually all of these reports, the success rates with these cytotoxic agents are less than those seen with talc, doxycycline, and even intrapleural bleomycin. There is the potential for systemic absorption, and consequently potential associated systemic toxicity from such agents. The costs of antineoplastic agents are much higher than those for doxycycline and talc. Because talc is well studied, inexpensive, effective, and readily available, it would be difficult to find a superior agent for use solely in the treatment of effusions; for these reasons, intrapleural therapy still remains experimental excepting the use of agents that cause pleurodesis.

Long-Term Drainage Catheters

For some patients, effective pleurodesis will not be attainable. In others, the life expectancy could be too short to justify such invasive procedures or minor surgeries (such as VATS), but control of the effusion is still important. Therefore, other effective means for the

palliation of pleural effusions are necessary. This need ultimately led to the development of the Denver Pleurx system (Denver Biomaterials Inc., Golden, CO), the only tunneled catheter approved by the U.S. Food and Drug Administration (FDA) for pleural effusion management.[96]

The details of the Denver catheter are described in detail elsewhere, but it consists primarily of a 15.5 Fr silicone catheter with side holes and a polyester cuff that induces fibrosis along the tunnel; fibrosis decreases the risks of dislodgement, infection, and pericatheter leakage.[96] There is a proximal hub that prevents air entry or fluid egress, and it is capped when not in use. The catheter is usually placed into a free-flowing effusion or large locule under local anesthesia at the bedside. After initial drainage of no more than 1500 mL, drainage usually is performed every other day by the patient, family member, or a visiting nurse. The tube may be removed if three drainages in a row are scant and imaging shows no reaccumulation of fluid, suggesting spontaneous pleurodesis. The pivotal, approval trial for the FDA in 1999 compared the Denver catheter with doxycycline sclerotherapy.[97] Quality-of-life benefits were the same for the two groups, and there was a greater improvement in dyspnea with the Denver catheter; hospitalization was shorter in the catheter group (1 day vs. 6.5 days), and spontaneous pleurodesis developed in 46% of catheter placements, but effusions did recur 13% of the time. Sclerotherapy may be given through the catheter as well. Catheter complications occur about 15% to 20% of the time and include poor drainage requiring replacement, external catheter migration, tumor tracking along the catheter route, and infection (pleural fluid and skin). A recent report demonstrates symptomatic benefit (but not pleurodesis) for 91% of patients with trapped lung or multiloculated effusions.[96] The Denver Pleurx system is likely to offer significant benefit to all patients with pleural effusion and might allow many stable patients to undergo drainage and sclerosis on an outpatient basis.

Approach to Management

This subject is not without controversy, particularly with respect to the method of pleurodesis. Surgeons are likely to favor a surgical approach, such as VATS or thoracoscopy with pleurodesis attempts using talc or pleural abrasion, whereas pulmonologists and oncologists are likely to favor chest tubes and talc. Newer approaches with smaller chest tubes allow for outpatient management of pleural effusions in a more stable patient population. Cost considerations are important as well; surgical approaches can add significant expense because of operating room time and the involvement of anesthesiologists, although some of these expenses can easily be recovered by quicker hospital discharges and elimination of complications. Certain physicians have strong feelings one way or the other based on their interpretations of the literature and their personal experiences; well-performed clinical trials are difficult to conduct in these situations and are unlikely to occur. For example, because of the low, but very real incidence of ARDS (and mortality) associated with the use of talc that has not been seen with the use of any other agents, some clinicians feel that intrapleural talc should never be used; others recommend talc as long as lower doses (2–5 g) are used, although ARDS can be associated even at these doses.[76,78,79,82] Because many patients achieve pleurodesis through the presence of a chest tube alone, that sole measure might be sufficient for a good percentage of patients, and certainly a trial of this can be considered in stable patients. Although one general approach is shown in the algorithm, the overall scheme needs to be individualized for the patient, with one physician (usually the medical oncologist) as the coordinator to ensure optimal outcomes.

PERICARDIAL EFFUSION

Malignant pericardial effusions are much less common than both ascites and pleural effusions. They are often an event that occurs with end-stage disease, and patients are often switched to a purely palliative mode on discovery of a malignant pericardial effusion, particularly if tamponade or near-tamponade physiology is present. Because primary intracardiac tumors are exceedingly rare, the most common cause of pericardial effusions is tumor metastatic to the heart or pericardium. About one-third of patients with end-stage lung or breast cancer have evidence of pericardial metastases and/or effusion present at autopsy, although only a small number of these are symptomatic. Figure 60-2 provides a treatment approach to malignant pericardial effusions.

Etiology and Pathogenesis

The pericardial space normally contains a tiny amount of fluid that serves to reduce friction, maintain position of the heart in the pericardium and mediastinum, and provide a barrier against infection. Malignant cells obtain access to the space either by direct invasion from an adjacent tumor in the lung or mediastinum or by hematogenous or lymphatic spread. Retrograde progression of disease through the lymphatic channels draining the heart and pericardium results in a majority of effusions.[98] The potential space in the pericardial cavity is much less than in other potential areas of fluid accumulation (abdomen, lungs), and, depending on the compliance of the pericardium and the acuity of fluid collection, symptoms can develop rapidly. Furthermore, because even a small amount of fluid that develops rapidly can compress the heart and thus impede diastolic filling, malignant pericardial effusions are often difficult to manage and tend to carry a grim prognosis.

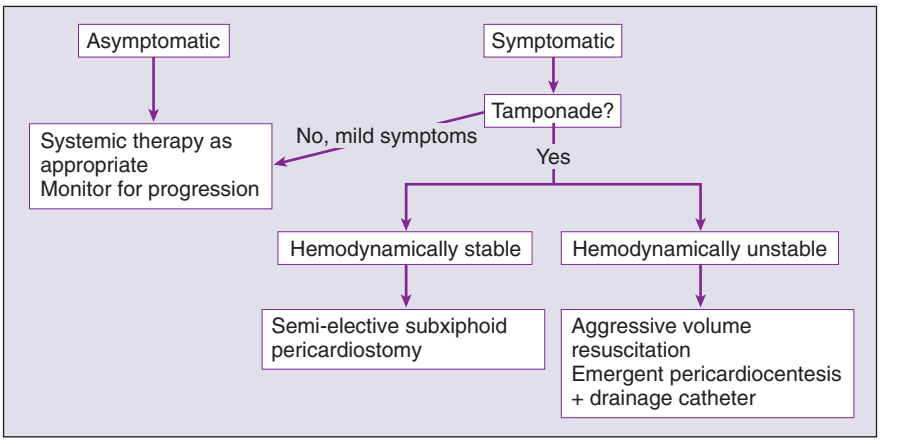

Figure 60-2 • Treatment approach to malignant pericardial effusions.

Clinical Presentation

The most common clinical manifestations of pericardial effusion are dyspnea, cough, chest pain, orthopnea, palpitations, tachypnea, tachycardia, and edema. Physical examination might show signs of a low-output cardiac state (coolness of the extremities, diaphoresis), jugular venous distention, distant heart sounds, narrowed pulse pressure, a pericardial friction rub, and a pulsus paradoxus. Pulsus paradoxus can be measured at the bedside using a sphygmomanometer that is deflated very slowly. During deflation, the first Kortokoff sounds are heard only during expiration and subsequently throughout the respiratory cycle. The difference in systolic pressures at which the Kortokoff sounds are heard between inspiration and expiration quantifies the pulsus paradoxus, which is normally no more than 10 mm Hg. Classically, Ewart's sign (dullness at the left infrascapular area due to bronchial compression by a large effusion) may be seen, but it is rarely observed in practice.[99] Electrocardiography might show low-voltage complexes across all leads (especially when compared with a prior study) and electrical alternans. Electrical alternans is considered a pathognomonic sign of pericardial tamponade; it is caused by a pendulum-like swinging of the heart in a fluid-filled pericardial cavity, but it is seen in less than 3% of cases.[100] Low voltage is defined as a total amplitude of the QRS complexes in each of the limb leads of 5 mm or less. Sinus tachycardia is often seen as well but has many other causes.

Diagnosis and Evaluation

A patient with a pericardial effusion, like a patient with pleural effusion, should be classified according to the likelihood of the effusion being malignant. The causes of pericardial effusions are shown in Table 60-3 and should be considered for all patients, because benign effusions clearly portend much better prognoses than malignant ones. Most effusions among patients with advanced cancer will, in fact, be due to that malignancy. An autopsy series of 3314 patients found that cardiac metastases occur in 10% of patients dying of cancer.[101]

Table 60-3 Major Differential Diagnosis of Pericardial Effusion by Etiology

Noninfectious
Malignancy (usually metastatic)
Myocardial infarction associated (Dressler's syndrome)
Uremia
Myxedema (rare cause of tamponade physiology)
Trauma (penetrating or nonpenetrating)
Chylopericardium
Acute idiopathic
Rheumatic fever
Collagen vascular disease (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, Wegener's granulomatosis)
Postsurgical (cardiac and intrathoracic)
Drug induced (procainamide, hydralazine, phenytoin, doxorubicin, isoniazid)
Infectious
Viral (coxsackievirus, echovirus, mumps, adenovirus, hepatitis, human immunodeficiency virus)
Bacterial (pneumococcus, streptococcus, staphylococcus)
Tuberculous
Fungal (histoplasmosis, coccidiomycosis, candida, particularly in immunosuppressed patients)

Many patients with malignant effusions have known advanced cancer, and therefore, there is little diagnostic dilemma. In those patients in whom advanced cancer is unlikely, a more thorough evaluation should be done.

Unfortunately, malignant pericardial effusion is often difficult to definitively diagnose.[100,102] Lymphatic obstruction by tumor might cause blockage without direct involvement of malignant cells in the pericardium, thereby making the usual gold standard test, cytology, unhelpful. Other causes such as prior radiation also can cause a pericardial effusion and should always be considered in a patient with such a history to avoid mistakenly classifying a patient as having advanced cancer.

Electrocardiogram and physical examination can be performed with particular attention to the aforementioned findings. Chest radiograph can show a water bottle-shaped pericardium or an enlarged silhouette. Echocardiogram should be performed, emergently if there are clinical signs of tamponade, and to assess the hemodynamic impact of an effusion; this test can detect a volume of fluid as little as 15 mL. Fluid first appears as a lucent space between the pericardium and epicardium, visible only during systole and behind the left ventricle; once reaching 25 to 50 mL, it may be seen throughout the cardiac cycle. Once the effusion can separate the pericardium from the epicardium, the pericardial image becomes stationary; once it extends behind the atrium, atrial wall motion is markedly increased. When tamponade physiology is reached, the echo-Doppler shows compression of the right side of the heart, increased respiratory variation of mitral and tricuspid inflow velocity, and right atrial and ventricular collapse during diastole. Assessment of tamponade should be based on clinical and imaging evidence, not just on the volume of fluid present. CT scan is also sensitive for diagnosing an effusion. It can detect as little as 50 mL of pericardial fluid and, similar to an echocardiogram, can give an idea of intracardiac masses.[103] MRI also can provide direct imaging of the pericardium.[104] Both of these tests can give some clues as to the nature of the fluid (bloody, serous, chylous), but they rarely provide clinically useful information. If there is a small, questionable effusion present, MRI can differentiate between a small effusion and epicardial fat. Because of the frequency with which oncology patients receive CT scans and MRIs, these studies often identify an effusion, prompting a further evaluation. Cardiac catheterization of the left and right sides of the heart can be used to confirm tamponade physiology (demonstrated by equivalence of pressures across all chambers) and improvement of these pressures after pericardiocentesis. However, this is usually not necessary.

Pericardiocentesis

Pericardiocentesis is usually performed with a 16- to 22-gauge needle (often a spinal needle) attached to a syringe inserted at roughly a 45-degree angle below the xiphoid process cephalad toward the tip of the left scapula. The needle is generally attached to an electrocardiograph machine during the procedure. Advancement into the myocardium usually reveals an injury pattern on the electrocardiogram. Although this procedure is usually performed semi-electively, pericardiocentesis occasionally must be done in an emergent setting, where removal of as little as 50 mL of fluid can improve hemodynamic status.[105] Complications include ventricular perforation, arrhythmias, and pneumothoraxes, and range from 5% to 20%. Complications are less likely (about 2%) when echocardiography is used to delineate the size and location of the fluid with respect to normal cardiac structures.[106] Among patients who are clinically unstable, with tamponade physiology and hypotension, vigorous volume resuscitation should be performed to increase cardiac filling pressures and cardiac output, even if signs of heart failure, such as edema or lung rales, are seen.[107]

Pericardial Fluid Evaluation

The evaluation of a patient with effusion depends on several characteristics. For those patients with small effusions and advanced

malignancy found incidentally on imaging, nothing needs to be done except a good physical examination and monitoring. For patients with a suspicion of cancer, or those patients who are symptomatic due to tamponade physiology, attempts at diagnosis and therapy should be made. Pericardial effusion is rarely the initial manifestation of malignancy. Two studies demonstrated that 7% of patients presenting with a pericardial effusion were ultimately given a new diagnosis of malignant disease.[108] Patients with no history of cancer who present with an effusion and absence of tamponade or significant clinical symptoms should be managed in a cautious, noninvasive manner. This approach usually includes treatment with anti-inflammatory therapy (such as nonsteroidal anti-inflammatory drugs) for potential idiopathic pericarditis for a period of 1 to 2 weeks.[108] Such management should be undertaken in cooperation with an experienced cardiologist. In terms of evaluating pericardial fluid, however, there are no specific guidelines for classifying an effusion as a transudate or exudate, or to further delineate the etiology of the effusion with criteria such as LDH, protein, glucose, pH, or cell count, as there are with pleural effusions. Interestingly, the best predictor for the behavior of a pericardial effusion of unknown etiology is from the clinical history of the patient. In a study of 322 patients from Sagrista-Sauleda and colleagues,[109] a large effusion with clinical signs of inflammation (two or more of the following: chest pain, fever, diffuse ST segment elevation, or friction rub) had a likelihood ratio of 20 for an idiopathic effusion, and those patients with tamponade without inflammation had a likelihood ratio of 2.9 for a malignant effusion.

It is worth repeating here that pericardial fluid, unlike pleural fluid, cannot be classified as a transudate or exudate. Nevertheless, aspirated fluid should be sent for cell count, cultures (if there is a possibility of infectious etiology), and cytology. The sensitivity of cytology for malignant pericardial disease varies widely, from 50% to 90%.[100,102] Reasons given for false-negative cytology include limited cellularity in the specimen, shrouding by blood, or the absence of an expert cytopathologist. Interestingly, DNA diploidy obtained from flow cytometry has been found to correlate with benign cytology, and aneuploidy is associated with malignant cytology but is not sensitive enough to be definitive.[110] It is uncommon for pericardial fluid cytology to provide the first diagnosis of a malignancy. In one study of 47 pericardial fluid specimens, only 10 were positive for malignancy, and none of these represented the first diagnosis of a malignancy in a patient.[111] It is imperative, however, that the physician realize that a negative cytology does not exclude malignant pericardial disease. By the same token, patients with a history of cancer could have an effusion for other reasons, particularly radiation.[112] One should be cautious, then, in providing the diagnosis of a malignant effusion (and usually advanced, incurable malignancy) unless definitive cytologic evidence is seen. For patients with a negative cytologic specimen but suspected malignancy, pericardial biopsy may be performed. Prospective studies have demonstrated a 5% to 20% positive yield for diagnostic pericardial biopsy specimens.[108] This is probably due to the blind nature of the biopsies and to the practice of taking biopsy specimens from the parietal pericardium, whereas the principal site of malignant involvement is the visceral pericardium, site of the epicardial lymphatics. The positive yield is much higher (54%) for biopsies performed during therapeutic (subxiphoid pericardiostomies) procedures; although there might be some selection bias, therapeutic procedures allow the pericardium to be visualized more directly and thus permit more accurate biopsy site selection.[108]

Pericardioscopy is a relatively new technique available in specialized centers that allows endoscopic inspection, aimed biopsies, and drainage of both pericardial surfaces, and can even be used to obtain epicardial biopsy specimens.[113] An expansion of this technique, using a perDUCER catheter, can be used for endocardial biopsies and thus far has been used for diagnosing and managing patients with nonmalignant pericarditis. This technique, however, also allows for guidewire and catheter placement, by which intrapericardial therapy may be administered. Ultimately, this technique might be expanded for use in evaluating and managing malignant pericardial etiologies.[114]

Treatment and Management

Asymptomatic malignant effusions do not require therapy. Volume depletion should be avoided, because adequate right ventricular preload is essential to allow sufficient cardiac output. For symptomatic patients pericardiocentesis may be performed, either as initial therapy or to allow stabilization until a more definitive procedure can be performed. Unfortunately, as many as three quarters of patients have recurrence and require treatment.[115]

Chemotherapy

A limited number of patients might benefit from systemic chemotherapy if such options are available (i.e., if they are expected to be chemotherapy responsive), or if a delay in treatment increases the risk of significant systemic progression. Such chemotherapy-sensitive tumors include leukemias, lymphomas, germ cell tumors, and even breast cancer. Although there might be reluctance on the physician's part to treat a malignant pericardial effusion with chemotherapy because of the feeling that even moderate effusions could become life threatening, there is ample evidence in the literature to support the use of chemotherapy in many circumstances. There are reports of successful resolution of effusions for patients with chronic myelomonocytic leukemia with hydroxyurea or chemotherapy.[116] Vaitkus and associates[115] reviewed the experience of treatment of 46 patients, mostly with breast cancer or lymphoma, who had malignant pericardial effusions treated with chemotherapy (38 of 46 patients initially having undergone therapeutic pericardiocentesis), and reported that systemic chemotherapy prevented recurrence in 67% of these patients. A special entity, primary cardiac lymphoma, although it responds to traditional chemotherapeutic regimens such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), is not responsive to radiotherapy and carries a poor prognosis, probably due to myocardial infiltration and tissue necrosis that might precede or result from chemotherapy.[117] Several researchers have reported pericardial effusions from leukemias with the presence of blast cells in the pericardial fluid, which were treated with emergent pericardiocentesis (because of tamponade) and immediate chemotherapy with good outcomes.[118] Other primary cardiac tumors, such as sarcoma and intrapericardial pheochromocytoma, tend not to be as responsive to chemotherapy, so control of the effusion should be the initial focus.[119] Vaitkus and coworkers[115] also reviewed the experience of 54 patients treated with radiotherapy and found that this procedure was successful two thirds of the time, mainly in cases of hematologic malignancies and breast cancer (93% and 71% success rates, respectively) although 45% of patients with other solid tumors also had successful control. It should be noted, however, that radiotherapy might induce scarring or fibrosis that makes further interventions more difficult, so this procedure should be saved for end-stage patients declining other interventions. Those patients with physiology demanding immediate intervention should have some sort of drainage performed, whereas those that are stable and potentially chemotherapy responsive should be considered for chemotherapy.

Percutaneous Tube Pericardiostomy

For patients not amenable to systemic therapy for whatever reasons, percutaneous drainage is performed. Because the rate of fluid reaccumulation is very high, prolonged catheter drainage is often used in addition to pericardiocentesis. This is now common practice, because it allows a more complete drainage than that attainable by pericardiocentesis alone. After the pericardiocentesis, a guide wire is left in place, and a pigtail catheter is placed via the Seldinger catheter-over-a-guide wire technique. The catheter is left in place for several days and is not removed until the drainage is less than 20 to 30 mL per 24-hour period, at which point the catheter is removed. There is a

small risk of infection with a catheter remaining in place for several days.[120] The catheter should be subject to intermittent rather than continuous drainage to maintain catheter patency. With this technique, however, there is still a relatively high likelihood that the fluid will reaccumulate unless other steps are taken. Unless the patient has a very short life expectancy (which still might require a repeat drainage) or, in the physician's mind, the patient has a tumor from which one would expect a response from chemotherapy, other interventions will be required.

Surgical Approaches

SUBXIPHOID PERICARDIOSTOMY (SUBXIPHOID PERICARDIAL WINDOW). The subxipoid pericardial window, first reported by Napoleon's surgeon, Larrey, in 1829,[121] is now the most common surgical procedure for pericardial effusions. The procedure may be performed under local anesthesia with intravenous sedation; a small incision is made from the xiphoid process caudally for approximately 5 cm, and the xiphoid is either bisected or resected. After dissection to the pericardium, adhesions and masses are identified, a 2- to 4-cm^2 piece of pericardium is resected, and a drainage tube is placed. The drainage tube remains in place for several days, which could allow for sclerosis simply by acting as a pericardial irritant.[122] Allen and colleagues[123] retrospectively compared the experience of 117 patients who underwent either percutaneous catheter drainage with ultrasound or fluoroscopic guidance ($n = 23$), or subxiphoid pericardiostomy ($n = 94$). Complication rates were 17% in the percutaneous drainage group and 1% in the pericardiostomy group, with 4% mortality and a 30% recurrence rate in the percutaneous drainage group, compared with 0% mortality and 30% recurrence in the pericardiostomy group. In the percutaneous group, pigtail catheters remained in place for an average of 4.2 days, and mediastinal drainage was maintained for 5 days in the surgical group, so there was minimal difference in the number of days hospitalized. The advantages of the surgical group come with the caveat that the 23 patients who underwent percutaneous drainage did so because they were deemed to be too hemodynamically unstable to undergo a surgical procedure, and thus bias could account, at least in part, for the advantages of subxiphoid pericardiostomy. For all patients in this study, the median survival time of those patients having a malignant pericardial effusion was a paltry 2.2 months, with 13.8% of patients having a 1-year survival. No patients who underwent pericardiostomy developed constrictive pericarditis. For patients who are hemodynamically stable, the subxiphoid pericardiostomy can and should be considered in lieu of percutaneous catheter drainage.

ALTERNATIVE SURGICAL TECHNIQUES. Before the revival of the subxiphoid pericardial window, alternative surgical techniques had been used, including sternotomy and pericardiectomy or creation of a window via thoracotomy or VATS.[124,125] Initially, the experience of Piehler and associates[124] with 145 patients suggested that the extent of pericardial resection affected the recurrence rate, thus favoring open surgical drainage rather than the easier subxiphoid pericardiostomy. Several recent studies, however, have demonstrated no difference between the open or VATS procedures and subxiphoid pericardiostomies.[126,127] Vaitkus and coworkers[115] reported a decreased number of further pericardial complications when subxiphoid pericardiostomies instead of open pericardiectomies were performed. There is a much lower incidence of postoperative complications (including pneumonia, thrombosis, arrhythmia, respiratory failure) after subxiphoid pericardial drainage compared with transthoracic pericardial resection (10% vs. 50%, respectively).[126,127] VATS offers a minimally invasive technique for treatment of effusions but still requires general anesthesia and the ability to tolerate single-lung ventilation, so it offers little advantage over subxiphoid pericardiostomy. It should therefore be saved for situations in which the subxiphoid approach fails, in which a VATS approach would assist with evaluation or treatment of simultaneous lung pathology, or in which a larger specimen of pericardium is required for clearer observation and evaluation of an undiagnosed effusion.[127,128] A pericardial-peritoneal shunt with a Denver-type catheter and pump, similar to that used in pleural effusions, has been used for some patients with success, but its use should be limited to patients whose effusions are refractory to other management techniques.[128]

PERCUTANEOUS BALLOON PERICARDIOTOMY. Percutaneous balloon pericardiostomy is an extension of a percutaneous pigtail catheter, except that a balloon-dilating catheter (20 mm diameter and 3 cm length) introduced over a guide wire creates a nonsurgical pericardial window. Ziskind and colleagues[129] provided the results from the first 50 patients treated with this technique. The procedure was considered successful in 46 of the 50 patients, with two patients requiring early operation for a bleeding vessel and persistent drainage and two patients requiring late drainage for recurrent tamponade. Minor complications included fever, thoracentesis, requirement for chest tube placement, and pneumothorax. The most significant complications were the development of pleural effusions requiring drainage. Subsequent studies have reported up to 100% success rates.[130,131] Long-term outcome from these patients was still poor, with a mean survival time of 3.3 months. The procedure has been slow to gain acceptance because of the need for specialized training and equipment but could become a more popular option as interventional radiologists become adept in this technique.

INTRAPERICARDIAL SCLEROSING AGENTS AND CHEMOTHERAPY. For pericardial effusions, as for pleural effusions, sclerosing agents may be used, and in general, do work.[132] Maher and associates[133] reported their experiences with 93 patients who underwent pericardial fluid drainage, followed by sclerosis with either doxycycline or tetracycline. A median of three instillations was required and was able to control the effusion 88% of the time. Shepherd and colleagues[134] reported similar results (75% success rate). The most common complaints with this procedure are pain (intrapericardial lidocaine should be injected before the sclerosing agent) and arrhythmias. Bleomycin has been compared with doxycycline in a prospective, randomized study showing equal efficacy and less pain; therefore, it should probably be considered instead of doxycycline as the sclerosing agent of choice.[135]

The use of direct intrapericardial instillation of chemotherapy and biologic therapy has been examined in several settings with limited data. For pericardial as for pleural effusions, it is somewhat difficult to determine whether intrapericardial chemotherapy functions because of tumor cytotoxicity or pericardial irritation leading to sclerosis, because the physiology and mechanisms of sclerosis are poorly understood. Imamura and coworkers[136] looked at the use of OK-432 (a heat-treated lyophilate of *Streptococcus pyogenes* A3) instilled directly into the pericardium after fluid drainage. All 10 patients in this study achieved complete control of the pericardial effusion, 7 of the 10 with only one treatment, for an average of 10.8 months. Complications were primarily fever and chest pain. Hypotension was also seen and was thought to be a result of rapid fluid reaccumulation in several patients. Moriya and associates[137] explored the use of intrapericardial carboplatin in 10 patients with advanced non-small-cell lung cancer; 8 patients showed complete regression of the effusion with minimal toxicities and minimal systemic distribution of the carboplatin. Cisplatin is the best-studied therapy, with overall success rates of 67% to 87%.[138] One of the earliest studies on the use of cisplatin comes from Fiorentino and colleagues, who gave five patients intrapericardial cisplatin (50 mg over 5 minutes 5 days in a row, with courses repeated every 2–3 weeks if there was fluid recurrence).[138] There was a 60% complete response rate in the effusion. Side effects were limited to mild nausea with no hematologic or renal toxicities. Kawashima and colleagues[139] gave intrapericardial aclarubicin to five patients with pericardial tamponade secondary to malignant effusions; in four of the five, physicians were able to

remove the pericardial catheter, and two of the five patients experienced a complete remission of the pericardial effusion. All patients demonstrated disappearance of the malignant cells from the pericardial space, with no cytopathologically demonstrable pericardial recurrence. Mitoxantrone and interferon have also been used, with similar results.[140,141] With intrapericardial use, however, there is a significant risk of pain, a requirement for multiple instillations, and a possibility of constrictive pericarditis for patients with a prolonged survival. Because of these limitations the use of pericardial sclerosis is declining, and intrapericardial chemotherapy remains highly experimental.

Summary

Malignant pericardial effusion is a dreaded complication of malignancy, indicative of advanced disease in most cases. The oncologist should take care to ensure that advanced disease is in fact present, and that the effusion has no other etiology in a patient who has a history of cancer. Management should be focused on immediate resuscitation and control of life-threatening symptoms. Asymptomatic patients with cancer and an effusion can be managed conservatively and observed with either repeat careful physical examination or serial echocardiograms. If there is a strong likelihood of tumor response to chemotherapy, or if chemotherapy is absolutely required (e.g., in cases of lymphoma or life-threatening systemic disease), it should be started as soon as possible. If emergent pericardiocentesis is required, it should be performed with placement of a percutaneous pigtail catheter. For patients who are clinically more stable but unable to be treated adequately with systemic chemotherapy, one could consider either percutaneous drainage or subxiphoid pericardiectomy under local anesthesia, with probably similar results; the latter demonstrates a lower rate of recurrence and is the procedure of choice. Such a management approach has been validated in several studies.[123,142] Use of other techniques, such as VATS, percutaneous balloon pericardiotomy, sclerosis, or intrapericardial chemotherapy offers new potential options for these patients should primary therapy fail.

ASCITES

Malignant ascites is a frequent occurrence in the patient with malignancy and is usually an indication of peritoneal carcinomatosis. Like malignant pericardial and pleural effusions, it is often a harbinger of advanced disease. It accounts for 10% of cases of ascites, and 1-year survival is less than 10%.[143]

Etiology and Pathogenesis

The peritoneal membrane contains lymphatics, which serve to collect fluid, proteins, cells, and other substances and return them to the systemic collection. There is a specialized anatomic feature, the stomata, which are relatively open connections that connect the abdominal cavity to submesothelial lymphatics and that are the sites of most lymphatic drainage of the abdomen.[144] Fluid accumulations, as in the pleural and pericardial cavities, can occur if there is overproduction or decreased drainage of fluid. Studies in adults have demonstrated that increased fluid production is a major cause of ascites among patients with peritoneal carcinomatosis.[145] Animal models in which mice were given intraperitoneal injections of tumor cells have demonstrated that obstruction to lymphatic flow can cause ascites as well, and this has been confirmed using lymphoscintigraphy in humans.[146,147] VEGF, an angiogenesis factor expressed by most tumors (including those that spread to the peritoneum), has been demonstrated in vivo to cause increased fluid production and to influence the development of ascites.[148–150] VEGF is probably the single biggest mediator of ascites production. Interleukin-2, tumor necrosis factor, interferon-α, and matrix metalloproteinases have also been implicated as factors contributing to the formation of ascites.[151–153] Intraperitoneal protein accumulation decreases the difference between plasma and peritoneal oncotic pressures and subsequently decreases filtration into the lymphatics.[154] Free fluid flow into the abdomen therefore increases. Fluid protein concentration can reach oncotic pressures similar to that reached in peritoneal dialysis, which is very effective in causing ultrafiltration.[155] The most common tumors that cause ascites are those of gastrointestinal and pelvic organs; the single most common is ovarian cancer.

Diagnosis and Evaluation

Many patients with malignant ascites have small amounts of fluid first noticed on imaging studies, such as those done for staging or evaluation after therapy or for another complaint. Symptoms resulting from large amounts of fluid usually include abdominal distention (such that trousers no longer fit properly), early satiety, nausea, vomiting, an increase in weight, edema, and shortness of breath. Physical examination in the evaluation of ascites is notoriously difficult, especially among obese patients with lesser amounts of fluid. The physical examination has been shown to be from 50% to 94% sensitive and from 29% to 82% specific, with ultrasound being the gold standard.[156] Physical examination can demonstrate a fluid wave, shifting, or flank dullness. The absence of flank dullness is the most accurate predictor against ascites, but one requires 1500 mL of fluid to be present to notice flank dullness. If there is suspicion of ascites in any patient, ultrasound is the easiest, fastest, and cheapest method of ascertaining a diagnosis of ascites; one series demonstrated that as little as 100 mL of fluid can be demonstrated on an ultrasonogram.[157] Radiologic studies such as CT or MRI can also give clear-cut evidence of ascites, but these are usually not necessary as part of the first-line evaluation. Plain-film radiograms can show a ground-glass appearance to the abdomen, loss of detail, haziness, or floating bowel on supine films but is nonspecific. Figure 60-3 gives a treatment approach to malignant ascites.

For many patients with known malignancy, the presence of ascites will not alter management, because advanced disease is already present. For some patients, particularly those without a known malignancy, the detection of ascites requires an appropriate evaluation to determine the etiology. For these patients, the differential diagnosis includes CHF, alcoholic cirrhosis, cirrhosis due to hepatitis B or C, previous abdominal surgeries, nonalcoholic steatohepatitis, and other

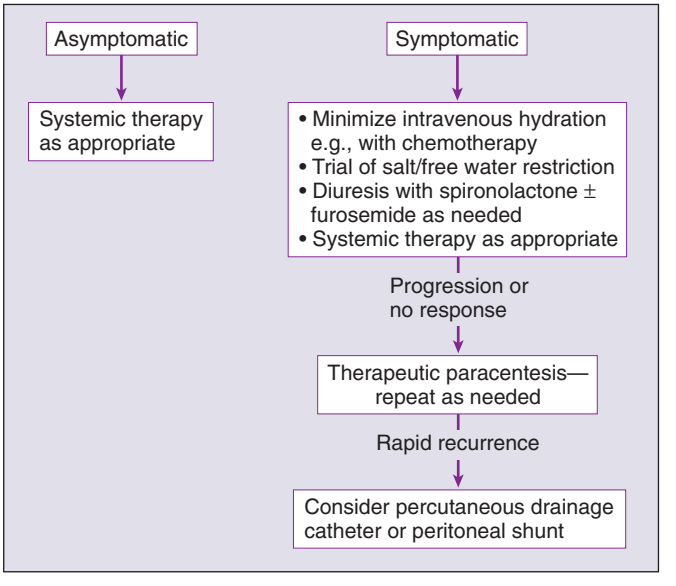

Figure 60-3 • Treatment approach to malignant ascites.

causes of increased portal venous pressure. It should be remembered that patients with a history of cirrhosis have a predilection for hepatocellular carcinoma.

In most cases of ascites in which malignancy is a possibility, cross-sectional imaging, such as with a CT scan, should be performed to seek a primary tumor site, hepatic metastases, or other evidence of peritoneal seeding. Women in particular should have either an ultrasonogram or CT scan to evaluate the ovaries. After this, a diagnostic abdominal paracentesis is indicated. Ultrasound may be used during the procedure to localize ascites and minimize the risk of injury to abdominal organs (particularly the liver and intestine).[157] After local anesthesia, an 18-gauge needle attached to a 25- to 50-mL syringe is inserted into a site indicated by ultrasound or into the areas percussed as dull in the flanks, if sufficient fluid is present. If cytology is required, several liters of fluid can be obtained using vacuum bottles. Even among patients with coagulopathies (such as cirrhosis), the risk of developing a hematoma is only 1% and that of causing peritonitis or hemoperitoneum is 0.1%; therefore, one can usually proceed without the use of clotting factors or platelets.[158] Patients on therapeutic anticoagulation should have their anticoagulation withheld for several days before paracentesis.

Visualization of the fluid can provide some useful clues; clear fluid is usually associated with cirrhosis. Infected fluid is cloudy. Milky fluid can indicate chylous ascites and should be sent for triglyceride evaluation. Such fluid often has triglyceride levels greater than 200 mg/dL and often as high as 1000 mg/dL. Some studies have demonstrated that the most common cause for chylous ascites is malignancy, although others have found cirrhosis as the primary cause.[159,160] Either way, if chylous fluid is found it should heighten the physician's attention to the potential for malignancy. Heterogeneously bloody fluid is associated with a traumatic tap, whereas homogeneously bloody fluid indicates prior bleeding (i.e., a nontraumatic tap) and could indicate malignancy. Ascites is bloody in up to one half of patients with hepatocellular carcinoma and in 22% of all patients with malignant ascites.[161] Spontaneous bacterial peritonitis (SBP) does not tend to develop to the extent that it does among patients with cirrhotic ascites, unless there has been previous surgery or a previous paracentesis. All patients should be evaluated for signs of SBP (including fever and abdominal pain), and a cell count on the ascitic fluid should be done; a polymorphonuclear cell count greater than 250 per cubic millimeter should prompt the use of empiric antibiotics in appropriate situations.[158]

The first and most important step in the evaluation of the patient with ascites of unknown etiology is to differentiate those causes arising from portal hypertension (usually cirrhosis) from other causes (including malignancy). The best test for this determination is the serum-to-ascites albumin gradient, which is the difference between serum albumin and ascitic fluid albumin. Low-protein ascites is usually from portal venous hypertension. A gradient equal to or greater than 1.1 g/dL indicates portal hypertension with 97% accuracy, whereas a lower gradient (high-protein ascites) indicates a lack of portal hypertension and possibly the presence of a malignancy.[160] The classical division of ascitic fluids into transudates and exudates using LDH, protein, and their serum-to-ascites ratios, akin to pleural effusions, has been shown to be not as useful. Total protein is not particularly useful for diagnosis of malignant ascites, although a value of less than 1 g/dL is useful in predicting a patient's increased risk for SBP.[162] This range of values is usually seen in cirrhotic patients. A glucose value below 50 mg/dL has been associated with malignancy but also can be indicative of infection.[27] An ascites-to-serum ratio of LDH greater than 1 indicates that the enzyme is actively being produced in the ascitic fluid and suggests malignancy, but not as specifically as with a pleural effusion. Triglyceride levels should be obtained in milky ascites but might or might not be particularly helpful. Other chemistries and cultures should be obtained if diagnoses other than malignancy are entertained.[143,158] Siddiqui and associates[163] have demonstrated that fibronectin is up to 100% sensitive and specific as a marker of malignant ascites in a small study of only 12 patients with malignant ascites; others feel that this test is not helpful, and it is not used routinely.[164]

The detection of tumor cells by cytology remains the gold standard for the detection of malignancy. For patients with peritoneal carcinomatosis due to cellular exfoliation into the ascitic fluid, malignant cells can be detected nearly 100% of the time.[161] On the other hand, patients with liver metastases and portal venous obstruction, chylous ascites from lymphomas and lymphatic obstruction, or hepatocellar carcinoma, might not have a positive ascitic fluid; the overall sensitivity for cytology is therefore on the order of 40% to 75% when 500 mL of fluid is obtained.[163,165] To increase the detection of tumor cells and differentiate mesothelial cells from malignant cells, immunohistochemistry for cytokeratin, vimentin, leukocyte common antigen, S100, CEA, HMB45, and other markers may be performed on the cytologic specimen. A small study by Loewenstein and coworkers[166] has shown that an elevated CEA level in ascitic fluid is a good marker for malignancy, although this has not been well validated and requires further evaluation. Elevated serum or ascites CA-125 and CEA levels certainly should prompt a careful evaluation for malignancies, particularly for ovarian cancer in women with highly elevated CA-125, although neither marker is specific for any particular malignancy (or even malignancies in general) and might reflect only intra-abdominal pathology rather than malignant disease.[154] No known studies have correlated levels of CA-125 and CEA with the likelihood of a malignancy, but one would expect higher levels of tumor markers to have a greater association with malignancy.

Women with only ascites and no evidence of primary malignancy on cross-sectional imaging present an interesting situation. These patients should undergo laparoscopic evaluation, at which time biopsy samples are taken from both ovaries, ascitic fluid is sampled, and random biopsies are performed throughout the abdomen. If ovarian carcinoma or adenocarcinoma consistent with ovarian carcinoma is seen, the procedure is converted to a laparotomy; it has been shown that aggressive surgical debulking to minimal residual disease improves response, survival time, and response to aggressive chemotherapy (usually taxane- and platinum-based) among patients with ovarian carcinoma. Such an approach can lead to a long disease-free interval and significant long-term survival. Even small, low-grade ovarian tumors, with the primary tumor not seen on imaging, can lead to diffuse peritoneal contamination, and hence, to the development of ascites.[167,168] Some patients might have papillary serous carcinoma of the peritoneum, which arises from the peritoneal surface but shares a common histogenesis with ovarian tissue and also might be difficult to detect on cross-sectional imaging. It is important to remember that patients with ovarian cancer with ascites are classified as only stage III, and hence this rather large subgroup should be treated aggressively whenever possible. Papillary serous carcinoma of the peritoneum should be treated in a fashion similar to ovarian carcinoma.[169] Laparoscopy should be performed diligently. In a study from van Dam and colleagues[170] of 104 women with advanced ovarian cancer who underwent laparoscopy for diagnosis, 58% of patients had tumor implanted at the trocar site when only the skin was closed at the conclusion of the procedure, but in those in whom all abdominal wall layers were closed, only 2% had such implantation. For patients with ascites, there is a risk of prolonged fluid drainage at trocar placement sites. In one study, 2 of 92 patients developed peritonitis and died after undergoing laparoscopic procedures in these circumstances.[171] For a more detailed discussion of the diagnosis and management of ovarian carcinoma, the reader is referred to Chapter 93.

Management

As with pleural and pericardial effusions, it is important to distinguish the appropriate situations in which to treat malignant ascites. Small amounts of ascites can be tolerated very well or not even

noticed. On the other hand, when symptoms such as dyspnea, abdominal pain, fatigue, anorexia, or early satiety arise, treatment can be required. The most worrisome sign is dyspnea, which can arise either from an inordinate amount of weight being carried by the patient or by compression of the pleural cavity leading to a decrease in total lung capacity. Clearly, the overall clinical status of the patient should be taken into account when making these treatment decisions. In light of the fact that ascites does not usually pose a life-threatening situation, and that the disease might respond well to systemic therapy in instances such as ovarian cancer, systemic chemotherapy can be considered front-line therapy. For other situations, such as pancreatic cancer, because responses to therapy are much less frequent, one would consider an early direct approach to control of the fluid. Certainly, in either case, because most techniques to manage fluid (e.g., diuresis, paracentesis) are relatively easy and performed on an outpatient basis, one could combine systemic chemotherapy with these other options.

Fluid Balance Management

Intravascular fluid that leaks into nonvascular compartments, also known as third spacing, results in decreased renal blood flow and consequently to sodium and water retention by the kidney, which ultimately leads to the propagation of further third-spacing of fluids. The use of fluid management techniques to manage malignant ascites is controversial. Because tumors that arise from peritoneal seeding are not caused by pressure gradient shifts, some feel that management using diuretics and salt management techniques that affect renal handling of excess fluid and sodium are useless, whereas others believe they can be effective.[172,173] One can attempt dietary restriction of sodium to less than 2 g/day and also restrict free water intake to help decrease the amount of ascites. Unfortunately, to the patient with advanced malignancy, this strategy can prove overly burdensome, particularly when the patient is undergoing other treatments such as chemotherapy. At a minimum, however, the physician should restrict intravenous hydration as much as possible when chemotherapy is being administered.

The next step in this mode of management is the use of diuretics, which offers a noninvasive mechanism to help maintain fluid balance. The advantage of this approach is that it can be done easily on an outpatient basis with oral medications, and it is even possible for patients to perform minor self-adjustments in medication after instruction, which also restores to patients a degree of control over their own health. A distal tubule diuretic such as spironolactone is usually used first. Such agents act on the distal nephron, thereby minimizing the chances for compensation by more distal renal elements. More important, it works at the site of the renin-angtiotensin-aldosterone axis, which is upregulated due to decreased renal perfusion when significant third-spacing occurs, as in ascites. Doses start at approximately 25 to 50 mg/day and can go as high as 200 mg/day. Painful gynecomastia can result, and if this proves bothersome, amiloride is an alternative. Spironolactone alone often is insufficient and not immediate in its effects. In such cases, furosemide (usually starting at 20 mg/day and titrated to much higher doses) has been used for either a short period or, commonly, in combination. Razis and associates,[174] along with others, however, have pointed out that loop diuretics such as furosemide are minimally effective, if at all, in the management of ascites. The maximal ascitic reabsorption rate is 930 mL/day, and patients should therefore be instructed to weigh themselves daily and allow no more than a 0.5 to 1 kg/day loss in weight; in the presence of peripheral edema, slightly more weight can be lost per day.[144] Overdiuresis can result in hypotension, volume depletion, azotemia, and electrolyte abnormalities (particularly hyperkalemia with spironolactone, hypokalemia with furosemide), and thus patients should be monitored closely. Patients should be instructed to monitor their weights between physician visits and even to modify the doses of diuretics used when certain weight goals are met.

Unfortunately, although diuretics initially are used by many physicians for the control of ascites and certainly are easy to administer, they are not very effective.[175] Malignant ascites is usually not very responsive to diuresis because the pathogenesis is usually not related to increased portal pressure, as it is in cirrhosis, but rather is related to increased fluid production from the presence of tumor cells in the peritoneum.[176] In the rarer cases in which massive hepatic metastases are present and portal hypertension is the etiology of ascites, patients are much more likely to respond to diuretics.[177] Pockros and coworkers[176] confirmed this, finding that patients with a large amount of hepatic metastases (and hence elevated portal venous pressure) had a serum-to-ascites-albumin gradient similar to cirrhotics and were more likely to respond to diuretics, whereas those patients with peritoneal carcinomatosis were less likely to respond to diuretic management of ascites. Although there are no direct comparative studies, it is because of these clinical experiences that diuresis is used much less frequently than paracentesis as a means of controlling ascites.[175]

Paracentesis

Paracentesis is the most frequently used and most effective management approach to malignant ascites, but its effects are only temporary.[175] Large-volume paracentesis can improve shortness of breath and early satiety quickly. Because one removes the fluid and not the cause of the fluid, however, there is rapid redistribution to the peritoneal cavity. Because of this, large-volume paracentesis can result in intravascular volume depletion, hypotension, azotemia, and other consequences of dehydration.[144] Colloidal volume expansion has been tried as a means to prevent these sequelae. In a randomized trial in cirrhotics by Gines and colleagues,[178] 105 patients receiving large-volume paracentesis were randomly assigned to receive albumin or not. Patients not receiving albumin were more likely to show signs of hemodynamic deterioration, worsening renal function, and hyponatremia (20.8% vs. 3.8%). Most of these patients, however, simply had laboratory abnormalities, because no advantages in clinical morbidity or survival ever have been demonstrated in this or any other study.[158] Further, a 5-L paracentesis would require approximately 50 g of albumin at a cost of up to several thousand dollars and would change a quick procedure into either a day-long one or one requiring an overnight hospital stay, which is not easily justified for patients with advanced malignancies in the absence of proven benefit.[7] Because of this, the use of any colloidal expanders is difficult to justify.

Complications of repeated paracentesis include bleeding, pain, the induction of peritonitis, and bowel perforation. The presence of loculated ascites can make adequate removal of fluid to provide a symptomatic benefit nearly impossible, and it can increase the risk of the procedure. Ultrasound guidance should be used to decrease the risk of complications.

Peritoneovenous Shunting

Peritoneovenous shunting, introduced by LeVeen for alcoholic liver disease, is effective in malignant ascites.[179] Because patients with intractable and debilitating ascites have a median survival of only 6 to 33 weeks and could probably be managed more easily with repeated paracentesis, patients selected for shunting should have an expected survival of several months requiring frequent paracentesis, as demonstrated by repeated recurrence of the ascites after drainage.[180] The device consists of a long, perforated tubing inserted in the peritoneal cavity, a tubing that inserts into the superior vena cava, and a one-way valve that connects the two. There are two types of shunts, the LeVeen shunt and the Denver shunt; the latter has a one-way pump that can be used by the patient or physician to clear debris in the shunt or valve. On inspiration, intrathoracic pressure is lowered and the one-way valve opens, allowing a baseline pressure difference between the thoracic cavity and abdominal cavity to increase by 3 to 5 cm H_2O from its baseline difference of 5 to 15 cm H_2O, causing fluid to flow across the pressure gradient and drain into the superior

vena cava. Placement of the shunt can be done under local anesthesia, with two to three separate incisions made. Parsons and associates demonstrated no survival or quality-of-life advantage when peritoneovenous shunting was compared with repeated paracentesis.[177] Peritoneovenous shunting is effective in controlling ascites between 62% and 88% of the time.[181,182] Early studies demonstrated a large number of pump failures due to occlusion (up to nearly two thirds), but more recent studies have demonstrated lesser rates of occlusion.[179,181,183] The manual pump present in the Denver device for clearing blockages has not demonstrated an advantage in the maintenance of shunt patency.[181] Flushing the pump and administration of thrombolytic agents might be able to restore patency and avoid pump removal and replacement in instances of pump failure.

Patients with ascites that is cytologically negative for tumor cells have a much longer shunt life than those patients with cytologic evidence of malignancy; this is probably due to sludging of the pump system with more viscous tumor cells or debris in the latter case. Immediately after placement of the pump, CHF can result from a rapid increase in intravascular volume from infusion of a large amount of ascitic fluid; this risk can be minimized by performing a large-volume paracentesis just before the procedure. Coagulopathy—specifically, disseminated intravascular coagulation (DIC)—is common when the pumps are used in cirrhotic patients, but not in those with malignant ascites (rate of 4%).[184] DIC probably arises as a result of fibrinolytic activity of ascitic fluid, and fibrinolytic activity is decreased in patients with malignant ascites.[185] Those patients with malignant ascites and good preshunt hepatic function seem to be at an even particularly low or negligible risk for DIC.[186,187] Widespread dissemination of tumor cells from the peritoneum to the lungs has been demonstrated in several studies.[179,183,187] The clinical significance of additional tumor emboli among patients with advanced refractory malignancy, although it represents a major potential complication of shunt placement, is unclear. Infection also remains a concern, but the incidence of shunt-induced peritonitis is much lower among patients with malignant disease than among those with cirrhosis, probably because of the higher levels of protein and immunoglobulin in the ascites.[162]

With significant potential complications and alternatives available, Souter and coworkers[183] suggest the following criteria for patients who should be considered for shunt placement:

- The goal of care is palliative.
- Expected survival is longer than 3 months.
- The rate of fluid reaccumulation is rapid after large-volume paracentesis.
- There is no loculation.
- Accumulated fluid is not bloody or viscous, which could lead to early shunt dysfunction.

Patients with peritonitis or those not able to handle large, rapid fluid shifts (patients with significant cardiac or renal dysfunction) would also not be candidates for shunt placement.

Drainage Catheters

External drainage catheters offer a different method for palliation of ascites, namely a route available for repeated drainage that does not require repeated needle insertion. Patients are therefore offered the ability to perform repeated paracentesis without increased morbidity and discomfort, possibly at home by themselves or with minimal assistance. Several different methods are available; most use vascular ports inserted into the peritoneum, tunneled catheters, or other similar devices to allow drainage after catheter access.[188–190] The best-described uses of this method are from Lomas and colleagues,[191] in which a patient with malignant ascites had 1 L of fluid removed per day for 3 months with a Tenckhoff catheter, and that from Belfort and associates,[192] in which 17 patients were implanted with a 20 Fr silastic tube with a Dacron cuff at the peritoneal surface, all of whom did well with repeated removal of ascites.[193] A disadvantage of repeated drainage of ascites via any means is that, among patients who do survive and undergo a number of procedures, there is a large amount of protein loss, particularly when compared with peritoneovenous shunting, in which the fluid is rerouted to the vascular system and protein might be retained. The most impressive protein loss seen comes from the Lomas and coworkers study,[191] in which the average albumin level fell from 2.8 g/dL to 1.8 g/dL. Other series, however, have demonstrated much smaller decreases in albumin level, especially when high-protein diets were used. If one considers that these patients have advanced, refractory malignancy, protein and albumin loss due to repeated drainage is probably not all that significant but should still be monitored.[189,192] There is a risk of infection with superficial catheters; in the aforementioned study by Belfort and colleagues,[192] in which patients were given cuffed catheters, 47% of patients (8 of 17) developed positive ascitic fluid surveillance cultures, and 12% (2 of 17) required removal due to "significant infection." In a study using a tunneled catheter (the Denver Pleurx catheter), 0 of 10 patients developed infections requiring catheter removal.[189] Although no comparison studies have been done with peritoneal catheters, randomized studies involving other catheter systems clearly have demonstrated decreased infection rates when catheters had their cuffs placed subcutaneously in a tunnel rather than at the surface.[192] Percutaneous catheters therefore remain an option for some patients, although they are not used frequently.

Surgery

Sugarbaker[194] has been an advocate of peritonectomy, in which various parts of the peritoneum, omentum, and some intra-abdominal organs are removed as a method of tumor cytoreduction (akin to debulking of ovarian cancer, which has now become a standard of care) in preparation for intraperitoneal chemotherapy. This approach has been used for patients with peritoneal carcinomatosis with the chemotherapy tailored toward the nature of the malignancy. Studies have shown modest success with this procedure in increasing survival time and in the prevention of the development of malignant ascites, but its use in the treatment of ascites has not been well evaluated.[195,196] It is likely to be of minimal use, because patients with advanced, malignant ascites often have chemotherapy-refractory disease and have too much systemic disease to benefit from cytoreduction; removal of ascites alone as palliation can usually be accomplished through much easier means. The role of intraperitoneal chemotherapy in the prevention of the development of ascites is intriguing, however, and is discussed next.

Intraperitoneal Therapy

Direct intraperitoneal therapy has been tried for quite some time in an attempt to deliver higher doses of chemotherapy locally with minimal systemic absorption and distribution.[197] Intraperitoneal therapy has been used to treat both ascites and intra-abdominal malignancies, such as ovarian cancer. Patients with disease responsive to chemotherapy are most likely to benefit from this procedure. In this manner, the intraperitoneal administration of cisplatin has been well studied, because ovarian cancer is one of the most common intra-abdominal tumors with a predilection for causing ascites and is very responsive to systemic cisplatin chemotherapy. Simultaneous administration of intravenous thiosulfate might decrease systemic absorption of cisplatin. Several investigators have found that intraperitoneal administration of cisplatin is indeed effective for control of intra-abdominal ovarian cancer, with perhaps better efficacy than that given intravenously.[198] The complexity of these procedures, their limited availability, and the fact that many or most patients who present with intractable ascites have already undergone numerous treatments and are probably resistant to chemotherapy, limits the role for intraperitoneal therapy in the management of ascites except in some special situations such as ovarian cancer and, of course, in clinical trials. It is important for the role of intraperitoneal chemotherapy immediately after initial surgical exploration for malignancy

to be examined further to determine whether it produces a survival advantage or a reduction in the rate of development of malignant ascites.

Summary

The level of aggressiveness that one undertakes in the management of ascites is highly dependent on the overall clinical status of the patient. For those patients with chemotherapy-sensitive tumors who are not heavily pretreated, chemotherapy should be an early step in management, particularly in cases of ovarian and hematologic malignancies. Although diuretic therapy probably does not have much of an effect, one can consider an early trial, in that it is relatively easy to carry out and can be particularly helpful for patients with increased portal pressures due to massive hepatic metastases. For those patients with a limited life expectancy but a large amount of ascitic fluid causing symptoms, paracentesis on an as-needed basis should be used, with the caveat that recurrence of the effusion is virtually assured and repeat paracentesis required unless other steps are taken. Intraperitoneal therapy of many types can be considered where available, particularly for ascites due to ovarian cancer or in the setting of a clinical trial. Patients who are likely to live a long time without chemotherapy-responsive tumors should be considered for a shunt or catheter drainage device, or for any available clinical trial.

G. COMPLICATIONS OF THERAPY

61 Neurologic Complications

Mark R. Gilbert

SUMMARY OF KEY POINTS

Incidence of Chemotherapy- and Radiation Therapy-Induced Neurotoxicity

- The actual incidence of treatment-related neurotoxicity is unknown, but the frequency is increasing.
- Improvements in supportive care, but not neuroprotective regimens, have allowed dose escalation for many drugs, so neurotoxicity often is the dose-limiting factor.
- Increased survival from cancer has resulted in an increasing prevalence of late-onset neurotoxicity.
- Newer treatments directed at tumors in the central nervous system often result in neurotoxicity, particularly with therapies administered directly into the brain.

Etiology of Neurotoxicity

- Direct effects on neurons, myelin, and supporting glial cells have been implicated.
- Effects on neuronal cytoskeleton and axonal transport, neuronal metabolism, and neurotransmitter function are the most commonly hypothesized mechanisms of toxicity. Alterations in specific ion channels have been reported in some cases of chemotherapy-induced peripheral neuropathy.

Evaluation of the Patient

- In general, chemotherapy or radiation toxicity should be considered a diagnosis of exclusion.
- Specific diagnostic tests do not exist for treatment-induced toxicity from most agents and regimens in use.
- The diagnosis often is made by recognition of a neurotoxic syndrome temporally related to treatment and by exclusion of other causes of neurologic dysfunction.

Grading of the Complication

- Grading scales are of limited value for monitoring individual patients and are used only for study populations.
- More refined grading for management is a component of neurologic and neuropsychologic testing.

Treatment

- With most neurotoxic syndromes, specific treatment is not available.
- Prevention or reduction of risk often is possible with proper monitoring or treatment planning.
- New agents are under development for management or prevention of neurotoxicity, but careful testing is required to ensure that the antineoplastic effect is not compromised.

INTRODUCTION

The neurotoxic effects of cancer chemotherapeutic agents and radiation therapy are of increasing importance in the management of patients with cancer. Although the exact incidence of treatment-related neurotoxicity is unknown, the frequency is certainly increasing. Several factors are known to be responsible for this increase in incidence of treatment-related neurotoxicity.

First, recent advances in supportive care allow the use of much higher doses of chemotherapeutic agents. For example, administration of granulocyte or granulocyte-macrophage colony-stimulating factors allows use of drug doses that previously would have caused severe bone marrow suppression. Unfortunately, similar factors for prevention of development of neurotoxicity do not exist. In initial studies of paclitaxel, a novel antitubulin agent, myelosuppression was dose-limiting. Use of colony stimulating factors has allowed dose escalation, but the development of severe peripheral neuropathy has been described in many patients receiving these higher doses.[1,2] Similarly, nephrotoxicity and myelosuppression limited dose escalation of cisplatin in the past. Innovative hydration schemes and the availability of colony stimulating factors have reduced the risk of these toxicities. Dose escalation has resulted in severe neurotoxicity and ototoxicity, now considered the dose-limiting toxic effects.[3]

Second, improvements in cancer treatment have increased the duration of survival from many malignant diseases. As a consequence, treatment-related neurotoxicity with a long latency between treatment and onset of symptoms is being recognized with increasing frequency. Childhood acute lymphoid leukemia often was fatal until recognition of the central nervous system (CNS) as a sanctuary for leukemia cells. Treatment of cerebrospinal fluid (CSF) with direct administration of methotrexate and use of cranial irradiation resulted in a marked increase in long-term remission and cure. This treatment of the CNS, however, also caused delayed neurotoxicity. Severe dementia developed in some patients, and many others experienced a decline in cognitive function years after completion of treatment.[4–8] Similarly, combined-modality treatment using both whole-brain irradiation and chemotherapy with high-dose methotrexate has markedly improved survival over that achieved with radiation therapy alone. A marked increase in leukoencephalopathy, however, has been observed with this combination regimen, particularly in the elderly.[9]

Third, newer agents, including biologic response modifiers, and novel routes of administration designed specifically to target the nervous system for management of brain metastases or primary brain tumors are very likely to result in an increase in neurotoxicity. Likewise, chemical disruption of the blood-brain barrier to improve drug delivery to brain tumors has led to a marked increase in neurotoxicity compared with that with standard systemic administration. Results of animal studies have demonstrated that chemical opening of the blood-brain barrier results in a marked increase in exposure of normal brain parenchyma to chemotherapy with a much smaller increase in delivery to the tumor.[10] Implantation of carmustine

(BCNU)-impregnated polymer wafers into the resection cavity has shown a survival benefit for patients with glioblastoma but with an increase in the incidence of brain necrosis and infection.[11]

Continued improvement in cancer treatment will result in prolonged survival and an increased rate of cure. Therefore long-term morbidity, particularly development of irreversible neurotoxicity, is a critical concern. This chapter discusses the agents most commonly responsible for neurotoxicity, describes the differential diagnosis for and evaluation of patients with neurologic dysfunction, and addresses management and prevention of chemotherapy- and radiation therapy-induced neurotoxicity.

SPECIFIC AGENTS

Cytosine Arabinoside

Cytosine arabinoside (ara-C), or cytarabine, can cause a wide range of neurotoxic effects. The toxicity that develops depends on the route of administration and the dose used.

Cerebellar Toxicity

Systemic administration of high-dose (greater than 1 g/m^2) intravenous ara-C can cause acute cerebellar toxicity.[12–15] Onset of neurologic symptoms generally is acute and often is noticed during administration of a multiday regimen.[12,13,16] Patients exhibit evidence of global cerebellar dysfunction, which manifests as truncal, limb, and gait ataxia; dysarthria; and nystagmus. In some cases, permanent cerebellar dysfunction results; in others, a mild cerebellar syndrome develops that resolves promptly after completion of the chemotherapy.[12,13]

Patients with irreversible cerebellar damage have a characteristic and selective loss of Purkinje cells in the cerebellum.[15] The pathogenesis of the specific cellular damage is unknown, and no pathologic findings have been described in the cerebella of patients who have recovered from transient cerebellar dysfunction.

The incidence of irreversible cerebellar toxicity with high-dose ara-C regimens has been reported to be 8% to 20%. Factors reported to affect the likelihood of development of cerebellar toxicity include size of current dose, cumulative dose, age (persons older than 50 years are at higher risk), and renal status (renal dysfunction with impaired drug clearance is associated with increased risk).[13,14,17,18] Whether patients in whom reversible cerebellar dysfunction develops with previous treatment are at higher risk for permanent dysfunction is unknown.

Encephalopathy

Acute encephalopathy, often accompanied by seizures, occurs less frequently than cerebellar dysfunction in patients receiving high-dose intravenous ara-C.[13] In most cases, somnolence and lethargy completely resolve soon after completion of chemotherapy. Patients with persistent encephalopathy usually have had additional medical problems, such as severe infection.[18] In addition, leukoencephalopathy that is clinically and pathologically indistinguishable from the leukoencephalopathy associated with methotrexate has been reported as a late complication of high-dose intravenous ara-C administration and with administration of ara-C directly into the CSF.[13]

Spinal Cord Toxicity

Direct administration of ara-C into the lumbar thecal space has been reported to cause myeloradiculopathy.[19–23] Patients exhibit evidence of both spinal cord and nerve root dysfunction. This complication is uncommon, usually being found only after an extensive course of intrathecal chemotherapy. In many instances, patients have received both intrathecal ara-C and methotrexate.[24,25] Neurologic signs typically are noticed days to weeks after treatment, although myelopathy may develop within minutes of administration. In most cases, loss of neurologic function progresses slowly over days, and only one half of patients demonstrate improvement or achieve full recovery.

Several hypotheses have been proposed for the mechanism of chemotherapy-induced myelopathy. Focal damage from injection of hyperosmolar solution,[26] barbotage from injection,[27] and direct toxic effects of chemotherapy on the spinal cord parenchyma[20] are the most common proposed mechanisms of subacute myelopathy. Histologic examination of the spinal cord shows focal areas of necrosis, most marked along the periphery of the spinal cord.[20,21,24] Microscopic examination shows axonal swelling with accompanying demyelination.[20,21,24] A newer formulation of ara-C uses a liposomal preparation. Although the pharmacokinetics of drug delivery in the CSF is improving, an increase in the incidence of arachnoiditis has been observed, and isolated cranial nerve palsies may be more frequent. With chemotherapy-induced spinal cord injury, myelin basic protein levels in the CSF may be elevated before marked neurologic damage occurs.[24,25] For patients with early symptoms, such as paresthesia, back pain, or Lhermitte's sign, the level of myelin basic protein in the CSF should be measured. If the level is elevated, further lumbar administration of chemotherapy should be avoided.[25]

Other Neurotoxicity Associated with Cytosine Arabinoside

Peripheral neuropathy has been reported after administration of high-dose ara-C.[28] In this report, symmetrical sensorimotor polyneuropathy developed 2 weeks after completion of treatment. Nerve biopsy demonstrated axonal damage with patchy regions of demyelination. In addition, a case of reversible parkinsonism has been reported after administration of high-dose ara-C.[13] Onset of tremor, bradykinesia, and mask-like facies were observed 3 weeks after completion of treatment. Treatment with carbidopa-levodopa provided only transient improvement. All parkinsonian features, however, resolved over 12 weeks.

L-Asparaginase

Cerebrovascular Events

Cerebrovascular events caused by L-asparaginase-induced coagulopathy constitute the most common form of neurotoxicity associated with L-asparaginase treatment. Both thrombotic and hemorrhagic strokes have been reported in patients receiving L-asparaginase.[29–31] Thrombosis of cerebral venous sinuses also has occurred in patients receiving this agent. The clinical manifestations of sinus thrombosis usually are acute and severe headache, nausea, and vomiting caused by the rapid increase in intracranial pressure. Changes in level of consciousness occur most frequently with sagittal sinus thrombosis with bilateral cerebral hemisphere involvement. Although most patients with sinus thrombosis demonstrate acute and rapidly progressive changes in neurologic function, some patients experience only headache and mild neurologic dysfunction.[29]

Patients in whom neurologic symptoms develop during L-asparaginase therapy should be evaluated with either head computed tomography (CT) or magnetic resonance imaging (MRI). MRI usually is preferred because it often depicts sinus thrombosis by absence of a flow void in the venous sinus. MRI also depicts early signs of ischemic brain injury, particularly on diffusion-weighted imaging, and punctate hemorrhages also may be seen.

Neuropsychiatric Effects

Less frequently, L-asparaginase treatment has been associated with development of neuropsychiatric symptoms,[32] most notably depression, delusions, hallucinations, disorientation, and altered level of consciousness. In the series described by Holland and colleagues,[32] 5 of 19 patients with acute leukemia experienced psychiatric symptoms. The onset of symptoms occurred 2 to 19 days after treatment, and the symptoms resolved completely in three patients who lived longer than 6 weeks. Neuropathologic analysis of the brains in two cases revealed leukemic infiltration. The combination of leukemic involvement of the CNS and treatment-induced depletion of L-

asparagine and L-glutamine in the brain has been proposed as a possible factor contributing to development of psychiatric symptoms.

Busulfan

Busulfan administration has been reported to cause generalized tonic-clonic seizures.[33] This reaction has been reported with high-dose treatment as a preparative regimen for bone marrow transplantation. Prophylactic treatment with anticonvulsants, particularly phenytoin, has been shown to reduce the risk of seizures.[34]

Methotrexate

Methotrexate can cause acute, subacute, or chronic neurotoxicity.

Acute Neurotoxicity

Administration of high-dose intravenous methotrexate (dosage greater than 3 g/m^2) has been associated with development of acute encephalopathy characterized primarily by somnolence, confusion, and seizures.[5,35] Although the pathogenesis of this syndrome is unknown, laboratory studies with rats have shown profound metabolic alteration in the brain after intravenous administration of high-dose methotrexate.[36] In these experiments, a widespread decrease in glucose utilization and protein synthesis was found. In similar studies, folinic acid (leucovorin) markedly diminished these metabolic effects,[37] a finding that suggested a possible role for leucovorin in decreasing the severity of methotrexate-induced somnolence syndrome. Although the somnolence and confusion that occur with acute methotrexate toxicity resolve completely, evidence shows that patients in whom this syndrome develops are at greater risk for chronic methotrexate-induced neurotoxicity.[38] Cases have been reported in which, despite resolution of the clinical symptoms, white matter changes persist on MR images.[39]

Subacute Toxicity

Subacute methotrexate-induced neurotoxicity generally develops weeks after methotrexate administration and occurs most frequently in patients who also have received cranial radiation.[5] Transient inhibition of myelin formation is thought to be the mechanism of toxicity. The syndrome is completely reversible over weeks, and corticosteroid treatment may accelerate recovery.

Chronic Neurotoxicity

Chronic methotrexate neurotoxicity is known as leukoencephalopathy. This syndrome develops months to years after methotrexate administration and has been seen after both intravenous and intrathecal administration of methotrexate.[4–8,40–50] Cranial radiation therapy, particularly when it precedes methotrexate administration, greatly increases the risk of leukoencephalopathy.[5,51] In addition, elevated CSF methotrexate concentration has been associated with an increased risk of neurotoxicity.[42] Younger patients are at higher risk for leukoencephalopathy.[52,54] Clinically, patients show progressive loss of cognitive function and focal neurologic signs, which may progress to profound dementia, coma, or death.[4–6,8,43] Some patients experience seizures as a consequence of widespread neuronal injury. No treatment is known, and the neurologic deficits generally are irreversible. Brain imaging with MRI or CT often shows large areas of abnormalities in cerebral white matter (Fig. 61-1). Elevated levels of myelin basic protein in CSF have been reported in patients with progressive neurologic dysfunction from methotrexate-induced leukoencephalopathy.[44]

Neuropathologic examination shows wide areas of coagulative necrosis with swollen axonal cylinders and demyelination.[4,40,45] Regions with vascular changes, particularly microangiopathic calcifications, are characteristic.[46,49,54] The pathogenesis of leukoencephalopathy is unknown, but results of laboratory studies with brain explant cultures suggest that the primary injury may be neuronal (axonal), and the characteristic demyelination may be a secondary phenomenon.[55]

Spinal Cord Toxicity

Chemotherapy-induced myelopathy is an uncommon toxicity of intrathecal treatment with methotrexate.[56–60] Myelopathy generally de-

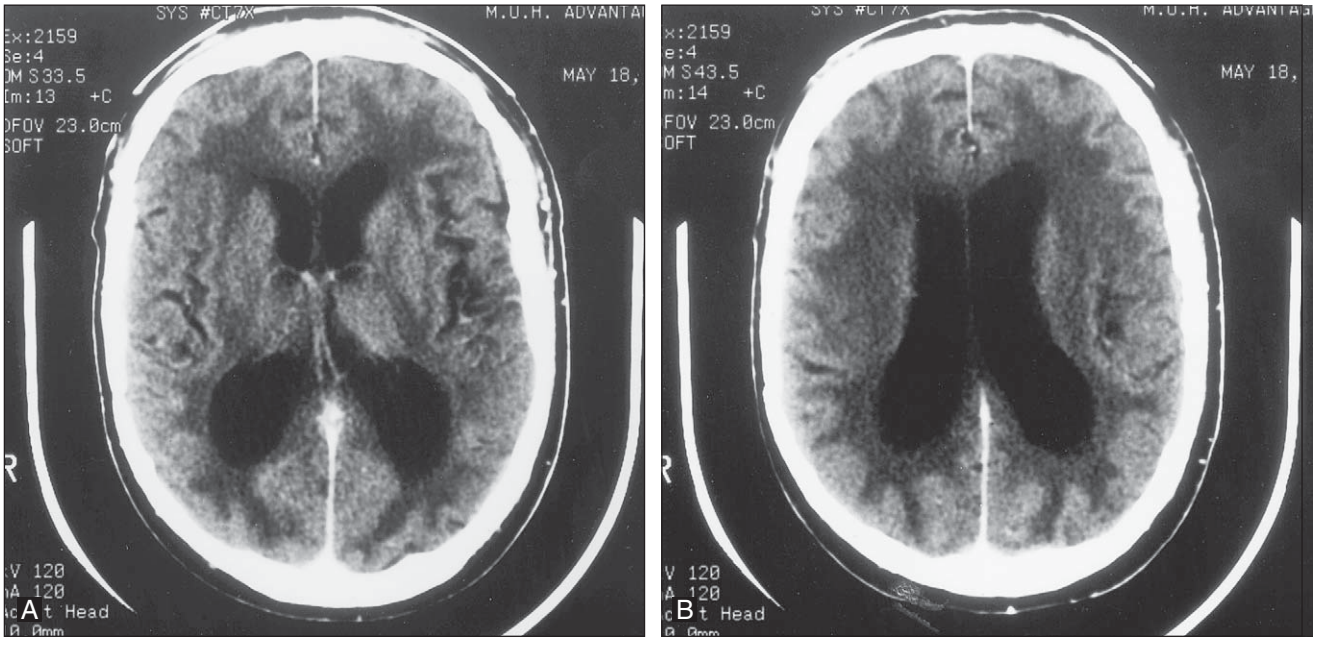

Figure 61-1 • Methotrexate-induced leukoencephalopathy. The patient was a 63-year-old man with meningeal lymphoma who underwent whole-brain radiation therapy. Several months later, his meningeal lymphoma recurred and was treated with intrathecal methotrexate. Progressive dementia developed. **A** and **B,** CT scans obtained 6 months after completion of intrathecal chemotherapy. Widespread destruction of white matter and diffuse atrophy are evident.

velops only after extensive intrathecal treatment. Both methotrexate and ara-C have been associated with myelopathy. The clinical syndrome of methotrexate-induced myelopathy is identical to that with ara-C (see earlier under "Cytosine Arabinoside"). Loss of neurologic function may be progressive; only approximately one half of patients experience either complete or partial recovery. The onset of symptoms generally is subacute. Symptoms develop over days to weeks, usually beginning days to weeks after administration of chemotherapy. The histologic findings are identical to those with ara-C-induced myelopathy.

Vinca Alkaloids

Treatment with vinca alkaloids, particularly vincristine, commonly is associated with neurotoxicity.

Peripheral Neuropathy

Peripheral neuropathy is the toxicity associated most frequently with vincristine and correlates with the cumulative dose of the drug.[61–66] Loss of deep tendon reflexes occurs in nearly all patients who receive several vincristine treatments. Distal sensorimotor polyneuropathy develops with continued treatment.[62,64,66] The predominant neurologic finding is loss of pain and temperature sensation in a stocking-and-glove distribution. Motor and vibration or proprioceptive loss usually is milder and occurs later with continued treatment.

The mechanism of toxicity is unknown but probably is related to the effects of the vinca alkaloids on microtubules. Vinca-induced disruption of axonal microtubules causes marked disarray of the axonal cytoskeleton and formation of neurofilamentous masses[65,67–71] and reversible neurofilament-containing crystalloid inclusions.[72] These effects are very likely to influence axonal transport, which depends on microtubules as the transport mechanism.[73] In patients with underlying neuropathy, such as diabetic neuropathy or Charcot-Marie-Tooth disease, vinca-induced neuropathy may be severe even with low cumulative doses.[74] Severe, even life-threatening neuropathy has been reported after administration of as little as 2 mg to patients with Charcot-Marie-Tooth disease (hereditary motor sensory neuropathy type 1), and evidence suggests that patients should be screened for this disorder before administration of vincristine.[74–76] Previous radiation treatment of peripheral nerves also increases the neurotoxic effects of vincristine.[77]

In addition to peripheral neuropathy, autonomic neuropathy and cranial nerve palsy have been reported. Autonomic neuropathy most commonly manifests as gastrointestinal dysmotility (obstipation or constipation). In severe cases, paralytic ileus and intestinal perforation have resulted.[66,78] Less frequently, orthostatic hypotension develops as a consequence of autonomic involvement. Vincristine-induced mononeuropathy involving the femoral nerve has been reported. Vincristine can cause cranial nerve palsies, affecting the optic (II), oculomotor (III), trigeminal, abducens, facial, acoustic, and vagus nerves.[62,66,79,80] In addition, patients occasionally report facial pain with vincristine treatment, possibly due to a transient effect on the trigeminal nerve or ganglion.[66]

Central Nervous System Effects

Vincristine has been reported to cause encephalopathy, coma, and seizures.[81–85] These effects are rare and reversible. The underlying mechanism is unknown in most cases, although in some reports these neurologic effects have been attributed to vincristine-induced syndrome of inappropriate antidiuretic hormone secretion (SIADH) and hyponatremia.[84,86–89] The mechanism of SIADH is unknown, but serum antidiuretic hormone levels are elevated.

Other Toxicity Associated with Vinca Alkaloids

Quadriplegia with vincristine treatment has been reported, in one case in association with Guillain-Barré syndrome.[90–92] The time of onset of has been variable. In some patients, quadriparesis develops soon after vincristine treatment, whereas in others, it occurs several weeks after treatment. In most instances, the weakness is partially reversible.[90]

Myopathy has occurred with vincristine therapy.[61,93] No clinical correlate has been found in cases in which histopathologic examination of muscle tissue has revealed spheromembranous degeneration.

Cisplatin

Peripheral Neuropathy

The most common neurotoxicity associated with cisplatin is peripheral neuropathy. The neuropathy predominantly involves the large sensory fibers, which mediate vibration and proprioceptive function. Deep tendon reflexes are lost because of toxic effects on the large myelinated sensory fibers, which provide the afferent arm of the reflex arc. Involvement of motor function generally is mild and is seen only in patients with severe sensory neuropathy. Development of neuropathy is dose-related. The earliest signs are detected when the cumulative dose exceeds 300 mg/m^2.[94] Schedule of administration may be a significant factor, because the reported incidence of neuropathy has been higher in patients receiving treatment on 5 consecutive days than in patients on a regimen with a shorter dosing schedule but the same cumulative dose.[95–97] Continued treatment with cisplatin in patients with neuropathy can result in severe sensory ataxia, which often impairs ambulation. The neuropathy is partially reversible, and patients with mild impairment generally are more likely to experience full recovery.[96] A longitudinal study confirmed there is often a delay in the onset of neuropathy. Eleven percent of the patients had neuropathy at the end of treatment, but the incidence had increased to 65% 3 months later. One year later, most of the patients had recovered, only 17% having persistent symptoms.[98]

The pathogenesis of cisplatin-induced neuropathy is unknown. Neuropathologic studies have shown involvement of the large sensory fibers with regions of axonal swelling and myelin breakdown and, in more severe cases, axonal loss.[99] The spinal cord shows almost exclusive involvement of myelinated axons in the dorsal columns—a finding consistent with the clinical features of vibratory and proprioceptive loss.[100] Platinum concentration in peripheral nerve and spinal ganglia was 20 times greater than in brain from patients at autopsy.[98] This finding may explain the predilection of cisplatin for sensory fibers and sparing of the CNS.

Spinal Cord Toxicity

Cisplatin treatment has been associated with the development of Lhermitte's sign, which is an electric shock-like sensation down the spine or into the extremities with neck flexion.[101,102] The phenomenon most commonly is associated with spinal cord demyelinating lesions in multiple sclerosis. A similar mechanism, cisplatin-induced demyelination, may be the cause in patients with this syndrome. Most patients achieve full recovery, although, as with recovery from cisplatin-induced neuropathy, improvement may take several months.

Other Neurotoxicity Associated with Cisplatin

Other neurotoxic effects reported with cisplatin include optic neuropathy, seizures, encephalopathy, and cortical blindness.[103] These complications of treatment are rare. Patients with optic neuropathy may have prolonged vision loss and demonstrate pallor of the optic disk.[104,105] The reported cases of seizures and cortical blindness have been self-limited, all patients recovering fully.[106–108] The cause of the seizures and cortical blindness from cisplatin treatment is unknown but may be similar to that in toxicity from other heavy metals (lead, thallium), although endovascular injury has been proposed as a possible mechanism.[103,107] Many of these patients have white matter abnormalities on brain MRI, consistent with posterior reversible encephalopathy syndrome (PRES; see later under "Dementia and Encephalopathy"). A syndrome also has been described in which patients experience focal neurologic deficits and seizures after intra-

venous administration of cisplatin. In these patients, findings on brain MRI were normal. One patient experienced recurrence of encephalopathy with cisplatin rechallenge, and a second patient died of status epilepticus. At autopsy, the brain of the latter patient showed only focal gliosis.[109]

Toxicity Associated with Intra-arterial Administration

Intra-arterial administration of cisplatin causes focal toxicity. Administration into the internal carotid artery can cause severe retinal toxicity.[110,111] Supraophthalmic administration can cause focal areas of brain parenchymal necrosis with resulting seizures and neurologic impairment.[111]

Ototoxicity

Ototoxicity is a dose-related effect of cisplatin. Patients receiving more than 200 mg/m^2 are at high risk for the development of hearing loss.[112] Hearing loss, particularly when it is moderate to severe, often is permanent.[112,113] Results of most studies suggest that patients with underlying hearing loss are at greater risk for functional hearing loss, although a small series found no relation to previous hearing loss.[112,114,115] Additional risk factors include age older than 46 years and previous cranial radiation therapy involving the ears or temporal lobes.[113,114] Patients with normal hearing lose high-frequency hearing first, but with continued treatment, hearing may be lost in all frequency ranges.[112] A rapid screening audiogram technique has been developed to monitor patients undergoing cisplatin treatment.[115] Postmortem pathologic examination of cochleae from patients with cisplatin-induced ototoxicity reveals extensive loss of the outer hair cells and less effect on the inner hair cells.[112]

Oxaliplatin

Oxaliplatin has been shown to cause two distinct types of neuropathy: acute and chronic.[116] The acute neuropathy syndrome may begin during oxaliplatin infusion or up to 1 to 2 days after completion of treatment. Patients experience paresthesia and dysesthesia of the hands and feet, jaw tightness, and a sensation of loss of breathing without respiratory distress. The last syndrome has been called pharyngolaryngodysesthesia.[117] Dysesthesias constitute the most prominent symptom, although many patients describe pain that is more like muscle spasms of the jaw, tongue, and extremities. Some patients are unable to relax a tensed muscle, such as a grasp, during these episodes. The incidence of acute neuropathy increases with continued dosing, and an increased incidence also has been noted with higher dosing regimens. Overall, acute, severe (grade 3 or 4) neurotoxicity has been estimated to occur in 10% of patients with the initial dose, but that increases to 50% by the ninth cycle of treatment.[118] Most patients experience some resolution of symptoms, but most have residual neuropathic symptoms up to 6 months after treatment cessation. The pathogenesis of acute oxaliplatin neuropathy is thought to be related to drug-induced alterations in voltage-gated Na^+ channels.[119]

The development of chronic neuropathy from oxaliplatin is related to cumulative dose, with most studies reporting early neuropathy noted after a total dose of greater than 540 mg/m^2. As with cisplatin, chronic oxaliplatin peripheral neuropathy affects large caliber sensory nerves, with the resultant loss of proprioceptive function as the predominent clinical manifestation. Additionally, the Lhermitte's-like phenomenon described with cisplatin also has been reported with oxaliplatin.[120] The chronic neuropathy may abate over several months after the cessation of treatment, although some reports suggest that symptoms may persist in a small percentage of patients for longer than 5 years.[121]

Cyclophosphamide

Cyclophosphamide can indirectly cause metabolic encephalopathy and seizures. High-dose cyclophosphamide can result in SIADH.[122–125] Unrecognized, this syndrome can lead to severe hyponatremia, coma, and seizures. Although not reported in the literature in association with cyclophosphamide-induced SIADH, rapid correction of hyponatremia can result in central pontine myelinolysis, which is irreversible loss of the central pontine pathways.[126] A locked-in syndrome may develop, or a chronic vegetative state can result from central pontine myelinolysis.

Ifosfamide

The most common manifestation of neurotoxicity associated with ifosfamide is encephalopathy. Severe ifosfamide-induced encephalopathy has been reported in children and adults.[127–131] Neurologic deterioration usually begins within hours of administration of ifosfamide.[127,129,131] Confusion, hallucinations, and aphasia are the most common initial signs. Progression to coma generally is rapid. Some patients also exhibit clinical evidence of seizure activity or myoclonus with intermittent twitching of the extremities.[127,130] Electroencephalography (EEG) shows severe slowing with delta wave activity and can display evidence of seizure activity.[127,130] In most cases, encephalopathy completely resolves over several days after cessation of therapy, although in one study, investigators found persistent mental status changes in some patients 10 weeks after treatment.[132] A recent study of 60 patients reported the incidence of ifosfamide neurotoxicity to be 26%.[133] Several risk factors have been reported to predispose patients to development of neurotoxicity from ifosfamide. These factors include low serum albumin concentration,[131] high serum creatinine concentration, pelvic cancer,[134] and previous treatment with cisplatin.[135] A recent report, however, could not confirm any risk factor except age, with an increased incidence of encephalopathy in younger patients.[133] Ifosfamide treatment has been associated with an extrapyramidal syndrome characterized by choreoathetosis, blepharospasm, and opisthotonic posturing.[136] These abnormalities resolved over several days.

5-Fluorouracil

Cerebellar Toxicity

5-Fluorouracil (5-FU) causes acute cerebellar dysfunction. Patients experience moderate to severe gait ataxia, scanning speech, appendicular ataxia marked by severe dysmetria, and often nystagmus.[137–140] These neurologic abnormalities resolve completely within several days after completion of therapy. The incidence of cerebellar toxicity has been reported to be 3% to 7% and correlates with dose and the interval between treatments.[141]

Neuropsychiatric Symptoms

Organic brain syndrome has been reported with 5-FU treatment.[142] Confusion and disorientation develop without evidence of cerebellar dysfunction. In one patient, retreatment with 5-FU resulted in a similar episode of mental deterioration. Oculomotor disturbances, specifically vergence disturbances characterized by diplopia on viewing distant objects, were reported in two patients.[143] A possible association of 5-FU treatment with recurrent acute toxic neuropathy also has been reported.[144]

Other Neurotoxicity Associated with 5-Fluorouracil Treatment

Several cases have been reported of multifocal inflammatory leukoencephalopathy associated with use of 5-FU and levamisole in adjuvant therapy for colon carcinoma.[145] Affected patients have a subacute neurologic syndrome characterized by focal neurologic findings and cognitive dysfunction. MRI shows widespread patchy white matter lesions that enhance with administration of gadolinium (Fig. 61-2). Histopathologically these lesions are characterized by an intense inflammatory infiltrate with extensive loss of myelin, but the axons generally are spared. Complete recovery occurs over weeks after cessation of 5-FU and levamisole administration. The benefit of corticosteroid treatment is uncertain in accelerating

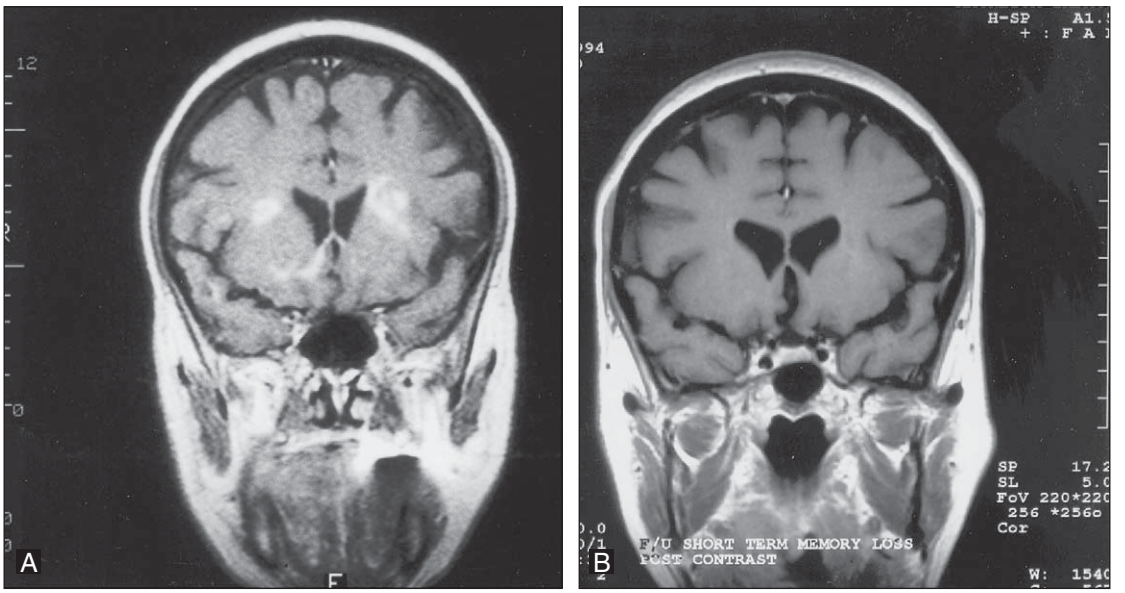

Figure 61-2 • Levamisole–5-fluorouracil (5-FU) multifocal inflammatory leukoencephalopathy. The patient was a 54-year-old woman in whom progressive encephalopathy and focal neurologic signs developed 4 months after initiation of adjuvant therapy with levamisole and 5-FU for colon carcinoma. **A,** Several white matter lesions are present, many of which enhanced with administration of gadolinium–ethylenediaminetetra-acetic acid (EDTA). **B,** Six months later, the patient had fully recovered. Resolution of the enhanced lesions is evident.

recovery. The pathogenesis of this idiosyncratic reaction is unknown, although levamisole can affect blood-brain barrier function, and this effect may be potentiated by 5-FU. Recognition of this treatment-induced leukoencephalopathy can be important, because the clinical presentation and MRI findings can be misinterpreted as brain metastasis. There are isolated reports of encephalopathy with single-agent therapy with 5-FU and recently reports of encephalopathy and coma with use of capecitabene, the oral prodrug of 5-FU.[146–148]

Fludarabine

Fludarabine can cause somnolence and a mild peripheral neuropathy at low doses.[149] At high doses, white matter changes, particularly in the occipital lobes and brainstem, have been reported.[150] Encephalopathy and cerebellar signs are common with this leukoencephalopathy. Progressive symptoms eventuating in coma and death have been reported. Pathologic evaluation has shown necrotic changes in the involved white matter.[150] The risk of development of progressive multifocal leukoencephalopathy, due to an infection with the JC virus, may be increased with fludarabine treatment. Diagnosis requires biopsy of involved brain or polymerase chain reaction testing of CSF.[151]

Nitrosoureas

Central Nervous System Toxicity

Nitrosoureas, most commonly carmustine (BCNU), can cause encephalopathy characterized by a progressive decline in cognitive function, development of seizures and coma, and death.[152–154] This complication most commonly is observed with intracarotid or supraophthalmic arterial delivery of nitrosourea, although a similar syndrome has been reported in patients who receive very high-dose intravenous carmustine treatment.[155] Histopathologically the toxicity associated with intra-arterial therapy is characterized by necrosis, regions of demyelination, edema, and axonal loss limited to the region perfused by the intra-arterial therapy. Because the predominant changes have been seen in the white matter, the condition is called *leukoencephalopathy*, indistinguishable from the changes seen with methotrexate and ara-C treatment. Similar pathologic changes are seen with high-dose intravenous carmustine, but both cerebral hemispheres are involved.[155] In addition, focal brain necrosis has been reported with intra-arterial nitrosourea treatment. This toxicity is thought to be a consequence of "streaming" of the drug along the vessel wall, without mixing with arterial blood.[156] This stream of concentrated drug may flow into a small branch of the artery. A small region of brain (or tumor) thus receives an enormous dose of drug, and focal necrosis results.

A biodegradable polymer containing BCNU has been shown effective in the management of recurrent malignant glioma. The BCNU-impregnated polymer also has been approved for treatment of newly diagnosed glioblastoma. This treatment usually is followed by conventional external beam radiation therapy.[157] This combination may increase the incidence of treatment-associated necrosis. The wafers are placed into the tumor cavity after surgical resection. Results of clinical trials indicate that the local therapy is well tolerated, although an increase in peritumoral edema necessitates a temporary increase in corticosteroid dose, and there are reports of treatment-associated necrosis.[158]

Retinal Toxicity

Retinal toxicity has been reported with intracarotid administration of nitrosoureas, particularly carmustine.[111,159] This retinopathy is painful and often results in permanent vision loss. Infusion above the ophthalmic artery eliminates this toxicity but may increase the likelihood of streaming (see preceding discussion, "Central Nervous System Toxicity").

Procarbazine

Early reports of procarbazine use describe neurotoxicity, both peripheral and CNS toxicity, as common side effects of treatment.

Peripheral Neuropathy

The peripheral neuropathy described with procarbazine use most commonly is described as paresthesia, often subjective and generally

transient. The incidence of paresthesia ranges from 2% to 20%; this variability may be related to dose or treatment schedule.[160–162]

Central Nervous System Toxicity

Signs of CNS depression, ranging from mild drowsiness to profound stupor, have been reported.[160,162] This toxicity worsens with use of phenothiazine to control emesis and may be related to the monoamine oxidase inhibitor-like qualities of procarbazine. No report has discussed the use of dietary restrictions in patients receiving procarbazine. CNS depression was reported to occur in 14% to 33% of patients in these series.[160–162]

Paclitaxel and Docetaxel

Paclitaxel and docetaxel are novel antineoplastic agents that bind to tubulin and promote formation and stabilization of microtubules.[144,163,164] In phase I and II testing of paclitaxel, myelosuppression was the dose-limiting toxicity. Since colony stimulating factors (e.g., granulocyte macrophage and granulocyte colony stimulating factors) have become widely available, however, peripheral neuropathy has become the dose-limiting toxicity.[1,2] The neuropathy is predominantly sensory, particularly affecting small-caliber (pain and temperature) sensory fibers.[165] The effect on motor fibers and large-caliber sensory fibers (vibration and proprioception) is less severe. Nerve conduction studies of large myelinated nerve fibers show evidence of both axonal injury and demyelination.[165] Neuropathy generally occurs at doses greater than 200 mg/m^2, and symptoms develop 1 to 3 days after treatment. Although much of the neurologic dysfunction reverses over several weeks, continued treatment causes progressive neurologic toxicity. The peripheral neuropathy associated with docetaxel appears to be similar to that with paclitaxel in preliminary reports, although in a randomized trial, the incidence and severity were less with docetaxel.[166,167] Peripheral neuropathy also is being reported with other microtubule-stablizing agents such as the epothilones.[168]

In one series, transient encephalopathy was reported to occur within hours of administration of standard doses of paclitaxel. All patients had undergone previous brain radiation therapy, and all recovered within hours.[169] Acute encephalopathy was reported to occur in six patients receiving a very high intravenous dose of paclitaxel (greater than 600 mg/m^2). Encephalopathy developed between 7 and 23 days after treatment. Three patients recovered; the other 3 patients died of progressive coma. Autopsy revealed generalized white matter atrophy.[170] Chronic neurocognitive changes also have been reported with extensive administration of taxanes.[171]

Tamoxifen

Tamoxifen can cause reversible retinal dysfunction at the conventional antiestrogen doses used for breast cancer therapy.[172–174] At higher doses, reversible encephalopathy with delusions, somnolence, and cerebellar dysfunction has been reported.[175–177]

BIOLOGIC RESPONSE MODIFIERS

Interleukin-2

Central Nervous System Toxicity

The vascular leak associated with intravenous interleukin-2 (IL-2) administration can result in encephalopathy and coma.[178] A high percentage of patients receiving both systemic IL-2 and lymphocyte-activated killer (LAK) cells experience encephalopathy or a neuropsychiatric syndrome.[178] In most cases, severe but reversible cognitive impairment occurs. In the presence of an intracranial mass lesion, the increase in brain edema leads to an asymmetrical shift in the brain, resulting in herniation. In a single case report, development of multifocal white matter lesions was associated with intravenous administration of IL-2. The lesions resolved completely over several months.[179] Another case report described fatal leukoencephalopathy associated with IL-2 treatment.[180]

Toxicity Associated with Interleukin-2 Treatment

In one series of five patients, the development of neuro-ophthalmic complications was temporally associated with intravenous IL-2 treatment.[181,182] Reported abnormalities included transient scotomata, diplopia, amaurosis fugax, and visual field cuts.

Interferons

Systemic administration of interferon affects both the CNS and the peripheral nervous system.

Central Nervous System Toxicity

Confusion, lethargy, mood changes, and loss of cognitive function are the most common CNS effects associated with use of interferons.[183–185] Encephalopathy, with perseveration and aphasia, also has been reported,[184] as has a parkinsonian syndrome with bradykinesia, mask-like facies, and micrographia.[186] In addition, major depression has been described with use of interferon-α (IFN-α).[187] The neurologic effects of interferon are dose-related, but they are more severe in patients with underlying neurologic abnormalities.[188] Although the neurotoxic effects of interferon therapy usually resolve completely within a few weeks, some patients may exhibit persistent behavioral changes.[183] Intraventricular administration of IFN-α caused severe neurologic toxicity in one study. Effects ranged in severity from headache and confusion to coma. Additional side effects of intraventricular administration included parkinsonism, hearing loss, and seizures.[189]

Peripheral Nervous System Toxicity

Mild peripheral neuropathy manifesting as paresthesia has been reported with interferon use,[184] as has a case of brachial neuritis in a patient with underlying neuropathy.[190]

Thalidomide and Lenalidomide

Thalidomide has both immunomodulatory and antiangiogenic properties, has shown significant activity in multiple myeloma, and is being evaluated in the management of several other cancers.[191] Somnolence, the predominant side effect, is dose-related, and the drug can be titrated in most patients to a level of tolerance. Peripheral neuropathy is treatment-limiting. The neuropathy has been characterized as sensory-motor axonal polyneuropathy manifesting as painful paresthesia or numbness.[192] Severity of symptoms correlates with cumulative dose. Nerve biopsy and examination reveal distal axonal degeneration and demyelination. A longitudinal study in patients with dermatologic disease confirmed the high incidence of neuropathy (25% in this study) and the association with daily dosing.[193] Early studies of lenalidomide indicate that peripheral neuropathy may occur in a small percentage of patients.[194] The available data are insufficient to determine if the incidence will be less than with thalidomide.

Bevacizumab

Bevacizumab is a humanized monoclonal antibody against vascular endothelial growth factor (VEGF) that has shown activity in a wide variety of cancer types including colon, lung, and renal cell cancers and glioblastoma. Exacerbation of hypertension is a commonly reported toxicity and may be related to the development of PRES, described in detail later on.[195,196]

Sorafenib

Sorafenib is an oral agent that is a RAF kinase inhibitor that inhibits VEGF receptors 2 and 3 and platelet-derived growth factor

receptor-β. Hypertension is a common toxicity with this agent, and as with bevacizumab therapy, reports of PRES are now emerging.[197]

Bortezomib

Bortezomib is a proteosome inhibitor that has demonstrated activity in multiple myeloma. Peripheral neuropathy, predominantly a sensory neuropathy, initially was reported during early phase I trials. A prospective study evaluated the occurrence of neuropathy in a group of 256 patients with refractory myeloma treated with standard dosing schedules of bortezomib.[198] The incidence of neuropathy was estimated to be approximately 35%, and neuropathy was more common in patients receiving bortezomib at 1.3 mg/m^2 than in those dosed at 1.0 mg/m^2. Cumulative dose also correlated with severity of the neuropathy, as did the presence of neuropathy before initiation of treatment. Most patients experienced either partial or complete resolution with cessation of treatment.

RADIATION NEUROTOXICITY

Radiation neurotoxicity is becoming an increasingly important and recognized complication of cancer therapy. New therapeutic strategies for systemic cancer and for CNS metastasis have improved survival, uncovering a greater incidence of late, chronic toxicity from radiation and combined chemoradiotherapy treatments. Advances in technology, such as radiosurgery and brachytherapy, allow local dose intensification of radiation treatment for brain tumors. Furthermore, advances in development of radiosensitizers will increase the effects of radiation therapy on tumor and surrounding normal tissue.

Central Nervous System Effects

Cranial radiation therapy can cause acute, subacute, and chronic neurotoxicity. Volume of brain treated, total dose, and dose fraction are the most important determinants of toxicity, although some variation in patient susceptibility is apparent.

Acute Toxicity

Acute toxicity manifests as rapid onset of alteration in level of consciousness. This disorder generally occurs within weeks of initiation of cranial radiation therapy.[199] Acute toxicity is most common in patients receiving whole-brain radiation therapy. The pathogenesis is unknown, and most patients experience complete recovery of neurologic function.

Early-Delayed Toxicity

Early-delayed toxicity is noticed weeks to 3 months after completion of radiation treatment.[200] Most commonly, patients have drowsiness, nausea, headaches, ataxia, and worsening of underlying neurologic dysfunction. Complete resolution is expected, although rare patients have an idiosyncratic reaction with widespread brain necrosis.[201] The pathogenesis of early-delayed toxicity is unknown, but the reaction has been speculated to be related to reversible demyelination. CT reveals decreased attenuation in the cerebral white matter; MRI reveals increased signal intensity in white matter on T_2-weighted images.

Recently, early treatment-related brain injury has been reported with the use of concurrent daily temozolomide with external beam radiation in patients with glioblastoma.[202] Changes are seen on brain imaging studies that emulate tumor growth with increasing edema and an increase in uptake of contrast material. These changes, now referred to as "pseudo-progression," may reflect an increase in blood-brain barrier breakdown that is the consequence of an augmentation of radiation effect from the coadministration of chemotherapy.

Chronic, Late Radiation Injury

Chronic, late radiation injury usually appears 9 months to 2 years after completion of radiation treatment, although some patients have experienced onset of symptoms 10 years after treatment.[201,203] Patients exhibit focal areas of radiation necrosis or evidence of diffuse radiation injury. The incidence of each type of injury depends on the dose of treatment, fractionation schedule, and area of treatment.[204,205] Focal necrosis often manifests as focal neurologic deficits, such as hemiparesis or aphasia. Global signs such as obtundation can occur when the localized necrosis causes increased intracranial pressure and herniation. Similarly, focal necrotic regions can cause seizures. Pathologic examination of the necrotic region reveals vascular injury to the small arteries and arterioles and evidence of coagulative necrosis, with destruction of all elements of the nervous tissue.[45] Treatment is directed at decreasing edema and mass effect. Patients generally respond to corticosteroids.[206] Surgical resection, if feasible, can be curative.

Diffuse Injury

Diffuse injury manifests as global neurologic dysfunction, with personality change, confusion, and lethargy, and can progress to dementia, obtundation, or coma.[200,205] Diffuse white matter changes are found on CT or MRI, manifesting as low attenuation on CT scans and high signal intensity in the periventricular and subcortical white matter on T_2-weighted and proton density MR images.[207–209] Mass effect and focal neurologic signs are not common, although late in the course, seizures and motor dysfunction can occur. The main risk factors for diffuse injury include the volume of brain treated, concurrent or adjuvant chemotherapy directed at the CNS, and use of short-course, high-dose-fraction regimens. The incidence is difficult to determine, but reports have shown neurologic and imaging changes in 32% to 50% of patients subjected to radiation therapy.[208–210]

The pathogenesis of diffuse radiation injury is not known, although distinctive neuropathologic changes have been described. The most prominent pathologic finding is vascular changes in the small arteries and arterioles. Hyalinization of the vessel walls with occlusion is common.[205,209] In addition, areas of necrosis, gliosis, and demyelination are found. No established treatment is recognized. Corticosteroids may provide transient relief of associated edema but do not alter the course of the syndrome.

Necrotizing Leukoencephalopathy

Necrotizing leukoencephalopathy is the most severe form of neurologic toxicity associated with radiation therapy. It is most common when CNS-directed chemotherapy is combined with radiation therapy. This syndrome is described earlier in the discussion of methotrexate-associated toxicity. The incidence of leukoencephalopathy is much greater in patients who receive chemotherapy after cranial radiation therapy than in patients receiving either treatment alone, or in those receiving chemotherapy before the initiation of radiation therapy.[211,212]

Mineralizing angiopathy has occurred in pediatric patients receiving both intrathecal methotrexate and radiation therapy.[211] The changes frequently are diagnosed as dystrophic calcifications during neuroradiologic examinations. Histopathologic analysis reveals deposits of calcium in small blood vessels, often with surrounding regions of necrotic brain. The clinical significance of these changes is uncertain.

Cranial radiation therapy has been associated with a wide spectrum of endocrinologic effects.[213] Most of these effects are attributed to damage to the hypothalamic-pituitary axis. These effects are generally dose dependent and may manifest several years after completion of the radiation treatment. Results of several studies have suggested differing vulnerability among the various endocrine loops.[214] Growth hormone deficiency and stimulation of precocious puberty have occurred at doses as low as 18 Gy.[215] Deficiency of gonadotropins, thyroid-stimulating hormone, and corticotropin usually results only when the hypothalamic-pituitary axis receives more than 40 Gy.[216] Similarly, hyperprolactinemia occurs most often in young

women receiving more than 40 Gy of radiation therapy. Careful long-term monitoring of these patients is critical.[217] Appropriate replacement therapy or prolactin suppression treatment should prevent sequelae.

Radiation Myelopathy

Several distinct syndromes have resulted from the effects of radiation injury to the spinal cord: an acute syndrome manifesting as paraplegia or quadriplegia; early transient myelopathy; delayed progressive myelopathy; and an anterior horn, lower motor neuron syndrome.

The acute syndrome is rare with today's dosing schedules. Case reports state that weakness evolves over a few hours or days.[218] The syndrome probably is caused by acute necrotizing radiation injury due to rapidity of onset and failure of neurologic recovery.

The early transient form appears 6 to 12 weeks after treatment.[219] Most patients exhibit Lhermitte's sign—an electrical shock-like sensation down the spine with neck flexion. No neurologic deficits are found, and the symptoms resolve spontaneously over several weeks. Transient demyelination is hypothesized to be the cause of the symptoms.

Delayed progressive radiation myelopathy is the most common radiation therapy-induced spinal cord disorder, although it is relatively rare. Signs and symptoms generally develop 6 months to 1 year after completion of radiation therapy, although some data suggest that the latent period may be as long as 18 months to 2 years.[220] The clinical picture may vary from patient to patient. Some patients have monoplegia, others paraplegia or quadriplegia. Sensory symptoms are generally more severe than motor symptoms. Some patients have Brown-Séquard syndrome. Progression may take several years.[218] The pathogenesis is thought to be similar to that of delayed neurotoxicity after cranial radiation therapy (see earlier discussion).[218,219] Pathologic examination reveals rarefaction of spinal cord white matter with small areas of necrosis. Degeneration of myelin sheaths and loss of oligodendrocytes have been noted. Other causes of spinal cord dysfunction need to be excluded, including intramedullary tumor or infection, multiple sclerosis, vitamin B_{12} deficiency, sarcoidosis, and Lyme disease. There is no treatment, and most patients experience progressive neurologic dysfunction over months to years.

Lower motor neuron syndrome occurs after spinal cord radiation therapy. Patients exhibit pure motor signs of weakness, atrophy, and fasciculations.[218] The syndrome manifests 3 months to 2 years after radiation treatment and is similar to polio. The pathogenesis is unknown. Hypotheses include loss of anterior horn cell neurons and radiation-induced injury to motor nerve roots. No treatment except supportive care exists.

Peripheral Nerve Toxicity

Peripheral nerves are relatively resistant to the effects of radiation therapy. Early effects, developing within 2 days of a single large-fraction treatment in an experimental animal system, include changes in vascular permeability of the nerve, changes in bioelectrical activity, and abnormal microtubule assembly in the axon.[221] Late changes include fibrosis in the nerve sheath and angiopathic changes in the small arterioles providing the vascular supply to the nerve.[222] Use of large (greater than 25 Gy) single doses or extended fractionated treatment to a very high total dose (greater than 80 Gy) is thought to be necessary for injury to the peripheral nerve. Similar changes have been found for some cranial nerves.

Brachial and lumbar plexopathies warrant a separate discussion. These syndromes result from radiation injury to the nerve fibers in the plexus. Brachial plexopathy is most common, caused by axillary radiation therapy for breast cancer.[223] Lumbar plexopathy is more commonly associated with pelvic external-beam radiation therapy, although local radioactive seed implantation (brachytherapy) may result in local nerve damage.[221]

The diagnosis of radiation plexopathy can be difficult and requires excluding tumor infiltration as the cause of the symptoms. This process is most difficult with brachial plexus dysfunction and in patients with apical lung cancer or metastatic breast cancer. The distinguishing features in comparing radiation with tumor brachial plexopathy have been described extensively.[223] None of the criteria are absolute, although tumor infiltration is more likely to be painful and involve the lower nerve roots (C7–T1) than is radiation injury, which is less likely to cause severe pain and generally involves higher roots (C5 and C6). Acute reversible radiation injury to the brachial plexus has been described. This condition often is painful, although the pain generally is mild. Patients experience weakness and atrophy in a C6–T1 distribution. Spontaneous recovery is typical.

Radiation has been reported to accelerate vascular injury, causing segmental obstruction of the subclavian artery.[224] This condition usually is painless. The motor and sensory loss evolves quickly, without subsequent progression or improvement.

Lumbosacral plexopathy is less common than radiation-related brachial plexopathy.[225] Onset of signs and symptoms usually is delayed until at least 1 year after radiation treatment. Pain is usual and mild. The pathogenesis is uncertain, although fibrosis causing nerve compression and ischemia is a likely cause. The diagnosis of radiation-related lumbosacral plexopathy is made by excluding tumor infiltration. Imaging (MRI or CT) often is useful, although in select cases, surgical exploration is indicated.

Muscle Injury from Radiation Treatment

Muscle is thought to be relatively resistant to the effects of radiation therapy, although results of several studies have suggested that at higher doses (greater than 50 Gy), significant late toxicity may occur.[222] Early effects are uncommon, symptoms generally are found after 1 year, and the onset of changes has been reported as late as 10 years after radiation therapy. Signs and symptoms include muscle contractures, loss of function, pain, extremity edema, and pathologic fractures. The synergy of the toxic effects with those of chemotherapy is uncertain, although most patients have received both modalities of treatment.[222] No treatment other than conservative measures including physical therapy is helpful.

DIFFERENTIAL DIAGNOSIS

Dementia and Encephalopathy

Acute Encephalopathy

A common neurologic problem in patients with cancer is acute encephalopathy.[226] The differential diagnosis includes an extensive array of potential causes. Most commonly, however, acute encephalopathy is caused by toxic or metabolic derangement. Frequent causes include narcotic effects, electrolyte abnormalities, hypoxia, and renal or hepatic dysfunction. Neoplastic meningitis frequently manifests as mental status changes as a result of increased intracranial pressure, seizures, or infiltration of the cortex through the Virchow-Robin spaces surrounding surface blood vessels. Likewise, brain metastasis can cause an acute change in mental status when a sudden increase in tumor size (often hemorrhage) results in a rapid change in intracranial pressure or when tumor-induced seizures occur. A paraneoplastic syndrome, limbic encephalitis, can manifest as a progressive dementia, which often is subacute. This paraneoplastic syndrome most frequently is associated with small cell lung cancer, but it has been described in association with other tumors. Patients often are found to have serum anti-Hu antibodies, also a feature of paraneoplastic sensory neuropathy.[227–229]

Cancer treatment can directly or indirectly cause acute encephalopathy. High doses of intravenous methotrexate or ara-C can cause reversible encephalopathy, often accompanied by lethargy.[5,13,35] Results of studies with animals and with patients in which positron

emission tomography was used after high-dose methotrexate showed temporary reduction in brain metabolic activity in both glucose utilization and protein synthesis.[36,230] Folinic acid (leucovorin) administration improved metabolic activity in laboratory studies.[37] Other agents known to cause encephalopathy include vincristine, ifosfamide, procarbazine, fludarabine, paclitaxel, cisplatin, and L-asparaginase. The immunostimulant levamisole combined with 5-FU causes reversible encephalopathy and has been associated with a demyelinating condition known as multifocal inflammatory leukoencephalopathy.[145] The hormonal agent tamoxifen has been reported to cause encephalopathy at high doses. Biologic response modifiers such as the interferons and interleukins commonly cause reversible encephalopathy, although permanent neurologic sequelae may result from prolonged use of interferon.[183,184] Radiation therapy can cause an acute syndrome manifesting as lethargy that generally is reversible.

PRES has been seen most frequently with use of the immunomodulators cyclosporine and tacrolimus, but cisplatin, gemcitabine, and combination chemotherapy regimens also have been associated with the syndrome. More recently, drugs that modulate the VEGF pathway, such as bevacizumab and sorafenib, have been associated with PRES. The clinical manifestations are encephalopathy, cortical blindness, and variable loss of other higher cortical functions, such as aphasia and apraxia. Brain imaging with CT and MRI reveals characteristic patchy white matter changes (Fig. 61-3). The pathogenesis of the syndrome is unknown, although hypertension and hypomagnesemia have been associated. Full recovery has occurred with cessation of treatment or adjustment of the dose of the immunosuppressant.[231–235]

Many chemotherapeutic agents provoke a change in mental status by causing secondary metabolic derangement. Cyclophosphamide and vincristine can stimulate SIADH.[89,90,123,124] The resulting hyponatremia can lead to seizures and encephalopathy. Hyponatremia secondary to cisplatin-induced salt-wasting nephropathy can cause the same neurologic problems. Treatment with L-asparaginase, corticosteroids, and streptozocin can lead to glucose intolerance. Left untreated, this condition can result in nonketotic hyperosmolar coma. Many chemotherapeutic agents can cause hepatic and renal dysfunction with consequent development of secondary neurologic symptoms.

Chronic Encephalopathy and Dementia

Dementia, or chronic progressive loss of cognitive function, most commonly is associated with treatment directed at the CNS. Leukoencephalopathy, characterized histologically by white matter changes consisting of axonal swelling and loss with regions of demyelination, is the classic chronic or late neurotoxic syndrome.[4,6] Cognitive changes are first noticed 6 months to 2 years after completion of treatment and often are progressive, leading to profound dementia, coma, or death.[4–6,8,43] Intrathecal chemotherapy with methotrexate, ara-C, or thiotepa is most closely associated with leukoencephalopathy, although a similar syndrome occurs with high-dose intravenous methotrexate and ara-C and with intra-arterial chemotherapy (with BCNU or cisplatin).[236,237] Previous treatment with cranial radiation therapy significantly increases the risk of leukoencephalopathy.[5,52] Cranial radiation therapy alone can cause leukoencephalopathy, although the incidence increases markedly when radiation therapy is combined with chemotherapy. Other agents such as ifosfamide can cause prolonged encephalopathy and are associated with acute toxicity.[132]

Diagnostic Evaluation

A thorough search for a treatable underlying cause of encephalopathy should be undertaken in all affected patients. The diagnosis of chemotherapy-induced encephalopathy is made by excluding other potential causes. The order of diagnostic tests is dictated by the findings on the physical and neurologic evaluations. Patients with focal neurologic abnormalities need early imaging studies (CT or MRI), although certain metabolic disorders (e.g., hypoglycemia) can manifest as focal neurologic deficits. A metabolic evaluation, including measurement of electrolytes, renal and liver function tests, measurement of oxygenation, serum calcium and magnesium, serum ammonia, and possibly thyroid and adrenal function testing, should be performed for most patients. Careful review of prescribed and over-the-counter medications may provide critical information. In some cases, blood and urine toxicology screening may be necessary. EEG often is helpful in directing the evaluation by indicating the presence of structural abnormalities (e.g., periodic localizing epileptiform discharges or focal slowing) or may indicate a global metabolic process (e.g., diffuse slowing with D waves or triphasic waves in hepatic encephalopathy). Patients in subclinical status epilepticus may have encephalopathy; in these cases, the EEG findings are diagnostic. Lumbar puncture often is needed to exclude infectious or neoplastic meningitis. In most cases, head MRI or CT should be performed before lumbar puncture to look for a mass lesion in the brain that would make lumbar puncture unsafe. The search for the underlying cause often is revealing. One group of investigators reported uncovering the cause of encephalopathy in 31 of 37 patients.[226]

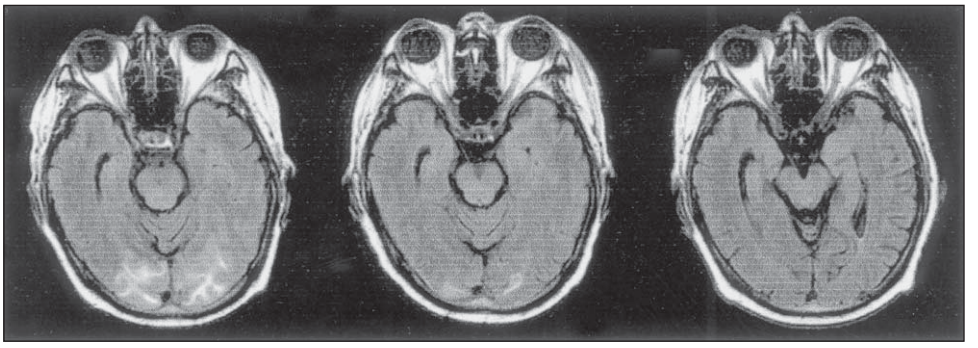

Figure 61-3 • Posterior reversible encephalopathy syndrome. The patient was a 47-year-old man with acute monocytic leukemia who had undergone allogeneic bone marrow transplantation and was receiving tacrolimus. He presented with headache, nausea, and vomiting. **A,** Magnetic resonance fast fluid-attenuated inversion recovery (FLAIR) image shows changes consistent with the syndrome. The patient's symptoms resolved within days of cessation of tacrolimus treatment. **B** and **C,** Repeated magnetic resonance images show resolution of the posterior abnormalities.

Table 61-1 Chemotherapeutic Agents That Cause Seizures

Agent	Route of Administration	Comment(s)
L-Asparaginase	Intravenous	Associated with cerebrovascular events
Bevacizumab	Intravenous	Associated with PRES
Busulfan	Oral	Bone marrow transplantation–preparative regimen
Cisplatin, oxaliplatin	Intravenous	Rare; may be associated with cortical blindness, PRES
Cytosine arabinoside	High-dose intravenous (acute)	Late with leukoencephalopathy
Ifosfamide	Intravenous	Associated with encephalopathy
Methotrexate	High-dose intravenous (acute)	Late with leukoencephalopathy
Metronidazole	Intravenous, oral	
Nitrosoureas	Intracarotid or supraophthalmic arterial	Often associated with focal brain necrosis
Sorafenib	Oral	Associated with PRES
Vincristine	Intravenous	

PRES, posterior reversible encephalopathy syndrome.

Seizures

Clinical Manifestations and Differential Diagnosis

The differential diagnosis for seizures in cancer patients includes an extensive list of possible causes. Causal factors can be broadly classified into toxic-metabolic and structural causes. Metabolic factors include hepatic and renal failure resulting from tumor growth or treatment toxicity, electrolyte abnormalities such as hypercalcemia from bone destruction or parathyroid hormone effect, hypomagnesemia from chemotherapy (cisplatin) or excessive vomiting, hyponatremia from SIADH or salt-wasting nephropathy (cisplatin), hypoxia, hyperglycemia from pancreatic failure (streptozocin), and glucose intolerance (corticosteroids). Several chemotherapeutic agents are known to be the direct cause of seizures (Table 61-1).

Structural causes of seizures include brain metastasis, dural metastasis, and meningeal carcinoma. Ischemic and hemorrhagic vascular events also may provoke seizures. A tumor-induced hypercoagulable state may greatly increase risk of stroke or venous sinus thrombosis.[238] A similar hypercoagulable state can be seen with L-asparaginase treatment. The paraneoplastic syndrome marantic endocarditis often results in cerebrovascular events, as can infectious endocarditis, a potential complication of treatment-induced neutropenia.[188] Cisplatin can cause vasospasm of the intracranial vessels, producing a stroke.[239] Furthermore, immunocompromised patients are at greater risk for CNS infection (including bacterial and fungal meningitis), brain abscess, and viral encephalitis (including progressive multifocal leukoencephalopathy).

Diagnostic Evaluation

The type of seizure dictates the initial evaluation. Focal seizures more commonly are associated with structural brain lesions, although metabolic disorders can precipitate focal seizures if an underlying structural problem is present. Generalized seizures may be the consequence of structural or metabolic processes or both.

The diagnostic evaluation generally involves a metabolic evaluation similar to that described for encephalopathy. Electrolyte imbalances, such as hyponatremia, hypomagnesemia, hypocalcemia or hypercalcemia, hyperglycemia, and hyperphosphatemia, are possible metabolic causes. Similarly, hepatic and renal dysfunction increase the likelihood of seizures, particularly in a patient with an underlying structural brain lesion. Most patients with cancer who experience a seizure require an imaging study of the brain (CT or MRI). These studies should be performed both with and without the administration of contrast material. EEG may be helpful in recognizing (or ruling out) ongoing seizure activity, in confirming the diagnosis of seizure if the event was not witnessed or not accompanied by tonic-clonic activity, or possibly in localizing a focal lesion or process. For example, EEG in patients with herpes encephalitis often demonstrates bitemporal periodic localizing epileptiform discharges, even before abnormalities are seen on MR images. Lumbar puncture may be needed to evaluate for infectious and neoplastic meningitis. Lumbar puncture should be performed after brain imaging, except in patients with suspected bacterial meningitis, in whom obtaining the scan would delay lumbar puncture and administration of antibiotic therapy.

The diagnosis of chemotherapy-induced seizures is made after other causes are excluded. For most chemotherapeutic agents, seizures develop acutely, either during or immediately after treatment. Seizures often are accompanied by encephalopathy. In most instances, the prognosis for recovery from the acute episode is good. Unfortunately, when seizures develop as a component of chronic or delayed neurotoxicity (leukoencephalopathy), the prognosis is poor, and neurologic dysfunction often progresses. In such instances, the seizures are a manifestation of widespread brain destruction.

Cerebellar Dysfunction

Clinical Manifestations and Differential Diagnosis

Cerebellar dysfunction in patients who have cancer occurs most commonly with metastatic spread to the cerebellum or brainstem. Meningeal carcinoma occasionally causes cerebellar signs by infiltrating cerebellar pathways. Patients with structural cerebellar lesions often show asymmetrical dysfunction, which can be useful in differentiating this condition from drug-induced cerebellar toxicity. Paraneoplastic cerebellar degeneration is is characterized by subacute progressive loss of cerebellar function.[228,240,241] Patients usually have symmetrical loss of all cerebellar function and exhibit appendicular and truncal ataxia, nystagmus, and scanning speech. This paraneoplastic syndrome occurs most commonly with lung cancer but also has been associated with gynecologic cancers and Hodgkin's disease. Many patients have antibodies in the serum, designated anti-Yo, that bind to cerebellar tissue, specifically Purkinje cells, and cross-react with tumor tissue.[240]

5-FU and ara-C can cause cerebellar toxicity from specific irreversible damage to the cerebellar Purkinje cells. The result is truncal ataxia, unsteady gait, dysarthria, and nystagmus.[12–15,137–144] The dysfunction usually is symmetrical. MRI findings immediately after chemotherapy are normal, but cerebellar atrophy often is detected at MRI months later.

Diagnostic Evaluation

Patients with cerebellar dysfunction should undergo MRI with and without gadolinium enhancement in an evaluation for metastatic lesions. In addition, the MRI findings may suggest the presence of neoplastic meningitis if enhancement is observed in the subarachnoid space. Patients with no evidence of brain metastasis need lumbar puncture to evaluate for neoplastic meningitis. Examination for the presence of serum anti-Yo antibodies should be performed, particularly in patients who have malignant lesions associated with this paraneoplastic syndrome.

In patients with only appendicular ataxia, the possibility of sensory ataxia must be kept in mind. The presence of sensory ataxia suggests the presence of severe sensory neuropathy, such as paraneoplastic sensory neuronopathy, dorsal column dysfunction from a structural lesion (e.g., epidural cord compression), or metabolic abnormality (e.g., vitamin B_{12} deficiency).

Cranial Neuropathy

Clinical Manifestations and Differential Diagnosis

Cranial neuropathy in patients with cancer most commonly indicates the presence of meningeal carcinoma, tumor involvement of the bones of the cranial base with encroachment of neural foramina, or rarely, brainstem metastasis.[242] Chemotherapy-induced cranial neuropathy is rare. Vincristine can cause cranial nerve palsy; extraocular eye movement abnormalities are most common.[62,66,79,80] Intraventricular administration of drugs and of biologic response-modifying agents can cause transient cranial nerve palsy, often due to abnormalities in CSF circulation.[243]

In both neoplastic meningitis and drug-induced cranial nerve palsy, the seventh (facial) cranial nerve most commonly is affected. Unfortunately, there is little to differentiate the clinical manifestations of drug-induced nerve palsy from those of neoplastic meningitis. Both conditions can involve several cranial nerves, be indolent in onset, and demonstrate spontaneous resolution. Therefore, examination of the CSF is critical in the care of patients with suggestive signs and symptoms. In addition to neoplastic meningitis, tumor encroachment on neural foramina at the skull base from bone metastasis can cause cranial nerve palsy, as can small intraparenchymal lesions (tumor, infarct, or hemorrhage), although such lesions are rare.

Diagnostic Evaluation

In the care of patients with cranial nerve palsy, serial examinations of the CSF often are needed to determine whether tumor cells are present. Evaluation of the bones of the skull base with thin-section CT helps determine the presence of metastatic bone lesions. MRI of the brainstem is performed to evaluate for intraparenchymal lesions, although in most instances, other brainstem signs are present, in which case this test should be part of the initial evaluation.

Optic Neuropathy and Ocular Toxicity

Clinical Manifestations and Differential Diagnosis

Optic neuropathy can be seen in patients with neoplastic meningitis, lymphoma, or leukemia with infiltration of the optic nerve.[244,245] In addition, compression from cranial base tumors can cause similar loss of vision. Optic neuritis, characterized by unilateral or bilateral loss of vision, has been reported as a rare paraneoplastic syndrome associated with small cell lung cancer.[246] Loss of vision often is accompanied by photosensitivity and papilledema. Antiretinal antibodies have been found in the serum of affected patients. Retinopathy most commonly is associated with intracarotid administration of nitrosoureas and cisplatin.[112,113,158,159] High concentrations of drug flow into the ophthalmic artery, which supplies the retina, causing severe pain and often complete loss of vision. Newer techniques, allowing administration above the ophthalmic artery, have reduced the incidence of this local toxicity.

Intravenous cisplatin administration has been associated with optic disk swelling and optic neuropathy.[104,105] This reaction is idiosyncratic, and the mechanism is unknown.

Diagnostic Evaluation

Chemotherapy-induced retinopathy from intra-arterial administration occurs soon after treatment and is rarely difficult to diagnose. Optic neuropathy from cisplatin is more indolent, and other causes must be considered, such as isoniazid, chlorpropamide, or ethambutol toxicity or paraneoplastic optic neuropathy. Optic nerve tumors and frontal lobe mass lesions can cause optic atrophy, although they are uncommon causes of isolated optic atrophy. MRI or CT may be helpful.

Spinal Cord Toxicity

Clinical Manifestations and Differential Diagnosis

The most common cause of spinal cord dysfunction in patients is epidural cord compression, either from direct extension of bone metastasis or from paravertebral spread through the intervertebral foramina. Intramedullary tumor and extramedullary intradural tumors can have myelopathic manifestations.[247] Similarly, epidural abscess and hematoma can be clinically indistinguishable from epidural tumor. Encephalomyelitis is a frequently described paraneoplastic syndrome associated with several types of tumors, particularly small cell lung cancer.[248] A rare paraneoplastic myelopathy has been described with lung cancer, renal cell carcinoma, and Hodgkin's disease. This syndrome is characterized by subacute progression of spinal cord dysfunction, usually in the thoracic region, although damage occasionally occurs at several levels. Pathologic examination reveals segmental necrosis.

Lumbar intrathecal administration of methotrexate and ara-C can result in focal myelopathy.[19–25] Symptoms and signs appear hours to days after treatment and can include sensory loss, upper and lower motor neuron dysfunction, radiating pain (similar to Lhermitte's sign), and bowel and bladder incontinence. The myelopathy may be transient or progressive; complete irreversible paraplegia usually is seen with progressive dysfunction. Myelopathy also has been reported with spinal radiation therapy. A rare, acute syndrome develops over days. The more common chronic myelopathy with radiation therapy develops months after completion of treatment.

Diagnostic Evaluation

The diagnostic evaluation of patients with spinal cord dysfunction is directed by findings on physical examination and the history. Rapid progression of symptoms suggests the presence of a rapidly growing tumor causing cord compression, epidural hematoma, or abscess. This finding warrants emergency evaluation with MRI. Early loss of bowel and bladder function or a suspended sensory level suggests the presence of an intramedullary lesion, best visualized by contrast-enhanced MRI.

Evidence of chemotherapy myelopathy may include edema on MRI and elevated myelin basic protein levels in CSF. The diagnosis of chemotherapy myelopathy often is made on the basis of temporal association with intrathecal treatment in the absence of other potential causes. Neoplastic meningitis can mimic spinal cord compression and requires CSF examination for diagnosis.

Peripheral Neuropathy

Clinical Manifestations and Differential Diagnosis

Peripheral neuropathy is a common paraneoplastic syndrome. Mild sensorimotor neuropathy is the most common neuropathy in patients with cancer.[249] The cause is unknown, but the condition is a distinct entity, separate from the diffuse weakness associated with cachexia. Rare pure motor and pure sensory paraneoplastic neuropathies also have been described. Sensory neuronopathy, most common with small cell lung cancer, causes severe sensory loss.[250,251] The intense

Table 61-2 Agents That Cause Peripheral Neuropathy

Agent	Comment(s)
Bortexomib	Primarily sensory, dose- and cumulative dose–related
Cisplatin	Large sensory fiber (vibration, proprioception); dose- and cumulative dose–related; dose-limiting
Cytosine arabinoside	Rare, symmetrical sensorimotor polyneuropathy
Interferons	Transient paresthesia
Oxaliplatin	Large sensory fiber (vibration, proprioception); dose- and cumulative dose–related; dose-limiting; acute hyperexcitability syndrome
Paclitaxel, docetaxel	Dose-related sensorimotor; dose-limiting
Procarbazine	Transient paresthesia
Thalidomide, lenalidomide	Sensory-motor axonal polyneuropathy; incidence related to duration and dose of treatment
Vincristine	Frequent; dose-related; autonomic and sensorimotor; exacerbated in patients with underlying neuropathy; dose-limiting

inflammatory reaction and neuronal destruction in the dorsal root ganglia have led to use of the term *dorsal root ganglionitis*. Some patients are found to have anti-Hu antibodies in serum.[228,251] Motor neuronopathy manifests as isolated lower motor neuron loss.[252] This syndrome has been found in both patients with Hodgkin's lymphoma and those with non-Hodgkin's lymphoma. The pathogenesis of this pure motor syndrome is unknown. Other causes of neuropathy that should be considered are diabetes, thyroid dysfunction, vitamin B_{12} deficiency, and alcoholic neuropathy.

Several cancer chemotherapeutic agents cause peripheral neuropathy. These are listed in Table 61-2. The peripheral neuropathy secondary to chemotherapy is temporally related to administration for most agents. Cisplatin is an exception, and delayed neuropathy occurs in some patients.

Carcinomatous meningitis can manifest as multilevel radiculopathy, initially mimicking peripheral neuropathy. Likewise, brachial and lumbar plexopathy from tumor infiltration or radiation therapy can mimic neuropathy, but careful neurologic examination determines the localized nature of the process.

Diagnostic Evaluation

The evaluation of a patient with neuropathy depends on the results of the neurologic examination. Determination of the components of the peripheral nervous system involved is critical in guiding evaluation. Pure motor loss in a patient with lymphoma strongly suggests the presence of a paraneoplastic process, although CSF analysis should be performed to exclude Guillain-Barré syndrome. Likewise, the presence of pure sensory neuropathy involving both small and large sensory fibers suggests dorsal root ganglionitis. Pure large-fiber sensory neuropathy is most common with cisplatin treatment. Nerve conduction testing and electromyelography (EMG) may be helpful in determining whether the process is axonal or demyelinating. Some patients should undergo lumbar puncture to exclude carcinomatous meningitis, or evaluation for Guillain-Barré syndrome.

Myopathy

Clinical Manifestations and Differential Diagnosis

Myopathy is a rare symptom in cancer, usually being the consequence of treatment. Dermatomyositis and polymyositis are paraneoplastic syndromes characterized by inflammatory myopathy and by the presence and the absence of a rash, respectively.[253,254] Dermatomyositis and polymyositis have been associated with many tumors, most commonly lung and gastrointestinal tumors. Patients have an elevated serum creatine kinase (CK) level. Although myopathy is a rare complication of chemotherapy, it has been described with use of paclitaxel and vincristine.[63,86,255]

Interferon and other biologic response-modifying agents can cause myalgia, but no evidence of muscle dysfunction or breakdown is found on histopathologic examination of muscle biopsy specimens. Cisplatin and other agents that induce electrolyte abnormalities (e.g., hypomagnesemia) can cause muscle cramping.

Diagnostic Evaluation

For patients with clinical evidence of myopathy, serum CK should be measured before EMG is performed. An elevated CK level suggests active muscle destruction, as in polymyositis or dermatomyositis or with use of paclitaxel or vincristine. Measurement of electrolytes (e.g., magnesium, potassium) may be useful. In patients with loss of strength or with muscle pain, EMG and muscle biopsy may be necessary.

GRADING OF NEUROTOXICITY

None of the uniform grading systems of neurotoxicity are suitable for use in serial clinical evaluations. The most commonly used neurotoxicity measures are based on the National Cancer Institute's Common Terminology Criteria for Adverse Events (CTCAE)—Neurology, as shown in Table 61-3. Although these toxicity tables are useful in the evaluation of groups of patients, they are not suitable for monitoring the clinical status of individual patients. Standard neurologic testing with careful recording is best suited for individual patient care. The techniques required for performing an in-depth neurologic evaluation are reviewed in classic neurology textbooks.[256,257] Quantitative measures of mental status function, motor examination results, and sensory function have been published.[258–260]

TREATMENT

No specific treatment exists to prevent or reverse neurotoxicity from most chemotherapeutic agents and regimens in use. Therefore, the focus should be on monitoring for development of toxicity so that treatment can be modified before the development of severe dysfunction. Rational treatment guidelines for minimizing neurotoxicity are needed.

Prevention

The key to prevention of permanent neurologic damage is to initiate a system for monitoring for toxicity. For example, patients receiving intrathecal chemotherapy are at risk of chemotherapy-induced myelopathy, an often irreversible toxicity. These patients may report vague neurologic symptoms or radicular back pain during the course of treatment that may be an early sign of neurologic damage. Findings at neurologic examination may not indicate loss of function, but

Table 61-3 National Cancer Institute Common Terminology Criteria for Adverse Events: Neurologic Toxicities

		Grade				
Adverse Event	**Short Name**	**1**	**2**	**3**	**4**	**5**
Navigation note: ADD is graded as Cognitive disturbance.						
Navigation note: Aphasia, receptive and/or expressive, is graded as Speech impairment (e.g., dysphasia or aphasia).						
Apnea	Apnea	—	—	Present	Intubation indicated	Death
Arachnoiditis/ meningismus/ radiculitis	Arachnoiditis	Symptomatic, not interfering with function; medical intervention indicated	Symptomatic (e.g., photophobia, nausea), interfering with function but not interfering with ADLs	Symptomatic, interfering with ADLs	Life-threatening; disabling (e.g., paraplegia)	Death
Also consider: Fever (in the absence of neutropenia, defined as ANC $<1.0 \times 10^9$/L); Infection (documented clinically or microbiologically) with grade 3 or 4 neutrophils (ANC $<1.0 \times 10^9$/L)–*Select*; Infection with normal ANC or grade 1 or 2 neutrophils–*Select*; Infection with unknown ANC–*Select*; Pain–*Select*; Vomiting.						
Ataxia (incoordination)	Ataxia	Asymptomatic	Symptomatic, not interfering with ADLs	Symptomatic, interfering with ADLs; mechanical assistance indicated	Disabling	Death
Remark: Ataxia (incoordination) refers to the consequence of medical or operative intervention.						
Brachial plexopathy	Brachial plexopathy	Asymptomatic	Symptomatic, not interfering with ADLs	Symptomatic, interfering with ADLs	Disabling	Death
CNS cerebrovascular ischemia	CNS ischemia	—	Asymptomatic, radiographic findings only	Transient ischemic event or attack (TIA) ≤24 hr duration	Cerebral vascular accident (CVA, stroke), neurologic deficit >24 hr	Death
Navigation note: CNS hemorrhage/bleeding is graded as Hemorrhage, CNS in the Hemorrhage/Bleeding category.						
CNS necrosis/cystic progression	CNS necrosis	Asymptomatic, radiographic findings only	Symptomatic, not interfering with ADLs; medical intervention indicated	Symptomatic and interfering with ADLs; hyperbaric oxygen indicated	Life-threatening; disabling; operative intervention indicated to prevent or treat CNS necrosis/ cystic progression	Death
Cognitive disturbance	Cognitive disturbance	Mild cognitive disability; not interfering with work/school/life performance; specialized educational services/devices not indicated	Moderate cognitive disability; interfering with work/school/life performance but capable of independent living; specialized resources on part-time basis indicated	Severe cognitive disability; significant impairment of work/ school/life performance	Unable to perform ADLs; full-time specialized resources or institutionalization indicated	Death
Remark: Cognitive disturbance may be used for ADD.						
Confusion	Confusion	Transient confusion, disorientation, or attention deficit	Confusion, disorientation, or attention deficit interfering with function, but not interfering with ADLs	Confusion or delirium interfering with ADLs	Harmful to others or self; hospitalization indicated	Death
Remark: Attention Deficit Disorder (ADD) is graded as Cognitive disturbance.						
Navigation note: Cranial neuropathy is graded as Neuropathy–cranial–*Select*.						
Dizziness	Dizziness	With head movements or nystagmus only; not interfering with function	Interfering with function, but not interfering with ADLs	Interfering with ADLs	Disabling	—
Remark: Dizziness includes disequilibrium, lightheadedness, and vertigo.						
Also consider: Neuropathy: cranial–*Select*; Syncope (fainting).						

Table 61-3 National Cancer Institute Common Terminology Criteria for Adverse Events: Neurologic Toxicities—cont'd

		GRADE				
Adverse Event	**Short Name**	**1**	**2**	**3**	**4**	**5**
Navigation note: Dysphasia, receptive and/or expressive, is graded as Speech impairment (e.g., dysphasia or aphasia).						
Encephalopathy	Encephalopathy	—	Mild signs or symptoms; not interfering with ADLs	Signs or symptoms interfering with ADLs; hospitalization indicated	Life-threatening; disabling	Death
Also consider: Cognitive disturbance; Confusion; Dizziness; Memory impairment; Mental status; Mood alteration–*Select*; Psychosis (hallucinations/delusions); Somnolence/depressed level of consciousness.						
Extrapyramidal/involuntary movement/restlessness	Involuntary movement	Mild involuntary movements not interfering with function	Moderate involuntary movements interfering with function, but not interfering with ADLs	Severe involuntary movements or torticollis interfering with ADLs	Disabling	Death
Navigation note: Headache/neuropathic pain (e.g., jaw pain, neurologic pain, phantom limb pain, postinfectious neuralgia, or painful neuropathies) is graded as Pain–*Select* in the Pain category.						
Hydrocephalus	Hydrocephalus	Asymptomatic, radiographic findings only	Mild to moderate symptoms not interfering with ADLs	Severe symptoms or neurological deficit interfering with ADLs	Disabling	Death
Irritability (children <3 years of age)	Irritability	Mild; easily consolable	Moderate; requiring increased attention	Severe; inconsolable	—	—
Laryngeal nerve dysfunction	Laryngeal nerve	Asymptomatic, weakness on clinical examination/testing only	Symptomatic, but not interfering with ADLs; intervention not indicated	Symptomatic, interfering with ADLs; intervention indicated (e.g., thyroplasty, vocal cord injection)	Life-threatening; tracheostomy indicated	Death
Leak, cerebrospinal fluid (CSF)	CSF leak	Transient headache; postural care indicated	Symptomatic, not interfering with ADLs; blood patch indicated	Symptomatic, interfering with ADLs; operative intervention indicated	Life-threatening; disabling	Death
Remark: Leak, cerebrospinal fluid (CSF) may be used for CSF leak associated with operation and persisting >72 hours.						
Leukoencephalopathy (radiographic findings)	Leukoencephalopathy	Mild increase in subarachnoid space (SAS); mild ventriculomegaly; small (± multiple) focal T_2 hyperintensities, involving periventricular white matter or <1/3 of susceptible areas of cerebrum	Moderate increase in SAS; moderate ventriculomegaly; focal T_2 hyperintensities extending into centrum ovale or involving 1/3 to 2/3 of susceptible areas of cerebrum	Severe increase in SAS; severe ventriculomegaly; near total white matter T_2 hyperintensities or diffuse low attenuation (CT)	—	—
Remark: Leukoencephalopathy is a diffuse white matter process, specifically NOT associated with necrosis. Leukoencephalopathy (radiographic findings) does not include lacunae, which are areas that become void of neural tissue.						
Memory impairment	Memory impairment	Memory impairment not interfering with function	Memory impairment interfering with function, but not interfering with ADLs	Memory impairment interfering with ADLs	Amnesia	—
Mental status*	Mental status	—	1–3 points below age and educational norm in Folstein Mini-Mental Status Exam (MMSE)	>3 points below age and educational norm in Folstein MMSE	—	—
Mood alteration–*Select*: • Agitation • Anxiety • Depression • Euphoria	Mood alteration–*Select*	Mild mood alteration not interfering with function	Moderate mood alteration interfering with function, but not interfering with ADL; medication indicated	Severe mood alteration interfering with ADLs	Suicidal ideation; danger to self or others	Death

Table 61-3 National Cancer Institute Common Terminology Criteria for Adverse Events: Neurologic Toxicities—cont'd

		Grade				
Adverse Event	**Short Name**	**1**	**2**	**3**	**4**	**5**
Myelitis	Myelitis	Asymptomatic, mild signs (e.g., Babinski's or Lhermitte's sign)	Weakness or sensory loss not interfering with ADLs	Weakness or sensory loss interfering with ADLs	Disabling	Death
Navigation note: Neuropathic pain is graded as Pain–*Select* in the Pain Category.						
Neuropathy: cranial–*Select* • CN I Smell • CN II Vision • CN III Pupil, upper eyelid, extraocular movements • CN IV Downward, inward movement of eye • CN V Motor–jaw muscles; Sensory–facial • CN VI Lateral deviation of eye • CN VII Motor–face; Sensory–taste • CN VIII Hearing and balance • CN IX Motor–pharynx; Sensory–ear, pharynx, tongue • CN X Motor–palate; pharynx, larynx • CN XI Motor-sternomastoid and trapezius • CN XII Motor–tongue	Neuropathy: cranial–*Select*	Asymptomatic, detected on exam/testing only	Symptomatic, not interfering with ADLs	Symptomatic, interfering with ADLs	Life-threatening; disabling	Death
Neuropathy: motor	Neuropathy–motor	Asymptomatic, weakness on exam/testing only	Symptomatic weakness interfering with function, but not interfering with ADLs	Weakness interfering with ADLs; bracing or assistance to walk (e.g., cane or walker) indicated	Life-threatening; disabling (e.g., paralysis)	Death
Remark: Cranial nerve *motor* neuropathy is graded as Neuropathy: cranial–*Select*. *Also consider*: Laryngeal nerve dysfunction; Phrenic nerve dysfunction.						
Neuropathy: sensory	Neuropathy–sensory	Asymptomatic; loss of deep tendon reflexes or paresthesia (including tingling) but not interfering with function	Sensory alteration or paresthesia (including tingling), interfering with function, but not interfering with ADLs	Sensory alteration or paresthesia interfering with ADLs	Disabling	Death
Remark: Cranial nerve *sensory* neuropathy is graded as Neuropathy: cranial–*Select*.						
Personality/behavioral	Personality	Change, but not adversely affecting patient or family	Change, adversely affecting patient or family	Mental health intervention indicated	Change harmful to others or self; hospitalization indicated	Death
Phrenic nerve dysfunction	Phrenic nerve	Asymptomatic weakness on exam/testing only	Symptomatic but not interfering with ADLs; intervention not indicated	Significant dysfunction; intervention indicated (e.g., diaphragmatic plication)	Life-threatening respiratory compromise; mechanical ventilation indicated	Death
Psychosis (hallucinations/delusions)	Psychosis	—	Transient episode	Interfering with ADLs; medication, supervision or restrains indicated	Harmful to others or self, life-threatening consequences	Death
Pyramidal tract dysfunction (e.g., ↑ tone, hyperreflexia, Babinski's sign, ↓ fine motor coordination)	Pyramidal tract dysfunction	Asymptomatic, abnormality on exam or testing only	Symptomatic; interfering with function but not interfering with ADLs	Interfering with ADLs	Disabling; paralysis	Death

Table 61-3 National Cancer Institute Common Terminology Criteria for Adverse Events: Neurologic Toxicities—cont'd

		GRADE				
Adverse Event	**Short Name**	**1**	**2**	**3**	**4**	**5**
Seizure	Seizure	—	One brief generalized seizure; seizure(s) well controlled by anticonvulsants or infrequent focal motor seizures not interfering with ADLs	Seizures in which consciousness is altered; poorly controlled seizure disorder, with breakthrough generalized seizures despite medical intervention	Seizures of any kind which are prolonged, repetitive, or difficult to control (e.g., status epilepticus, intractable epilepsy)	Death
Somnolence/ depressed level of consciousness	Somnolence	—	Somnolence or sedation interfering with function, but not interfering with ADLs	Obtundation or stupor; difficult to arouse; interfering with ADLs	Coma	Death
Speech impairment (e.g., dysphasia or aphasia)	Speech impairment	—	Awareness of receptive or expressive dysphasia, not impairing ability to communicate	Receptive or expressive dysphasia, impairing ability to communicate	Inability to communicate	—
Remark: Speech impairment refers to a primary CNS process, not neuropathy or end organ dysfunction.						
Also consider: Laryngeal nerve dysfunction; Voice changes/dysarthria (e.g., hoarseness, loss, or alteration in voice, laryngitis).						
Syncope (fainting)	Syncope (fainting)	—	—	Present	Life-threatening consequences	Death
Also consider: CNS cerebrovascular ischemia; Conduction abnormality/atrioventricular heart block–*Select*: Dizziness; Supraventricular and nodal arrhythmia–*Select*; Vasovagal episode; Ventricular arrhythmia–*Select*.						
Navigation note: Taste alteration (CN VII, IX) is graded as Taste alteration (dysgeusia) in the Gastrointestinal category.						
Tremor	Tremor	Mild and brief or intermittent but not interfering with function	Moderate tremor interfering with function, but not interfering with ADLs	Severe tremor interfering with ADLs	Disabling	—
Neurology—Other (Specify)	Neurology—Other (Specify)	Mild	Moderate	Severe	Life-threatening; disabling	Death

ADD, attention deficit disorder; ADLs, activities of daily living; ANC, absolute neutrophil count; CNS, central nervous system; CT, computed tomography.

an elevated CSF myelin basic protein level indicates that with subsequent treatment, the risk of myelopathy is high.[24,25]

Vincristine treatment can cause peripheral neuropathy. Some patients exhibit autonomic neuropathy out of proportion to the sensorimotor neuropathy. The autonomic dysfunction can lead to intestinal dysmotility, ileus, and viscus perforation. Therefore, all patients undergoing vincristine chemotherapy should be carefully evaluated for the development of abdominal symptoms. Obstipation from vincristine would mandate avoiding further vincristine treatment.

Modification of Drug Dosing or Order

In certain treatment regimens, altering the order of the drugs administered can result in a marked decrease in the risk of neurotoxic complications. The risk of methotrexate-induced leukoencephalopathy after therapy for meningeal leukemia or carcinoma is reduced if the chemotherapy treatments, particularly intrathecal chemotherapy, precede cranial radiation therapy.[5] The reason for this schedule-dependent toxicity is unknown. It has been suggested that radiation opens the blood-brain barrier, thereby increasing exposure of the brain to subsequent chemotherapy effects. Other regimens in which dose order seems important include combination chemotherapy with cisplatin and ifosfamide. Patients receiving cisplatin before ifosfamide are at greater risk for ifosfamide-induced encephalopathy.[135]

Despite concern for synergistic neurotoxicity, certain regimens have been shown not to cause excessive neurotoxic effects. For example, a phase I study of paclitaxel and cisplatin included frequent neurologic examinations as a critical component.[261] Despite the well-recognized effects of both drugs on the peripheral nervous system, minimal overlapping toxicity occurred. Cisplatin treatment caused dose-related loss of vibratory sensation, whereas paclitaxel treatment correlated with loss of peripheral motor function. These findings underscore the importance of including careful neurologic testing as a component of phase I and II trials of new drugs and combination therapies.

Protective Agents

Interest continues in developing agents that either block development of certain chemotherapy-induced neuropathies or help reverse toxicity. Published reports of studies of neuroprotection during chemotherapy have recently been reviewed.[262] In the former category, the agent ORG 2766 has been reported to protect against cisplatin neuropathy. This drug, a synthetic analog of corticotropin, was tested in a double-blind, placebo-controlled trial in which patients with

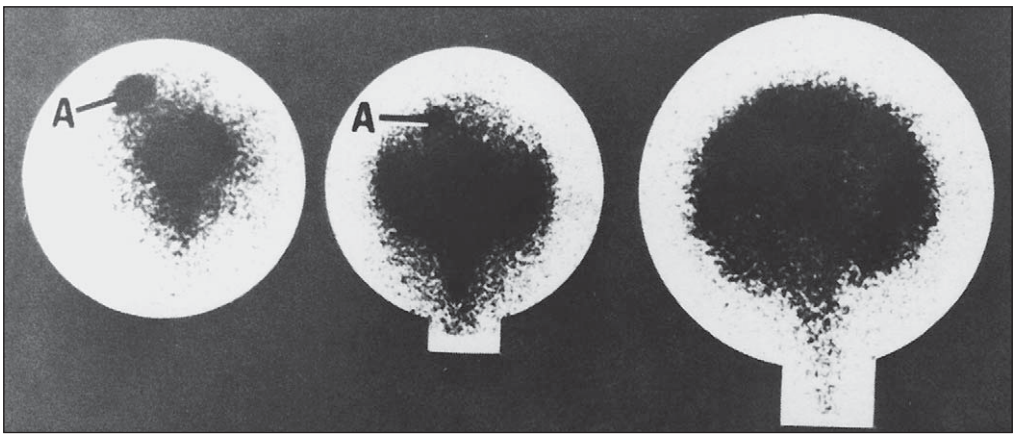

Figure 61-4 • Normal cerebrospinal fluid indium 111–diethylenetriaminepenta-acetic acid (DTPA) flow scan. Anterior cortical views immediately after injection *(left)*, at 4 hours *(middle)*, and at 24 hours *(right)*. A, reservoir.

ovarian cancer underwent intensive cisplatin therapy. A dose-related protective effect was found.[30] Although the mechanism of action is unknown, results of laboratory studies suggest that ORG 2766 works synergistically with trophic factors (e.g., nerve growth factors) to promote nerve regeneration.[263,264] Results of a study conducted with a tissue culture model suggested that corticotropin fragments may have a direct cellular protective role.[265] Amifostine, an organic thiophosphate, protects normal cells from the effects of radiation. Amifostine has been tested as a neuroprotectant with paclitaxel therapy in two phase III studies: A study of non-small-cell lung cancer found a reduction in incidence of radiation esophagitis but not in paclitaxel-induced neuropathy.[266] In a second study of ovarian cancer, the incidence of grade 3 and grade 4 peripheral neuropathy was significantly reduced.[267] Glutamine also has been evaluated as a neuroprotectant for the peripheral nervous system.[268] In a study with a small group of patients, the incidence of peripheral neuropathy among patients receiving paclitaxel plus glutamine (10 g orally, three times a day for 4 days after paclitaxel) was compared with the incidence when paclitaxel was given alone.[268] A statistically significant reduction in severe neuropathy was found in the glutamine treatment group, with significant decreases in the incidence and severity of dysesthesia, motor weakness, worsening of gait, and impairment of activities of daily living. Acetyl-L-carnitine has been reported to lessen neuropathic symptoms in patients receiving paclitaxel or cisplatin.[269] Alpha-lipoic acid, a broad-spectrum antioxidant, reportedly may help ameliorate symptoms from docetaxel and cisplatin or oxaliplatin neuropathy. Leucovorin may be helpful in reversing acute methotrexate-induced encephalopathy and somnolence.[37] The administration of methylene blue has been reported to accelerate recovery from ifosphamide-induced encephalopathy.[270] There is no known therapy for chemotherapy-induced leukoencephalopathy once brain injury has developed.

The acute neuropathic syndrome associated with oxaliplatin has generated special interest because of the painful nature of this toxicity. Various treatments including infusions of calcium gluconate, oral gabapentin, oral carbamazepine, intravenous amifostine, and intravenous glutathione have been used to prevent the development of this complication.[113,271] Infusions of calcium gluconate and alpha-lipoic acid also have been used to treat the acute neuropathy once it has developed.

Recognition of Groups at High Risk for Development of Neurotoxicity

Certain patients are at high risk for the development of treatment-related neurotoxicity. Patients with underlying peripheral neuropathy (e.g., Charcot-Marie-Tooth disease, diabetic neuropathy) have been reported to be much more susceptible to development of severe neuropathy, including potentially fatal autonomic neuropathy.[272,273] Such patients need careful monitoring with immediate cessation of treatment if autonomic dysfunction develops. Similarly, in patients in whom peripheral neuropathy may be a component of the cancer, such as multiple myeloma, the use of a neurotoxic agent such as bortezomib may increase the likelihood and severity of neuropathy.[194]

Patients with meningeal tumors (carcinoma, leukemia, lymphoma) often require extensive intrathecal chemotherapy. An intraventricular reservoir often is placed for this purpose. Before the reservoir system is used to administer chemotherapy, it is essential that correct placement and normal CSF flow be confirmed. This procedure is most readily performed by injecting indium 111-labeled albumin into the lateral ventricle through the reservoir system.[274,275] Not only does this test help confirm catheter placement, but also monitoring the flow of tracer at 6, 24, and 48 hours helps determine the presence of abnormalities of clearance from the ventricular system or drug resorption at the arachnoid granulations. Figure 61-4 shows normal CSF flow and resorption of tracer through the arachnoid granulations. By contrast, Figures 61-5 and 61-6 show poor outflow from the lateral ventricles persisting 24 hours after contrast injection. Poor clearance of drug markedly increases the neurotoxicity of intraventricular treatment. Patients with poor ventricular outflow may

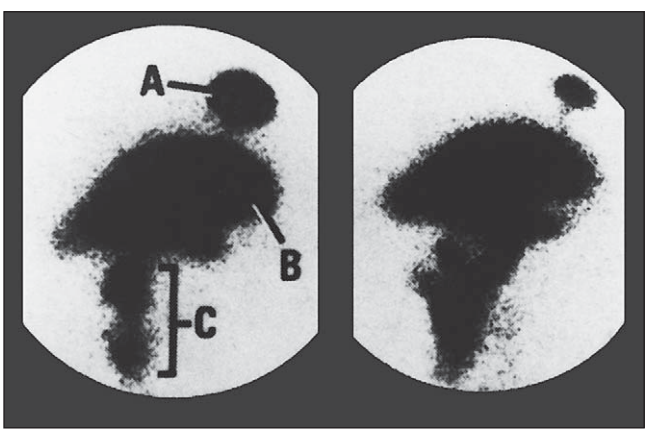

Figure 61-5 • Ventricular outlet obstruction, lateral cortical view. Scans immediately after injection *(left)* and hours later *(right)*. The reservoir (A), lateral ventricles (B), and fourth ventricle (C) are visible.

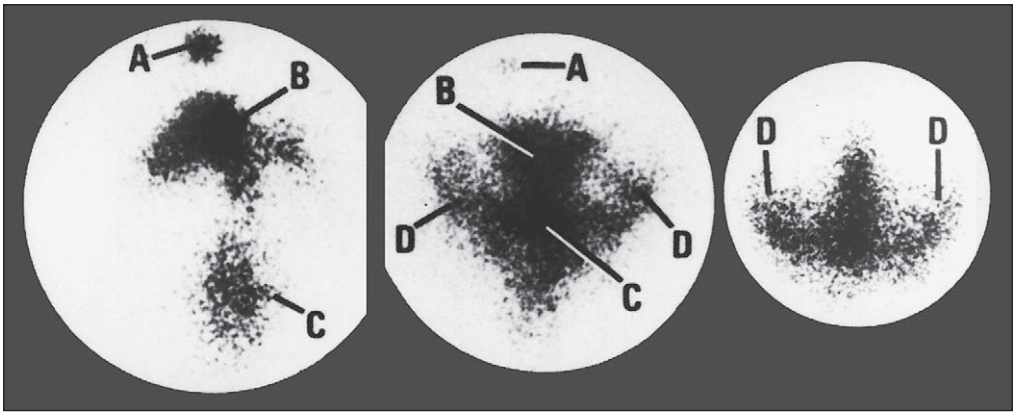

Figure 61-6 • Obstruction of flow over cortical convexities. Scans immediately after injection *(left)*, at 4 hours *(middle)*, and at 24 hours *(right)*. Visible are the reservoir (A), lateral ventricles (B), fourth ventricle (C), and tracer rising over the low portion of the cortical convexities (D).

need local radiation therapy for restoration of normal flow before instillation of chemotherapeutic agents.

Irreversible ototoxicity from cisplatin administration is more severe in patients with underlying hearing loss. Hearing loss with cisplatin also may be accelerated when the inner ear region and temporal lobe are included in the irradiated field.[118] Radiation treatment before or after cisplatin administration can cause this synergistic ototoxicity.

CONCLUSIONS

The incidence of chemotherapy-induced neurotoxicity is increasing as a consequence of advances in supportive care, use of higher doses of drugs, newer treatments targeted at the CNS, and prolonged patient survival, which allows toxicities with long latencies to become evident. The diagnosis of treatment-associated neurotoxicity is made after other diagnostic possibilities are excluded and when the pattern of toxicity is consistent with recognized neurotoxic effects. In most cases, options for management of treatment-associated neurotoxicity are limited. The optimal strategy is early recognition of neurotoxicity, careful monitoring of patients at increased risk for toxicity, and modification of regimens to avoid synergistic toxicity when possible. Future directions should include investigation of the mechanisms of toxicity and development of techniques for protecting the nervous system without altering the antineoplastic effect of treatment.

62 Pulmonary Complications of Anticancer Treatment

Mitchell Machtay

SUMMARY OF KEY POINTS

Radiation Pneumonitis

Risk Factors

- Older age
- Lower performance status
- Lower baseline pulmonary function
- Large radiation volume treated with more than a "threshold" dose (it is frequently debated what this threshold dose is; the range is from 5 to 20 Gy)
- Cumulative radiation dose
- Lower lobe primary tumor
- Levels of cytokines such as TGF-β and interleukin-6

Diagnosis

- The most predominant symptoms are dyspnea and hypoxia, especially on exertion.
- Fever (usually low grade), cough, pleuritic chest pain, and other pulmonary symptoms are also common.
- Diffusing capacity of the lung for carbon dioxide is the most sensitive value during pulmonary function testing.
- Interstitial or ground-glass infiltrate usually, but not always, corresponds well to the irradiated volume.
- Findings at bronchoscopy are relatively unremarkable (bronchial lavage may reveal lymphocytosis).
- Pulmonary embolism, infection, and progressive tumor must be ruled out. These conditions can coexist with radiation pneumonitis.
- Response to corticosteroids is usually rapid.

Treatment

- The best treatment is prevention. Patients must be selected carefully for thoracic radiation, and irradiated volumes must be limited.
- Corticosteroids are very useful in the management of acute and subacute pneumonitis (although they have no prophylactic or therapeutic value in the management of long-term radiation fibrosis).
- Consultation with a pulmonologist is necessary.
- Oxygen is administered as indicated to prevent hypoxia.
- High doses of corticosteroids (60 mg/day of prednisone) with slow tapering are needed for severe grade 2 or any grade 3 radiation pneumonitis.
- If prolonged corticosteroid treatment is anticipated, prophylaxis against corticosteroid complications is needed. These measures include gastrointestinal prophylaxis, diet and pharmacologic management of hyperglycemia, infection prophylaxis, and osteoporosis prophylaxis.
- Antibiotics, bronchodilators, diuretics, and anticoagulation are administered as indicated for coexisting cardiopulmonary illnesses.

Drug-Induced Lung Injury

Risk Factors

- Usually, bleomycin, nitrosoureas, and mitomycin or combinations of several potentially pneumotoxic agents that on their own may only have modest pneumotoxicity (e.g., gemcitabine and weekly docetaxel)
- Bone marrow transplantation
- Concurrent or recent thoracic radiation therapy
- Lower baseline pulmonary function

Diagnosis

- Dyspnea and hypoxia are predominant, but a wide range of possible symptoms exists.
- Interstitial or ground-glass infiltrate usually is diffuse throughout both lungs and may be worse in the lower lobes.
- Findings at bronchoscopy are relatively unremarkable (bronchial lavage may reveal lymphocytosis).
- Pulmonary embolism, infection, and progressive tumor must be ruled out and may coexist with drug-induced lung injury.
- Injury is usually (but not universally) corticosteroid responsive; less likely to respond well to steroids than radiation pneumonitis but more likely to respond well than late radiation fibrosis.

Treatment

- When the diagnosis is suspected, the suspected causative agent should be discontinued.
- Consultation with a pulmonologist is necessary.
- Oxygen is administered as indicated to prevent hypoxia. (Note that high FiO_2 levels may be dangerous in bleomycin-related pneumonopathy).
- High doses of corticosteroids (≥60 mg/day of prednisone) with slow taper may be needed for severe grade 2 or any grade 3 pneumonitis.
- If prolonged corticosteroid treatment is anticipated, prophylaxis against corticosteroid complications entails gastrointestinal prophylaxis, diet or pharmacologic management of hyperglycemia, infection prophylaxis, and osteoporosis prophylaxis.
- Antibiotics, bronchodilators, diuretics, and anticoagulation are administered as indicated to manage coexisting cardiopulmonary illnesses.

INTRODUCTION

Although relatively uncommon, pulmonary disorders are among the most feared complications of anticancer therapy. Many cancer patients are elderly and/or suffering from one or more underlying comorbidities; therefore, a relatively minor challenge to the lungs can result in respiratory failure and death.

The two major categories of pulmonary complications are radiation pneumonopathy and drug-induced pneumonopathy. These conditions do not include other major categories of pulmonary disease in cancer patients, such as pulmonary embolism, infection (community-acquired, atypical, and aspiration pneumonia), and anatomic complications of tumor and/or medical-surgical interventions, such as pulmonary hemorrhage and fistula. Radiation therapy or chemotherapy can contribute to these multifactorial problems of the respiratory system.

Radiation pneumonopathy and drug-induced pneumonopathy share several important features, most notably that they are usually processes of the interstitium of the lung and thus can cause marked impairment of gas exchange and dyspnea. Corticosteroids are the mainstay of management of both types of pneumonopathy but at best may provide a only a temporary symptomatic improvement and at worst can cause life-threatening infections or other complications. Better techniques for avoiding treatment-related pneumonopathy—and better therapy for established pneumonopathy—will come only from improved understanding of and intervention against the complex molecular processes that cause and maintain these pathologic states.

PULMONARY TOXICITY OF THORACIC RADIATION THERAPY

Thoracic radiation is probably the most important cause of pulmonary toxicity in oncology. Lung toxicity from radiation is a clinically relevant issue for lymphoma, breast cancer, bone marrow transplantation (BMT), esophageal cancer, and lung cancer. Figure 62-1 illustrates a typical case of radiation pneumonitis and its sequelae.

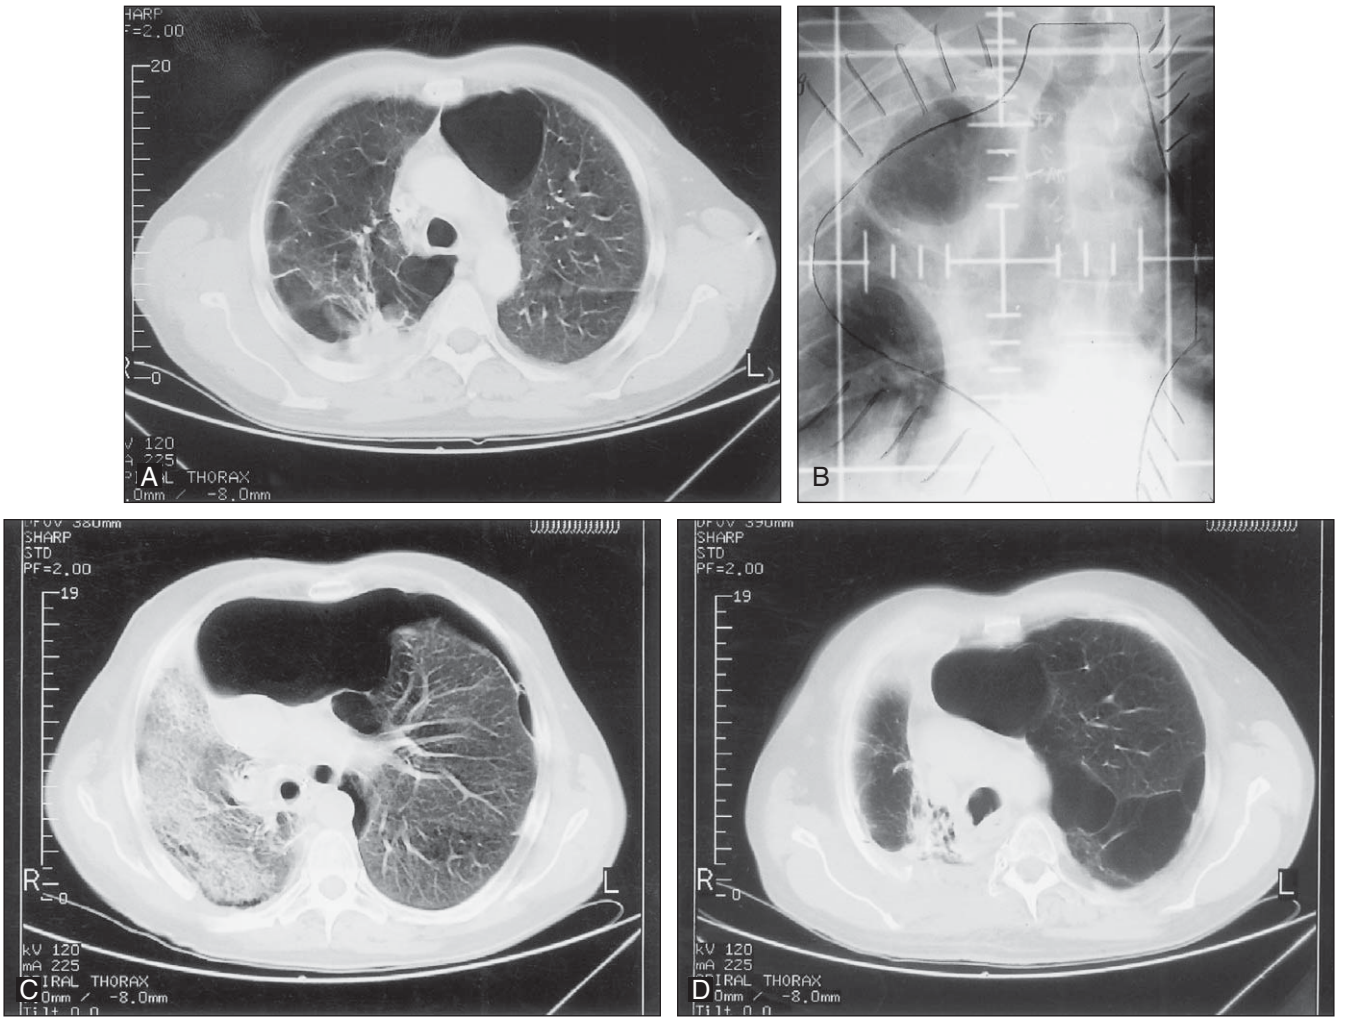

Figure 62-1 • Case example of radiation pneumonopathy. **A,** Diagnostic computed tomographic (CT) scan shows signs of advanced chronic obstructive pulmonary disease with bullous disease in an elderly man who had dyspnea and chest pain. Posteriorly located adenocarcinoma of the lung was found and clinically staged $T_3N_0M_0$. **B,** Radiation simulation image. The patient underwent gross total surgical resection but was found to have positive tumor margins and received radical radiation therapy to the chest. **C,** CT scan. Approximately 6 weeks after radiation therapy, progressively severe dyspnea developed, culminating in profound dyspnea necessitating hospitalization. Grade 3 acute radiation pneumonitis in the right lung was found with left-sided pneumothorax. The patient was treated with steroids, antibiotics, and a Pleurx catheter. **D,** CT scan. Approximately 1 year later, the patient's condition was stable with no evidence of recurrent cancer. The patient had discontinued steroid therapy but needed intermittent oxygen therapy for radiation fibrosis of the right lung.

The mechanisms behind radiation-induced lung injury remain poorly understood despite decades of study. A detailed review of the histopathologic and molecular events occurring in radiation pneumonopathy is beyond the scope of this chapter; several excellent reviews have been published in the last decade.[1–3] Irradiation damages endothelial cells, epithelial cells (particularly surfactant-producing type II pneumocytes), and reticuloendothelial cells within the lung through several mechanisms, including apoptosis and induction of stress response genes. It is now generally agreed that cytokines, such as transforming growth factor beta (TGF-β), play a major role in promoting radiation pneumonopathy, including development of long-term fibrosis.[4,5] It can be difficult histopathologically (or molecularly) to differentiate established radiation lung injury from other forms of end-stage lung disease, such as idiopathic pulmonary fibrosis, drug-induced injury, or even very advanced chronic obstructive pulmonary disease. Traditional clinical understanding of radiation lung injury recognizes two distinct syndromes: radiation pneumonitis and radiation fibrosis of the lung. Radiation pneumonitis is characterized by intense interstitial inflammation and alveolar exudate. It develops over several weeks to months after irradiation and (if the host/patient survives) resolves within 6 to 12 months. Radiation pulmonary fibrosis, in contrast, generally does not begin until several months after radiation therapy but progresses relentlessly over years. Radiation pneumonitis usually responds well to corticosteroids; in fact, a dramatic response to steroids helps to distinguish this disorder from other diagnoses. In contrast, corticosteroids do not influence the progression of radiation pulmonary fibrosis.

In most cases, radiation lung injury is confined to the regions of the lung within the radiation field or portal. This conventional wisdom has been challenged by several researchers who have found evidence of "out-of-field" radiation injury, which may be manifested in a syndrome similar to bronchiolitis obliterans with organizing pneumonia (BOOP).[6] In the most severe cases, diffuse acute respiratory distress syndrome can result from partial lung irradiation even with steroid treatment.[7] Autoimmunity has been hypothesized as a mechanism of out-of-field radiation lung injury, with the possibility that localized lung damage triggers diffuse lymphocyte-mediated hypersensitivity against pulmonary self antigens.[8]

Radiation lung injury may have any of a variety of clinical and radiographic presentations, but the hallmark symptom is generally dyspnea out of proportion to other findings. The most common imaging finding is an interstitial infiltrate corresponding to the radiation portals, but it is not unusual to find consolidation, nodularity, or even pleural effusions. The extent of radiographic findings does not necessarily correlate with the extent of symptoms or the patient's clinical course.[9] This problem can make the differential diagnosis among recurrent/progressive cancer, infection, and radiation lung injury extremely difficult, particularly in patients with lung cancer. Positron emission tomography with fluorodeoxyglucose may be helpful for differentiating recurrence from radiation toxicity, although intense radiation pneumonitis and even actively developing fibrosis causes elevated fluorodeoxyglucose uptake.[10]

Incidence of Radiation Lung Injury and Predictive Factors

The most important factor influencing development of clinically relevant radiation lung injury is the volume of lung irradiated; this issue is extensively discussed in the radiation oncology literature.[11–15] In radiation oncology, the lung is considered a parallel-architecture organ, meaning that destruction of very small portions of it should not cause overall organ dysfunction. In contrast, other organs, such as the spinal cord, are considered series-architecture organs, in which destruction of one region will lead to irreversible dysfunction downstream from that injury.[16]

Irradiation of the entire lung volume (bilateral lungs) is uncommon today, except as part of total body irradiation for selected BMT conditioning regimens. As reviewed by Sampath and colleagues, the therapeutic index for whole-lung irradiation is extraordinarily narrow and highly dependent on total dose, fractionation, partial lung transmission shielding, and dose rate[17]; a typical dose of 12 Gy total body irradiation has approximately 11% rate of severe pneumonitis, compared with approximately 2% when lung transmission shielding is used to reduce the lung dose to 6 Gy. At the other extreme, irradiation of small lung volumes rarely results in radiation pneumonitis. For example, in tangential irradiation of the breast (after lumpectomy) or chest wall (after mastectomy), the risk of clinically significant radiation pneumonitis is approximately 1%, increasing to approximately 5% with the addition of irradiation of the regional (axillary/supraclavicular) nodes.[18–20] Furthermore, radiation pneumonitis after small-volume thoracic radiation therapy such as this may be relatively mild and usually resolves completely.

Understanding the true incidence of radiation pneumonopathy is complicated by limitations of the historical and current standards for defining and grading this illness.[19] The traditional scoring system developed by the Radiation Therapy Oncology Group (RTOG), which dates back to the early 1970s, is shown in Table 62-1.[20,21] This system is no longer endorsed by major academic centers or organizations because of its several limitations[22]; however, understanding of this system is important because most modern publications rely on it. Among the limitations of the RTOG scoring system are that grade 1 radiation lung injury is almost certainly

Table 62-1 Traditional Scoring System for Radiation Lung Injury Based on the Radiation Therapy Oncology Group

Grade	(Acute) Radiation Pneumonopathy (Within 90 Days of Start of XRT)	(Late) Radiation Pneumonopathy (>90 Days After Start of XRT)
1	Mild, dry cough; dyspnea on significant exertion	Asymptomatic (e.g., slight radiographic findings only) or mild symptoms (e.g., dry cough).
2	Dyspnea on minimal exertion and/or persistent cough (requiring narcotics)	Moderate symptomatic fibrosis and/or pneumonitis (severe cough), fever, patchy radiographic appearances
3	Obvious severe radiation pneumonitis with dyspnea at rest and/or severe cough unresponsive to narcotics. Oxygen and/or steroids are indicated.	Severe symptomatic fibrosis/pneumonitis with dense radiographic changes
4	Life-threatening respiratory insufficiency requiring continuous oxygen/mechanical ventilation	Life-threatening respiratory insufficiency requiring continuous oxygen/mechanical ventilation
5	Death	Death

RTOG, 2000 #497;RTOG, 2000 #498.

underreported and that the distinction between grade 2 and grade 3 toxicity is highly subjective. Furthermore, the RTOG has in the past arbitrarily divided toxicity scales into early versus late on the basis of a 90-day cutoff point from the start of radiation therapy; this is inappropriate for many types of complex radiation injuries such as pneumonopathy. The new Common Terminology Criteria (CTCv3) for adverse events has been adopted for current and future studies.[23,24] The CTCv3.0 definitions and grading for selected pulmonary events are shown in Table 62-2. There have been numerous changes to the scoring criteria in the pulmonology section, and sep-

Table 62-2 CTCv3.0 Selected Common Terminology Criteria for Adverse Events Related to the Lung

Event	Grade 1	Grade 2	Grade 3	Grade 4
Acute respiratory distress syndrome	N/A	N/A	Present; intubation not required	Present; intubation required
Aspiration	Asymptomatic ("silent")	Symptomatic (e.g., altered eating habits, coughing/choking episodes); medical intervention required	Clinical or radiographic signs of pneumonia; unable to aliment orally	Life-threatening aspiration pneumonia
Atelectesis	Asymptomatic	Symptomatic (e.g., dyspnea, cough), medical intervention indicated (e.g., bronchoscopy)	Severe; operative intervention (e.g., stent, laser) indicated	Life-threatening respiratory compromise
Carbon monoxide diffusion capacity (DLCO)	90% to 75% of predicted value	74% to 50% of predicted value	49 % to 25% of predicted value	<25% of predicted value.
Cough	Symptomatic, nonnarcotic medication used	Symptomatic, requires narcotics	Symptomatic and significantly interfering with sleep or activities of daily living	N/A
Dyspnea	Dyspnea on exertion but able to walk up one flight of stairs without stopping.	Dyspnea on exertion, unable to walk one flight of stairs or one city block without stopping	Dyspnea with activities of daily living	Severe dyspnea at rest; intubation/ventilator indicated
FEV1	90% to 75% of predicted value	74% to 50% of predicted value	49% to 25% of predicted value	<25% of predicted value
Fistula	Asymptomatic (imaging findings only)	Symptomatic; medical management	Symptomatic; invasive management indicated	Life-threatening consequences (e.g., requiring multiple thoracotomies)
Hypoxia	N/A	Decreased O_2 saturation with exercise (<88% pulse oximetry)	Decreased O_2 saturation at rest; continuous oxygen therapy indicated	Life-threatening; intubation/ventilator indicated
Pleural effusion (nonmalignant)	Asymptomatic	Symptomatic, requiring intervention such as diuretics or 1 to 2 therapeutic thoracenteses	Symptomatic requiring supplemental oxygen, >2 thoracenteses and/or chronic indwelling catheter and/or pleurodesis	Life-threatening (e.g., causing hemodynamic instability and/or intubation/ventilator indicated)
Pneumonitis/pulmonary infiltrates	Asymptomatic (imaging finding)	Symptomatic but not interfering with activities of daily living	Symptomatic, interfering with activities of daily living; O_2 indicated	Life-threatening; intubation/ventilator indicated
Pneumothorax	Asymptomatic (imaging finding)	Symptomatic, requiring intervention (e.g., hospitalization for observation or temporary chest tube)	Sclerosis and/or operative indication required	Life-threatening (e.g., causing hemodynamic instability and/or intubation/ventilator indicated)
Prolonged intubation (following elective surgery/intubation)	N/A	Extubated within 24 to 72 hours postoperatively	Extubated >72 hours	Tracheostomy indicated
Pulmonary fibrosis	Minimal imaging findings, estimated % of total lung volume that is fibrotic is estimated <25%	Estimated % of total lung volume that is fibrotic is 25% to 49%	Dense widespread infiltrates/consolidation with estimated % of total lung volume that is fibrotic 50% to 75%	Estimated % of total lung volume that is fibrotic is >75%; honeycombing

Note that this is an abbreviated/abridged version of the CTCv3; the complete version can be found at ctep.cancer.gov/forms/CTCAEv3.pdf.

Note that as with the older scoring systems, grade 5 (not shown) is death, and grade 0 is the absence of the particular toxicity. Note that for some adverse events, Grades 1 to 2 (mild to moderate) might not be applicable (e.g., ARDS); conversely, for some adverse events, Grade 4 (life-threatening) might not be applicable (e.g., cough).

Table 62-3 Selected Clinical Studies of the Incidence and Severity of Radiation Pneumonopathy

Study	Patient Population	Rate of Grade 2 Pneumonopathy (%)	Rate of Grade 3+ Pneumonopathy (%)	Comments
LUNG CANCER STUDIES				
Byhardt et al.[120]	388 patients treated with chemo-RT.	NS	17	2-dimensional, large-field XRT. Grade 3 RP 20% with concurrent chemo-RT versus 10% with sequential chemo-RT
Keller et al.[121]	488 patients with postoperative RT ± concurrent chemo	NS	3.5	Moderate (50 Gy) XRT dose; high performance status population.
Turrisi et al.[122]	417 patients (limited stage small cell cancer) with concurrent chemo-RT	12	5	No difference between once daily and twice a day XRT
Wang et al.[13]	223 patients treated with 3-D XRT + concurrent chemo	NS	32	Higher rate than other studies may reflect the use of actuarial statistics and CTCv3 definition
Hope et al.[123]	219 patients treated with high-dose 3-D XRT.	12	11	Strong association of RP with tumor location, lung DVH characteristics
STUDIES IN CANCERS OTHER THAN LUNG CANCER				
Lind et al.[124] (breast cancer)	613 patients with breast cancer		NS	RP was significantly more common with regional nodal irradiation
Yu et al.[125] (breast cancer)	189 patients with breast cancer randomized between different chemo regimens prior to RT	5	<1	High rate (24% to 39%) of radiographic changes but low rate of clinical RP
Hughes-Davies et al.[126] (Hodgkin's disease)	172 patients with bulky intrathoracic Hodgkin's disease	14	NS	1% fatal toxicity
Koh et al.[26] (Hodgkin's disease)	64 patients with Hodgkin's disease	3	<1	RP associated with larger lung volume irradiated
Cooper et al.[127] (esophageal cancer)	117 patients with esophageal cancer treated with chemo-RT	NS	4	
Ishikura et al.[128] (esophageal cancer)	139 patients with esophageal cancer treated with chemo-RT	2	2	Radiation-induced cardiac complications and/or pleural effusions were more common than RP

arate scales are no longer used for early and late radiation therapy-related events.

Despite limitations of the scoring systems for radiation lung injury, some clinical studies provide insight into the complex relations among volume of lung irradiated, regions of lung irradiated, radiation dose, and host factors. Table 62-3 summarizes the literature on this topic. Most clinical radiation oncology studies have focused on the concept of the dose-volume histogram (DVH), in which percentage of total lung irradiated is plotted against radiation dose. The concept of DVH and V20 is shown in Figure 62-2. With modern radiation planning software integrating findings at computed tomography (CT), DVHs are easy to generate. However, there is no consensus on how to interpret these plots. Some researchers suggest that the most relevant information obtained from DVHs is the V20 (percentage of total lung volume irradiated to more than 20 Gy (conventionally fractionated radiation therapy); others recommend

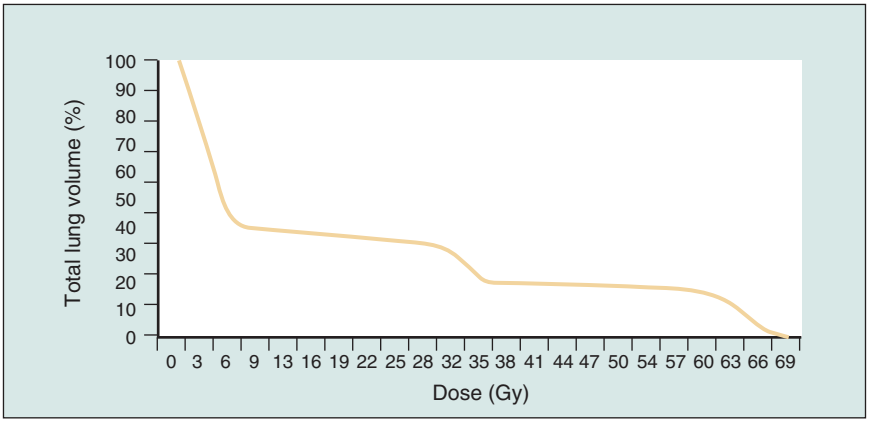

Figure 62-2 • Graphic representation (*yellow curve*) of dose-volume histogram for total lung volume irradiated to a nominal dose of 63 Gy in a patient with lung cancer. In this case, the V20 (the percentage of total lung volume receiving >20 Gy) is approximately 36%, which is considered a moderate-risk dose level for clinical radiation pneumonopathy.

emphasizing V30 (percentage of total lung volume irradiated to >30 Gy), V13, V5, and so on. Other researchers recommend using mean lung dose or complex formulas based on multiple parameters of the DVH curve to predict radiation pneumonitis. Retrospective studies conducted with moderate to large samples of patients with analyzable DVHs and clinical courses consistently show that lung toxicity is associated with lung DVH characteristics that reflect large volumes of irradiated lung. However, studies have not clearly defined a safe lung DVH in therapy for lung cancer. It is clear that irradiation of a smaller lung volume results in less pneumonopathy; a randomized trial showed that the incidence of radiation pneumonitis was significantly reduced from 29% to 17% with the use of "involved-field" radiotherapy, despite the use of higher tumor radiotherapy doses in the involved field arm.[25]

One flaw with the use of DVH analysis to predict radiation pneumonopathy is that the DVH is based solely on anatomic data, with no consideration of lung physiology or the patient's underlying health. In a DVH, every cubic centimeter of lung tissue is considered to have the same physiologic utility to the patient. This might be accurate for relatively young and healthy individuals such as Hodgkin's disease patients, who have a modest risk of radiation pneumonopathy,[26] but is almost certainly wrong for elderly smokers with cancer of the lung or esophagus. Among lung cancer patients, a higher risk of radiation pneumonopathy is seen for lower-lobe cancer treatment.[15,27] Nuclear medicine scans such as lung ventilation/perfusion scans may therefore be a useful adjunct to radiation planning.[28] Although radiation dose-volume parameters are the major predictor of radiation pneumonopathy, other factors are important. Some of these are treatment-related factors, including daily radiation fraction size[29] and the use of concurrent chemotherapy. The issue of chemotherapy has been particularly controversial and difficult to study. It appears that neoadjuvant chemotherapy before radiotherapy does not greatly affect the risk of radiation pneumonopathy. However, concurrent chemoradiotherapy probably increases the risk significantly; the maximum tolerated dose of localized radiotherapy with concurrent chemotherapy for non-small-cell lung cancer is generally considered to be 74 Gy.[30] Higher doses are achievable with radiotherapy alone.[14,31] A combination of concurrent radiotherapy and gemcitabine appears to have a particularly high rate of radiation pneumonopathy, and extreme caution is advised for this combination.[32] Several other drugs, most notably the anthracyclines (e.g., doxorubicin), methotrexate, and bleomycin, should be considered contraindicated during thoracic radiotherapy. Concurrent thoracic radiotherapy plus a taxane (paclitaxel or docetaxel) is a commonly used and generally safe combination, although it has been suggested that the risk of radiation pneumonopathy might be slightly higher than expected from historical series based on older chemo-RT regimens, particularly with weekly taxane schedules.[33,34] It may be especially prudent to use three-dimensional radiotherapy techniques and to carefully analyze lung DVH parameters in patients who are receiving a concurrent taxane.

Nontreatment factors that appear to be predictive of radiation lung injury have been studied. Not surprisingly, pretreatment performance status has been shown to correlate with development of clinical radiation pneumonopathy.[35] Underlying pretreatment pulmonary function is probably an important factor as well,[36] although study results have been inconsistent.[37,38] This might be because in many cases, poor pretreatment pulmonary function is due to effects of the cancer itself, in which case an effective treatment (such as radiotherapy) may substantially improve rather than harm pulmonary function.

Diagnosis and Management of (Acute and Subacute) Radiation Pneumonitis

With modern, conformal, multifield radiation therapy, it is no longer possible to simply look for pathognomonic rectangular infiltrates on a chest radiograph. A patient who has recently undergone radiation treatment and has dyspnea or other pulmonary symptoms of greater than grade 1 intensity should undergo CT scanning, in some cases with high-resolution CT imaging. CT angiography may also be indicated to rule out pulmonary embolism. Imaging will typically reveal an interstitial infiltrate and/or ground-glass appearance, which can be very difficult to distinguish from an infection. Suspected moderate to severe radiation pneumonopathy should be evaluated by a pulmonologist for consideration of bronchoscopy to rule out infection, particularly if fever is present.[39]

Pulse oximetry or arterial blood gas testing should be performed to assess the need for supplemental oxygen. Pulmonary function testing, especially the diffusion capacity of the lung for carbon monoxide (DLCO) test, is useful as part of the diagnostic workup, in particular to assess the severity of gas-exchange dysfunction. Spirometric parameters of pulmonary function are frequently reversible after radiation pneumonopathy, while DLCO abnormalities are less likely to improve.[40] The tests and procedures to be considered in evaluation of cancer patients with suspected pneumonopathy are summarized in Table 62-4. This workup should be considered appropriate for either suspected radiation-related or chemotherapy-related pneumonopathy.

If the clinical manifestations and test results are consistent with grade 2 or greater radiation pneumonitis, administration of corticosteroids should be instituted in most cases. Controlled randomized trials of corticosteroids for radiation pneumonitis have not been conducted with human subjects. However, the efficacy of corticosteroids has been well established in nonrandomized clinical studies[41] and in preclinical models.[42] There is no single "standard" dose schedule for steroid therapy for radiation pneumonopathy; the exact schedule must be tailored to the individual patient. In general, for severe (grade 3) radiation pneumonitis, prednisone approximately 1 mg/kg/day is indicated for 2 weeks. Brief hospitalization for intravenous administration of steroids may be indicated. Early onset of radiation pneumonitis following the completion of radiotherapy may predict a more virulent course and therefore might require a more aggressive management approach.[7] Moderate radiation pneumonitis (grade 2) may be effectively managed with somewhat lower initial doses of steroids (e.g., 0.5 to 0.75 mg/kg/day of prednisone); however, the patient must be evaluated frequently to ascertain that his or her condition is not progressing to grade 3 or worse radiation pneumonitis. After several weeks, the dose should be tapered gently, by approximately 10 mg every 2 weeks. It is not unusual for patients to have a symptomatic relapse in the setting of steroid taper.[43] If relapse occurs, it is important to rule out concomitant infection. If the diagnosis of recurrent radiation pneumonitis is confirmed, the steroid dose should be increased and titrated accordingly.

With these guidelines, the typical patient with grade 3 or intense grade 2 radiation lung injury will take steroids for approximately 2 to 4 months. Some patients need steroids for considerably longer, although the benefit after 6 months is dubious (when radiation pneumonitis has generally resolved and might be superseded by fibrosis). At the outset, the physician should explain to the patient the potential need and implications of longer-term steroid use. A proton-pump inhibitor or histamine$_2$-blocker should be prescribed to counteract gastritis. Consideration should be given to evaluation for, and medical prophylaxis against, osteoporosis. Patients should be counseled about exercise (as tolerated by their pulmonary symptoms) and diet to minimize problems with steroid-induced hyperglycemia and muscle wasting. Blood chemistry values, including fasting glucose, liver function tests, and albumin, should be checked periodically. If a diuretic is being used with steroids, it is important to check serum electrolyte levels frequently.

It is uncertain whether a low-dose "prophylactic" antibiotic should be prescribed. In any given patient with interstitial pneumonitis after thoracic radiotherapy, it can be very difficult to entirely rule out a concomitant infection, particularly if bronchoscopy or other invasive

Table 62-4 Evaluation of the Cancer Patient with Pulmonary Symptoms (Especially Dyspnea) and Suspected Radiation or Chemotherapy Pneumonopathy

Study	Rationale
Basic, minimal workup	
CT of chest, preferably both with and without contrast	Assess extent/appearance/location of infiltrates/effusions; correlate with radiation therapy and/or surgical data. Rule out recurrent/progressive cancer and/or other etiologies for dyspnea.
Pulse oximetry	Assess degree of hypoxia and possible need for supplemental oxygen.
Pulmonary function testing (spirometry and DLCO)	Assess extent and type of pulmonary function (radiation/drug pneumonitis is a restrictive pattern, with DLCO often markedly abnormal compared with baseline levels).
CBC/diff; chemistry panel	Rule out leukocytosis and/or leucopenia (possible signs of infection), anemia, hepatic and/or renal insufficiency (all factors that can lead to pulmonary distress).
Extended workup (if diagnosis is in question and/or if there is possibility of coexisting cardiorespiratory problems)	
High-resolution pulmonary-embolus protocol CT scan, V/Q scan and/or pulmonary angiogram	Rule out pulmonary embolism.
Electrocardiogram	Rule out cardiac ischemia and/or dysrhythmia.
Blood test for B-type natriuretic peptide (BNP)	Rule out CHF.
Arterial blood gas testing	More accurate measure of oxygenation than pulse oximetry; measurement of pH and CO_2 levels.
Blood cultures	Rule out sepsis and/or endocarditis.
Bronchoscopy	Rule out infection (particularly if atypical infection is suspected) and assess for possible recurrent cancer.
PET/CT scan	Assessment of status of the cancer; possible role as adjuvant form of imaging the extent of lung injury.
Open lung biopsy (e.g., thoracoscopic biopsy)	Definitive diagnosis but high-risk procedure. Avoid if diagnosis is highly likely and response to steroids is good.

Notice that chest x-ray is not a sufficiently sensitive or specific test to warrant inclusion in this table.

diagnostic procedure was not done.[39] In light of the profound lymphopenia that most patients have after chemoradiation therapy and steroid treatment (as with typical concurrent paclitaxel-radiation therapy regimens), it might be appropriate to prescribe an every-other-day dose of trimethoprim-sulfamethoxazole (Bactrim) when starting high-dose steroids.[44,45] If findings at chest CT suggest the presence of coexistent active infection, broader and more intense antibiotics are indicated. The patient should undergo bronchoscopy if there is no improvement after several days of steroid and antibiotic therapy.

The prognosis of grade 1 to 2 radiation pneumonitis is relatively good with meticulous supportive care and the use of steroids as needed. Grade 3 radiation pneumonitis, however, at least in lung cancer patients, has a much worse prognosis.[7,13] It is uncertain whether this is the direct result of radiation pneumonitis or coexisting problems, including tumor recurrence and infection.

It is uncertain how to manage radiation pneumonopathy that is refractory to steroids and/or in the patient who has severe contraindications to steroids. There have been case reports of the use of antirheumatic medications such as cyclosporin,[46,47] but there is little scientific evidence to support their use.

As described in the following sections, patients with radiation pneumonitis should receive supportive care based on careful and frequent assessment of their symptoms and risk factors for further complications of their illness.

Management of (Chronic and Late) Radiation Pulmonary Fibrosis

Although radiation pneumonitis usually is relieved with steroids, radiation pulmonary fibrosis is not. Some patients undergoing steroid therapy for radiation pneumonitis eventually start to experience worsening pulmonary function. This decline may be caused by pulmonary fibrosis but also may be caused at least in part by disorders such as infection, cardiac problems, and pulmonary embolism, and reevaluation is indicated. If it has been more than 6 months since the patient has undergone radiation therapy and/or chemotherapy, increasing the steroid dose is unlikely to yield benefit.

Management of radiation pulmonary fibrosis is supportive. Emphasis is on administration of oxygen, management of acute infection, bronchodilator therapy if needed, gentle diuresis if needed, and maximization of the other components of tissue oxygen delivery (e.g., cardiac and blood pressure medications and correction of anemia). Acute episodes of radiation pneumonitis may still occur, particularly if the patient receives a "radiation recall" type of drug; therefore, steroids might be needed periodically. It is unknown whether pulmonary rehabilitation programs involving exercise and weight maintenance are helpful for radiation pulmonary fibrosis. Patients who are disabled or immobilized owing to their pulmonary insufficiency might benefit from DVT prophylaxis. Tobacco should be strictly avoided.

Trials of Prevention or Management of Radiation Pulmonary Fibrosis

As is shown in Table 62-5, results of studies have suggested that prophylactic administration of amifostine during thoracic radiation therapy ameliorates radiation pneumonopathy.[48,49] However, these data are based on preclinical data supporting the role of amifostine as a protective agent against radiation pulmonary fibrosis. However, at this time, the routine use of amifostine is not standard, since the "positive" studies were relatively small, while a larger confirmatory study was disappointing.[50] In addition, amifostine is logistically and financially difficult to deliver and is associated with its own toxicities

Table 62-5 Randomized Trials of the Effect of Amifostine on Radiation Pneumonopathy after Radiation Therapy (± Chemotherapy) for Lung Cancer

Study	Patients/Characteristics	Amifostine Dose	Grade 2+ RP Without Amifostine (%)	Grade 2+ RP with Amifostine (%)
Antonadou et al.[129]	97 patients with Stage III NSCLC treated to 55 to 60 Gy without chemo	340 mg/m^2/day	43	9 ($P = 0.001$)
Antonadou et al.[130]	73 patients with stage III NSCLC treated to 55 to 60 Gy + chemo	300 mg/m^2/day	56	19 ($P = 0.002$)
Komaki et al.[131]	53 patients with Stage III NSCLC treated to 69.6 Gy + chemo	500 mg twice per week	16*	0* (Grade 3) ($P = 0.02$)
Movsas et al.[50]	205 patients with Stage III NSCLC treated to 69.6 Gy + chemo	500 mg four times per week	27	27

NSCLC, non-small cell lung carcinoma; RP, radiation pneumonopathy.
*Grade 3 RP.

(nausea, fatigue, skin rash). Its effectiveness is likely highly correlated with dose and schedule, and amifostine has no known role or rationale as a treatment once radiation has been completed.

Other nonspecific antioxidants have been studied as means of decreasing radiation fibrosis, although they are not necessarily specific for the lung.[51–53] Gene therapy to deliver antioxidants to the lung is under study. Researchers from the University of Pittsburgh have developed a system in which the gene for the potent antioxidant enzyme manganese superoxide dismutase can be transfected into a plasmid and administered by inhalation.[52] This approach, still highly experimental, might offer a treatment without the systemic effects that amifostine and steroids induce.

The use of angiotensin-converting enzyme inhibitors, particularly captopril, has shown promise in preclinical rodent studies.[57] The mechanism of efficacy is unclear and might be related to the beneficial vasodilatory effects of these drugs on small blood vessels or might be due to antioxidant activity. One ongoing RTOG trial is testing the potential efficacy of captopril versus usual supportive care for lung cancer patients who are receiving radiation therapy and are thought to be at significant risk of radiation pneumonopathy. Increased understanding of the cytokine-based mechanisms of radiation lung injury may offer opportunities for intervention.[53,54] Because TGF-β is thought to be the dominant profibrotic cytokine and perhaps even a cause of radiation pneumonitis, attempts are underway to develop molecules with anti-TGF-β activity. As one example, keratinocyte growth factor, which is FDA-approved for amelioration of bone marrow transplant-associated mucositis, is under study in preclinical models of radiation fibrosis.[55]

Other Forms of Radiation-Induced Lung Injury

There is increasing recognition that high-dose radiation can contribute to other serious problems within the lung. One of the most feared complications is bronchopleural fistula, a postoperative complication that is significantly increased by the use of preoperative radiation therapy or chemoradiotherapy and is very difficult to manage.[56,57] Patients who receive neoadjuvant chemoradiation for stage III lung cancer should be considered for additional bronchial stump reinforcement (e.g., intercostal muscle flap) at the time of surgery in an effort to minimize this risk.

Endobronchial brachytherapy for palliation of obstructive endobronchial malignant tumors is associated with an approximately 10% risk of severe pulmonary complications, including massive hemoptysis and bronchial stenosis.[58] It often is difficult to differentiate the contribution of irradiation to these serious events from the contribution of the tumor itself. It should be noted that with the recent significant increase in external beam radiotherapy doses, similar complications are occasionally seen without brachytherapy as well.[59] It is likely that radiotherapy dose per fraction and the use of concurrent chemotherapy increase the risk of these understudied types of complications. As is shown in the case example in Figure 62-1, radiation lung injury can be associated with pneumothorax, perhaps as a result of radiation fibrosis causing increased traction on the lung as well as direct radiation injury to the pleura.[60]

PULMONARY TOXICITY OF SYSTEMIC ANTICANCER THERAPIES

Many chemotherapy drugs can cause pulmonary toxicity, the incidence ranging from less than 1% to more than 30%. The drugs that are most associated with pulmonary toxicity are bleomycin, methotrexate, cytosine arabinoside, mitomycin, and the nitrosoureas (especially carmustine [BCNU]). Table 62-6 is a broad categorization of anticancer therapies into high, moderate, and low risks of pneumotoxicity, although any individual patient may experience severe lung problems from any agent.

Unlike thoracic radiation therapy, which usually affects only the portion of lung within the radiation field, systemic agents often cause diffuse pneumonopathy. Although it is relatively rare in comparison with radiation pneumonopathy, chemotherapy-induced lung injury can be extremely intense and can even have a higher fatality rate than radiation pneumonitis. As with radiation pneumonitis, corticosteroids are commonly used and may be effective, particularly in early stages of injury. It is particularly important to rule out alternative and concurrent diagnoses (see Table 62-4). Unlike radiation injury, drug-induced lung toxicity can occur in a time frame during which it is possible to discontinue the offending agent. A review of some of the systemic agents associated with pulmonary toxicity follows.

Bleomycin

Bleomycin is the chemotherapy drug most commonly associated with lung damage. The reported incidence ranges from 3% to 40%.[61,62] This drug is used predominantly in the management of Hodgkin's disease and germ cell tumors, cancers that occur mainly in younger patients with less underlying pulmonary comorbidity than lung cancer patients. There are a number of similarities between bleomycin pneumonopathy and radiation pneumonopathy, including two patterns of disease (pneumonitis and fibrosis). As with radiation, the clinical manifestations of bleomycin lung toxicity usually occur weeks to months after the initiation of treatment. The infiltrates can be diffuse or limited to basilar and subpleural aspects of the lungs.[63] A

Table 62-6 Anticancer Therapies Categorized by Risk of Pneumotoxicity

Highly pneumotoxic agents (risk of pulmonary SAE probably >5%)	Bleomycin; BCNU; mitomycin; interleukins. Bone marrow transplantation (with or without TBI). Large-volume thoracic radiation therapy (e.g., T_4N3 lung cancer). Surgical resection for lung cancer.
Moderately pneumotoxic agents (risk of pulmonary SAE probably 1% to 5%)	Methotrexate; busulfan; melphalan; CCNU/MeCCNU; cyclophospamide; ifosfamide; fludarabine; gemcitabine; paclitaxel/docetaxel. Small-volume thoracic radiation therapy (e.g., breast cancer). Non-lung cancer oncologic surgery.
Uncommonly pneumotoxic agents (risk of pulmonary SAE probably <1%)	5-FU; capecitabine; cisplatin/carboplatin; doxorubicin; actinomycin-D; etoposide; topotecan/irinotecan; vincristine/vinblastine; vinorelbine; temozolomide; tamoxifen; aromatase inhibitors for breast cancer. Hormonal therapies for prostate cancer; steroids.
Pneumotoxicity risks present but of uncertain frequency	Anti-EGFR agents (e.g., ZD-1839); monoclonal Antibodies (e.g., anti-VEGF MoAb_; imatinib (Gleevac).

BCNU, carmustine; CCNU, lomustine; EGFR, epidermal growth factor receptor; 5-FU, 5-fluorouracil; MeCCNU, semustine; MoAb, monoclonal antibody; SAE, serious adverse event; TBI, total body irradiation; VEGF, vascular endothelial growth factor.

nodular pattern occasionally occurs, mimicking cancer progression. Imaging other than CT scanning is investigational, although there are reports of abnormal fluorodeoxyglucose-PET scan results in bleomycin pneumonopathy.[64]

As in radiation pneumonopathy, dyspnea is the primary symptom of bleomycin lung toxicity, although, as is the case with radiotherapy, other symptoms such as cough and fever often occur as well. Pulmonary function testing shows a restrictive pattern; DLCO is frequently abnormal. DLCO should be measured before bleomycin is started and periodically between cycles. A significant decrease in DLCO should prompt consideration of discontinuation of this drug. Although there is no consensus on what represents a "significant decrease" in DLCO, some investigators have conservatively used a criterion of a 20% decrease to warrant discontinuation of bleomycin.[65]

There appears to be an association between cumulative bleomycin dose and risk of pneumonopathy. Again, there is no consensus regarding the absolute maximum cumulative bleomycin dose for an individual patient; values of 300 to 400 mg maximum have been suggested.[61,66] (A typical cumulative dose of bleomycin from six cycles of ABVD (Hodgkin's disease) is approximately 120 mg/m^2.) Again, however, it must be stressed that occasionally life-threatening or even fatal pneumonopathy can occur with cumulative bleomycin doses less than 100 mg. Another important predictive factor (in addition to age and dose) for bleomycin pneumonopathy appears to be renal insufficiency,[61,66] which is particularly concerning in patients who are receiving nephrotoxic agents such as cisplatin. Other possible risk factors may include concomitant use of a colony-stimulating factor,[67] combined treatment with radiotherapy, and concomitant delivery with gemcitabine.[69,70] Exposure to high oxygen concentrations, as part of operative anesthesia, has been associated with potentiation of bleomycin pneumonopathy, particularly in animal models,[71] and in some cases led to acute respiratory distress syndrome.[72,73] Extreme caution is advised when supplemental oxygen is being electively prescribed for bleomycin-treated patients, especially those who are currently undergoing or recently finished bleomycin (less than 12 months) and/or have documented bleomycin pneumonopathy.[74]

Bleomycin pneumonitis is rarely fatal; one study estimated a lethality risk of about 3%, with a suggestion that older age was associated with a higher risk for death.[75] Most patients achieve complete or near-complete recovery.[75–79] Corticosteroids may have some benefit,[61,76,80] although the data are not as clear as those for radiation pneumonitis. Some cases of steroid-responsive bleomycin pneumonitis/fibrosis may represent early hypersensitivity, BOOP-like events. After bleomycin chemotherapy, cancer survivors may have significant declines in pulmonary function for approximately 6 months, but by 2 years after chemotherapy, few have significant respiratory dysfunction.

Antimetabolites

Methotrexate, which is commonly used in therapy for rheumatoid arthritis as well as for cancer, is the antimetabolite drug that is most commonly linked to pulmonary injury. It can cause interstitial pneumonitis similar to that caused by bleomycin and other drugs.[81–84] Steroid therapy may be indicated for severe cases.

Gemcitabine has become one of the most commonly used chemotherapy drugs for solid tumors, including lung cancer. When gemcitabine is used as a single agent in previously untreated cancer patients, the risk of significant pulmonary toxicity is small, although it is associated with an occasional severe respiratory insufficiency that may be related to capillary leak syndrome.[85] However, increasing data suggest that combinations of gemcitabine with other agents may severely potentiate those agents' pneumonopathy (see discussion in previous sections regarding thoracic radiotherapy and bleomycin), in particular, the combination of gemcitabine with taxanes.[86,87] Steroid therapy can be a useful adjunct to supportive treatment.[77] Gemcitabine may also be associated with radiation recall pneumonitis, even a year or more after thoracic radiation therapy. Gemcitabine radiation recall reaction appears to be more likely to affect parenchymal organs such as the lung than the more common dermatologic radiation recall reactions associated with other chemotherapeutic agents.[78]

Fludarabine is now commonly used to manage hematologic malignant disease, including chronic lymphocytic leukemia, and, like other antimetabolite drugs, is relatively well tolerated. In approximately 8% of cases, fludarabine causes pulmonary toxicity characterized by fever and interstitial pneumonitis.[79,88] Although this syndrome is probably steroid responsive, it is critical to rule out opportunistic infection given the patient population usually treated with this drug.

Alkylators and Nitrosoureas

Alkylators and nitrosoureas are frequent components of conditioning regimens for BMT, a procedure that is associated with a high rate of pulmonary toxicity. It is difficult to isolate the effect of these drugs in this setting, in which many other insults to the lung often occur, but it is likely that they contribute, particularly at BMT dose intensity.[85,86] Results suggest that pulmonary toxicity from BMT with whole-body irradiation-containing regimens is similar to that from regimens without whole-body irradiation.[89,90] This underscores the relationship between high-dose alkylator therapy and pneumonopathy.

In the non-BMT setting, classic alkylators, such as cyclophosphamide, ifosfamide, and melphalan, have occasionally been associated with interstitial pneumonitis and acute or subacute dyspnea that may

be steroid responsive.[91,92] However, these drugs have caused long-term pulmonary fibrosis, even several decades after treatment.[91]

For nitrosoureas such as BCNU, pulmonary injury is considered a dose-limiting toxicity and has been well studied.[93] The predominant problem with these agents is pulmonary fibrosis, which appears to be chronic and dependent on dose and patient age.[94–96] In one study, BCNU pulmonary fibrosis in patients treated for glioma was rare at cumulative doses less than 960 mg/m^2.[96] The association between other nitrosoureas and pulmonary toxicity is not commonly reported but does occasionally occur.[97–109] The pulmonary fibrosis that is caused by nitrosoureas does not appear to be steroid responsive. The unpredictable and untreatable nature of nitrosourea-induced pneumonopathy has recently limited the use of these drugs in several settings.[98]

Anthracyclines and Other Antitumor Agents

Essentially every cytotoxic chemotherapy has been associated with pulmonary toxicity. Case reports and/or literature reviews can be identified even for drugs that are rarely associated with pneumonopathy, such as vinorelbine,[99] paclitaxel,[100] and oxaliplatin.[101] Response to steroids has been variable. Several other agents, however, deserve special mention.

The antibiotic chemotherapy drug mitomycin is well known as a potentially pneumotoxic agent that can cause noncardiogenic pulmonary edema, pneumonitis, and pleural effusion. Toxicity is difficult to predict and not clearly dose related[102–111] but is estimated to occur in 5% of patients or more.[103] In a prospective study of patients treated with mitomycin, 28% of patients tested had significant (>20%) declines in DLCO, and 5% had grade 3+ lung toxicity.[103–112] Mitomycin-induced pulmonary toxicity appears to be steroid responsive.[104]

Anthracyclines are vital drugs for the treatment of breast cancer among other malignancies; while they are associated with significant cardiac risk (which can mimic pulmonary toxicity), they rarely independently cause pneumonopathy. However, the combination of anthracyclines such as doxorubicin with thoracic radiotherapy can be highly toxic. For example, a randomized trial of concurrent versus sequential chemoradiotherapy (including doxorubicin) for small cell lung carcinoma was closed early because six fatal cases of pneumonopathy developed among 82 patients who were treated concurrently.[105] There may be a risk of radiation recall-like reactions in patients receiving doxorubicin after high-dose thoracic radiation therapy, at least in the vulnerable lung cancer population.[106]

Like the anthracyclines, the taxanes (paclitaxel and docetaxel) are widely used solid tumor antineoplastics. Docetaxel seems to be more associated with pneumonopathy than does paclitaxel. The risk of pneumonitis appears to be schedule-related, with a significantly higher risk with the use of weekly (versus every 3 weeks) docetaxel.[107] This contrasts with the nonpulmonary toxicities of this drug, which appear to be lessened with the weekly schedule.[107] Docetaxel has also been associated with enhancement of radiation pneumonopathy in lung cancer patients.[108] The combination of paclitaxel plus radiotherapy following anthracycline-based chemotherapy might not be feasible in breast cancer patients owing to pulmonary toxicity[109] despite the relatively modest amounts of lung in the irradiated field. As was noted previously, the combination of taxanes with gemcitabine appears to result in a significant risk of pneumonopathy[78] and should be used with extreme caution in patients with underlying lung disease.

Biologic Agents

Increasingly, cytotoxic therapies such as chemotherapy and/or radiotherapy are being replaced or supplemented by "biologic" agents that kill or inhibit cancer cells through highly specific pathways independent of direct DNA damage. Many of these drugs are still very new, and their toxicity profiles are still being generated. Therefore, data regarding pulmonary toxicity of these agents are incomplete.

Immunomodulatory anticancer agents are one of the oldest classes of biologic therapies. Pneumonopathy associated with interleukins or interferons occasionally occurs,[110] as well as a syndrome of noncardiogenic pulmonary edema, which differs from typical drug-induced interstitial pneumonitis.[111] Noncardiogenic pulmonary edema is generally reversible with steroids and supportive care and rarely progresses to fibrosis.

Several randomized trials suggested that the addition of interferon to conventional lung cancer therapy increased the risk of pneumonopathy.[112,113]

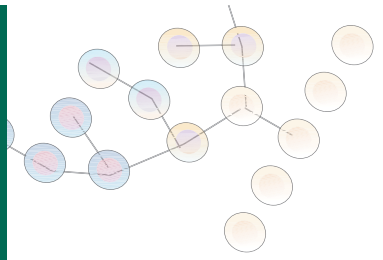
Targeted therapies against signal transduction pathways have become a heralded advance in several hematologic and solid tumor types. Most of these drugs have not been studied extensively enough to fully characterize their pulmonary risks. Two agents that have been well studied are the oral tyrosine kinase inhibitors (against the intracellular portion of the epidermal growth factor receptor) gefitinib and erlotinib (Fig. 63-3). These agents are associated with an uncommon but sometimes very severe syndrome of interstitial pneumonitis. This pneumonitis appears to be more common in the Japanese population, with a reported incidence of about 3%.[114] In a placebo-controlled trial of patients with advanced lung cancer, erlotinib was not associated with an increased risk of serious pulmonary adverse events.[115]

The risk of pneumonopathy from targeted therapies does not appear to be limited to the lung cancer population. Imatinib, used for several types of hematologic malignancies and gastrointestinal stromal tumors, has been associated with interstitial pneumonitis as well.[116] The anti-CD20 antibody Rituximab has been rarely implicated in pneumonopathy.[117]

At this time, there are no specific contraindications to the use of signal transduction inhibitory agents based on pulmonary risk;

Figure 62-3 • Case example of drug-induced interstitial pneumonitis that was presumed to be related to erlotinib. This patient previously underwent chemotherapy and right pneumonectomy but developed recurrent disease. Erlotinib was started, but the patient developed progressive dyspnea 1 month later. CT scan revealed interstitial pneumonitis of the (remaining) left lung. Erlotinib was discontinued, and steroids were started, but the patient soon thereafter died of progressive cancer.

however, current protocols call for the drugs to be discontinued if thoracic imaging reveals evidence of interstitial pneumonitis.



A final category of potentially pneumotoxic drug agents are the antiangiogenic compounds. These are relatively rarely associated with typical drug-induced pneumonitis.[118] However, the prototype antibody against VEGF, bevacizumab, has been associated with life-threatening pulmonary hemorrhage. This seems to be more associated with centrally located squamous cell lung carcinomas and might be related to rapid tumor response resulting in bronchovascular fistula. Further studies and means of predicting who is at risk for this devastating complication and how to avoid it are necessary in order to advance the use of this class of agents.[119]

63 Cardiac Effects of Cancer Therapy

James L. Speyer, Boris Kobrinsky, and Michael S. Ewer

SUMMARY OF KEY POINTS

Incidence

Cardiomyopathy/Congestive Heart Failure

- Anthracyclines: 5% to 20% of patients receiving cumulative doxorubicin more than 450 mg/m^2, higher in children
- Other antineoplastics (mitoxantrone, cyclophosphamide): less than 2%
- Trastuzumab
- Imatinib
- Lapatinib
- Sunitinib
- Radiation therapy: common 5 to 20 years after single anteroposterior port

Arrhythmias

- Paclitaxel: less than 1%
- Dihydroazacytidine
- Interleukin-2, interleukin-6
- Interleukin-11
- Rituximab
- Arsenic trioxide

Myocardial Ischemia

- Radiation therapy
- 5-Fluorouracil (5-FU): 1% to 4.5% with infusion schedules
- Capecitabine

Pericardial Disease

- Radiation therapy: effusions in 6% to 30% of patients receiving radiation therapy to the chest, constriction in 2% of patients receiving radiation therapy to the chest with current techniques
- Cardiac tamponade
- Busulfan

Fluid Retention

- Docetaxel, interleukins, interferons, tumor necrosis factor, cytokines, granulocyte-macrophage colony-stimulating factor, monoclonal antibody (CD20)
- Dasatinib
- All-*trans* retinoic acid

Hypertension

- Bevacizumab

Hypotension

- Rituximab
- All-*trans* retinoic acid
- Bortezomib
- Paclitaxel
- INF
- Denileukin diftitox

Endocardial Fibrosis

- Busulfan

Etiology of Complications

- Anthracycline-induced cardiomyopathy
- Her2 signaling pathway and decreased repair
- Radiation-induced cardiomyopathy
- Radiation-induced myocardial ischemia
- Decreased systemic vascular resistance

Diagnosis

- Clinical cardiac symptoms—New York Heart Association Classification
- Hemodynamics—Bristow Staging Score
- Radionuclide scans—serial scans including baseline
- Endomyocardial biopsy—Billingham Histopathologic Scoring System
- Doppler echocardiography—pericardial effusion/constriction, left ventricular systolic/diastolic dysfunction
- Troponin
- Natriuretic peptide

Treatment

Cardiomyopathy/Congestive Heart Failure

- Sodium and fluid restriction
- Diuretics
- Afterload reduction (angiotensin-converting enzyme inhibitors)
- Angiotensin receptor blocking agents
- Beta blockers
- Discontinue offending agent

Risk Reduction with Anthracyclines

- Anthracyclines: limit dose (e.g., doxorubicin: <450 mg/m^2); use less toxic analogs
- Alteration of dose schedule
- Unique delivery systems (e.g., liposomes)
- Pegylated liposomal doxorubicin
- Blocking agents (dexrazoxane: ICRF-187, ADR 529) (Zinecard)

Radiation-Induced Pericardial Disease

- Acute pericarditis: nonsteroidal anti-inflammatory drugs, steroids
- Constriction: pericardiectomy

INTRODUCTION

The cardiac side effects of cancer therapies include the entire breadth of cardiac pathology. They provide a considerable challenge to the clinician because they produce signs and symptoms of disease that are not specific to treatment and their differential diagnosis therefore includes a broad spectrum of other etiologies. The sequelae of the tumors being treated, underlying cardiac disease, and effects of nononcologic interventions can affect the heart in ways that often cannot be distinguished clinically from the cardiac effects of cancer treatment. These factors make the diagnosis, assessment, and clinical course of the cardiac effects of cancer therapy especially challenging. Despite these considerations, it is clear that dysrhythmias, ischemia, congestive heart failure (CHF), peripheral vascular disease, and pericardial disease can be caused by a variety of cancer therapies and the various combinations of agents and modalities that are used in the treatment of malignancy.

A variety of approaches can be used to effectively evaluate patients with these side effects. The patient with cancer who presents with

cardiac problems can be approached by considering all known side effects associated with the therapy or therapies that he or she is receiving or has received in the past. Alternatively, the entire spectrum of treatment-related, as well as nontreatment-related, causes of the patient's cardiac presentation can be considered. Because the latter approach is closer to the usual clinical process of differential diagnosis, this chapter is organized in that manner. However, to consider side effects by therapeutic agent and modality, a summary is organized according to the effects of specific agents (Table 63-1).

In the cancer patient, a complex of interactions result from specific agents or modalities, causing damage through different pathophysiologic mechanisms, such as ischemia, free radical myocardial damage, radiation damage, alterations in conduction, and other factors that increase myocardial stress such as increased work, wall stress, and underlying ischemia. These may be modulated by cardiac repair mechanisms or strategies to reduce stress on the heart. Drugs that reduce cardiac repair or add to cardiac work or wall stress may in turn increase cardiac toxicity and worsen a patient's condition. In the

Table 63-1 Cardiovascular Complications of Cancer Therapies

Chemotherapy Drugs		Biologic Response Modifiers	
Therapy	**Complications**	**Therapy**	**Complications**
Anthracyclines (e.g., doxorubicin)	Cardiomyopathy	IFN-α	Hypotension
	CHF*		Tachycardia
	Dysrhythmias	IFN-β	Hypotension
Epirubicin	Pericardial effusion	TFN-γ	Hypotension
Anthrapyrazoles	Cardiomyopathy	Interleukin-1α	Hypotension
	CHF	Interleukin-2	CHF
Mitoxantrone	Cardiomyopathy		Hypotension
	CHF*		Dysrhythmias
Cyclophosphamide	CHF		Ischemia
	Hemorrhagic myocarditis*	Interleukin-4	Myocarditis
	Pericardial effusion	Interleukin-6	Dysrhythmias

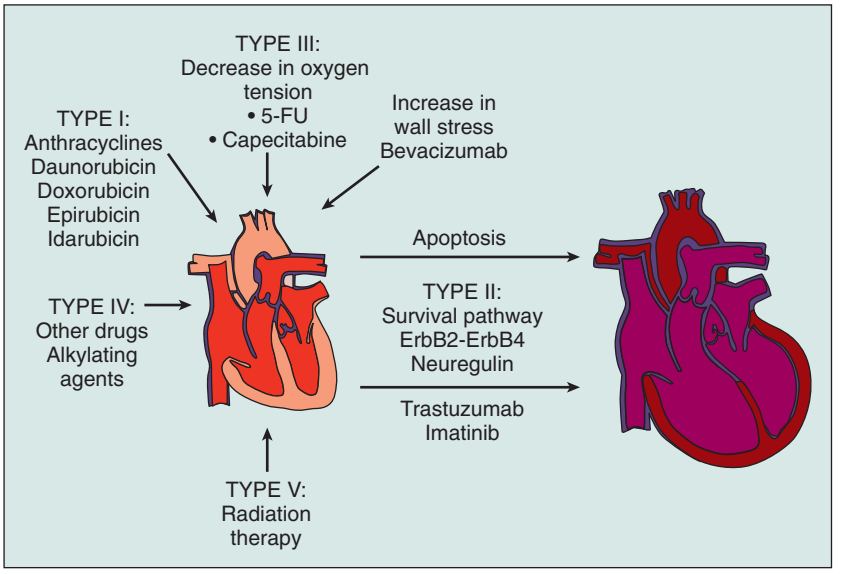

Figure 63-1 • Mechanisms of cardiac toxicity and repair with proposed modified classification system.[1,78]

case of some newer anticancer treatments, these drugs may cause additive or synergistic damage. Ewer and Lippman[1] have proposed a classification schema that indicates different types of myocyte damage leading to CHF with different pathophysiologic mechanisms and different clinical courses. A schematic model of these interactions as well as other sources of cardiac stress depicts multiple sources of cardiac stress and repair (Fig. 63-1).

Finally, as with all potentially negative effects of treatment, the clinician needs to balance the potential risk or negative impact on the patient with the potential benefit. Simply withholding treatment may eliminate the risk of a side effect but deprive the patient of a potentially beneficial therapy. At times, this may be the correct approach. At other times, giving treatment with judicious monitoring and appropriate toxicity reduction may on balance benefit the patient more.

CONGESTIVE HEART FAILURE

Previously, the major emphasis in drug-induced cardiac toxicity has been on anthracycline-induced damage because of the widespread use of these drugs, their unique mechanism of action and pathologic appearance, and clinically relevant toxicity. While anthracyclines remain an important part of any discussion of cardiac toxicity, the recent introduction of many new agents with activity, especially in cell-signaling pathways, makes consideration of treatment-related cardiac effects more complex and clinically important. The mechanisms by which these drugs inhibit tumor cell growth may also be involved in the normal response to stress by cardiac myocytes and can result in clinical toxicity alone or in combination with other drugs or sources of cardiac stress (e.g., traztuzumab, lapatinib, imatinib). Others may have direct cardiac toxicity.

Anthracyclines

Chemotherapy that incorporates an anthracycline antibiotic is a significant cause of CHF in cancer patients who are treated with these agents (Table 63-2). The anthracyclines are of special interest, in part because CHF resulting from these agents can progress to death. We now are able, in large part, to prevent the potentially deadly aspects of CHF from anthracycline use. Most information relating to anthracycline-induced cardiomyopathy is derived from studies with doxorubicin and, to a lesser extent, with daunorubicin. However, other clinically available drugs of this class also have been associated with clinically indistinguishable cardiotoxic effects.

Cardiac biopsy specimens have demonstrated that the dose-related cardiomyopathy that is associated with anthracyclines is biventricular. Retrospective studies indicate that the incidence of clinically recognizable congestive failure with doxorubicin is 7% to 15% in patients who have received a cumulative dose greater than 450 to 500 mg/m^2 without cardioprotection (Fig. 63-2).[2,3] Above this dose the incidence of clinical CHF rises more steeply. (Cumulative cardiotoxic doses associated with the use of other anthracyclines vary, but the shape of the curve that plots cumulative dose against the likelihood of CHF is similar for all anthracyclines that have been studied.) Caution must be exercised in evaluating patients who are receiving anthracyclines, because this cardiomyopathy is variable, and instances of CHF have been observed at lower cumulative doses.[4] The actual incidence of clinical CHF may be higher than was reported in retrospective trials.[5,6] Prospective clinical trials suggest that when patients are observed closely, the number who develop early signs of CHF at cumulative doses of 450 mg/m^2 may exceed 25%. The cardiotoxic effects of anthracyclines probably start with the first dose. Each subsequent administration constitutes a sequential stress superimposed on existing cardiac injury that may have resulted from prior doses of anthracyclines or from other causes. In addition, nonanthracycline-related stress or damage occurring months or years later finds the heart with pre-existing damage and adds a cumulative burden or sequential stress.[7] Other chemotherapy drugs (e.g., trastuzumab) that

may have a collateral effect of decreasing cardiac repair mechanisms can increase anthracycline toxicity (see later discussion).

Factors associated with an increased risk of anthracycline-induced chronic cardiomyopathy are derived from retrospective studies in adults.[2] They include age greater than 70 years, exposure to ionizing radiation to the chest wall, and pre-existing cardiac disease or risk factors. Prior cardiac risk factors include active CHF, history of myocardial infarction within the preceding year, hypertension, aortic stenosis, diabetes mellitus, and prior exposure to anthracyclines. The relative contributions of each of these factors are not well defined, and when an individual patient has more than one risk factor, the damage can be increased considerably. One possible common denominator among these entities is increased wall stress; any condition that results in increased wall stress warrants heightened scrutiny and efforts to mitigate the cardiotoxic effects of anthracyclines. Children are a subset of patients who are at increased risk for developing anthracycline cardiac toxicity with a different clinical course and some difference in mechanism (see later discussion).

The natural history of the cardiomyopathy from anthracycline use varies. In some patients, it worsens despite maximal medical therapy and can lead inexorably to death. Other patients are left with permanent reduction in left ventricular ejection fraction (LVEF) and persistent symptoms of CHF. Still others can experience gradual improvement in symptoms and LVEF,[8] perhaps owing in part to compensation and myocardial remodeling.

Pathophysiology

Anthracycline-induced cardiomyopathy is the result of a series of repeated chemical injuries to the myocardium (possibly with some recovery) that gradually impair cellular defenses, resulting in cell damage with decreased contractility and, eventually, cell death. This is consistent with the gradual onset, variability of course, risk factors for increased susceptibility, and laboratory and pathologic findings of the cardiomyopathy that results from use of these drugs.

The common mechanism for anthracycline cardiomyopathy appears to be via free radical damage. Reduction of the quinone groups on the B ring of the anthracene structure (Fig. 63-3) results in a semiquinone radical before further reduction to the alcohol (e.g., doxorubicinol). Interaction with oxygen yields free radical oxygen (O_2*). Further reaction of the semiquinone with H_2O_2 yields the OH^- radical. These reactions can proceed in either an iron-independent or iron-dependent fashion.[9]

Formation of an Fe^{3+}-doxorubicin complex can catalyze these reactions, greatly enhancing free radical generation. An Fe^{3+}-doxorubicin DNA complex has been demonstrated, which results in increased cell destruction. Free radicals can cause damage at a variety of intracellular sites, including the nuclear envelope, cell membrane, mitochondria, DNA, and sarcoplasmic reticulum.[9,10] In the myocyte, damage to the sarcoplasmic reticulum produces a decrease in bound calcium, which results in decreased contractility by its action on the actin-myosin complex. Free Ca^{2+} also may activate proteases within the heart, causing myofibrillar damage.

Anthracycline-induced free radical damage is not confined to the myocardium. It may indeed play some role in tumor cell killing, although this is primarily thought to be related to other mechanisms (e.g., DNA intercalation, inhibition of topoisomerase II).

The susceptibility of myocardial cells to free radicals may be explained in part by differences in cellular defenses. Of the primary cellular enzymatic defenses against free radicals—superoxide dismutase, catalase and glutathione peroxidase—only superoxide dismutase is unaffected by doxorubicin. In some mammalian systems, myocytes contain very low catalase compared to other cells, such as liver cells.[11] Furthermore, doxorubicin can decrease cellular glutathione peroxidase. The complete translation of the observations from the rodent system to humans is not clear.

In clinical practice, the anthracyclines appear to have a mechanism of activity similar to that just described. The mechanisms do not, however, fully explain the cardiac effects of the related anthracene compounds (e.g., mitoxantrone). In isolated myocyte models, specific inhibitory agents (dexrazoxane) inhibit anthracycline-induced cardiac damage but not that of mitoxantrone, suggesting that some other mechanism for cardiac toxicity also might exist.[12] In a spontaneously hypertensive rat model, though, dexrazoxane inhibits both doxorubicin and mitoxantrone-induced cardiac toxicity.[13] Some investigators have suggested that in addition to the preceding mechanism,

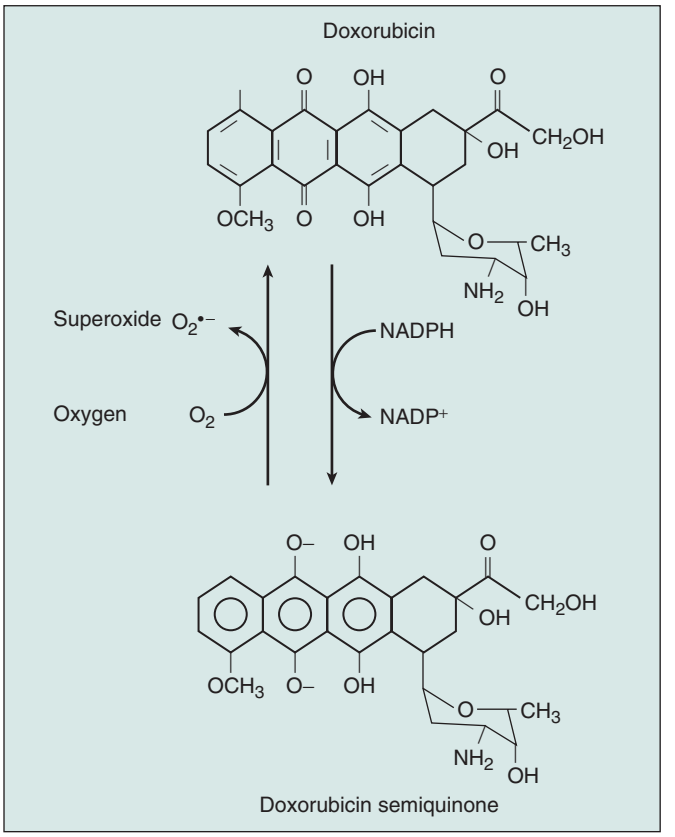

Figure 63-3 • Redox cycling of doxorubicin by flavin-centered reductases. (From Muggia FM, Green MD, Speyer JL [eds]: Cancer Treatment and the Heart. Baltimore, Johns Hopkins University Press, 1992, p 12.)

cardiac damage in children is due at least in part to interference with cell growth.[14]

Diagnosis

Patients may present with any or all symptoms of CHF, including decreased exercise tolerance, dyspnea, or signs of pulmonary and circulatory congestion. In our experience, sinus tachycardia and an inability to return promptly to basal cardiac rate after exertion in an otherwise oncologically stable patient are the earliest sign of myocardial toxicity and usually predate more classic symptoms of heart failure. These can be graded by the well-established system for grading CHF.[15] A system of staging anthracycline-induced hemodynamic changes in humans was developed by Bristow.[16] Severity is most frequently indicated by LVEF (absolute value and decrease during treatment) and clinical findings, often using the New York Heart Association classification of CHF.

Determination of LVEF by either cardiac ultrasound or gated radionuclide scanning techniques is used to assess anthracycline cardiac toxicity. However, changes in systolic function often are seen in cancer patients, and they might not be related to anthracycline-associated damage. Such changes may occur as a consequence of anemia, the extent of tumor burden, and a variety of metabolic aberrations that might or might not be related to the malignancy or its treatment. One way to monitor patients with echocardiography or nuclear imaging is to obtain a baseline study prior to therapy and then obtain values at intervals as the cumulative dose increases. At high cumulative doses, it might be desirable to make more frequent observations. Scans are examined for sequential changes in wall motion as well as LVEF. Any decrease in LVEF, including those that remain within the "normal" range as well as those that decrease to a clearly abnormal value, could indicate anthracycline damage.[17] Careful monitoring with multiple gated acquisition (MUGA) scans may permit treatment with greater cumulative doses of doxorubicin than an empiric stopping dose of 450 to 500 mg/m^2.[3,5,17,18] Serial determinations might, however, result in premature abandonment of an important therapy because of false-positive results on an ultrasound or MUGA scan. It is important to bear in mind that the likelihood of CHF follows an exponential curve, that early toxicity can be difficult to quantify, and that an additional two or three cycles of chemotherapy may expose patients to life-threatening cumulative dosages. Decreases in the absolute value of LVEF by 10% to 20% or to less than the lower limit of normal for the laboratory may warrant discontinuation of therapy. The key is that a decrease in LVEF usually precedes the development of clinical CHF and that termination of drug therapy might stop the progression of the biochemical process before clinical symptoms became apparent. Algorithmic validation of this approach has been published and supports this approach, but it is not fail-safe. When exceeding of recommended cumulative dosages can be anticipated, cardioprotective strategies are clearly appropriate.

Although MUGA scans have been used in most adult investigational studies and for clinical follow-up, Doppler echocardiography is also a useful tool for both preanthracycline evaluation of the heart (allowing assessment of underlying valvular and pericardial pathology as well as myocardial systolic and diastolic function) and clinical follow-up during treatment. Newer computer-assisted echocardiographic technologies, including automated border detection-derived quantification of cardiac volumes and LVEF, could make nuclear quantification modalities (which require radioisotopes) obsolete in patients whose hearts can be imaged ultrasonically.[19] Doppler evaluation of diastolic parameters, including rates of isovolemic relaxation and rapid filling, can be useful in the early detection of anthracycline-induced myocardial dysfunction.[20] Echocardiography has been used extensively in children, in whom the shorter periods of time needed to acquire data are helpful. In patients with cardiac dysrhythmias, the rhythm disturbance can interfere with cardiac gating, and echocardiography offers advantages. Patients who have received radiation to the left side of the chest can be difficult to study with cardiac ultrasound and often are better candidates for nuclear imaging.[21]

Myoscint scans may complement MUGA scans. In trials using Myoscint scans, a monoclonal antibody to cardiac myosin is tagged with iodine 131, which may provide more direct evidence of myocardial damage and overcome some of the lack of specificity of MUGA scans. These scans have been used as an adjunct to MUGA scans in a randomized trial of epirubicin and dexrazoxane. To date, neither the parameters of diastolic dysfunction nor any of the newer nuclear imaging techniques have been sufficiently sensitive to replace MUGA scans.[22]

Measurement of cardiac troponins is a highly sensitive method of detecting myocardial cell injury in acute coronary syndromes and has led investigators to study the applicability of such measurements to assessing anthracycline-induced myocardial cell damage. Elevated serum troponin T levels in children receiving doxorubicin for acute lymphoblastic leukemia (ALL) have been demonstrated to predict the echocardiographic findings of left ventricular dilatation and left ventricular wall thinning months later.[23] In at least one series,[24] troponin I levels rose in anthracycline-treated patients before deterioration in LVEF was visible by MUGA scanning. Troponin I levels were elevated and correlated with a fall in LVEF in breast cancer patients receiving high-dose chemotherapy with and without anthracyclines.[25] Markers of cardiac damage have not yet been demonstrated to help in making clinical decisions to continue or stop the administration of anthracyclines. The level of B natriuretic peptide, a measure of CHF, has also been used to monitor anthracycline-induced cardiac damage.[26,27]

Anthracyclines cause a unique pattern of histologic damage, as was originally demonstrated in animal models and confirmed by endomyocardial biopsies in humans (Table 63-3). A continuum of change is well described, from dilation of vacuoles to mitochondrial swelling, myofibrillar dropout, and, ultimately, cell death.[28] The changes that are seen on endomyocardial biopsy appear to parallel the clinical findings, and there is a good correlation with the clinical

Table 63-3 Histopathologic Scale of Doxorubicin Cardiomyopathy*

Grade 0	Within normal limits
Grade 1	Minimal numbers of cells (<5% of total number of cells per blocks) with early change (early myofibrillar loss or distended sarcoplasmic reticulum)
Grade 1.5	Small group of cells involved (5% to 15% of total number), some of which have definite change (marked myofibrillar loss or cytoplasmic vacuolization)
Grade 2	Groups of cells (16% to 25% of total number), some of which have definite change (marked myofibrillar loss or cytoplasmic vacuolization)
Grade 2.5	Groups of cells involved (26% to 35%), some of which have definite change (marked myofibrillar loss or cytoplasmic vacuolization)
Grade 3	Diffuse cell damage (>35% of total number of cells) with marked change (total loss of contractile elements, loss of organelles, mitochondrial, and nuclear degeneration)

*Other grading scales that may incorporate an intermediate grade of 0.5 are sometimes encountered. The individual defined grades are uniform between these various scales. (Mackay B, Ewer M, Carrasco CH, Benjamin RS: Assessment of anthracycline cardiomyopathy by endomyocardial biopsy. Ultrastruct Pathol 1994;18:203–211.)

Adapted from Billingham ME, Mason JW, Bristow MR, Daniels JR: Anthracycline cardiomyopathy monitored by morphologic changes. Cancer Treat Rep 1978;62:865.

examination and results of MUGA scans.[29] The consistency of these findings among nonmammalian species has provided the basis for a number of animal models of anthracycline cardiomyopathy.[30]

The principal advantage of endomyocardial biopsy is the relative specificity of the test. The procedure is usually done by performing a right heart catheterization and using a specially designed bioptome to obtain a number of small tissue fragments from the interventricular septum. These are fixed for routine histologic examination using hematoxylin and eosin or are fixed in glutaraldehyde for examination under the electron microscopic. The procedure is usually performed on an outpatient basis, and in experienced hands, the incidence of serious complication is less than 1%.[31]

The disadvantages of endomyocardial biopsy include the necessity for special expertise in obtaining and interpreting the biopsies, the cost, and the possible, though low, risk of complications. In the modern clinical setting, it is unusual to need biopsies for arriving at appropriate medical decisions, but the biopsy still has a role in clinical investigation.

Decreasing Anthracycline Cardiotoxicity

Risk Reduction

The most obvious way to reduce risk is not to administer the medication at all or to discontinue it. Current approaches to risk reduction include changes in dose and schedule, use of analogs, new delivery systems, and specific blocking agents. Dose adjustment can be achieved by limiting anthracycline doses in patients at increased risk for toxicity or by empiric limitation of cumulative doses of doxorubicin to 400 to 450 mg/m^2. Both of these approaches have merit, but neither prevents toxicity in all patients. Moreover, limiting therapy or discontinuing therapy prematurely could deprive patients who are not experiencing toxicity of therapy from which they are continuing to benefit. As has been noted, a combination of dose restriction with careful cardiac monitoring may offer the safest practical approach to patients receiving doxorubicin.[5] However, such strategies do have some risk of both suboptimal tumor management and cardiotoxicity.

Dose Schedule Changes

Alterations in the dose schedule of anthracyclines are based on the hypothesis that chronic cardiac toxicity is related primarily to peak drug concentration, whereas the antitumor effect is more related to total drug exposure (concentration time, or area under the curve). Clinical trials of weekly schedules versus those in which the drug is given every 21 days support this hypothesis: Weekly schedules resulted in decreased clinical toxicity[1] and improved endomyocardial biopsy scores.[32] Extending this approach to continuous infusion maximizes the reduction in plasma drug concentration while still maintaining oncologic effect. Several studies have demonstrated decreased cardiac toxicity with prolonged continuous infusions (e.g., 24 to 96 hours) compared with standard rapid infusion schedules.[33] The cardiac toxicity is less when measured by clinical examination, MUGA scan, or cardiac biopsy without apparent loss of antitumor efficacy. While all of the studies demonstrate that continuous infusion schedules clearly reduce cardiac toxicity, they do not totally prevent it. They do, however, allow significantly higher cumulative dosages to be administered with acceptable cardiotoxicity. In the case of doxorubicin, for example, approximately 900 mg/m^2, or twice the usual cumulative dosage, can be given when the drug is administered by 96-hour continuous infusion. Mucositis is the factor that limits the duration of infusional regimens to a maximum of 96 hours. Continuous infusion schedules have not been universally accepted, in part because of the increased cost and the necessity for long-term or implantable access lines and infusion pumps.

New Delivery Systems

Liposomal drugs may permit more specific organ targeting of anthracyclines, thereby producing less systemic and cardiac toxicity. The drug can be incorporated into a variety of liposomal drug preparations.[34,35] Initial activity was reported in Kaposi's sarcoma for daunorubicin[34] and doxorubicin.[35] More recently, activity also has been reported in ovarian cancer and breast cancer. In animal models, the pegylated liposomal preparation of doxorubicin, Doxil, is less cardiotoxic than is the free drug. In one trial, patients who were treated with the pegylated doxorubicin (Doxil) had lower cardiac biopsy scores (0.5 versus 2.25) than did controls who were treated with the standard doxorubicin protocol.[36,37] Similar reductions in cardiac toxicity, as measured by biopsy score, were reported in a group of 29 women with breast cancer who were being treated with TLC D-99 liposomal doxorubicin, a new pegylated preparation.[38] Pegylated liposomal doxorubicin (PLD) consists of STEALTH technology-based liposomes containing doxorubicin HCL in an aqueous core. Liposomes are covered by surface-bound methoxypolyethylene glycol that is covalently linked to liposome phospholipids, utilizing the process called pegylation.[39] PLD takes advantage of its stable pegylated cover to be protected from enzymatic and phagocytic degradation. The small size of liposome (100 nm) enables drug preferential penetration through the compromised tumor vasculature and accumulation in tumors, thereby producing less systemic toxicity and less cardiac toxicity. In a phase III study of 509 women with metastatic breast cancer, 18.8% of patients in the doxorubicin arm developed decline in LVEF versus 3.9% of patients (all of them asymptomatic) in the PLD arm. Overall risk of cardiotoxicity was significantly higher in the doxorubicin arm than in the PLD arm (HR = 3.16, $P < 0.001$). Pegylated liposomal doxorubicin demonstrated efficacy comparable to that of doxorubicin (overall survival was 21 months for PLD versus 22 months for doxorubicin).[40] Other unique delivery systems that have not had significant clinical impact include starch microspheres,[41] albumic microspheres,[42] and lipiodol.[43]

Analogs

Analog development holds the promise of good antitumor activity with decreased cardiac toxicity. Many anthracyclines that are in clinical use (e.g., epirubicin and esorubicin) have been shown to produce less cardiac toxicity in preclinical animal models and were developed as potentially less cardiotoxic compounds than doxorubicin. Although this is still an important avenue of research, it has not yet resulted in a major reduction in clinical cardiac toxicity when the drugs are administered at equimyelotoxic doses.[44] Twenty-five of 261 patients who received more than 600 mg/m^2 of epirubicin (with single doses of epirubicin 45 to 90 mg/m^2 day 1 and day 8 q 28 days) developed CHF (10%), including seven who died of cardiac toxicity.[44] In a later analysis, the same group reported that 59% of patients who had received 850 to 1000 mg/m^2 of epirubicin exhibited a 25% fall in ejection fraction 3 years after the completion of epirubicin, and 20% developed symptoms of CHF. Therapy with angiotensin-converting enzyme (ACE) inhibitors reversed the clinical symptoms in most, but not all, cases.[45] Biopsy studies have been limited but suggest some cardiac protection over the native compound.[46] Some degree of cardiac toxicity indicated by a change in LVEF or development of clinical CHF was observed in patients receiving adjuvant therapy[46] with high doses (epirubicin 200 mg/m^2 and cyclophosphamide 4 g/m^2)[47] or in combination with paclitaxel,[48] although in all of these, the incidence of clinical CHF was low. In the Canadian trial that compared FEC (5-fluorouracil [5-FU], epirubicin, and cyclophosphamide) to CMF (cyclophosphomide, methotrexate, and 5-FU), there was no clinical cardiac toxicity in the 351 patients in the FEC arm; one of the 359 patients in the CMF arm did show cardiac toxicity, however.[44]

Blocking Agents

Differences in the biochemical mechanisms of antitumor activity and cardiac toxicity provide a potential avenue of selectively inhibiting or preventing the adverse effect. Targets for this approach include agents that prevent free radical generation or salvage free radicals. Several free radical scavengers, including α-tocopherol (vitamin E),[49] N-

acetyl cysteine,[50] coenzyme Q-10,[51] and prenylamine,[52] have been tested as selective cardiac protectors with negative or inconclusive results. Dexrazoxane (Zinecard) is the one drug that has been approved for this use and is clearly cardioprotective. The compound is a bisdioxopiperazine that is hydrolyzed intracellularly to form a bidentate chelator, similar in structure to EDTA; it effectively binds intracellular iron. The putative mechanism of cardioprotection is that dexrazoxane strips Fe^{2+} from the iron-doxorubicin complex, thereby preventing free radical generation (Fig. 63-4). Randomized trials in patients with breast cancer[18] and small cell lung cancer[53] indicate that dexrazoxane can reduce doxorubicin-induced cardiac damage as measured by clinical examination, MUGA scan or endomyocardial biopsy. Dexrazoxane's limiting toxicity of myelosuppression did not add significantly to the toxicity of the regimens. Conflicting results for its effect on antitumor activity have been reported, but most trials indicate no negative effects.[5] However, a possible increase in early disease progression in one large study has led to some concern.[54] Additional trials have suggested that the drug affords cardioprotection in breast cancer without interfering with antitumor efficacy.[55–57] Furthermore, analysis of randomized trials in breast cancer suggests that even when dexrazoxane is added after the sixth course of chemotherapy (300 mg/m^2), there is significant cardioprotection while maintaining the antitumor activity of the regimen. This concern has led to limitation of its approval to metastatic disease after patients have received doxorubicin alone.[58] While these analyses argue for the use of this agent in the management of breast cancer, it is now clear that anthracyclines cause cardiac damage considerably earlier than had been previously appreciated, and protection after multiple cycles of chemotherapy might not represent the optimal approach to cardioprotection.[59] Coadministration of dexrazoxane with a less cardiotoxic doxorubicin analog could offer the best future means of reducing anthracycline-related cardiac toxicity. Of interest, dexrazoxane has been shown in animal systems to protect against the cardiotoxic effects of epidoxorubicin but may have less effect with mitoxantrone.[12] Clinical testing of dexrazoxane in combination with epidoxorubicin has been shown in randomized trials in women with breast cancer to protect against cardiac toxicity without inhibiting antitumor activity,[60] and these results have been extended to sarcoma treated with high-dose epirubicin.[22]

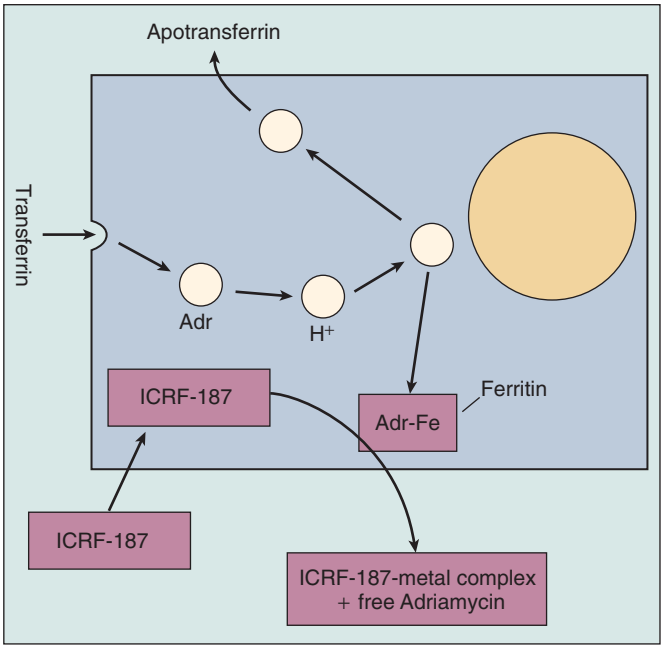

Figure 63-4 • Proposed mechanism for ICRF-187 inhibition of doxorubicin Fe complex formation. (From Muggia FM, Green MD, Speyer JL [eds]: Cancer Treatment and the Heart. Baltimore, Johns Hopkins University Press, 1992, p 27.)

Pediatrics

Overall, children are at increased risk for developing cardiac toxicity. In a large retrospective cohort study (Childhood Cancer Survivor Study), 10,397 survivors of childhood cancer were followed for a median of 17 years; the relative risk of grade 3 or 4 CHF was 15.1 (95% CI: 4.8 to 47.9); that of coronary artery disease was 10.4 (95% CI: 4.1 to 25.9 to 3.5).[61]

Children are particularly sensitive to treatment with anthracyclines. It occurs at relatively lower cumulative doses and appears to increase over time. In a study of 830 children treated in the Netherlands, the incidence of CHF with a median of 8.5 years follow-up was 2.5%, rising to 5.5% at 20 years. Higher cumulative doses were associated with greater risk, 9.8% in children who received greater than 300 mg/m^2.[62] Longitudinal studies by Lipshultz and colleagues in 115 pediatric leukemia patients (median follow-up: 11.2 years) also indicated that cumulative anthracycline dose is the most important risk factor. However, many children developed significant changes in cardiac function at lower doses (228 mg/m^2); 59% showed increased afterload, and 23% showed decreased contractility.[63] Younger age at treatment, radiation exposure, female sex, and tumor type are also risk factors.[64]

The pathophysiology of anthracycline cardiac damage in children appears to be a product of both direct myocyte damage and a progressive loss in heart muscle mass leading to decreased contractility. In the leukemia studies, the reduction in fractional shortening *z*-scores (related to impaired contractility and increased afterload) was progressive at more than 12 years follow-up.[63] Treatment is similar to that with adults. Enalapril and ACE inhibitor may delay the pathologic process but do not prevent it.[64] Dexrazoxane (Zinecard) however can prevent or significantly reduce anthracycline cardiac toxicity. It was first reported by Wexler in a group of children with pediatric solid tumors.[65] In a larger randomized trial involving 206 children with ALL receiving doxorubicin, cardiac injury measured by rise in troponin T levels was observed in 21% of children receiving dexrazoxane versus 50% in those receiving doxorubicin alone ($P < 0.001$). Moreover, there was no evidence that dexrazoxane compromised the treatment efficacy. At 2.5 years, the event-free survival and continuous complete remission rates were 83% and 81%, respectively, for both groups.[66]

Other Causes of Congestive Heart Failure

Chemotherapy

TRASTUZUMAB. Trastuzumab (Herceptin) and possibly related compounds are the chemotherapeutic agents that are most associated with CHF other than the anthracyclines. Although the signs and symptoms of heart failure are the same, the clinical course and pathophysiologic mechanism may be quite different. Combinations of trastuzumab with other cardiotoxic agents, including the anthracyclines, may cause additive or synergistic toxicity. The monoclonal antibody to Her2/neu receptor, trastuzumab, is widely used in breast cancers that overexpress Her2/neu. The significant reduction in risk of recurrence when applied in the adjuvant setting means that many more patients will be receiving this drug. Cardiac toxicity was reported in the single-agent phase II trial reported by Cobleigh and coworkers.[67] In the pivotal stage III trial in metastatic disease that led to initial drug approval, an unexpectedly high incidence of cardiac toxicity was observed: 27% when an anthracycline and cyclophosphamide were combined with trastuzumab compared with 8% with the chemotherapy alone. A similar though smaller effect (13% versus 1%) was observed when paclitaxel was combined with trastuzumab. It should be noted that all of the patients who were treated with paclitaxel had received prior anthracyclines.[68] Seidman and colleagues reviewed the records of 1219 patients in seven trastu-

zumab trials.[69] They report an incidence of cardiac dysfunction of 3% to 7% with trastuzumab alone, 27% with anthracycline and cyclophosphamide, and 13% with paclitaxel. Further data from prospective trials are still necessary to better quantify the contribution of trastuzumab to chemotherapy-induced toxicity.[70] In the NSABP B31 adjuvant breast cancer trials, 3-year cumulative incidence of grade 3 and 4 toxicities were reported in 4.1% of patients receiving trastuzumab after doxorubicin and cyclophosphamide followed by paclitaxel chemotherapy compared to 0.8% of patients who received chemotherapy alone.[71] Additional questions that are being addressed in several large trials include the relative effects of the duration and sequence of trastuzumab therapy combined with chemotherapy. The addition of carboplatin to paclitaxel and trastuzumab does not appear to increase cardiac toxicity,[72] nor does the combination of vinorelbine and trastuzumab.[73,74] Cardiac observations with combinations of trastuzumab and gemcitabine, capecitabine, and other drugs are underway. The lesser cardiotoxic potential of liposomal doxorubicin led to a recently completed a trial of 30 patients with metastatic breast cancer who were treated with PLD in combination with trastuzumab. In this relatively small study, 10% of patients developed asymptomatic decline in LVEF of at least 15%. No symptomatic CHF was observed.[75] Trastuzumab-induced cardiac toxicity differs from anthracycline cardiac toxicity in the following ways:

- It is not dose related.
- It is usually reversible. In one report, 79% of patients responded to medical management, yet some also recover without specific treatment.
- Many patients can be successfully rechallenged after a return of cardiac function to normal without symptom recurrences or further deterioration on LVEF.
- It does not present with the same ultrastructural changes on endomyocardial biopsy.
- The biochemical mechanisms of damage are different.

In recognition of these important differences, Ewer and Lippman have proposed a classification system of chemotherapy-induced CHF that divides anthracycline-induced cardiac damage (type I) from trastuzumab damage (type II).[1] We propose further revising this system to include other causes of cardiac damage in cancer patients (see Fig. 63-1).

There is increasing knowledge about the mechanism of trastuzumab cardiac toxicity that points to a role of inhibition of normal cardiac repair pathways. This would explain the increased toxicity when trastuzumab is combined with doxorubicin and might suggest additive toxicity with other sources of cardiac stress. Her2 heterodimerizes to Her4, leading to autophosphorylation of the Her2 tyrosine kinase domain.[76] This complex, which is the antitumor target of trastuzumab, is also active in cardiac repair. The complex is activated by neuregulin 1, which is secreted in paracrine fashion by cardiac endothelial cells that are under stress.[76] Activation of the complex leads to multiple downstream effects that in turn lead to hypertrophy of cardiac myocytes in vivo. In mice, deletion of Her2 results in a dilated cardiomyopathy.[77] Chien proposed a model in which various types of cardiac stress such as mechanical strain, anthracyclines, or hypoxia trigger two competing pathways of cardiac myocyte survival (mediated by neuregulin-1 or gp 130 cytokines) or apoptosis. The clinical outcome depends on which process prevails. In this model, treatment with trastuzumab blocks the survival pathway by preventing Her2/Her4 heterodimerization, thus shifting the balance to apoptosis. The result is decreased cardiac contractility and CHF.[78]

LAPATINIB. Oral lapatinib (Tykerb) is a small molecule dual selective inhibitor or ErbB1 (EGFR) and ErbB2 (Her2/neu) tyrosine kinases. In part because of the cardiac effects of trastuzumab, cardiac function has been carefully monitored in early clinical trials. Isolated cases of clinical CHF with reduction in LVEF were reported in early phase I and II trials. In a retrospective analysis from 3500 patients from all reported trials, Perez and colleagues reported a 1.3% incidence of asymptomatic CHF and a 0.1% incidence of symptomatic CHF. Because of the possibility of interactions with other agents, cardiac toxicity is still carefully monitored in current trials of this agent.[79]

MITOXANTRONE. Mitoxantrone was developed primarily as a noncardiotoxic analog of the anthracyclines. It is an anthracendione that lacks the amino sugar that is common to anthracyclines. Data from collected single-agent studies and two randomized studies indicate that mitoxantrone may result in a congestive cardiomyopathy but at a lower incidence than doxorubicin when equimyelotoxic doses are compared.[80] The incidence of cardiotoxicity at cumulative doses of greater than 160 mg/m^2 is about 5%, although the incidence of clinical CHF is less than 2%. The clinical presentation is similar to that seen with doxorubicin. The diagnostic evaluation and endomyocardial biopsy changes are similar to those seen with doxorubicin. The biochemical mechanism of damage is not clear. Prior therapy with doxorubicin increases the risk of mitoxantrone cardiac toxicity; changing from one anthracycline to another or to an analog might not protect from cardiotoxicity. As was stated previously, the mechanism of cardiac toxicity might not be the same as for doxorubicin.

PHOSPHORAMIDE MUSTARDS. High-dose intravenous cyclophosphamide infusion (120 to 240 mg/kg over 1 to 4 days) has been associated with CHF and death from hemorrhagic myocarditis.[81,82] In contrast to that from anthracyclines, cardiac toxicity from cyclophosphamide is acute and is not related to the cumulative dose. Mortality is high in the face of fulminant hemorrhagic myocarditis. The majority of patients who are treated with high-dose cyclophosphamide will demonstrate a decrease in QRS voltage and a decrease in systolic function, which often are asymptomatic and reversible. Postmortem studies and an experimental animal model suggest that the loss of systolic function is due to direct endothelial injury resulting in capillary microthrombosis and interstitial fibrin deposition.

IFOSFAMIDE. Ifosphamide also has been associated with the development of CHF in a dose-dependent fashion. In one series of 52 patients receiving a high dose (10 to 18 g/m^2) as part of high-dose chemotherapy with ABMT, 9 patients (17%) developed CHF (8 severe enough to require admission to the intensive care unit) at a mean of 12 days (range: 6 to 23 days) after therapy.[83] Most of these patients received prior doxorubicin, raising the possibility of sequential stress. Of interest, autopsy data (endomyocardial biopsies were not performed) did not reveal hemorrhagic myocarditis.

INTERLEUKIN-2. The major cardiovascular effects of interleukin-2 (IL-2) include hypotension (secondary to decreased peripheral vascular resistance), dysrhythmias, and ischemia. Primary myocardial suppression is also suggested by a decrease in LVEF and an increased end-diastolic volume. This results from inadequate cardiac compensation in the face of changes in peripheral resistance.[84]

IMATINIB. Imatinib (Gleevec), an oral agent small molecule that competes for BCR-ABL, C-KIT, PDGFR, and ABL-2 protein kinase-binding sites by impeding protein kinase phosphorylation and activation of downstream kinases, has significant activity in chronic myeloid leukemia (CML) and some activity in ALL and gastrointestinal stromal tumor and may also have cardiac side effects. Although no cardiac events were noted in a series of 553 CML patients receiving imatinib,[85] two cases of CHF with elevated BNP levels were reported in patients with gastrointestinal stromal tumor,[86] and 10 patients (8 CML, 1 ALL, 1 myelofibrosis) with CHF were reported by Kerkela and colleagues[87] In two patients, pathologic whorls suggestive of toxic myopathy (but different from anthracycline effects) were observed on endomyocardial biopsy. A murine model with imatinib revealed

similar findings and a dilated cardiac myopathy. There is controversy about the extent of this problem. The mechanism of imatinib toxicity, if it exists, is probably through a type II mechanism (see Fig. 63-1). The actual incidence or significance of these findings is a matter of debate but has led to a cautionary warning by the manufacturer.[88]

SUNITINIB. Sunitinib (Sutent) is an oral agent and a small molecule that inhibits PDGFR, VEGFR, KIT, FLT3, CSF-1R, and RET tyrosine kinases that are important for tumor cell growth, survival, metastases, and angiogenesis. In two studies of 169 patients with metastatic renal cell carcinoma who failed prior cytokine-based therapy, the drug showed that 14% of patients had declines in LVEF below normal level. In the first study, 4.7% of patients had a LVEF drop of 20% or more with no reported symptoms.[89] In addition, grade 3 hypertension was reported in 6%. In the second study, one patient developed dyspnea.[90] However, in another study of 207 patients with gastrointestinal stromal tumor, there were no cases of decrease in LVEF or CHF.[91] At this time, the drug maker recommends stopping sunitinib in the event of clinical heart failure and interrupting and/or reducing the dose in asymptomatic patients with an LVEF drop of less than 50% or in those with LFEV more than 20% below baseline.[92]

OTHER COMBINATIONS. Combinations of chemotherapeutic agents have been reported to cause varying degrees of CHF. When doxorubicin was first combined with paclitaxel, an 18% incidence of CHF was reported with cumulative doxorubicin doses of 400 mg/m^2.[93] Not all investigators reported this high rate, however.[94] When the paclitaxel was initially administered as a 24-hour infusion, increased plasma and tissue concentrations of doxorubicin and the doxorubicinol metabolite were observed. Limiting the doxorubicin dose and allowing for an interval between doxorubicin and paclitaxel administration reduced the incidence of CHF to 4.7% of 657 patients, with a higher incidence of 25% in patients who received more than 440 mg/m^2.[95] Combinations of doxorubicin with docetaxel have not been associated with increased cardiac toxicity. In a randomized trial comparing doxorubicin and docetaxel with doxorubicin and cyclophosphamide in 429 women with breast cancer, CHF was not increased (3% versus 4%), and the decline in LVEF—30 points from baseline—was less (1% compared with 6%).[96] The incidence of CHF has been reported to be 6% for the combination of epidoxorubicin and paclitaxel.[97] Several trials have raised the possibility of increased cardiac toxicity when doxorubicin is combined with high-dose cyclophosphamide[98] in the transplant setting.

Radiation

Radiation to the myocardium can cause interstitial myocardial fibrosis. This occurs through capillary damage, organization of fibrinous exudates with microcirculatory damage, and fibrosis.[99] Echocardiography and MUGA scans can help to differentiate primary myocardial damage from the pericardial damage that often occurs in the same patients.[100] Repeated doses or very high radiation doses (>6000 cGy) are associated with a greater risk of radiation damage. Biventricular dysfunction is common, although usually asymptomatic, occurring 5 to 20 years after radiation therapy. This is especially likely in patients who have been treated through a single anteroposterior port.[101] As a result of advances in radiotherapy techniques, clinically significant radiation-induced myocarditis is rare; presumably, the rates of late dysfunction will become less frequent as well.

Serial large retrospective reviews suggest that radiation therapy to the heart leads to increased mortality. Breast cancer cohorts in which the radiation dose to the heart varies depending on whether the cancer was in the right or left breast provide evidence for assessing this toxicity. In a meta-analysis of 40 trials from the 1980s of more than 19,000 women with breast cancer who were treated with radiation, the Early Breast Cancer Trialists Collaborative Group (2000) found an increased mortality from cardiovascular disease.[102] However, a more recent study with up to 15 years of follow-up of more then 15,000 breast cancer patients who were treated with more modern heart-sparing techniques revealed no excess in cardiac disease among those who were treated for left-sided versus right-sided breast cancer.[103] In another retrospective study of 27,283 patients, there was a progressive 6% yearly decline in ischemic heart disease hazard of death in patients with left-sided breast cancer versus right-sided breast cancer who were treated with radiation after 1979.[104] In the largest data analysis of 308,861 women from U.S. Surveillance Epidemiology and End Results, 115,165 of whom had been treated by radiation, Darby and colleagues found progressive decrease in the cardiac mortality ratio (left versus right tumor) from 1.42 after 10 to 14 years for those irradiated in 1972 to 192 to 1.27 after 10 years for those irradiated in 1983 to 1992.[105] Harris and colleagues studied long-term side effects (median follow up of 12 years) of radiation therapy of 961 breast cancer patients treated with right-side versus left-side heart irradiation with lower volume of heart exposure techniques used in University of Pennsylvania since 1977. Although "there was no difference in overall mortality from any cardiac cause," the authors found a 6.4% cumulative risk of cardiac death for the left-sided irradiation versus 3.6% for right-sided irradiation at 20 years.[106] The new methods of radiation therapy, such as tomotherapy, intensity-modulated radiation therapy, mixed electron/photon beams, respiratory gating,[107] and prone accelerated partial breast irradiation,[108] have a potential of further decrease of radiation-caused cardiac mortality and morbidity.

Increased caution must be exercised, however, when radiation therapy is combined with doxorubicin therapy or possibly other cardiotoxic drugs because there appears to be a synergistic toxic effect on the myocardium. This can occur even if the two therapies are separated by long time periods. Prior radiation is a well-recognized risk factor for developing doxorubicin toxicity.[109] Conversely, radiation can cause a sudden decrease in ventricular function in a patient who either is receiving or has received doxorubicin. There are insufficient data to assess a possible interaction between radiation and trastuzumab therapy.

Therapy

Treatment of all cardiomyopathies is similar, regardless of their etiology (Box 63-1). Ceasing treatment with the offending agent is of prime importance, and changing from one agent to another, especially when an anthracycline is involved, will not protect from further cardiotoxicity. Fluid and sodium restriction and the use of diuretics may provide some relief in acute situations. Afterload reduction with agents such as ACE inhibitors is clearly beneficial, and in stable patients, beta-adrenergic blockers such as carvedilol appear to be of significant benefit.[110] Clinical improvement in anthracycline-induced CHF has been demonstrated, as has improvement in LVEF as measured by serial MUGA scans.[17,111] In an animal model, treatment with angiotensin II receptor blockers may also be of benefit.[112] Currently, no therapy is available that can reverse the damage done to the injured myocardium; and dexrazoxane, despite its mechanism of protection in the acute stage of cardiac damage, would not be expected to repair existing damage. Early treatment of significant cardiac dysfunction may mitigate the progression of disease. Digitalis can improve symptoms but probably does not extend life.

CONGESTIVE STATES ASSOCIATED WITH OTHER CANCER TREATMENT

General considerations of fluid and electrolyte management should be carefully considered in administering anticancer treatment. Possible fluid overload states can result from intensive hydration regimens (e.g., for cisplatin) or with transfusion. Patients with anemia and low serum albumin are more susceptible to high output states. Malignant pleural and pericardial effusions, as well as ascites or

Box 63-1. DOXORUBICIN-INDUCED CARDIOMYOPATHY

Monitoring

- Physical examination is the best way to monitor patients for doxorubicin-induced cardiomyopathy (e.g., sinus tachycardia is a nonspecific early sign), with radionuclide scans or echocardiograms at baseline, 300 mg/m^2, 450 mg/m^2, and each 100 mg/m^2 thereafter.
- Patients who are at increased risk—for instance, those who have had prior treatment with anthracyclines, are older than 70 years of age, have had prior chest radiation therapy, or have pre-existing cardiac disease—might need to be observed more closely. Therapy should be withheld if the left ventricular ejection fraction falls to less than 0.45 or to 0.2 below baseline. (Other investigators have used a fall of 0.15 as the cutoff for discontinuing therapy.)
- Most centers still use endomyocardial biopsy as the confirmatory tool. Biopsy should be considered in patients with a cumulative dose of 450 mg/m^2 or more, and therapy should be withheld in any case if the Billingham biopsy score is 2 or greater.
- Cardiac troponin C and I are under investigation for monitoring purposes.

Cumulative Dose Limitation

If monitoring strategies are in place, most patients who are thought to be benefiting from therapy can be safely treated to doses exceeding 450 mg/m^2.

Dosage Schedule Modification

The incidence of cardiomyopathy may be decreased by modifying the dose schedule. For example, intravenous bolus schedules may be adjusted by dividing the 21-day dose into three weekly doses or a continuous infusion schedule in which the full dose is given over 72 to 96 hours through central catheters with portable infusion pumps.

Cardioprotection

Dexrazoxane (ICRF-187: ADR 529), a chelating agent that binds intracellular iron and prevents free radical production, has been shown in clinical trials to markedly reduce the incidence and severity of cardiomyopathy.

Treatment

- The first step in treatment is to stop the doxorubicin and then not to use it again in the future. As with other cardiomyopathies, fluid intake is limited.
- Sodium, diuretics, afterload, and cautious use of afterload reduction, especially with angiotensin-converting enzyme inhibitors, may result in clinical improvement.
- The course can vary, ranging from improvement to steady worsening with biventricular failure and death as the outcome.

intrathoracic malignancies, can cause external compression of the heart with resulting symptoms of CHF. Thyroid dysfunction sometimes is identified in cancer patients and responds to the usual therapeutic interventions.

DYSRHYTHMIAS

Dysrhythmias are commonly seen in the course of treatment of malignancies. The entire spectrum of supraventricular and ventricular bradydysrhythmias and tachydysrhythmias can be seen in cancer patients for a variety of reasons that might or might not be related to the cancer or its treatment. These include intracardiac or paracardiac tumor, electrolyte imbalance, fever, and hyperadrenergic states. Dysrhythmias related to therapy may, in turn, be related to coronary or myocardial disease resulting from anticancer therapy or to the direct dysrhythmogenic effects of the anticancer therapy itself.

Radiation injury has been implicated in the development of sinus node dysfunction, atrioventricular block, and conduction disturbances below the bundle of His.[113]

Occasional dysrhythmias have been reported with the anthracyclines. While these usually occur in the setting of the drug-induced cardiomyopathy, the dysrhythmias are not a prominent part of the clinical picture. Sinus tachycardia, however, is exceedingly common in patients with an anthracycline-induced cardiomyopathy and may be the earliest sign of the cardiomyopathic effect of anthracyclines. Supraventricular dysrhythmias also may occur with the development of pulmonary venous hypertension. Ventricular dysrhythmias occur in the setting of left ventricular failure. Sudden death, however, remains rare.

Arsenic trioxide (Trisenox), an important agent for treatment of acute promyelocytic leukemia, has been reported to cause cardiac arrhythmias associated with QT interval prolongation[114] as well as complete atrioventricular block.[114,115] QT prolongation can be a risk factor for torsade de pointes, a life-threatening form of ventricular arrhythmia.[116] The prevalence of QT prolongation increased from 14.4% at baseline to 68% of treated patients in one study.[114] However, in the same study, analysis of 99 patients and 1189 electrocardiographic recordings suggests that QT prolongation may be a reversible effect, provided that careful patient cardiac evaluation is done before and during therapy as well as detection and timely correction of electrolyte abnormalities. Indeed, only 2 patients out of 99 developed significant arrhythmias.[114] Rare deaths have been reported; female gender and African extraction may be risk factors, but further study is needed. Reports are anecdotal.

Taxol has been implicated in the development of dysrhythmias. A 30% incidence of asymptomatic bradycardia has been observed with this agent; however, the bradycardia seldom requires termination of the agent. In addition, atrioventricular block of varying degrees, bundle branch block, and ventricular tachycardia have been described[117] and may require specific therapy. Supraventricular tachycardias were reported in 8 of 41 (20%) patients receiving therapy with dihydro-5-azacytidine, an investigational pyrimidine, for mesothelioma.[118]

Interleukin-11 (Neumega) is used for the reduction of chemotherapy-induced thrombocytopenia. In one trial, 6 of 58 patients (10%) developed symptomatic dysrhythmias.[119] Five patients had atrial fibrillation, and one patient had atrial flutter. The authors speculated that these effects might have been secondary to fluid retention.

Dysrhythmias also have been reported with the monoclonal antibody to CD20 (Rituximab).[120]

Nonspecific dysrhythmia is common in cancer patients and might be due to fluid and electrolyte shifts associated with vomiting, as well as hyperadrenergic states that may accompany anemia and a variety of other factors. Most of these rhythm disturbances can be managed with correction of the underlying abnormality and do not require specific antidysrhythmic therapy.

MYOCARDIAL ISCHEMIA

A variety of ischemic syndromes have been ascribed to oncologic therapy. Much of the data is anecdotal, however, as there is a high incidence of coronary artery disease in the population in which cancer is also common. Chemotherapy may shift a previously stable oxygen

supply and demand balance in favor of an increased demand in the face of a fixed supply that results in the ischemic syndrome. The clinical picture is further confused by the high incidence of intercurrent intrathoracic malignant disease, anemia, fever, and infections and concomitant treatment with other drugs, all of which can affect the balance. Furthermore, the malignancy itself may cause chest pain in a patient with noncritical ischemic disease.

There is, however, convincing evidence that thoracic radiation therapy is associated with the development of coronary artery disease.[121] In addition to the very substantial body of evidence that radiation causes small vessel damage, which ultimately leads to myocardial fibrosis and cardiomyopathy, there also are data that implicate radiation therapy in the development of epicardial (particularly ostial) coronary artery disease.[121,122] The original data came largely from case reports of myocardial ischemia and infarction in young adults (without other risk factors for coronary atherosclerosis) following mediastinal radiation therapy. Two basic pathologic mechanisms have been implicated. The first relates to the direct effects of radiation on the endothelial cells of epicardial coronary arteries, leading to accelerated atherogenesis. The second—and more typical—pathology is that of severe medial and adventitial fibrosis, perhaps mediated through radiation damage to the vasa vasorum. Typically, this vessel fibrosis is associated with a paucity of the intimal lipid deposition that characterizes atherosclerotic lesions.[123–125] With newer cardiac-sparing radiation therapy techniques, the likelihood of cardiac damage has been reduced.

Fluoropyrimidines are the most commonly chemotherapy drugs associated with myocardial ischemia. The largest number of cases of ischemia that have been ascribed to anticancer therapy are associated with treatment with 5-FU.[126] Several case reports called attention to this possible association. There have been isolated reports of patients with normal coronary angiography who developed typical symptoms and electrocardiographic evidence of ischemia after 5-FU infusion, but a review of over 1000 patients receiving 5-FU revealed an incidence of cardiac toxicity of 4.5% in patients in whom coronary disease was known to predate treatment compared to an incidence of 1.1% in those not known to have coronary artery disease prior to therapy. Thus, it was not surprising that an early prospective analysis was not convincing for a causative role of this drug in the development of angina or myocardial infarction. In a prospective series of 910 patients,[127] however, 5 patients (0.55%) developed signs and symptoms that were consistent with coronary artery spasm. All five patients had ST segment elevation and ventricular dysrhythmias. Four had documented infarction, and two had cardiac arrests, leading to the hypothesis that there might be 5-FU- or metabolite-mediated increases in coronary vasomotor tone. Coronary artery spasm as a mechanism for 5-FU-associated ischemia could explain the increased incidence of ischemia in patients with underlying coronary disease as well as in those with angiographically normal coronary vessels. Nitrates and calcium blockers may be protective. There is some suggestion that the association of 5-FU with myocardial ischemic events is more striking in patients who are treated with continuous infusion therapy.[126] The association is more common in patients who are receiving concomitant radiation therapy[128] or treatment with cisplatin.

Capecitabine (Xeloda), an oral prodrug for 5-FU, has also been associated with cardiac toxicity. In a review of 832 patients, incidence was similar to that with 5-FU (3% for all toxicities and 1% for grades 3 to 4). Individual cases of myocardial infarction, angina pectoris, myocardial ischemia, myocarditis, and tachycardia were described.[129] It is possible that combination with oxaliplatinum may increase this toxicity. In combined data from two trials of 153 patients, cardiac toxicity was observed in 6.5% of patients; 4.6% were ischemic.[130]

Although the vinca alkaloids also have been reported to precipitate angina and myocardial infarction,[131] this observation is strictly anecdotal.

PERIPHERAL VASCULAR DISEASE

Raynaud phenomenon has been described in patients receiving cisplatin-based therapy.[132] It also has been described after therapy with vinblastine, vincristine, and bleomycin. These may be similar in mechanism to other ischemic syndromes (e.g., coronary ischemia or cerebral vascular ischemia), which have been described with these agents as well as 5-FU. Increased thromboembolism has been observed when thalidomide is combined with doxorubicin[133] and with gemcitabine and infusional 5-FU.[134] A similarly high incidence of thromboembolic events was reported with the combination of gemcitabine, cisplatin, and SU5416.[135] As is the case for radiation-induced coronary artery disease, clinically significant occlusive lesions in other arteries, such as the carotids,[136] have been reported following irradiation.

PERICARDIAL DISEASE

Most pericardial disease presenting in cancer patients may be attributed to the underlying malignancy, the most common malignancies being melanoma, breast cancer, and lung cancer. Patients may have metastatic disease to the pericardium or obstruction of lymphatic or venous flow, producing a pericardial effusion. Even in patients without clinically manifest disease, asymptomatic pericardial effusions are common. Pericardial effusions have been ascribed to the anthracyclines[137] as well as cyclophosphamide[138] and dihydro-5 azacytidine.[118] With the exception of irradiation, pericardial manifestations of cancer treatment are seldom troublesome. Interestingly, in series in which pericardial effusions were reported with doxorubicin or cyclophosphamide, most patients ultimately went on to demonstrate evidence of myocardial toxicity from the drugs. Isolated pericarditis was rare.

There have been case reports of high-dose busulfan causing cardiac tamponade in children with thalassemia[139] and a report of busulfan-related endocardial fibrosis.[140]

FLUID RETENTION

Docetaxel (Taxotere), an active taxane analog of paclitaxel (Taxol), has broad antitumor activity but is associated with fluid retention in some patients. Severe fluid retention and CHF are rare. This syndrome is progressive with more treatment cycles. It does not appear to be of cardiac or renal origin. Premedication with steroids substantially reduces this problem.[141]

Dasatinib (Sprycel) is an oral agent that is active in 14 of 15 imatinib-resistant BCR-ABL tyrosine kinase mutants and inhibits other tyrosine kinases such as SRC, C-Kit, and PDGFR. In a study of 84 CML and Ph^+ ALL patients, 15% of patients developed pleural effusion, 19% developed peripheral edema, 14% developed pulmonary edema, and 7% developed pericardial effusion.[142] Also in studies of patients with leukemia, dasatinib caused QT prolongation in nine patients, three of whom (<1%) had QTcF greater than 500 msec.[143] Therefore, special attention should be paid to correction of hypokalemia and hypomagnesemia prior to dasatinib treatment as well as to patients with known QT prolongation and patients who are taking other medicines that can cause QT prolongation.[143]

All-*trans* retinoic acid, an oral agent that overcomes promyelocyte retinoic acid receptor maturation block caused by a t(15,17)-related protein, has become an important part of acute promyelocytic leukemia treatment. The drug causes retinoic acid syndrome,[144] which consists of respiratory distress, hypoxemia, weight gain, pleural and pericardial effusions, pulmonary infiltrates, fever, hypotension, and acute renal failure, after a median of 11 days (2 to 47 days) in approximately 25% of treated patients.[145] The treatment is high-dose dexamethasone given as soon as the syndrome is suspected[144] and temporary discontinuation of all-*trans* retinoic acid, depending on the clinical situation.

RADIATION-INDUCED PERICARDIAL DISEASE

Pericardial disease is a well-known side effect of thoracic radiation therapy. Effusions have been reported in 6% to 30% of patients receiving radiation therapy to the chest using older radiation techniques.[146] Since the 1960s, there have been numerous reports of patients who had received high-dose mediastinal radiation for the treatment of lymphoma and ultimately developed pericardial disease. Similar reports ascribing pericardial disease to radiation therapy for breast cancer also appeared in the late 1960s.

The clinical spectrum of radiation-induced pericardial disease is wide. Acute pericarditis occurs in 10% to 15% of patients with Hodgkin's disease who receive more than 4000 rads to the mediastinum.[147] The clinical onset of symptoms related to the pericarditis is anywhere from 0 to 85 months after therapy, with a peak occurring between 5 and 9 months. The acute pericarditis may be symptomatic, with the patient experiencing chest pain and fever and the physician noting a pericardial friction rub. However, acute pericardial inflammation probably is often asymptomatic. In any event, the acute pericarditis usually resolves spontaneously. In symptomatic patients, treatment with nonsteroidal anti-inflammatory drugs (including aspirin) or corticosteroids is probably warranted.[148]

The acute effects of radiation on the pericardium appear to be due to an increase in capillary permeability in the pericardium resulting in a fibrinous exudate. Ultimately, fibrosis and calcification can occur. Fewer than half of symptomatic and asymptomatic patients with acute pericarditis will go on to develop chronic pericardial disease or tamponade. Constrictive pericarditis has been described anywhere from 2 to 20 years after radiation. Signs of constriction may include a pericardial knock, Kussmaul's sign, peripheral edema, and evidence of bowel edema or hepatic congestion. The pericardium might appear thickened on a thoracic CAT scan or an echocardiogram. The diagnosis of constrictive physiology can almost always be confirmed by Doppler echocardiography. In such patients, pericardiectomy might be warranted; however, the surgery is often difficult and carries significant morbidity and mortality.

Radiation-induced pericardial disease depends on the extent to which the heart has received radiation and the dose of radiation delivered to the heart. With current techniques in mediastinal radiation, including the use of modern megavoltage equipment and the delivery of divided radiation to the anterior and posterior thorax with a subcarinal shell and intensity-modulated radiation therapy, it is likely that the incidence of pericardial disease has been significantly decreased, perhaps to the range of 2% to 2.5%.[149]

CARDIOCIRCULATORY EFFECTS OF BIOLOGIC RESPONSE MODIFIERS

Bevacizumab (Avastin) is a recombinant monoclonal humanized IgG1antibody that selectively interacts with vascular endothelial growth factor (VEGF) and competitively inhibits its binding to VEGFR-1 (Flt-1) and VEGFR-1 (KDR/Flk-1) endothelial cell surface receptors, thereby disrupting microvascular proliferation and metastasis of tumors. Bevacizumab showed its activity as an adjunct to cytotoxic drug combination and is approved for use in colon, lung, and breast cancer. An 8% to 18% incidence of grade 3 or 4 hypertension was found in many phase I and II studies.[150] In the phase III trial, there was an 11% incidence of grade 3 hypertension in the group of 393 patients who were treated with bevacizumab in combination with irinoitecan and 5-FU/leucovorin (B/IFL), as compared to the 2.3% in the group of 397 patients who were treated with IFL alone. Hypertension was successfully controlled with ACE inhibitors, diuretics, and other antihypertensive medications.[151] Rarely, the drug must be discontinued; the blood pressure might remain elevated despite treatment interruption.

Recombinant technology has made a number of new agents available for clinical trial. They have a variety of side effects. In some cases, these adverse effects may actively be the molecular indicator of a variety of cellular interactions. Hypotension and tachycardia are observed with a number of agents. With interferon-alpha, these have been reported in 6% to 14% of patients.[152] It is difficult in these studies to separate changes in blood pressure from dysrhythmias or ischemic events. Hypotension is a more consistent feature of interferon,[153] although fewer patients have received other biologic therapies.

Hypotension (along with dysrhythmias, ischemia, and decreased contractility) is a major side effect of interleukin-2 and was observed to occur in more than 70% of patients in the early IL2/LAK trials.[154] The primary mechanism appears to be decreased vascular resistance.[84,155] In the early days of therapy, patients develop increased heart rate, increased cardiac index, and decreased left ventricular stroke volume work index, peripheral vascular resistance, and mean arterial blood pressure. The clinical presentation is similar to that of septic shock, with a vascular leak syndrome, fluid retention, and noncardiogenic pulmonary edema. The mechanism may be similar to that of septic shock, with induction of cytokines and effector cells and the release of vasoactive agents. Reductions in dose and continuous infusion schedules have lessened these toxicities[156–158] but also may decrease the antitumor effects.[159] In one study,[160] oral L-carnitine appeared to decrease these complications. IL-2 toxicity often requires intensive-care management, support with pressors, and, at times, ventilatory support.

Hypotension also has been described with tumor necrosis factor,[161] granulocyte macrophage colony-stimulating factor,[162] interleukin-11,[119] and monoclonal antibodies.[117] With tumor necrosis factor, the hypotension often is dose-limiting.[161] With granulocyte macrophage colony-stimulating factor, it is observed at high doses and is associated with a capillary leak syndrome and decreased peripheral resistance.[162] The mechanism with these two agents is not as well defined, nor is the clinical problem as acute as it is with IL-2. Hypotension also has been reported with interleukin-1 in phase I trials.[163]

The possibility of cardiac toxicity was raised in early trials of interleukin-4, especially when one patient was found to have biopsy-proven myocarditis.[164] Interleukin-6 has been associated with cardiac dysrhythmias.[165] Syncope or near-syncope was reported in 6 of 58 patients in a trial of IL-11 (5 patients at the 50-mg/kg level and 1 patient in the in placebo group). Six patients also had documented dysrhythmias.[119]

Changes in peripheral vascular resistance and hypotension may be generalized effects of biologic therapies. Further elucidation of their mechanisms and management is required.

The complexities of bone marrow transplantation have led to cardiac toxicity in a number of patients. In a series of 170 patients who were monitored prospectively, life-threatening pericardial effusions or cardiac arrest were observed in fewer than 2% of cases.[166] Decreased ejection fraction was observed in 17 patients. In a retrospective study of 138 patients treated with high-dose therapy and stem cell rescue, cardiotoxicity occurred in 17 patients. It occurred more frequently in patients with lymphoma and breast cancer.[167] It is difficult, however, to determine which of the many drugs used in the regimen, particularly the chemotherapy induction, is responsible for these changes.

LONG-TERM EFFECTS OF CHEMOTHERAPY

One additional caution must be raised. As an increasing number of patients are long-term survivors of childhood cancers, adult patients who received adjuvant therapy without disease recurrence, or long-term survivors of more advanced adult malignancies, unanticipated cardiovascular effects may be observed. Long-term observation and study of these patients are necessary. Identification of such effects may bring into question the overall risk-benefit ratio of the

original treatment. In a long-term (median: 10.2 years) follow-up study of 992 males in the United Kingdom who had been treated with chemotherapy or radiation for testicular cancer, the incidence of cardiac events (angina, chest pain, or myocardial infarction) was increased when compared to controls treated with orchiectomy alone (chemotherapy alone: rate ratio = 2.59; radiation therapy: RR 2.40; and chemotherapy plus radiation: rate ratio = 2.78). Neither the radiation fields nor the specific chemotherapeutic agent (bleomycin, vinblastine, cisplatin, or carboplatin) fully explained these findings.[168]

64 Reproductive Complications

Tracey O'Connor and Donald L. Trump

SUMMARY OF KEY POINTS

- Reproductive complications secondary to cancer or its treatment are expected to increase as the number of cancer survivors increases.

Cancer-Related

- Oligospermia is present in more than 50% of patients with Hodgkin's disease and testicular cancer.
- Patients with baseline oligospermia are more likely to become infertile following treatment.

Treatment-Related Complications

- Surgery
- Radiation therapy
- Hormonal therapy
- Chemotherapy and bone marrow transplantation

Surgery

- Prostatectomy and other pelvic surgeries are associated with erectile dysfunction; retroperitoneal dissection is associated with retrograde ejaculation.
- Nerve-sparing surgery improves potency and decreases retrograde ejaculation rates in patients with prostate, testicular, and rectal cancers.
- Gynecologic surgery can have a direct impact on sexual function by altering the normal female genital anatomy.
- Altered body image can have a profound impact on sexual function.

Radiation Therapy

- Prepubertal testicles and ovaries are more resistant to the effects of radiation.
- Testicular spermatogenesis is affected by doses as low as 15 cGy, and complete aspermia may occur with a dose of 600 cGy.
- Leydig cell dysfunction occurs at doses exceeding 2000 cGy.
- Ovarian function is more resistant to the effects of radiation. The effects are age related, with a significantly increased risk of permanent menopause in patients older than 40 years at dosages exceeding 150 to 400 cGy.
- Erectile dysfunction occurs by 2 years from treatment in 60% to 80% of prostate cancer patients receiving external beam radiation radiations. The majority are attributed to vascular insufficiency.

Hormonal Therapy

- Gonadotropin-releasing hormone (GnRH) agonists and antagonists result in medical castration with resultant loss of libido and impotence.
- Antiandrogen therapy results in a lesser degree of impotence compared to GnRH analogs in the treatment of prostate cancer.

Chemotherapy and Bone Marrow Transplantation

- Alkylating agents are associated with the highest rates of infertility.
- Doses and duration of treatment are directly associated with risk of infertility.
- Risk of infertility and amenorrhea is related to age, dose, and duration of therapy.
- Prepubertal males and females have the highest tolerance for chemotherapy. Normal puberty has been reported in both genders.
- Premature ovarian failure is age-related, the highest risk being in patients older then 40 years. The younger the female, the lower is the risk of amenorrhea and the higher are the chances that menstruation will resume on completion of chemotherapy.
- High doses of alkylating agents such as cyclophosphamide greater than 7.5 g/m^2 are likely to be associated with abnormal sperm count in children. Doses greater than 9 g/m^2 are associated with prolonged infertility. The mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) regimen that is used in Hodgkin's disease is particularly associated with male infertility. In some males, fertility recovered several years after completion of therapy.
- Females who resume menstruation after treatment are at higher risk of early menopause.
- Radiation therapy during bone marrow transplantation conditioning results in male infertility and a high rate of premature ovarian failure. Bone marrow transplantation without radiation has been associated with a high rate of fertility preservation in females treated before puberty or at a very young age.

Cancer and Pregnancy

- Cancer complicates 1 in every 1000 pregnancies.

Chemotherapy

- The highest risk of congenital abnormalities is during the first trimester of pregnancy and is especially common with antimetabolites such as methotrexate.
- Data available from leukemia and breast cancer patients suggest that chemotherapy during the second and third trimesters of pregnancy results in normal offspring. No long-term complications have been identified.

Radiation Therapy

- Risks are highest during organogenesis period (first trimester).
- Mental retardation and microcephaly may occur with second-trimester and early third-trimester exposure.

Prevention and Treatment

- Sperm cryopreservation should be discussed with all males who undergo potentially sterility-inducing treatments.
- Use of GnRH analogs may have a protective effect on ovarian function, but no protective effects on spermatogenesis have been established yet. Their use is considered experimental.
- Gonadal shielding and ovarian transposition ameliorate the effects of radiation on gonadal function.
- Assistive reproductive technologies and alternative methods of sperm collection have resulted in successful pregnancies for couples with severe male infertility secondary to cancer or its treatment.
- The use of sildenafil has reestablished potency in a large number of patients with surgery- or radiation-induced erectile dysfunction.

INTRODUCTION

Advances in the treatment of cancer have resulted in marked improvements in survival and cure rates, causing the number of cancer survivors to rise.

Cancer patients often suffer acute and long-term complications related to cancer and its treatment. Insults to reproductive health constitute an often overlooked dimension. Sexual dysfunction and infertility can have a major impact on patient well-being, interpersonal relationships, and family planning.

Attention to reproductive health issues and patient involvement in treatment planning early in the course of the disease and its treatment are key. This review focuses on the reproductive complications of cancer and its treatment.

REPRODUCTIVE PHYSIOLOGY

Gonadal Form and Function

The ovary produces mature fertilizable eggs as well as sex steroids and reproductive/gonadal peptides. These activities are carried out in an integrated manner by the different compartments of the ovarian functional unit, the follicle. The granulosa cells are the source of the sex steroids estradiol and progesterone as well as the peptides inhibin, activin, and follistatin. De novo synthesis of progesterone by the theca cells is dependent on an abundant supply of cholesterol. Granulosa cells also produce progesterone independently.[1] Estrogen biosynthesis, by contrast, requires cooperation of both the granulosa and the theca-interstitial cells. Precursor steroids (mainly androstenedione) synthesized in the theca cells are transferred across the basement membrane of the follicle to the granulosa cells, where they are aromatized to estrogens. The peptides inhibin, activin, and follistatin are expressed in various tissues, including the ovary and anterior pituitary.

Humans have approximately one million follicles at birth. During the reproductive years, typical cyclic follicular recruitment, selection, and dominance eventually deplete the ovary of follicles, leading to cessation of ovarian function and menopause.

In males, the testes secrete androgenic hormones and produce mature spermatozoa. These two processes are highly interrelated and regulated by multiple factors. Much like the ovary, compartments of the testes serve different functions. The seminiferous tubules consist of Sertoli cells that support the developing sperm and germ cells and are the sites for spermatogenesis. The interstitial or Leydig cells are essential for testosterone synthesis. Testosterone is transported from the Leydig cells to the seminiferous tubules, where it enhances spermatogenesis. Testicular hormones are responsible for the induction of male genitalia development during embryogenesis.

Hypothalamic-Pituitary-Gonadal Axis

The main regulators of testicular and ovarian function are the gonadotropins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The biosynthesis and secretion of gonadotropins are modulated by an interplay of hypothalamic factors: gonadotropin-releasing hormone (GnRH), intrapituitary factors (pituitary peptides—activin and follistatin), and feedback by gonadal factors.[1] Gonadotropin expression is controlled by the hypothalamus primarily through the action of GnRH. GnRH is produced in the medial basal hypothalamus and released in a pulsatile fashion to the anterior pituitary, where it binds to plasma membrane receptors on the gonadotropes and stimulates release of FSH and LH. Depending on the reproductive stage, estrogens can either increase or decrease gonadotropin production. Increased levels of estrogen in females or testosterone in males downregulate gonadotropin secretion. However, increased levels of estrogens at the time of LH surge exert a positive feedback effect. In addition to steroid hormones, the gonadal proteins activin, inhibin, and follistatin modulate release of FSH.[2] Inhibin decreases and activin stimulates gonadotropin function. Follistatin also inhibits FSH but is less potent than inhibin.

Regulatory effects of gonadotropins on the ovaries and testes are similar. In the testes, LH interacts with high-affinity receptors on the plasma membrane of the Leydig cells and, through a cAMP-activated series of steps, stimulates the synthesis of the enzymes of testosterone production. The epithelium of the seminiferous tubules is the primary site of action of FSH. FSH binds to cell surface receptors of the Sertoli cells, stimulating the synthesis of androgen-binding proteins and aromatase enzyme complex that convert testosterone to estradiol. LH and FSH effects on the ovaries strongly resemble those in the testes. Activation of gonadotropin receptors on the plasma membranes of the granulosa and theca cells stimulates the adenylate cyclase system, inducing the regulation of female steroid hormone production and follicular maturation.[3]

DIRECT EFFECTS OF CANCER ON REPRODUCTIVE FUNCTION

Although this chapter concentrates on the impact of cancer therapy on reproductive function, it is important to note that cancer can have important direct effects on sexual and reproductive function.

Gonadal tumors can result in reproductive dysfunction secondary to gonadal germinal tissue destruction as well as to aberrations in hormonal balance. Ovarian sex cord–stromal tumors are often associated with hormonal effects such as precocious puberty, amenorrhea, virilizing symptoms, or postmenopausal bleeding. Male sex cord tumors may be associated with precocious puberty, feminization syndrome, and gynecomastia. Reproductive organ cancers and other cancers involving the pelvis may have direct anatomic interference with coitus or indirect interference secondary to pain. Females with invasive vulvar and vaginal cancers and advanced cervical cancers often present with postcoital bleeding or dyspareunia. Males with testicular cancer may have diffuse testicular pain, swelling, and tenderness that interfere with intercourse. Penile cancer usually presents as a penile sore or mass, but when neglected, it can result in ulceration, bleeding, or secondary infection, which can interfere with coitus.

Central nervous system damage by primary or metastatic cancer or indirectly through paraneoplastic involvement can have a considerable impact on reproductive function. Pituitary prolactin-secreting adenomas are commonly associated with impotence in men and amenorrhea and galactorrhea in women. Other pituitary adenomas can affect reproductive function by destroying LH- and FSH-producing gonadotropes. Craniopharyngiomas and other metastatic cancers can directly invade the pituitary gland and produce hypothalamic-pituitary dysfunction. Metastatic disease that affects the hypothalamus-pituitary axis will also lead to reproductive dysfunction. Paraneoplastic syndromes are an infrequent but well documented cause of reproductive dysfunction. Ectopic adrenocorticotropic hormone secretion (e.g., small cell lung cancer) can result in Cushing-like disease including amenorrhea. Other neurologic paraneoplastic syndromes can have a direct impact on reproductive function through the involvement of the autonomic system such as in Lambert-Eaton syndrome or indirectly by resulting in personality changes such as in limbic encephalitis.[4]

Testicular cancer and Hodgkin's disease are among the most common diseases affecting young men of reproductive age, and both are associated with an increased rate of infertility.

Men with Hodgkin's disease may have pretreatment impairment of spermatogenesis. A recent study of patients with Hodgkin's disease reported that 47% had abnormal semen analysis.[5] In this study, semen quality correlated significantly with the hemoglobin level but not with disease stage or fever. In another study of 158 patients with Hodgkin's disease, elevated erythrocyte sedimentation rate and advanced disease stage were associated with poor semen quality.[6] The association between testicular cancer and abnormalities of spermato-

genesis is even more pronounced. The degree of spermatogenic abnormalities in these patients is greater than can be attributable to local tumor effect or the degree of systemic involvement. A recent study found that sperm count was lower in 83 patients with testicular germ cell cancer (15×10^6/mL versus 48×10^6 mL) compared with healthy men.[7] Histologic investigations have revealed a high prevalence of dysfunctional spermatogenesis even in the contralateral testicle that is uninvolved with cancer.[8] An increased risk of testicular cancer has also been observed in men presenting with an abnormal semen analysis and infertility. Infertile men with abnormal semen analyses have a 20-fold higher incidence of testicular cancer compared to the general population.[9] The specific links between the pathologic events that cause infertility and testicular cancer remain unclear.

EFFECTS OF CANCER THERAPY ON SEXUAL AND REPRODUCTIVE FUNCTION

Surgery

The surgical treatments that have the most significant impact on reproductive function are those involving the pelvis. These include radical prostatectomy, radical cystectomy, rectal cancer surgery, orchiectomy and retroperitoneal dissection, and radical hysterectomy.

Prostate Cancer

Erectile dysfunction in patients undergoing radical prostatectomy is commonly seen after surgery.[10–13] Steineck and colleagues randomized 376 patients to radical prostatectomy versus watchful waiting; the incidence of erectile dysfunction was significantly higher in the surgical group (80%) versus the observation group (45%).[14] Identification and sparing of the neurovascular bundles that carry cavernous nerves is associated with a significant improvement in potency rate following radical prostatectomy.[15] Bilateral nerve-sparing surgeries are considerably more effective in maintaining erection compared to unilateral nerve-sparing surgeries. Potency rates following bilateral sparing surgery at 3 years were 76% compared to 30% with unilateral sparing surgery in previously potent patients younger than 60 years of age. The rates of potency are lower in older patients and in patients with known erectile dysfunction prior to surgery.[16]

Testicular Cancer

Retroperitoneal lymph node dissection (RPLND) frequently damages the sympathetic nerves that innervate the seminal vesicles and the bladder neck. This leads to loss of seminal vesicle emission or emission without bladder neck closure (retrograde ejaculation).[17,18] In the series reported by Hartmann and colleagues, patients who had received more than one modality of treatment (such as chemotherapy or radiation therapy and RPLND) had the highest incidence of infertility.[19] Six out of 29 patients who underwent bilateral RPLND in this series suffered from dry ejaculation. A selective RPLND, as described by Donohue and colleagues, results in the sparing of a unilateral sympathetic chain and preservation of antegrade ejaculation.[20] Jacobsen and colleagues reported preserved antegrade ejaculation in 89% of patients undergoing a RPLND after chemotherapy.[21]

Rectal Cancer

Conventional rectal surgery is associated with high rates of impotence and retrograde ejaculation, likely owing to the damage of the pelvic autonomic parasympathetic and sympathetic nerves by blunt dissection. Williams and colleagues described the outcomes of 78 patients who underwent abdominoperineal resection or low anterior resection. Two thirds of patients who underwent abdominoperineal resection had impaired sexual function compared to 30% of patients who underwent low anterior resection.[22] Total mesorectal excision is a standard procedure in rectal cancer surgery. This technique requires sharp dissection of the mesorectum and emphasizes autonomic nerve preservation, resulting in a lower rate of local recurrences and a higher rate of potency preservation. A comparison of sexual outcomes of patients with conventional surgery and mesorectal excision showed that the ability to have intercourse dropped from 75% to 13% in the conventional surgery arm compared to a drop from 67% to 29% in the total mesorectal excision group.[23] Limited information is available about sexual dysfunction in women with rectal cancer. One study reported that 39% of sexually active women and 62% of all women treated for rectal cancer had Female Sexual Function Index scores that were considered abnormal despite the use of nerve-sparing surgery at the reporting institution.[24] Physical factors such as vaginal stenosis, urinary and fecal incontinence, and dyspareunia have a significant impact on female sexual function, and issues such as low libido, decreased vaginal lubrication, and body image concerns also contribute.

Other Surgeries

Gynecologic surgeries can alter sexual function directly by affecting the anatomy of the female genital tract. In a large Swedish study, patients who had been treated with radical hysterectomy were compared to controls matched for age and geographic region. The researchers found no difference in sexual desire or orgasm between the groups. Patients who had been treated with radical hysterectomy reported statistically significant differences in vaginal lubrication, vaginal length, and vaginal elasticity compared with controls.[25] In contrast, a recent publication found that women who had been treated with radical hysterectomy resembled their age- and race-matched peers who have never had a cancer diagnosis or hysterectomy in sexual well-being.[26] While sexual problems occur with considerable frequency in breast cancer patients and often extend beyond the acute phase of treatment, several prospective studies show no difference in quality-of-life outcomes or sexual functioning for breast cancer survivors on the basis of surgical treatment.[27,28] The use of breast-conserving treatment (versus mastectomy) is not predictive of sexual health after mediating variables are controlled in the analysis.[29]

Radiation Therapy

Radiation therapy affects reproductive function through direct effects on the pituitary, hypothalamus, gonads, uterus, and penile arterial and nerve supplies.

Central Nervous System Effects on Reproductive Function

Mounting evidence suggests that cranial irradiation reduces fertility and sexual function in survivors of childhood cancer. External irradiation to the brain can cause damage to the hypothalamus and impair its function; pituitary cells are more resistant to irradiation. Pituitary dysfunction secondary to irradiation is attributed to disturbance in the hypothalamic-pituitary axis. Hypopituitarism develops slowly after brain irradiation and can be associated with an increase in prolactin levels.[30] The hypothalamic-pituitary function was studied in 31 patients with nasopharyngeal tumors treated with primary radiation therapy (4000 to 6000 cGy).[31] All patients had normal baseline pituitary function. At 1 year from treatment, elevations in thyroid-stimulating hormone and blunted LH response to luteinizing hormone-releasing hormone (LHRH) suggest an abnormality in the pulsatile release of LHRH in males. Three females developed amenorrhea in association with elevated prolactin levels.[31] A dose-dependent response has been suggested, with thyroid-stimulating hormone and gonadotropin abnormalities more commonly seen with brain irradiation doses exceeding 3000 cGy.[32] A recent multicenter study of 593 long-term survivors of acute lymphoblastic leukemia disclosed an increased rate of infertility among children treated with whole-brain radiation.[33] The study suggests that cranial irradiation affects fertility by disrupting gonadotropin secretion. The fertility of female survivors who were treated around the time of menarche was significantly lower than that of sibling controls (rate ratio = 0.59).

Fertility in male patients who received cranial radiation doses of 2400 cGy before the age of 9 years was one third that of controls (rate ratio = 0.35). Survivors who were treated at other ages did not have fertility deficits. This suggests a window period in which normal gonadotropin function is most essential for gonadal maturation.[33] This study also shows that reproductive dysfunction can occur at lower doses of brain irradiation (1200 to 2400 cGy) than was previously suggested.

Radiation Effects on Testicular Function

The testis is one of the most radiosensitive tissues; very low doses of radiation cause significant impairment of testis function. Damage may be caused by direct irradiation of the testis or, more commonly, from scattered irradiation during treatment of adjacent targets. Permanent Leydig cell dysfunction occurs with a dose of 2000 to 3000 cGy. Therapeutic irradiation (2400 cGy) to the testes in patients with acute leukemia causes Leydig cell dysfunction, which is manifested by low testosterone levels or a poor testosterone response to gonadotropins.[33,34] Spermatogenic elements are much more sensitive to radiation than are Leydig cells. Radiation doses as low as 15 cGy transiently suppress spermatogenesis, and doses higher than 600 cGy permanently destroy the germinal elements.[35] Berthelsen evaluated the effects of adjuvant irradiation for seminoma on gonadal function. Retroperitoneal and ipsilateral iliac irradiation resulted in an estimated 200- to 1300-cGy scatter to the unaffected contralateral testicle.[36] Two thirds of patients developed azoospermia, and it took a median of 540 days from the end of treatment before spermatozoa were again found in semen samples. A median of 1250 days passed before the pretreatment sperm count was reached. Sperm counts were low (median: 6×10^6 per ejaculate) up to 5 years after treatment, and serum FSH was elevated (median: 61 IU/L).[36] The time to sperm count recovery is dose dependent at least in the range of 19 to 148 cGy.[37] There is no evidence of an increase in post-treatment congenital abnormalities, and the post-treatment conception rate was 60% to 70%.[36]

Radiation Effects on Ovarian Function

The ovaries of prepubertal children and adolescents, with their greater number of follicles, are relatively resistant to therapy-induced damage. Irradiation that does not involve the pelvis usually does not result in ovarian failure, while individuals who are treated with abdominal, pelvic, or spinal irradiation are at an increased risk of developing ovarian failure, especially if both ovaries are within the field. The effect of radiation on the ovaries is dose-dependent. Recent studies suggest that the LD_{50} (the radiation dose that is required to kill 50% of oocytes) is less than 2 Gy.[38] The ovaries of younger individuals are less sensitive to damage from radiation than are those of older adults.[39] While a radiation dose of 6 Gy is sufficient to result in permanent ovarian failure in women older than 40 year old, higher doses in the range of 1 to 20 Gy result in permanent ovarian failure in the majority of patients who are treated in childhood.[40]

Pelvic Radiation as a Cause of Reproductive Dysfunction

Radiation therapy is commonly employed as definitive treatment for patients with localized or locally advanced prostate cancer. Although the etiology of erectile dysfunction after definitive radiation therapy for prostate cancer is likely to be multifactorial, mounting evidence suggests that the arteriogenic mechanism is more important in this setting then the cavernosal mechanism. Maintenance of normal erection requires both vasodilation of penile arteries (arteriogenic element) and concomitant relaxation of the corporal smooth muscles (cavernosal element). Duplex ultrasonography can assess arteriogenic function by measuring peak penile blood flow and cavernosal function by measuring distension of the corpora cavernosa in the setting of normal penile flow.[41] Duplex ultrasonography in prostate cancer patients with radiation therapy-induced erectile dysfunction confirmed a 63% rate of arteriogenic dysfunction.[41] This contrasts with prostatectomy-induced erectile dysfunction, in which only 32% had arteriogenic dysfunction while 52% had cavernosal dysfunction.[41] Erectile dysfunction is frequently seen after external beam radiation for prostate cancer and increases in frequency with time. Potency and age prior to treatment are risk factors for erectile dysfunction following completion of therapy. Data from one institution on 802 patients before and after treatment for prostate cancer show that only 15% of patients (24.5% of whom were previously potent) who elected radiation therapy had normal erectile function at a median of 53 months of follow-up.[42] Others have shown higher rates of potency, especially when erectile dysfunction prior to radiation is accounted for. In 290 prostate cancer patients treated with radiation, 62% and 42% of those who were potent before treatment maintained potency at 12 and 24 months, respectively.[43] Potency rates drop further with time. Conformal radiation therapy limits the radiation field while delivering a high dose of radiation to the prostate and may be associated with a lower degree of impotence.[44,45] Mantz and colleagues described a 5-year potency rate of 53% among 287 prostate cancer patients who were treated with 6000 to 7200 cGy conformal radiation therapy.[45] The use of brachytherapy in the treatment of prostate cancer has also been associated with a lower incidence of impotence. Prostate brachytherapy as monotherapy was associated with 5- and 6-year potency rates of 76% and 52%, respectively, among previously potent patients.[46,47] The addition of external beam radiation or antiandrogen therapy to brachytherapy decreases the rates of potency substantially.[46,47]

Pelvic radiotherapy for cervical carcinoma is associated with vaginal atrophy, shortening, or agglutination, making intercourse difficult or impossible for these women.[48] In addition, patients often become menopausal as a result of pelvic radiation. Women who have been treated with pelvic radiation report severe sexual dysfunction despite the fact that their desire for sexual intimacy is similar to that of controls. At 2 years of follow-up, Jensen and colleagues reported 85% of women having no interest in sex, 55% having dyspareunia, and 50% having vaginal shortening. These problems were very significant in comparison to the women's own premorbid sexual function and age-matched controls.[49]

Abdominal and pelvic radiation therapy may be part of therapy for management of Wilms' tumor, pelvic rhabdomyosarcoma, and Ewing sarcoma of the pelvis or spine. Young patients exposed to flank radiation (20 to 30 Gy) may have preservation of ovarian function. If women do conceive after this degree of abdominal radiation, there is a significant risk of preterm delivery, low-birth-weight infants, and infants that are small for gestational age compared to controls.[50] Other data suggest a particularly high risk of preterm delivery and low birth weight but no congenital malformations in women who conceive within 1 year after completion of irradiation implying uterine or hormonal defects as the cause of these abnormalities.[51]

Hormonal Therapy

Ablative hormonal therapy is often used in patients with androgen- or estrogen-sensitive tumors. The most common applications are prostate cancer and breast cancer.

Gonadotropin-Releasing Hormone Agonists and Antagonists

Leuprolide and goserelin are two potent GnRH analogs that are commercially available in the United States. These two analogs are much more potent in stimulating gonadotropin release than is GnRH. Initial treatment with GnRH agonists results in an LH and FSH surge with resultant gonadal steroid synthesis stimulation. However, after 10 to 14 days of continuous exposure to GnRH analogs, GnRH receptors on gonadotropin cells in the pituitary are downregulated, resulting in inhibition of LH/FSH release and gonadal suppression. Following prolonged GnRH analog therapy, testosterone and estrogen levels are suppressed to castrate levels. In males, this is usually associated with substantial loss of sexual desire

and marked decrease in frequency, magnitude, duration, and rigidity of nocturnal erections.[52] Treatment exceeding 2 years results in atrophic testes, which might not recover even if GnRH is discontinued.[53] In females, the use of GnRH in the adjuvant treatment of breast cancer is associated with an increased rate of sexual dysfunction, but the symptoms are usually reversible on discontinuation of therapy.[54]

Antiandrogens

Antiandrogens bind to and block the activity of androgen receptors. Androgen receptor blockage is associated with a rise in FSH/LH and a resultant rise in serum testosterone.[55] Antiandrogens, such as flutamide, bicalutamide, or nilutamide, are commonly used in the management of prostate cancer either with LHRH analogs or following LHRH agonist/antagonist failure. When combined with LHRH analogs, antiandrogens do not add to the incidence of gynecomastia (12% to 13%) or hot flashes (60% to 64%) and do not affect the incidence of impotence, which is universal in these patients.[56] High-dose bicalutamide has been evaluated as monotherapy in patients with advanced prostate cancer. While some studies suggest comparable clinical activity, there is significantly less impotence and loss of libido with antiandrogen monotherapy.[57] Recent reports, however, suggest that the ability to maintain potency while receiving antiandrogen monotherapy is limited. A study evaluating flutamide as monotherapy in 147 previously untreated prostate cancer patients resulted in 22% preservation of sexual activity and 20% preservation of morning erection at 2 to 6 years from start of therapy.[58] The median time to loss of morning erections and sexual activity was 12.9 and 13.7 months, respectively.[58]

Endocrine Therapy and Breast Cancer

Tamoxifen, a selective estrogen receptor modulator, is a commonly prescribed adjuvant hormonal therapy. Tamoxifen has estrogenic effects in bone and endometrium and antiestrogenic effects in breast tissue. This results in an antitumor effect while maintaining bone density. In premenopausal women, the hypothalamus perceives the antiestrogen effect as a state of estrogen deficiency, thus resulting in an increase in LH and FSH and hyperestrogenemia. In postmenopausal women, in whom FSH and LH are elevated and estrogen levels are depressed, tamoxifen reduces gonadotropin secretion.

Treatment with tamoxifen following primary therapy for breast cancer is associated with a high incidence of hot flashes (20% to 50%); less information is available on the incidence of sexual function.[59] Tamoxifen does not make a significant contribution to sexual dysfunction in women greater than age 50,[60] and in a randomized study that examined only premenopausal women, patients receiving tamoxifen alone did not report worse sexual function.[61]

Aromatase inhibitors are increasingly being used as the standard hormonal therapy for postmenopausal women with breast cancer and are successful in increasing distant and overall disease-free survival as well as preventing contralateral breast cancer compared with tamoxifen. Aromatase inhibition results in a marked decrease in estrogen synthesis, leading to minimal levels of circulating estrogen. Aromatase inhibitors such as anastrozole and letrozole are associated with a lower incidence of hot flashes and have been generally better tolerated than tamoxifen. In a recently published report of the quality-of-life measurements of postmenopausal women participating in the ATAC trial (anastrozole [Arimidex] or tamoxifen alone or in combination), patients reported diminished libido (34% versus 26%) and dyspareunia (17% versus 8%) significantly more frequently with anastrozole than with tamoxifen treatment.[62]

Chemotherapy

Effects in Men

Many anticancer drugs, particularly alkylating agents, are gonadotoxic. Though the ultimate assessment of germinal cell function is the attainment of fatherhood, multiple confounding factors exist that make this endpoint difficult to interpret. Therefore, most studies focus on semen analysis and biochemical markers of fertility for practical reasons.

Cyclophosphamide treatment frequently results in testicular dysfunction. In a series of 116 males treated with cyclophosphamide alone, 52 (45%) had evidence of testicular dysfunction.[63] The incidence of gonadal dysfunction increases with the total dose of cyclophosphamide, occurring in over 80% of postpubertal patients receiving more than 300 mg/kg.[64] Cisplatin disrupts spermatogenesis in a dose-dependent fashion. A threshold level of 600 mg/m^2 has been identified, above which significant impairment of spermatogenesis is seen.[65]

Combination chemotherapies containing alkylating agents are far more fertility-impairing than are nonalkylating combinations. The majority of men who are treated with mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) become severely oligospermic or azoospermic, and testicular biopsies confirm germinal aplasia.[5,66] Procarbazine has significant effects on testicular spermatogenesis, and its effects are often irreversible. Non-procarbazine-containing regimens such as cyclophosphamide, vincristine, and prednisone are usually associated with only transient FSH elevations and oligospermia.[67] Chapman and colleagues followed 64 patients with Hodgkin's lymphoma treated with mechlorethamine, vinblastine, procarbazine, and prednisone.[68] Only 4 out of 64 who were treated with the procarbazine-based regimen recovered spermatogenesis after a median follow-up of 51 months.[68] Comparison of the procarbazine-containing regimen MOPP to ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine) in patients with Hodgkin's disease revealed a considerably higher azoospermia with MOPP (100%) than in ABVD (35%). Recovery of azoospermia rarely occurred with MOPP and occurred in the majority of patients receiving ABVD.[69] Dose-dependent infertility is clearly evident in Hodgkin's disease patients receiving combination chemotherapy. Azoospermia occurred considerably less often in patients receiving two cycles of MOPP compared to six cycles.[70]

Combination chemotherapy in testicular cancers is associated with FSH elevation and oligospermia. These findings are complicated further by the fact that the majority of testicular cancer patients have abnormal spermatogenesis prior to initiation of therapy. Cisplatin-based regimens are associated with suppression of spermatogenesis following completion of therapy. In 89 patients who were normospermic prior to chemotherapy, the postchemotherapy count was normospermic in 64%, oligospermic in 16%, and azoospermic in 20%. There was clear evidence for recovery beyond 1 year, and the probability of spermatogenesis increased to 48% at 2 years and 80% by 5 years.[71] Testicular cancer patients with pretreatment oligospermia or with persistent FSH elevation at 2 years from treatment are unlikely to recover normal spermatogenesis following treatment.

Effects in Women

Follicular growth and maturation are affected by chemotherapy. Histologic evaluation of ovaries among women who have been treated with cytotoxic chemotherapy show fibrosis and follicular destruction.[72,73] Premature ovarian failure is a common result of chemotherapy and is dependent on patient age, drug dose, and the duration and type of chemotherapy administered. Alkylating agents are strongly associated with ovarian dysfunction. Daily cyclophosphamide treatment for durations exceeding 1 year are associated with amenorrhea in females younger than 40 years of age.[74,75] Most series report a 50% or higher incidence of amenorrhea within 1 month of starting cyclophosphamide.[76] Younger females are more tolerant of the effects of chemotherapy and have a better chance of resuming menstruation after completing chemotherapy. In assessing the effects of adjuvant CMF (cyclophosphamide, fluorouracil, and methotrexate) on reproductive function in breast cancer patients, Mehta

and colleagues reported a median of 5.5, 2.3, and 1.1 months to onset of amenorrhea in patients younger then 35, 35 to 45, and older than 45 years, respectively.[77] In another study among patients 30 to 40 years of age, a mean dose of 9.3 g of cyclophosphamide was associated with amenorrhea, while patients older than 40 years required a median dose of 5.2 g.[78] A median of 20.4 g was required before the onset of amenorrhea in patients less then 30 years of age.[78] Menses resumed in 50% of those younger than 40 years, while it rarely occurred in females older than 40 years of age.[78] Treatment with the alkylating agent melphalan resulted in amenorrhea in 73% of patients between 40 and 49 years of age compared to 22% in patients younger then 40 years of age.[79] Similar results have been described with other alkylating agents, such as busulfan and chlorambucil. Younger women have a larger number of oocytes in reserve and thus a lesser likelihood of experiencing permanent ovarian damage after alkylating agent chemotherapy in comparison to older females. Other nonalkylating chemotherapies, such as antimetabolites, bleomycin, vinca alkaloids, and daunorubicin, are not a frequent cause of amenorrhea.

Combination chemotherapies have been evaluated more extensively as a cause of premature ovarian failure. Doxorubicin-based regimens in the adjuvant treatment of breast cancer resulted in a 96% frequency of amenorrhea in women 40 to 49 years of age compared to 0% among women 30 years or younger.[80] These regimens frequently incorporated other alkylating agents. Data collected from patients who were treated with MOPP for Hodgkin's disease similarly confirm the importance of age at the time of treatment.[81] Treating lymphoma patients with regimens that do not include procarbazine (e.g., ABVD) results in a lower incidence of premature menopause.[67,82] The importance of age and chemotherapy intensity has been stressed by a survey of 96 female patients who had been treated with combinations of ifosfamide, methotrexate, cisplatin, etoposide, and doxorubicin for localized osteosarcoma. The study evaluated the incidence of treatment-related amenorrhea and post-treatment fertility.[83] All 24 patients who were treated at a prepubertal age developed menarche at a median age of 13 years. After menarche, 16 had normal menses, and 8 had permanent irregular cycles.[83] Sixty-eight patients (11 to 43 years) were postpubertal on initiation of chemotherapy. Sixty-nine percent of these developed amenorrhea, typically after one cycle of therapy. A four-drug regimen was associated with amenorrhea in 89% of patients, while a three-drug regimen was associated with amenorrhea in only 53%. Amenorrhea was also related to age; 19 of 51 patients younger then 20 years maintained menses through chemotherapy versus only 2 of 17 in patients who were older then 20 at time of treatment. The majority regained menstruation on completion of chemotherapy. Among 22 patients who married after treatment, 20 patients became pregnant at a median age of 27 years. None of the pregnancies resulted in congenital anomalies.[83]

The duration of combination chemotherapy is also of paramount importance in induction of amenorrhea. Treatment of premenopausal women with a combination of cyclophosphamide, methotrexate, fluorouracil, vincristine, and prednisone resulted in amenorrhea in 55% of patients who were treated for 12 weeks and in 83% of patients who were treated for 36 weeks.[84]

Effects in Children

EFFECTS OF CHEMOTHERAPY ON TESTICULAR FUNCTION IN BOYS. The prepubertal testes are more resistant to the effects of chemotherapy than are the adult testes. This relative resistance might be due to the nonproliferative status of the prepubertal germinal layer. Although it can take years, a certain degree of spermatogenesis recovery occurs in most boys who receive a total dose of cyclophosphamide of less then 10 g.[85] Gonadal function was assessed in 17 male survivors of childhood sarcomas who were treated with vincristine, actinomycin, and cyclophosphamide with or without doxorubicin.[86] Only two patients who received less than 7.5 g/m^2 of cyclophosphamide had normal semen analysis. All patients who received more than 7.5 g/m^2 had abnormal semen analysis, and all 5 out of 5 who received more than 25 g/m^2 had azoospermia more than 5 years after therapy.[86] Most patients (15 out of 16) maintained a normal testosterone level.[86] MOPP therapy leads to a considerably higher rate of testicular damage, presumably secondary to the added effect of procarbazine. Nine out of 19 prepubertal patients receiving MOPP or cyclophosphamide-based therapy (exceeding 9 g of cyclophosphamide) were sterile at a median of 9 years of follow-up.[87] Pubertal alkylating therapy might be more detrimental to gonadal function than in the prepubertal setting. In a cohort of 12 prepubertal and pubertal patients receiving MOPP therapy, all pubertal patients developed irreversible azoospermia, while two prepubertal patients were able to recover spermatogenesis. Pubertal treatment with MOPP was also associated with a high incidence of gynecomastia in association with low-normal testosterone levels and elevated LH and FSH.[88]

EFFECTS OF CHEMOTHERAPY ON OVARIAN FUNCTION IN GIRLS. The majority of prepubertal girls and adolescent females who receive standard combination chemotherapy will retain or recover ovarian function during the immediate post-treatment period. Prepubertal ovaries are relatively resistant to the effects of chemotherapy in comparison with postpubertal ovaries. However, histologic examination and ultrasound examination of the ovary following cancer therapy have revealed a decreased number of ovarian follicles compared to age-matched controls.[89] Menopause appears to be triggered when the number of ovarian follicles drops below a threshold, and a reduction in the population of follicles resulting from cancer therapy could result in premature menopause.[90]

Most prepubertal females who received MOPP therapy for Hodgkin's disease achieved normal puberty and were subsequently able to carry normal pregnancies.[91,92] Treatment of females with acute leukemia with a multidrug regimen of prednisone, vincristine, methotrexate, and 6-mercaptopurine with or without cyclophosphamide resulted in ovarian failure in only one of 17 prepubertal females.[93] Byrne and colleagues evaluated retrospectively fertility rates in childhood and adolescent cancer survivors.[94] In their comparison of 2283 survivors and 3270 siblings controls, there was no apparent effect of alkylating-agent therapy administered alone (relative fertility: 1.02), and only a moderate fertility deficit was evident when alkylating-agent therapy was combined with radiation below the diaphragm (relative fertility: 0.81) among women. The overall relative fertility in women was 0.93, which compared favorably to men's relative fertility of 0.76.[94] Childhood cancer therapy has also been associated with an increased risk of early menopause. In a large cohort of childhood cancer survivors, the principal risks for early menopause were treatment after the onset of puberty, treatment with radiotherapy below the diaphragm, and alkylating agents.[95] Survivors who were diagnosed after puberty and treated with radiation therapy below the diaphragm were 8.5 times more likely to reach menopause in their twenties. The average age for menopause in survivors who were treated with both an alkylating agent and radiation therapy below the diaphragm was 31 years.[95]

High-Dose Chemotherapy (Bone Marrow Transplantation)

Effects in Females

Gonadal dysfunction after high-dose chemotherapy is dependent on age, sex, type of conditioning regimen, and previous therapy. In women, increased age and treatment with an alkylating conditioning regimen including total body irradiation (TBI) result in a high rate of ovarian failure. In 144 women who were transplanted for leukemia after TBI and cyclophosphamide, amenorrhea was present for 3 years following transplantation in all women. Only nine patients eventually recovered their ovarian function.[96] The likelihood of recovering

ovarian function decreased by a factor of 0.8 per year of age.[96] TBI enhances the risk of ovarian failure. Ovarian failure usually occurs within 3 months of TBI. A single nonfractionated dose of 10 Gy is likely to result in more damage to the ovary and a lower chance of ovarian recovery than is a fractionated 12-Gy total dose.[96] Recovery of ovarian function is more likely with chemotherapy-only conditioning regimens but is usually limited to females younger than 30 years of age. In a conditioning regimen of cyclophosphamide of 200 mg/kg, all females 26 years of age or younger recovered their ovarian function, while only 5 out of 16 women over age 26 did so.[96] In another report on patients with non-Hodgkin's lymphoma, who were treated with consolidation high-dose chemotherapy (cyclophosphamide, carmustine, and etoposide), 9 out of 56 patients were able to conceive despite receiving a total dose of 10,800 mg/m^2 of cyclophosphamide.[97] Pregnancies were limited to females younger then 29 years of age; no birth defects were reported.[97] The addition of busulfan to cyclophosphamide is rarely associated with ovarian recovery, even in younger patients.[98]

Bone marrow transplantation may also be complicated by graft-versus-host disease. When severe, graft-versus-host disease can cause vaginal strictures and adhesions that interfere with intercourse.[99]

Effects in Males

The majority of males transplanted with or without TBI have marked elevations in their LH and FSH. Testosterone levels may be depressed but are usually maintained in the normal range, reflecting adequate compensatory reaction by Leydig cells to the rise in LH. Infertility is the rule in adults and young males receiving high-dose chemotherapy with or without TBI, reflecting the relative sensitivity of the germinal component to chemotherapy and/or radiation therapy relative to Leydig cells. Decreased libido has been reported in bone marrow transplantation patients. This is probably multifactorial and results from psychological stress, mild suppression of testosterone levels, and vascular and neurologic damage. Testosterone levels were found to be in the low normal range in a study of 24 males with features of hypogonadism and erectile dysfunction following transplantation.[100] While supplementation with testosterone resulted in an improvement in libido, there was no clear beneficial effect on erectile dysfunction.[100] Doppler studies in these patient confirmed evidence of cavernosal arterial insufficiency and strongly correlated with prior TBI therapy.[100,101]

Effects in Children

Permanent ovarian failure is less commonly seen in prepubertal females than in adults. A combination of high-dose chemotherapy and TBI is associated with a higher incidence of ovarian failure than chemotherapy alone. Sarafoglou and colleagues reported a median age of 8.6 years for prepubertal females with acute leukemia treated with bone marrow transplantation (TBI-based regimen) who developed ovarian failure.[102] The median age for prepubertal females who went on to enter puberty was 6.1 years.[102] Even in those who enter puberty, normal uterine maturation is impaired, and the endometrium is atrophic secondary to radiation therapy. Supplementation with hormone replacement improves mucosal thickness, but the total volume of the uterus remains contracted.[103] Long-term follow-up of childhood acute leukemia survivors reveals that TBI is indeed the most important factor in development of gonadal failure. In 77 survivors of leukemia, three groups of treatment were identified: chemotherapy, chemotherapy and cranial irradiation, and chemotherapy and TBI.[104] Forty-four out of 44 patients who were treated with chemotherapy entered and progressed through puberty without sex hormone supplementation. Only one of 18 of patients who were treated with chemotherapy and cranial irradiation developed early amenorrhea accompanied with elevated gonadotropin levels. Eight of 15 patients who were treated with chemotherapy and TBI developed gonadal failure (3 men and 5 women), requiring long-term sex hormone supplementation.[104]

CHEMOTHERAPY AND RADIATION DURING PREGNANCY

Cancer complicates 1 in 1000 pregnancies.[105] The most frequent cancers during pregnancy are cervical cancer, breast cancer, melanoma, ovarian cancer, thyroid cancer, and leukemia.[106] As more women defer childbearing into their thirties and beyond, more cancers are expected to be diagnosed during pregnancy. Chemotherapy has an essential role in the management of many of these tumors. The timing and selection of chemotherapeutic agents should be optimized to maximize the clinical benefit to the patient while minimizing the risk to the fetus (Box 64-1).

Fetal Stage of Development and Pregnancy Outcome

The most important factor influencing fetal outcome in cancer patients who are treated during pregnancy is the stage of fetal development on initiation of treatment. The first trimester is the most susceptible period. The blastocyst is relatively resistant to teratogens for the first 2 weeks because it lacks an established circulation. Following implantation but prior to organogenesis, the blastocyst may exhibit damage from chemotherapy resulting in abortion or may survive without manifesting any abnormalities. Organogenesis begins in the fifth gestational week and continues until the eighth week. During organogenesis, the stem cell population is limited, and damage from chemotherapy may result in major defects. Exposure to chemotherapy during the first trimester may result in a malformation rate of 10% to 20% compared to an estimated rate of 3% in the general population.[107] By the thirteenth week of gestation, all organs have developed, with the exception of the brain and gonads.[108] Exposure to chemotherapy on completion of organogenesis (second and third trimesters) is thus unlikely to result in major birth defects but may result in fetal growth retardation. Treatment of patients with hematologic malignancies and breast cancer during the second and third trimesters has not been associated with any increase in the rate of congenital anomalies.[109–111]

Effects of Different Classes of Chemotherapy on Pregnancy Outcome

Different classes have varying teratogenic potential. Alkylating agents and antimetabolites appear to have a greater potential of causing a

Box 64-1. CHEMOTHERAPY AND RADIATION DURING PREGNANCY

The risk of congenital anomalies is highest for first-trimester exposure and is most commonly associated with antimetabolites such as methotrexate. Decision making should be individualized, and decisions regarding termination or continuation of pregnancy should take into consideration the risks to the mother and the fetus. In first-trimester pregnancies that require initiation of chemotherapy, termination of pregnancy should be considered. In patients who elect to proceed with pregnancy, the choice of chemotherapy should take into account the risks of congenital malformations. Treatment of patients with hematologic malignancies and breast cancer during the second and third trimesters has not been associated with an increased rate of congenital anomalies. A delay in chemotherapy for a few weeks or until delivery for third-trimester pregnancies can be considered if the mother's outcome is unlikely to be compromised. Delivery induction for gestations of more then 32 weeks is another acceptable option for third-trimester pregnancies.

Radiation therapy should be avoided at all stages of pregnancy. First- and second-trimester exposures are associated with congenital abnormalities, and third-trimester exposure can result in cognitive dysfunction.

detrimental effect than do antitumor antibiotics, platinum analogs, and vinca alkaloids.[112]

Alkylating Agents

Fetal abnormalities have been reported from first-trimester exposure to cyclophosphamide, chlorambucil, and busulfan.[113–117] No definite causal relationship is available with other agents, such as thiotepa, melphalan, and dacarbazine, but exposure data in the first trimester for these compounds are limited.

Antibiotic Agents

No definite causal relationship with congenital malformations has been documented with dactinomycin or bleomycin. There have been reports of normal children born to patients exposed during the first, second, and third trimesters.

Antimetabolites

Methotrexate is known for its teratogenic effects and has been used as an abortifacient. Congenital anomalies have been described with first-trimester use. Malformations include severe skull abnormalities, heart defects such as dextroposition, and digital anomalies.[118,119] Exposure starting as late as 11 weeks has been associated with anomalies.[119] 5-Fluorouracil may be similarly associated with congenital anomalies when administered in the first trimester. One case of multiple congenital anomalies including radial dysplasia, absent digits, and hypoplasia of multiple organs has been reported in a first-trimester exposure.[120] Cytarabine has been commonly used in second- and third-trimester pregnancies in hematologic malignancies without a reported increase in congenital defects. First-trimester exposure has been associated with congenital abnormalities, including microtis and auditory canal atresia, lobster claw hand and other digital anomalies, and lower-extremity defects.[121,122] Other studies have reported normal pregnancy outcome in first-trimester exposures.[123] There is currently no information on pregnancy outcomes in patients who have been treated with the newer antimetabolite gemcitabine.

Anthracyclines

First-trimester exposures have been associated with normal and abnormal fetal outcomes. Imperforate anus, rectovaginal fistula, and microcephaly have been described following first-trimester exposure to doxorubicin.[124]

Vinca Alkaloids

Definite fetal anomalies secondary to vinca alkaloids have not been reported. Sporadic anomalies have been reported in patients receiving combination therapy. Several pregnancies with exposure to vinca alkaloids during the first trimester of pregnancy have resulted in normal neonates.[107,125]

Platinum Analogs

Ten pregnant women with cancer have been reported who received cisplatin during the second or third trimester.[126] None of the neonates demonstrated any congenital anomalies, but fetal growth was restricted in 50% of pregnancies.

Taxanes

Limited information is available on the clinical effects of taxanes on pregnancy. There has been one report of an ovarian cancer patient treated during the third trimester of pregnancy with carboplatin and paclitaxel without any adverse events in the newborn.[127] Treatment of a case of metastatic breast cancer with docetaxel during the second and third trimesters of pregnancy resulted in a normal healthy newborn.[128]

Topoisomerase II Inhibitors

Etoposide has not been reported to cause congenital malformations. However, fetal marrow suppression manifesting as severe neonatal anemia and leukopenia has been reported in a patient treated for leukemia.[129]

In general, chemotherapy has not been associated with an increased risk of congenital malformations if administered in the second or third trimesters, but an increased incidence of growth restriction and premature birth has been noted. An increased risk of congenital anomalies has been associated with treatment in the first trimester. Doll and colleagues reported a 15% incidence of fetal malformations in association with first-trimester chemotherapy exposure versus 1.3% for second- and third-trimester exposures.[130] This risk is apparently highest for antimetabolites, especially methotrexate. If cancer occurs in the first trimester and systemic cytotoxic therapy is clearly indicated, termination of the pregnancy should be considered. Delay in chemotherapy until it can be given more safely in the second and third trimesters should be considered if the outcome for the mother is not at risk. The long-term effects on progeny have not been adequately evaluated for different chemotherapeutic agents. Anecdotal data suggest that most offspring who are exposed in utero exhibit normal physical and mental development. Eighty-four children who were born to patients with hematologic malignancies and were exposed to chemotherapeutic agents in utero were followed for a median of 18.7 years.[131] In all the children who were studied, the learning and educational performances were normal, and no congenital, neurologic, or psychological abnormalities were observed. There was no apparent increase in malignancies. Some of these individuals became parents during the period of follow-up. Twelve second-generation offspring were evaluated, and all of them were normal.[131]

Targeted Therapy

Several newer agents have been developed to target specific growth receptor, antigens, or kinases that are essential for cell growth and development. Two commercially available agents are the anti-Her2/neu antibody trastuzumab and the anti-CD-20 antibody rituximab. Reproductive data in monkeys using 25 times the human equivalent of trastuzumab did not show any evidence of teratogenicity. However, trastuzumab diffuses through the placental circulation, and acute or long-term effects on human progeny have not been evaluated. Rituximab has not been evaluated extensively in reproductive animal models. A 29-year-old patient with diffuse large cell lymphoma was treated during her second and third weeks of pregnancy with a combination of rituximab and CHOP therapy.[132] She delivered a healthy female newborn at 36 weeks.

Imatinib is now a standard therapy for patients with chronic myeloid leukemia. A series of 19 pregnancies involving 18 patients (10 females and 8 males) who conceived while receiving imatinib for the treatment of chronic myeloid leukemia was recently reported. All female patients discontinued therapy immediately on recognition of pregnancy. There were three spontaneous abortions, including two of the ten pregnancies in female patients. In addition, two (13%) of the 16 babies who were born from these parents had congenital abnormalities (one baby with hypospadias, one with mild rotation of the small intestine). Given the constraints of the small series, this could represent a higher-than-expected frequency of congenital abnormalities. At present, the recommendation is for patients on imatinib to practice effective barrier forms of birth control and to discontinue imatinib if pregnant or lactating.[133]

Immunomodulators

Limited data are available on the effects of interferons and interleukins on pregnancy. In animals, interferon-α and interleukin-2 have abortifacient and embryolethal effects. More than 20 case reports of pregnancy during interferon-α treatment in all three trimesters have been reported.[134–136] None of the cases were associated with congenital anomalies, but growth retardation and premature births were more frequent than expected.[136]

Effects of Radiation Therapy on Pregnancy Outcome

Human data regarding the effects of radiation on fetal outcome is limited to accidental exposure and to nuclear disaster victims. Similar to chemotherapy, the effects seem to be most pronounced during the period of organogenesis. During the period of 8 to 25 weeks of pregnancy, the central nervous system is particularly sensitive to the effects of radiation. The most comprehensive review of clinical effects of pelvic radiation therapy was reported by Dekaban.[137] Pelvic irradiation up to 3 weeks following conception did not result in severe congenital anomalies, although a considerable number of embryos may have been resorbed or aborted.[137] Irradiation between weeks 4 and 11 led to the development of severe congenital anomalies in many organs. Exposure between weeks 11 and 16 led to anomalies of the eye, skeleton, and genital organs; stunted growth; microcephaly; and mental retardation.[137] Exposure between 16 to 20 weeks was associated with mild microcephaly, mental retardation, and stunted growth. Later exposures were unlikely to cause structural abnormalities.[137]

Data from survivors of the atomic bombs in Hiroshima and Nagasaki suggest a dose-dependent effect of radiation on congenital anomalies, a dose of 50 cGy resulting in a 40% risk of microcephaly. Doses in excess of 10 cGy may result in cognitive impairment, and higher exposures result in further exacerbation of mental retardation. In utero radiation exposure also results in an increased risk of carcinogenesis with an estimated 6% risk of cancer by age 15 per Gy of exposure.[138]

Radiation therapy should be avoided during pregnancy because of the significant physical, functional, and mental dysfunction that can result from exposure in the first and second trimesters. Even in cases such as breast cancer, in which breast irradiation is given with abdominal shielding, the estimated fetal exposure with 5000 cGy to the primary tumor is 14 to 18 cGy. This is well above the proposed threshold for microcephaly and mental retardation.[139]

PREVENTION

Modifying the treatment and its timing as discussed previously may reduce reproductive complications, but care must be taken not to compromise treatment efficacy, and detailed discussions with patients are mandatory (Box 64-2).

Retroperitoneal nerve-sparing dissections result in significant improvements in potency rates after radical prostatectomy. Similar results are reported in rectal surgeries with nerve-sparing dissection. Alternative chemotherapeutic regimens with low gonadal toxicity potential should be considered when possible. The substitution of ABVD therapy has resulted in similar or better efficacy in the treatment of Hodgkin's lymphoma and a lower rate of ovarian and testicular failure.

Unfortunately, most cancer diagnoses have limited options of treatment, and the choice of a regimen with a low potential for gonadal toxicity is often not feasible. Spermatogenesis and follicular growth and maturation are particularly sensitive to the effects of chemotherapy because of their high mitotic rate. Thus, treatment interventions that suppress germinal function during administration of cytotoxic therapy may limit the gonadal toxicity. GnRH analogs have been shown to inhibit spermatogenesis in various animals and in humans. The use of GnRH analogs has been reported to protect rat testes from chemotherapy and radiation.[140,141] However, treatment of testicular cancer and Hodgkin's disease patients with LHRH analogs has failed to show any protective effects against the development of azoospermia.[142–144] Effective inhibition of spermatogenesis may require several weeks of hormonal manipulation with GnRH analogs. Treatment with GnRH analogs for several weeks prior to initiation of chemotherapy is often not feasible clinically and may account for the failure of previous studies to show a protective effect on gonadal function.

Box 64-2. PREVENTION AND TREATMENT OF SEXUAL AND REPRODUCTIVE DYSFUNCTION OF CANCER THERAPY

Prevention

The best prevention is the selection of equally effective treatments but with lower toxicities. Treatment of Hodgkin's disease with ABVD rather than MOPP will often result in fertility preservation. Bone marrow-conditioning regimens that do not incorporate total body radiation should be considered in bone marrow transplant patients. Ovarian and testicular suppression with GnRH analogs has not been shown conclusively to protect gonadal function and should be limited to clinical studies.

All males who are contemplating future fatherhood and for whom either chemotherapy that has been associated with infertility (such as alkylating agents) or pelvic radiation is planned should be offered sperm banking. Oocyte banking and ovarian cryopreservation continue to be investigated in females and have not yet been standardized. In vitro fertilization with embryo cryopreservation may represent another alternative for females who are undergoing gonadal-toxic treatments.

Treatment

Treatment involves hormonal replacement for patients with premature ovarian failure and low testosterone levels. Estrogen replacement ameliorates menopausal symptoms, including hot flashes, vaginal dryness, and dyspareunia. Vaginal-directed estrogen therapy can improve local vaginal symptoms in patients with relative contraindications to systemic estrogen replacement. For patients with a history of breast cancer, nonhormonal vaginal moisturizers and lubricants remain the first line of therapy.

Testosterone replacement in men improves the libido and reduces hot flashes and can improve potency in severe androgen deficiency cases. Impotence secondary to surgery or radiation therapy may be successfully treated with sildenafil. This agent should be avoided in patients with significant cardiovascular illness and is contraindicated in patients who are receiving nitrates. Sildenafil therapy should be considered as a first-line pharmacologic therapy in impotent patients with normal testosterone levels and in whom psychosocial etiologies are not suspected.

Assisted reproductive technologies such as intrauterine insemination, in vitro fertilization, and ICSI should be considered as options for restoring fertility in couples who have difficulty conceiving after cancer therapy.

Similar attempts to protect the ovaries from cytotoxic chemotherapy by suppressing cycling through GnRH analogs and oral contraceptives have been made. A small study of patients with Hodgkin's disease receiving alkylating agent-based chemotherapy and oral contraceptives showed that five of six patients resumed normal menstrual function at 26 months.[145] Other studies of oral contraceptives and GnRH analogs failed to show any protective effects in patients with Hodgkin's disease in comparison with controls.[143,146] However, one prospective study in patients with lymphoma showed a significant protection against ovarian failure with cotreatment with GnRH analogs.[147] Eighteen patients with lymphoma were treated with a monthly injection of depot GnRH agonist starting prior to chemotherapy and continuing for a maximum of 6 months. Most of these patients (15 of 18) were treated with the MOPP/ABVD combination chemotherapy followed by mantle field irradiation in 10 patients. This group of prospectively treated lymphoma patients was compared to a matched control group of 18 women. Only 39% of the patients receiving chemotherapy alone resumed spontaneous ovulation in

comparison with 94% of those receiving GnRH analogs along with chemotherapy.[147,148]

Other means of protection from radiation effects include gonadal shielding. In females receiving pelvic radiation, transposition of the ovaries might be one alternative to avoid radiation damage. Transposition of one or two ovaries can be done at the time of laparotomy or laparoscopically. Spontaneous pregnancy rates after ovarian transposition are low, presumably because of the distorted tubo-ovarian anatomy secondary to the procedure itself or the local therapy (radiation) to the pelvic area.[149]

TREATMENT

Treatment of reproductive complications aims at relieving the symptoms related to gonadal failure and providing assistance in achieving reproduction. This section focuses on hormone replacement, treatment measures for impotence, and reproductive assistance technologies.

Hormonal Replacement

Premature ovarian failure results in the sudden onset of menopausal symptoms secondary to an abrupt decrease in estrogen levels. Sexual symptoms related to ovarian failure include vaginal atrophy, thinning of vulvar tissue and the vagina, decreased vaginal lubrication and elasticity, mood swings and irritability, and hot flashes. Estrogen replacement therapy (in combination with progesterone in patients without hysterectomy) can reverse most of these symptoms and should be discussed with all patients with iatrogenic ovarian failure. Risks, including increased rate of cardiovascular and cerebral accidents, and benefits such as osteoporosis prevention should be addressed prior to initiation of therapy.[150] Hormonal replacement therapy in breast cancer patients continues to be an area of concern because of the theoretical potential of promoting tumor growth. However, no reports have yet shown a detrimental effect of estrogen replacement in this cancer population. Patients who are not candidates can be treated symptomatically with vaginal moisturizers (e.g., Replens) and water-based lubricants (e.g., K-Y liquid). Vaginal-directed estrogen therapy with an Estring vaginal ring, estrogen creams, or Vagifem tablets have also resulted in improvements in symptoms of vaginal dryness and dyspareunia and a decrease in the incidence of urinary tract infections.

Male hypogonadism secondary to chemotherapy and radiation therapy is associated with loss of libido, hot flashes, and impotence. Testosterone replacement as a depot injection or in a transdermal formulation may restore sexual function in those instances.[151,152]

Management of Erectile Dysfunction

The advent of sildenafil citrate (Viagra) marks an important milestone in the treatment of male impotence. The physiologic mechanism of penile erection involves the release of nitrous oxide in the corpus cavernosum during sexual stimulation. Nitrous oxide results in an increase in cyclic guanosine monophosphate, which in turn results in corpus cavernosum smooth muscle relaxation and allows an increase in blood flow. Sildenafil improves the ability to achieve and maintain an erection by blocking the degradation of cyclic guanosine monophosphate.

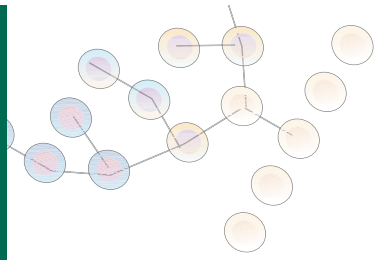
Sildenafil leads to successful intercourse in prostate cancer patients with erectile dysfunction after prostatectomy, external beam radiation, or brachytherapy. Response rates typically range between 70% and 80%.[153–156] The ease of oral administration and the efficacy of this agent have made it the most commonly prescribed agent for erectile dysfunction.[157] Because sildenafil potentiates the hypotensive effects of nitrates, prescribers should ensure that patients taking sildenafil do not have any significant cardiac history and are not receiving any concomitant nitrate medications. Alternative therapies include penile injections, vacuum devices, or intraurethral suppositories. These are more cumbersome to the patient and are associated with high dropout rates.[158] In refractory situations, surgical intervention with penile implants may be considered.

Assisted Reproductive Technologies

Once germinal testicular aplasia or premature ovarian failure occurs secondary to cancer therapy, the damage might be irreversible. Unless sperm or embryonic banking is performed prior to treatment, these patients will not be able to parent their own biological children. This issue has not been given adequate attention, and its importance to patients has long been overlooked. A survey of 904 men diagnosed with cancer revealed that 51% of men wanted children in the future.[159] Only 60% of men recalled being informed about infertility, and only 51% had been offered sperm banking.[159] Lack of prior discussion about sperm banking with patients was the most common reason for failing to bank sperm.[159]

Several advances in reproductive technologies allow for fertility preservation in patients who are undergoing gonadal toxic therapies. Intrauterine insemination is accomplished by selecting washed sperm with high motility and injecting them directly into the uterus at the time of ovulation. This procedure requires cryopreservation of 5 to 10 million normal sperm. In vitro fertilization with embryo transfer involves culturing the aspirated oocytes and spermatozoa in vitro, followed by the transcervical replacement of the embryo into the uterine cavity. With in vitro fertilization with embryo transfer, the number of sperm required is 0.5 to 1 million.[160] Intracytoplasmic sperm injection (ICSI) involves the injection of a single sperm into the cytoplasm of the oocyte with transcervical placement of the embryo into the uterine cavity. ICSI reduces the criteria for sperm cryopreservation theoretically to the presence of one motile sperm. This makes almost any male cancer patient who is not completely azoospermic a candidate for sperm cryopreservation. Even in patients with complete ejaculatory azoospermia, testicular sperm extraction followed by ICSI and embryo cryopreservation might represent an option for fertility preservation.[161,162] Testicular sperm extraction is typically achieved by obtaining open biopsies of testicular tissues with or without microdissection.[163] ICSI is now performed in 60% to 80% of assisted reproductive procedures in some metropolitan U.S. areas and is the procedure of choice for couples with a male infertility factor. In patients for whom sperm is stored or extracted successfully, successful pregnancy rates in the range of 30% are expected.[162,164] Transrectal electroejaculation is yet another viable method for sperm collection for the purpose of cryopreservation or in vitro fertilization in patients with retrograde ejaculation.[165] Other options of sperm collection in patients with retrograde ejaculation are insemination by using sperm-rich urine (after masturbation) or bladder washings. Successful reports of insemination by using these collection methods have been reported, using techniques ranging from intrauterine insemination to ICSI.[166]

Oocyte cryopreservation has been associated with few pregnancies. Low pregnancy yield as well as the need to delay chemotherapy to achieve appropriate follicular stimulation limits the use of this technique for female fertility preservation. Ovarian tissue cryopreservation is a novel technique that is under investigation. The procedure involves oophorectomy and cryopreservation prior to the initiation of cancer treatments. On completion of cancer-directed therapy and when conception is planned, the frozen banked ovarian tissue is thawed and autotransplanted in the patient. Successful ovulation after autotransplantation has been reported, and the procedure continues to be under investigation.[167] Another option for fertility preservation involves in vitro fertilization and embryo cryopreservation prior to initiation of treatment. The technique is cumbersome and expensive, can delay the initiation of effective chemotherapy, and constitutes an ethical dilemma.



For patients who are unable to conceive secondary to uterine or cervical abnormalities attributed to the cancer or its treatment, in vitro fertilization with implantation in a surrogate has been described.[168]

65 Endocrine Complications

Manpreet K. Chadha and Donald L. Trump

SUMMARY OF KEY POINTS

Introduction

- Endocrine dysfunction may directly result from cancer or as a consequence of cancer therapy (surgery, radiation, chemotherapy, biologic agents, and hormone therapy). Endocrine dysfunction may be an intentional consequence or an adverse effect of antineoplastic therapy.
- Hypopituitarism with clinically significant deficiencies of growth hormone, thyrotropin, gonadotropin, and corticotrophin may result from radiation (cranial or total body irradiation), surgery, or chemotherapy.
- Thyroid dysfunction from neck irradiation, immune therapy (interleukin-2), and small molecule inhibitors such as sunitinib may result in either hyperthyroidism or hypothyroidism.
- Gonadal dysfunction following surgery, radiotherapy, or chemotherapy results in disruption of puberty, infertility, and premature menopause.
- Adrenal dysfunction from chemotherapy (ketoconazole, aminoglutethimide) may result in glucocorticoid or mineralocorticoid deficiency.
- Pancreatitis and occasionally pancreatic exocrine or endocrine deficiencies may result from chemotherapy (L-asparaginase and streptozotocin).

Diagnostic Considerations

- A detailed history along with a complete physical examination is the key to the diagnosis. Locations of primary as well as metastatic tumor along with past and current therapies are necessary elements of evaluation.
- Signs and symptoms such as delayed or precocious puberty, fatigue, weight loss or gain, amenorrhea, orthostatic hypotension, hyperpigmentation, or electrolyte abnormalities should prompt consideration of unrecognized endocrine dysfunction.
- When one hormonal deficiency is identified, others should be sought.

Evaluation and Treatment

Hypothalamic-Pituitary Axis

- Basal serum hormone concentrations are usually sufficient; however, dynamic testing might be required to diagnose partial deficiencies.
- Patients often have multiple, concurrent hormone deficiencies. Replacement therapy should be started as soon as possible.

Thyroid

- Primary hypothyroidism is characterized by low free thyroxine (T4) level and elevated thyroid-stimulating hormone (TSH), while central hypothyroidism is associated with low free T4 and inappropriately normal or low TSH levels. Replacement with levothyroxine is indicated and highly effective.
- Hyperthyroidism is caused by increased T4 and/or T3 (tri-iodothyronine) levels with a low serum TSH level. Treatment options include surgery, radioiodine ablation or antithyroid medications (propylthiouracil). Rarely, hyperthyroidism may be associated with production of TSH-like substances by germ cell or choriocarcinoma. Management in these instances involves thyroid suppression and treatment of the primary tumor.

Adrenal

- Low- or high-dose corticotrophin test can distinguish between central and primary causes of adrenal insufficiency. Acute adrenal insufficiency is a medical emergency and should be treated by immediate parenteral glucocorticoid replacement and supportive care. Chronic insufficiency is treated by oral glucocorticoid supplement with or without mineralocorticoid.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

- Hyponatremia is classically associated with cyclophosphamide and vinca alkaloids. Measurement of serum and urine osmolality, renal function tests, and assessment of volume status of a patient are the key to diagnosis. Treatment involves fluid restriction and increased salt intake. Refractory cases might need loop diuretics, doxycycline, or newer vasopressin receptor blockers.

INTRODUCTION

Endocrine dysfunction is an increasing cause of morbidity in cancer patients. Improved cancer therapies and new agents with endocrine side effects are primarily responsible for the increase. For example, the Childhood Cancer Survivor Study showed that one or more endocrine conditions were reported in 43% of childhood brain tumor survivors.[1] Timely recognition and management of endocrine dysfunction are essential to prevent further morbidity and impairment of quality of life in cancer patients. Table 65-1 outlines the causes of endocrine dysfunction in this population. Appropriate evaluation and treatment of common endocrinopathies are discussed in the latter sections of this chapter. A special section is included on surveillance of childhood cancer survivors for detection of late endocrine

Table 65-1 Causes of Endocrine Dysfunction in Patients with Cancer

Age (children more sensitive)
Prior pituitary compromise by tumor/surgery
Length of follow-up

complications of various cancer therapies. Tumors of endocrine origin and neuroendocrine tumors are discussed in relevant sections of this textbook.

ROLE OF SURGICAL THERAPY

Historically, surgery has been used as a means of disrupting normal endocrine function with therapeutic intent.[2] Response rates of 15% to 30% were reported after hypophysectomy or adrenalectomy in advanced breast cancer.[3,4] However, these procedures resulted in significant morbidity, including hypoadrenalism and hypopituitarism, requiring lifelong replacement therapy. For premenopausal women, ovarian ablation by surgical oophorectomy remains a therapeutic option in metastatic and adjuvant settings. These surgical procedures have been largely supplanted by pharmacologic agents such as luteinizing hormone-releasing hormone agonists along with aromatase inhibitors (inhibit adrenal steroidogenesis) to attain functional castration.[5,6] Orchiectomy is considered a therapeutic option for men with metastatic prostate cancer.[7]

Normal pituitary function may be altered by surgical resection of a pituitary tumor or by injury to the pituitary stalk disrupting the hypothalamic-pituitary axis. In the former case, anterior pituitary hormones are primarily affected; in the latter case, both the anterior and posterior pituitary hormones are affected.

Similarly, resection of a tumor involving other endocrine glands may result in deficiencies of hormones secreted from these glands: thyroid (hypothyroidism), parathyroids (hypoparathyroidism), pancreas (diabetes mellitus), ovaries (hypogonadism), testes (hypogonadism), or adrenals (hypoadrenalism). Unilateral gland resection rarely results in noticeable hormone deficiencies. Extensive neck surgery and irradiation for advanced head and neck cancers may result in parathyroid hormone deficiency. This might be due to interference with the vascular supply of the parathyroids. Permanent hypoparathyroidism can result inadvertently from total thyroidectomy; the reported incidence is up to 40%.[8] Subtotal removal of parathyroid glands as a part of therapy for parathyroid hyperplasia can also cause hypoparathyroidism. It is often possible to preserve parathyroid function by careful surgical technique and/or by autotransplanting the parathyroid tissue to another part of body.

ROLE OF RADIATION THERAPY

Endocrine organs may be intentionally or unavoidably exposed to ionizing radiation during treatment for malignancy, and high-dose radiation may result in endocrine dysfunction. Table 65-2 lists factors that are known to be associated with a high risk of endocrine dysfunction following radiation. Assessment of late effects of radiation may be difficult and subjective. Various groups have attempted to develop a scoring system to standardize toxicity reporting and description. An example is the LENT-SOMA (Late Effects on Normal Tissue–Subjective, Objective, Management and Analytic) to grade radiation-induced toxicity to the hypothalamic-pituitary axis and thyroid.[9] These scales grade the radiation-induced side effects on these organs exposed to irradiation in a manner similar to common toxicity criteria grading of adverse effects. Newer scales have been designed by the European Organization Treatment of Cancer and Radiation Therapy Oncology Group to grade toxicities related to radiation.[10] The late toxicity assessment of a treatment might depend on the toxicity scale used. The LENT-SOMA scale seems to be the most accurate scale so far.[11,12]

Hypothalamic-Pituitary Axis

Anterior pituitary dysfunction can result from irradiation of nasopharyngeal, extracranial, or primary brain tumors, especially those involving the pituitary. Total body irradiation as part of a bone marrow transplant preparative regimen[13] and prophylactic cranial radiation in patients with acute lymphoblastic leukemia can also cause hypopituitarism.[14] Approximately 19% of patients have a deficiency in one or more anterior pituitary hormones as early as 2 years after cranial irradiation for nasopharyngeal carcinoma.[15]

Data indicate that the hypothalamus is more radiosensitive and is damaged by lower doses of cranial radiation than is the pituitary.[16] Secondary pituitary atrophy evolves with time owing to impaired secretion of hypothalamic regulatory factors or direct radiation-induced damage. This necessitates prolonged follow-up and yearly testing of pituitary function in patients who have received cranial irradiation. The frequency, rapidity of onset, and severity of endocrine abnormalities correlate with the total radiation dose delivered to the hypothalamic-pituitary axis, the fraction size, younger age at irradiation, prior pituitary compromise by tumor and/or surgery, and the length of follow-up.[17]

Somatotrophes (cells that secrete growth hormone) are the most vulnerable to radiation damage; hence, growth hormone deficiency (GHD) is the most commonly seen endocrine dysfunction, following cranial irradiation. GHD may occur in isolation following irradiation of the hypothalamic-pituitary axis with doses less than 30 Gy. The clinical manifestations of GHD are most evident in the growing child: reduction in growth velocity and short stature. Some data suggest that children are more sensitive to radiation effects than are adults.[18] Although poor linear growth is very common in children with GHD, it is not universal or immediately apparent. Several studies suggest that the slowing of growth might not occur for the first year or two after onset of GHD. In postpubertal individuals, GHD is associated with a decrease in muscle mass along with an increase in adiposity.[19]

The hypothalamic neurons secrete gonadotropin-releasing hormone (GnRH) in pulses that are necessary for normal secretion of gonadotropins from the pituitary. This GnRH-pulse generation is affected differentially by the dose of radiation that is received. Abnormalities in gonadotrophin secretion are dose-dependent. Precocious puberty can occur after a radiation dose less than 30 Gy in girls and in both sexes equally with a radiation dose of 30 to 50 Gy.[20,21]

Radiation-induced precocious puberty might be caused by damage to inhibitory GABAergic neurons, leading to disinhibition and premature activation of GnRH neurons.[22] Higher-dose irradiation (>30 Gy) is associated with delayed sexual maturation due to gonadotropin deficiency from damage to GnRH secretory neurons.[23]

Deficiency in other pituitary hormones is less common. Five years after treatment, a study of 251 patients who had been treated for pituitary disease with external radiotherapy described an incidence of thyroid-stimulating hormone (TSH) deficiency of 9% at 20 Gy, increasing to 52% at 42 to 45 Gy.[24] A similar trend for incidence of adrenocorticotrophic hormone (ACTH) deficiency relation was seen. Hyperprolactinemia can be seen after high-dose radiotherapy (>40 Gy) and has been described in both sexes and all age groups but is most common in young women.[25] Constine and associates[26] described a 50% frequency of hyperprolactinemia in 32 patients who were treated with radiation for brain tumor with doses ranging from 39.6 to 70.2 Gy. Other investigators reported rates of 20% after treatment for nasopharyngeal carcinoma. Hyperprolactinemia can cause pubertal delay or arrest in children, galactorrhea and/or amenorrhea in women, and decreased libido and impotence in adult males.

Radiation-induced anterior pituitary hormone deficiencies are irreversible and progressive but are treatable with appropriate hormone replacement therapy. Careful surveillance and close follow-up with an endocrinologist are warranted.

Thyroid

Irradiation of the thyroid may produce hypothyroidism, Graves disease, silent thyroiditis, benign nodules, and thyroid cancers.[27] Hancock and colleagues described their experience with thyroid disease among patients treated with irradiation with or without chemotherapy for Hodgkin's disease at Stanford University.[28] Of 1787 patients, 1677 received irradiation to the thyroid. At 26 years of follow-up, the actuarial risk of thyroid disease was 67%. Hypothyroidism developed in the majority of the patients (47%). The risk of Graves disease was 7 to 20 times higher than that for normal subjects. The risk of thyroid cancer was noted to be 15.6 times the expected risk for normal subjects. The association between thyroid cancer and radiation is discussed in further detail in Chapter 75. These data remind clinicians to follow thyroid function closely in patients who have been treated with upper mantle or cervical irradiation. Similar results were noted in the Childhood Cancer Survivor Study with an evaluable cohort of 1791 (959 males) Hodgkin's disease survivors. Among patients with Hodgkin's disease, the risk of hypothyroidism at 20 years from the time of diagnosis in those treated with 45 Gy or more was 50%.[29] Total dose of irradiation received has been shown to correlate with the incidence of hypothyroidism in many studies.[27–30] There is controversy regarding the effect of age at the time of irradiation, gender, and association with the prior use of lymphangiograms.[27,29]

Radiation-induced thyroid dysfunction is thought to be caused by damage to small thyroid vessels and to the glandular capsule. Focal and irregular follicular hyperplasia, hyalinization, and fibrosis beneath the vascular endothelium, lymphocytic infiltration, single and multiple adenomas, and thyroid carcinomas are histomorphologic features that are described in such patients.[27,28]

A rare complication of external neck irradiation is acute radiation thyroiditis.[30] It is more commonly associated with therapeutic doses of radioiodine for thyroid diseases. Patients typically present with fever, pain in the anterior cervical region, and transient hyperthyroidism. Hyperthyroidism with a clinical picture that resembles Graves disease may be seen after neck irradiation for Hodgkin's disease.[31] The incidence is uncertain owing to the small number of cases reported. The clinical picture is characterized by diffuse thyroid enlargement, suppressed TSH, high levels of thyroid hormones, and development of thyroid autoantibodies. Ophthalmopathy, with or without overt hyperthyroidism, may be seen and is thought to be related to autoantibodies, similar to Graves disease.[32]

Parathyroid Glands

There are several studies that link prior head and neck irradiation and hyperparathyroidism.[33,34] Cohen and colleagues[35] followed a cohort of patients who were treated with radiation to the tonsils before the age of 16 years. Among the 2923 patients, 32 patients were found to have clinical hyperparathyroidism. This is a 2.5-fold to 2.9-fold increase compared with the general population in the same age group. There is a long latency period (>25 years) between exposure and onset of hyperparathyroidism. Clinical presentations vary from asymptomatic increases in serum parathormone levels and hypercalcemia to disabling metabolic bone disease or nephrolithiasis. Individuals with a history of head and neck radiation should be monitored with calcium levels periodically (every 1 to 2 years) and indefinitely.[36]

ROLE OF SYSTEMIC THERAPY

Chemotherapy is not widely recognized to contribute to endocrine dysfunction; however, many data indicate to the contrary. Effects of systemic chemotherapy on ovarian and testicular function are discussed in Chapter 64.

Hypothalamic-Pituitary Axis

In children, chemotherapeutic agents alone may disrupt growth hormone (GH) secretion even in the absence of cranial radiation. Roman and colleagues studied growth and GH secretion in 60 children who were in complete remission after treatment with chemotherapy and surgery for solid tumors.[37] They observed growth hormone deficiency in 45% of those studied and found that these children were more likely to have received high doses of chemotherapy (actinomycin D), but they could find no correlation with the duration of treatment, length of follow-up, tumor type, sex, or age. Depending on the intensity of chemotherapy, significant height loss can be detected in 40% to 70% of patients at 6-year follow-up.[38] Adjuvant chemotherapy can also aggravate growth failure in children with brain tumors receiving craniospinal radiation.[39]

Rose and colleagues reported hypothalamic dysfunction in patients with non–central nervous system tumors who received chemotherapy but did not receive cranial irradiation or traumatic brain injury.[40] Of 31 identified patients, GHD was identified in 15 (48%), central hypothyroidism in 16 (52%), and pubertal abnormalities in 10 (32%) patients. GHD and hypothyroidism were coexistent in eight patients (26%). Overall, 81% ($n = 25$) had GHD, hypothyroidism, precocious puberty, or gonadotropin deficiency.

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion may result from the effects of many chemotherapeutic agents, either by potentiation of antidiuretic hormone (ADH) effect or by increased ADH secretion. The most commonly implicated agents are vinca alkaloids and cyclophosphamide. The vinca alkaloids are reported to stimulate the central release of ADH from the neurohypophyseal system,[41] whereas alkylating agents enhance renal tubular sensitivity to ADH.[42] Regardless of the mechanism, the result is an increase in water reabsorption by the distal tubules of the kidney, leading to volume expansion and dilutional hyponatremia. Many case reports also implicate platinum agents,[43] vinorelbine,[44] taxanes,[45] and methotrexate.[46] Clinically significant hyponatremia may occur with administration of these agents. Management requires fluid restriction and, at times, salt replacement.

Thyroid

Clinically evident thyroid dysfunction is rarely associated with the use of standard chemotherapy agents. However, a growing body of

literature points to the increased prevalence of endocrine dysfunction after bone marrow transplantation, which may be seen following high doses of chemotherapy in absence of any radiation. There are reports of thyroid dysfunction in nearly 50% of allogeneic bone marrow transplant recipients treated with busulphan and cyclophosphamide alone.[47] Thyroid dysfunction may present as low T3 syndrome (free T4 normal, TSH normal, and free T3 below normal), chronic thyroiditis, and transient subclinical hyperthyroidism or hypothyroidism. Chemotherapy may potentiate radiation-induced damage to normal tissue. Among 32 patients treated for medulloblastoma in childhood, Paulino found that 18 patients developed hypothyroidism after a median time of 41 months after irradiation. Hypothyroidism was reported in 10 of the 12 patients (83%) who received 23.4 Gy plus chemotherapy (vincristine, *N*-[2-chloroethyl]-*N′*-cyclohexyl-N-nitrosourea [CCNU], cisplatin, or cyclophosphamide) and 6 of 10 (60%) of those who received 36 Gy plus chemotherapy (vincristine, CCNU, prednisone) versus only 2 of the 10 (20%) of those who received 36 GY radiation alone.[48]

Aminogluthemide, now an infrequently used drug to disrupt adrenal and peripheral steroid hormone synthesis, inhibits cholesterol conversion to pregnenolone. It causes thyroid dysfunction after long-term use due to blockade of iodination of tyrosine.[49] Figg and associates reported that 9 of 29 men who were treated with aminogluthemide for metastatic prostate cancer had clinical and biochemical evidence of hypothyroidism.[50]

Chemotherapeutic agents can also interfere with circulating thyroid hormones, thereby altering their free blood levels. 5-Fluorouracil increases total T3 and T4 levels, but free T4 index and TSH remain normal, indicating increased levels of thyroxine-binding globulin or enhanced binding capacity.[51] L-Asparaginase causes transient thyroxine-binding globulin deficiency by diminishing hepatic synthesis and also inhibits TSH secretion from the pituitary, resulting in decreased total T4 as well as free T4 levels.[52] Transient hyperthyroidism after L-asparaginase therapy for acute lymphoblastic leukemia has also been observed.[53] These thyroid function abnormalities are mild and short-lived and generally do not require specific therapy.

In postmenopausal women, tamoxifen therapy is associated with changes in thyroid hormone concentrations, though patients may remain clinically euthyroid.[54] Mamby and colleagues undertook a randomized, placebo-controlled trial with tamoxifen 10 mg orally, twice daily, with 14 patients in each group.[55] Thyroid function test assessment before and 3 months after initiation of therapy was done. Serum thyroid-binding globulin increased, as did T4 uptake and T4 levels in the tamoxifen-treated group compared to placebo. TSH levels and free thyroxine index remained unchanged; patients were clinically euthyroid and did not require treatment.

Adrenal

A method of medically ablating or reducing adrenal function was sought for a number of years as an alternative to surgical resection of the adrenal glands. Surgical adrenalectomy was used primarily for the treatment of advanced breast cancer. Aminoglutethimide and ketoconazole both suppress adrenal function. These drugs appear to have their effect through their ability to inhibit important cytochrome P-450 isozymes, which are necessary for adrenal steroid synthesis.[56,57] Aminoglutethimide, at doses of 1000 to 1500 mg/day, and ketoconazole, at doses of 800 to 1200 mg/day, produce adrenal insufficiency in 30% to 40% of patients. Although standard glucocorticoid treatment is generally required in these patients during treatment, mineralocorticoid replacement is usually not required. The antiadrenal effects of ketoconazole and aminoglutethimide are reversible with treatment discontinuation. Full recovery within 1 to 2 weeks is usual.

Mitotane (1-dichloro-2-[o-chlorophenyl]-2-[p-chlorophenyl]-ethane), is an oral chemotherapeutic agent that is used to treat adrenal carcinoma based on its potent antiadrenal effects.[58] It is used primarily to treat adrenal hyperfunction associated with adrenal carcinoma or ectopic production of corticotrophin. It has been reported to result in sustained remission for some patients with metastatic adrenal carcinoma with long-term administration.[59] Although the mechanism of action is incompletely understood, adrenal necrosis and permanent adrenal insufficiency can result, necessitating lifelong glucocorticoid administration.

Pancreas

Pancreatic exocrine or endocrine insufficiency attributable to chemotherapy is uncommon. Acute pancreatitis has been described as a complication of L-asparaginase therapy and can be fatal.[60] Although rare, several cases of diabetes mellitus have been associated with L-asparaginase therapy.[61] Hyperglycemia is usually transient and responds to intravenous fluids and drug discontinuation. A plausible mechanism may be inhibition of protein synthesis by L-asparaginase leading to interference with insulin production.[62] High triglyceride levels have been associated with L-asparaginase use, though it is not clearly associated with incidence of pancreatitis in these patients. Knoderer and colleagues retrospectively described 33 patients (13%) with asparaginase-associated pancreatitis in a cohort of 254 patients over a 5-year period.[63] Twelve cases were noted after *Escherichia coli* asparaginase, and 20 cases were noted after PEG-asparaginase therapy. The incidence of pancreatitis was found to be independent of the individual or cumulative asparaginase dose. The interval to pancreatitis diagnosis was longer for PEG-asparaginase than for *E. coli* asparaginase ($P = 0.02$). Patients who received prednisone ($P = 0.02$) and daunomycin ($P = 0.006$) were more likely to develop pancreatitis than were those who received dexamethasone ($P = 0.04$). Use of other chemotherapy agents was not observed to have a significant effect on the incidence of pancreatitis.

High-dose cytarabine can rarely result in pancreatitis. Siemers and colleagues described two patients with evidence of pancreatitis among 30 patients treated with cytarabine.[64] Prior therapy with L-asparaginase was found in another small series of patients who received cytarabine and developed pancreatitis.[65]

Streptozotocin is a nitrosurea that is used primarily for the treatment of pancreatic endocrine tumors. In preclinical models, streptozotocin causes beta cell necrosis and insulin-dependent diabetes in many species.[66] Mild glucose intolerance has been described in patients receiving this agent; however, specific treatment is rarely required.[67]

Androgen ablation therapy may also be associated with diabetes. Keating and colleagues showed an increased incidence of diabetes in prostate cancer patients receiving GnRH agonist. A potential mechanism is the increase in body fat mass associated with hypogonadism, which results in insulin resistance.[68]

ROLE OF BIOLOGIC AGENTS

Biologic agents are increasingly important in cancer treatment, and various endocrine complications are being recognized with the use of these agents.

Immune therapies may cause thyroid dysfunction. Atkins and colleagues[69] were the first to describe an association between therapy with recombinant interleukin-2 and thyroid abnormalities. Interleukin-2 therapy is known to be associated with both hypothyroidism and hyperthyroidism, though the former is more common.[70] In Atkins and colleagues' original report, seven patients (21%) had laboratory evidence of hypothyroidism, a decline in the serum thyroxine concentration and serum free thyroxine index, and an increase in the serum TSH concentration 6 to 11 weeks after treatment.[69] All five symptomatic patients had borderline or elevated serum antimicrosomal antibody titers after treatment; two had serum antibodies to thyroglobulin. Five of the seven patients with hypothyroidism (71%) but only 5 of the 27 euthyroid patients (19%) had evidence of tumor regression ($P < 0.02$). Fifteen patients (47%) became hypothyroid with high serum TSH levels within 60 to 120 days after the

start of treatment. The proposed mechanism is autoimmune with development of antithyroid antibodies. Proposed mechanisms are that either the interleukin-2 treatment itself triggers autoreactive B-cell clones or cellular and/or cytokine-mediated thyroid destruction leads to activation of autoreactive B-cell clones.

Hypothyroidism is a recognized complication of tyrosine kinase inhibitors. Sunitinib maleate is an oral tyrosine kinase inhibitor that was recently approved for the treatment of gastrointestinal stromal tumors and renal cell carcinoma. Desai and colleagues reported hypothyroidism in patients undergoing sunitinib therapy.[71] One potential mechanism may be sunitinib-induced destructive thyroiditis through follicular cell apoptosis. Sunitinib is also a RET/PTC tyrosine kinase inhibitor that is involved in pathogenesis of papillary thyroid cancer and perhaps affects normal thyroid function as well.

Imatinib also interacts with thyroid hormone replacement and results in increased TSH levels in hypothyroid individuals who are on levothyroxine therapy. However, it does not appear to have a direct effect on the thyroid but alters the levels of thyroxine binding protein.[72] Berman and colleagues reported hypophosphatemia and associated changes in bone mineral metabolism in patients taking imatinib for either chronic myelogenous leukemia or gastrointestinal stromal tumors.[73] Patients were found to have high levels of urinary phosphate and markedly decreased serum levels of osteocalcin and N-telopeptide, indicative of reduced bone turnover. Imatinib inhibits platelet-derived growth factor receptor, which in a rat model has been demonstrated to have a critical role in skeleton development.

Interferon-beta (IFN-β) and interferon-alpha (IFN-α) may both increase ACTH, prolactin, growth hormone, and cortisol levels in patients.[74] An assessment of IFN-α-induced endocrine stimulation in patients with myeloproliferative disorders revealed that on day 1 of therapy, a significant stimulation of the hypothalamic-pituitary axis was apparent, an effect that disappeared by the third week of therapy.[75] The acute stimulatory effect of IFN-α on cortisol release appears to be mediated by the release of hypothalamic corticotropin-releasing hormone. There are reports of alterations in the levels of sex hormones during IFN therapy, and male sexual dysfunction has been noted.[76]

Clinicians should keep in mind that there are limited data regarding the effects of many new agents and one must be alert to endocrine dysfunction in patients receiving such drugs.

EVALUATION AND TREATMENT OF COMMON ENDOCRINE DYSFUNCTION

A detailed history, including treatment history and physical examination, should be done in any patient who is suspected of having endocrine dysfunction. Evaluation should be directed by this information and the location and type of tumor. The initial approach to the diagnostic workup is outlined in the following sections. Endocrinology consultation should be sought for more complex and multisystem involvement. Table 65-3 shows a brief outline of evaluation of common endocrine disorders. The workup for gonadotropin deficiency and hormone replacement is discussed in detail in Chapter 64.

Hypothalamic-Pituitary Axis Disorders

Growth Hormone Deficiency

EVALUATION. The assessment of pituitary GH production is difficult because GH secretion is pulsatile and serum GH levels are often low between the pulses. Therefore, measurement of a single serum GH level is of limited use in diagnosing GHD. Serum insulin-like growth factor (IGF-1) and IGF binding protein-3 (IGFBP-3) concentrations may be measured as a surrogate marker for GH production, and further evaluation is indicated if these results are below the mean for normal children of the same age. An IGF-1 level below 84 ng/mL using the Esoterix assay reportedly is highly indicative of GHD.[77] Confirmation can be done by GH secretion provocative tests.

According to the consensus guidelines for the diagnosis and treatment of adults with GH deficiency, the insulin hypoglycemia test is the gold-standard GH provocative test.[78] According to the Food and Drug Administration, GHD is diagnosed if the maximum stimulated serum GH concentration is less than 5.1 μg/L (polyclonal radioimmunoassay) or less than 2.5 μg/mL (immunochemiluminescent assay).[79] Even though reliable, this test requires strict monitoring. The insulin hypoglycemia test is contraindicated in debilitated patients, those with cardiovascular or cerebrovascular disease, and those with a history of seizure, abnormal electroencephalogram (EEG), or history of brain surgery.[77–79] In these patients, the combined arginine/GHRH stimulation test may be used. The arginine stimulation test involves intravenous infusion of 0.5 g/kg body weight (to a maximum of 30 g) of arginine given over 30 minutes and measuring serum growth hormone level at 0, 30, 60, 90, and 120 minutes. Though historically the insulin hypoglycemia test was considered the gold standard for GHD, the arginine-GHRH test is much safer, is 95% sensitive and 91% specific (at a cutoff of 4.1 μg/L), and has essentially replaced the former.[80]

The diagnosis of GHD in childhood is a complex process that requires clinical and growth assessment combined with biochemical tests and radiologic evaluation. GHD may be an isolated finding or a component of multiple pituitary hormone deficiency. In a child

Table 65-3 Diagnostic Evaluation of Common Endocrine Disorders

Disease	History	Signs	Screening	Confirmatory Tests
GH deficiency	Fatigue, poor stamina, hypoglycemia	Slow growth velocity, delayed puberty, truncal fat distribution	IGF-1, IGFBP-3, and bone maturation	Insulin hypoglycemia test, arginine, L-dopa, clonidine
Hypothyroidism (primary or secondary)	Fatigue, cold intolerance, weight gain, cognitive dysfunction, mental retardation, constipation, growth failure, dry skin, depression, menstrual disturbances	Slow movement and slow speech, delayed relaxation of tendon reflexes, bradycardia, coarse skin, periorbital edema, macroglossia	Free T4, TSH, and bone maturation	TSH surge
Hyperthyroidism	Hyperactivity, tremors, diarrhea, sweating, weight loss, heat intolerance	Atrial fibrillation, lid lag, proptosis, goiter	Free T4, T3, and TSH	Radioiodine uptake scan
Adrenal insufficiency (primary or secondary)	Dehydration, hyperpigmentation, weakness, fatigue	Electrolyte disturbance, hypotension, nausea, vomiting	Early morning serum cortisol level	Low- or high-dose ACTH stimulation test

with clinical criteria for GHD, a peak GH concentration less than 10 mg/L has traditionally been used to support the diagnosis after a provocative GH test.[81] Supportive evidence is indicated by very short height (more than 2.5 standard deviations below the mean height for normal children of the same age), delayed bone age, poor growth velocity (less than twenty-fifth percentile), and a predicted adult height substantially below the mean parental height.[77] IGF-I/IGFBP-3 levels and GH provocation tests should be done after hypothyroidism has been excluded as a cause of slow growth. Great care should be taken in using insulin or glucagon provocative tests in a young child, and testing should be monitored by an experienced team.

TREATMENT. Children with proven GHD should receive GH therapy as soon as possible after diagnosis. The goal of therapy is to maximize height attained before puberty. The usual starting dose of GH is 25 to 50 μg/kg/day, administered subcutaneously in the evening.[72,73] Each dose produces a pharmacologic level of GH for approximately 12 hours. Evaluation of the growth response and adjustment of GH dose should occur every 4 to 6 months, and assessment should include measurement of height, weight, and arm span. GH dose is increased as weight gain occurs to maintain a stable dose per kilogram of body weight. Serum IGF-1 measurements are recommended yearly. If IGF-1 increases above the upper limits of normal for age and gender, the GH dose should be decreased.

GH therapy in adults is approved by the Food and Drug Administration only if there is evidence of hypothalamic or pituitary disease and a subnormal serum GH response to a provocative test. The goal of the therapy is to improve muscle and cardiac function, restore normal body composition, and improve serum lipids. The usual starting dose for adults between 30 to 60 years of age is 300 μg/day; the dose is increased every 1 to 2 months by 100 to 200 μg/day, guided by clinical response and measurement of serum GH levels.[77,78]

Hyperprolactinemia

EVALUATION. The presenting symptoms of hyperprolactinemia include amenorrhea, galactorrhea, impotence, and infertility. The diagnosis of hyperprolactinemia is made by a random serum prolactin level measurement. Dynamic testing of the lactotrophin reserve with thyrotropin-releasing hormone is not useful because it does not differentiate between the different causes of hyperprolactinemia.[82] Hypothyroidism must also be ruled out as a cause of clinical findings, and careful review of medications should be done to rule out drug-induced hyperprolactinemia.

TREATMENT. Dopamine released from hypothalamic nerve endings acts as a prolactin inhibitory factor, and dopaminergic agonists are useful in the treatment of hyperprolactinemia. Commonly used agents include bromocriptine and cabergoline. The most common side effects of these drugs are nausea, postural hypotension, and mental fogginess. Less common side effects include nasal stuffiness, depression, Raynaud phenomenon, alcohol intolerance, and constipation. The usual starting dose is 0.25 mg of cabergoline twice a week or 1.25 mg of bromocriptine once a day. The doses can be increased on the basis of serum prolactin level and the side effect profile.

Thyroid Disorders

EVALUATION. Primary hypothyroidism is characterized by a high serum TSH (normal range: 0.5 to 5 mU/L) concentration and a low serum free T4 concentration (normal range- 0.8 to 1.8 ng/dL). Secondary hypothyroidism is characterized by a low serum T4 concentration and a serum TSH concentration that is not appropriately elevated.[83] To distinguish between pituitary and hypothalamic causes of hypothyroidism, thyrotropin-releasing hormone stimulation test and/or imaging studies of the sellar and suprasellar region should be done. Patients who are diagnosed with central hypothyroidism should also be evaluated for coexistent adrenocortical, gonadal, posterior pituitary, and, in children, growth hormone function. As was noted previously, patients with cranial irradiation or traumatic brain injury are at high risk for panhypopituitarism.

Primary hyperthyroidism is associated with low TSH and high free T4. Graves disease is associated with uniformly high 24-hour radioiodine uptake, while toxic adenoma is associated with focal high uptake. If free T4 and T3 are high with a normal or high TSH in a clinically hyperthyroid patient, pituitary magnetic resonance imaging should be done to look for a pituitary mass (TSH-secreting adenoma).

TREATMENT. Thyroid hormone replacement with levothyroxine (T4) is usually sufficient. The goal of therapy is to attain normal TSH (in primary hypothyroidism) and free T4 levels (in secondary hypothyroidism). The average replacement dose of T4 in adults is approximately 1.6 μg/kg body weight per day. Treatment with liothyronine (T3) may be required in patients with no response to levothyroxine therapy or in patients with myxedema coma.

Thyroid ablation with surgery, radioiodine, or pharmacologic agents (propylthiouracil, methimazole) should be considered in patients with hyperthyroidism. Beta blocker therapy is used as a clinical adjunct in most patients. The goal of therapy is to keep the TSH and T3 and T4 in the normal range. Surgery is indicated primarily in patients who have large or obstructive goiter.

Syndrome of Inappropriate Antidiuretic Hormone

EVALUATION. SIADH is characterized by hyponatremia, a low plasma osmolality, an inappropriately elevated urine osmolality (above 100 mosmol/kg), and a high urinary sodium concentration (usually above 40 mEq/L). Other supportive findings include low BUN and serum uric acid concentration, normal plasma creatinine concentration, normal acid-base and potassium balance, and normal adrenal and thyroid function.[84]

TREATMENT. Water restriction is the mainstay of therapy in asymptomatic hyponatremia and in chronic SIADH. Severe, symptomatic, or resistant hyponatremia requires the administration of salt tablets or hypertonic saline administration. A loop diuretic (such as furosemide once or twice a day) may be used to enhance the effect of fluid reduction, since it directly interferes with the countercurrent concentrating mechanism by decreasing sodium and chloride reabsorption in the medullary portion of the loop of Henle.[85] In patients who remain refractory, demeclocycline (300 to 600 mg twice a day) or lithium may be used.[86] These drugs act on the collecting tubule cell to diminish its responsiveness to ADH, thereby increasing water excretion. ADH receptor antagonists are being evaluated that are selective for the V2 (antidiuretic) receptor and may thus reverse the hyponatremia. Conivaptan blocks V2 and V1a receptors and is available in parenteral form.[87]

Hyperparathyroidism

EVALUATION. Primary hyperparathyroidism is characterized by elevated parathormone level and hypercalcemia. Supportive findings include low serum phosphate level, an increase in 24-hour urinary calcium excretion, a decrease in serum calcitriol and 25(OH) cholecalciferol, and an increase in biochemical markers of bone turnover (collagen cross-links, osteocalcin, bone-specific alkaline phosphatase). Patients may present with classic symptoms of the disease (nephrolithiasis or bone disease), or they may have nonspecific symptoms such as fatigue, weakness, mild depression, vague abdominal pain, and constipation.

TREATMENT. Patients should be advised to avoid factors that can aggravate hypercalcemia, including thiazide diuretic and lithium carbonate therapy, volume depletion, prolonged bed rest or inactivity, and a high-calcium diet (>1000 mg/day). Daily vitamin D intake

of 400 to 600 IU daily should be maintained, as vitamin D deficiency stimulates parathormone secretion and bone resorption and therefore is deleterious in patients with primary hyperparathyroidism. Surgical removal of the parathyroid glands remains the mainstay of therapy in most patients. Medical therapy involves estrogen plus progestin, bisphosphonates, or raloxifene. These drugs inhibit bone resorption and increase bone density and possibly lower serum calcium concentrations in patients with hyperparathyroidism. Calcimimetics and vitamin D analogs act by suppressing parathyroid hormone release and counteract the effects of hyperparathyroidism at the level of the parathormone receptor. Calcimimetics are currently being studied for primary and secondary hyperparathyroidism.[88]

Adrenal Disorders

EVALUATION. There is controversy about the optimal biochemical approach to diagnosis of corticotropin deficiency. In moderate to severe corticotropin deficiency, the early morning serum cortisol levels are consistently less than 250 nM. A corticotropin stimulation test may be used to confirm the diagnosis. Both low-dose (1 μg) and high-dose (250 μg) corticotropin stimulation tests are useful to distinguish primary from pituitary (secondary) causes of adrenal insufficiency. Serum cortisol levels are measured at 0, 30, and 60 minutes after intravenous administration of corticotropin. If corticotropin and adrenal secretion are normal, the serum cortisol levels should increase to 20 mg/dL or higher. In patients with severe corticotropin deficiency, the serum cortisol response will be lower or absent as a result of adrenal atrophy. Primary adrenal insufficiency is characterized by low response to both low-dose and high-dose corticotropin stimulation tests. Acute adrenal crisis is an oncologic emergency. Electrolyte disturbances such as hyponatremia, hyperkalemia, azotemia, hypercalcemia, and hypoglycemia are common.

TREATMENT. Adrenal insufficiency requires glucocorticoid supplementation and at times mineralocorticoid supplementation. Pituitary or isolated ACTH deficiency is not characterized by mineralocorticoid deficiency. Patients with symptomatic adrenal insufficiency should be treated with hydrocortisone or cortisone in the early morning and afternoon. The usual initial oral dose is 25 mg of hydrocortisone (15 mg in the morning and 10 mg in the afternoon). This may be decreased over time, with the goal of using the minimal effective dose to prevent weight gain and osteoporosis.[89] Patients with primary adrenal insufficiency require mineralocorticoid replacement with fludrocortisone (0.05 to 2 mg orally each day).

Box 65-1. TREATMENT OF ACUTE ADRENAL CRISIS

1. Check airway, breathing and circulation, and baseline vital signs. Establish intravenous access with a large-gauge needle.
2. Assess serum electrolytes, glucose, and random plasma cortisol and ACTH levels.
3. Replace intravascular volume with isotonic saline (at least 2 to 3 liters), and maintain hydration.
4. Intravenous corticosteroid administration preferably with dexamethasone (4 mg intravenous every 8 hrs) intravenously. Hydrocortisone 100 mg IV every 6 hours may be used but can interfere with ACTH stimulation test.
5. Treat underlying causes of the adrenal crisis (e.g., infection).
6. Perform a short ACTH stimulation test to confirm the diagnosis of adrenal insufficiency if the patient does not have known adrenal insufficiency.
7. Begin mineralocorticoid replacement with fludrocortisone (0.1 mg by mouth daily) after volume replacement.

Box 65-2. YEARLY SURVEILLANCE FOR ENDOCRINE DISORDERS IN CHILDHOOD CANCER SURVIVORS

1. Detailed history and physical examination, including accurate height and weight measurements (arm span measurement if unable to assess height)
2. Determination of bone age (radiograph of left hand and wrist) in children who are growing too fast or too slowly
3. Ascertainment of Tanner stage of pubertal development and interpretation of whether the pubertal status and rate of progression are appropriate for chronologic age
4. Measurement of IGF-I and IGFBP-3 levels in children who are growing too slowly (to assess for GHD)
5. Measurement of serum LH, FSH, and sex hormone levels (testosterone or estradiol) in children with delayed or interrupted progression of puberty
6. Measurement of free T4 and TSH levels

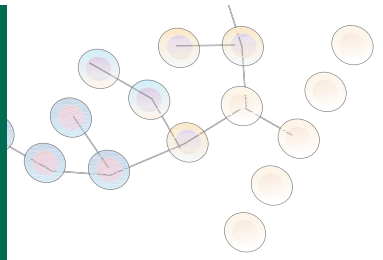
During periods of stress, patients with adrenal insufficiency require higher-than-usual doses of hydrocortisone, and in severe illness, they might require intravenous high-dose hydrocortisone therapy due to acute adrenal crisis. Box 65-1 outlines a treatment algorithm for acute adrenal crisis, which should be treated as an oncologic emergency.

SURVEILLANCE OF CHILDHOOD CANCER SURVIVORS

With improved therapy for most childhood cancers, there is an increasing population of childhood cancer survivors.[90] Such individuals are at risk for long-term endocrine complications related to the tumor and/or the treatment received. The risk of a particular endocrinopathy depends on the tumor location and the dose and duration of radiotherapy and chemotherapy received. Box 65-2 depicts a summary of recommended yearly surveillance in childhood cancer survivors for endocrine complications.[91] Close follow-up should be performed every 4 to 6 months if the initial tests are normal but the child remains symptomatic.

Children typically exhibit catch-up growth and weight gain after completion of therapy. Some children transiently develop breast buds corresponding to this period of newly improved nutrition. These children should be examined every 3 to 6 months to evaluate for precocious puberty. Assessment of Tanner stage of pubertal development is useful to assess for precocious or delayed puberty. Further testing should be guided by the physical findings.

Surveillance for adrenocortical deficiency is indicated primarily for high-risk patients such as those who received cranial irradiation in excess of 40 Gy. There is controversy regarding how long the surveillance should be carried out. The surveillance is guided largely by the pattern of growth and development. If normal growth and pubertal development are attained, the surveillance can be stopped.



CONCLUSION

Endocrine disorders are common in patients with cancer and are related primarily to cancer therapy. Careful clinical examination and yearly surveillance should be done in cancer survivors. A high degree of clinical suspicion is necessary in patients who are on newer therapies with which there is limited experience. Most endocrine disorders are readily treatable, and an accurate diagnosis should be pursued aggressively.

66 Second Malignant Neoplasms

John P. Plastaras, Daniel M. Green, and Giulio J. D'Angio

SUMMARY OF KEY POINTS

Epidemiology

- Pediatric patients who survive their primary cancer are at increased risk of developing a new malignancy.
- The magnitude of this risk is modulated by several factors, including the patient's genetic susceptibility, the type of surgical procedure used for removal of the tumor, the use of radiation therapy as part of the treatment plan, the chemotherapeutic agents that are employed, the severity of immune suppression that is present at the completion of all treatment, and environmental exposures.
- The potential risk of a second malignant process following treatment of adults should not lead to therapeutic compromises when treatment, often aggressive, is of known benefit.

General Recommendations

- All former cancer patients should remain under a physician's care indefinitely.
- All former cancer patients should undergo frequent physical examinations (preferably by a physician or other specifically trained health care worker who is familiar with the problem of therapy-induced malignancy).
- Physicians should counsel cancer survivors regarding the potential for the adverse effects of tobacco use, including the potential to interact with the adverse effects of their prior therapy, such as irradiation of the oropharynx, esophagus, and/or lungs.

Specific Recommendations

- Plain radiographs should be obtained for patients who have been irradiated whenever local pain occurs in a previously irradiated bone.
- Patients who have received irradiation to volumes that include the breast, uterine cervix, or intestine should undergo routine evaluation with available screening tests, such as mammography, Pap smear, and stool examination for the presence of occult blood.
- Annual mammography should be initiated no later than 10 years after breast irradiation.
- Careful physical examination of irradiated patients will facilitate the early identification of thyroid nodules and skin cancer.
- All patients who have been treated with an alkylating agent, procarbazine, or a topoisomerase II inhibitor, should have a complete blood count every 6 to 12 months for a minimum of 12 years after diagnosis.
- Presence of macrocytosis and/or cytopenia should prompt evaluation of the bone marrow.

INTRODUCTION

Second malignant neoplasms (SMNs) develop in patients as a result of genetic and iatrogenic factors and their interplay. The therapies that are employed are different for children and adults because of the differences in the primary cancers that are encountered. Primary cancers in adults are usually of epithelial origin, unlike the embryonal and sarcomatous neoplasms encountered at earlier ages. In addition, some of the cancers that are encountered in adults are the result of therapies they received for nonmalignant conditions that were treated when they were children. This discussion therefore has been divided into two parts according to the age group being considered.

CHILDREN AND ADOLESCENTS

SMNs are a recognized complication of successful treatment of children and adolescents for cancer. The frequency of these had been reported to be 1.9% at 10 years after diagnosis, 5.0% to 12.0% at 25 years after diagnosis, 3.3% to 4.9% at 25 years after diagnosis among 3-year survivors, 3.2% to 12.0% at 20 years after diagnosis among 5-year survivors, and 4.2% to 7.8% at 25 years after diagnosis among 5-year survivors.[1–8] These series differed with respect to the time period during which the patients were treated, the completeness of follow-up, and the treatment exposures that the patients experienced. SMNs are a major threat to the long-term survivors of childhood cancer, in whom they are looming ever larger as a cause of death. Moller and colleagues reported results of a survey in the Nordic countries, where the proportions of deaths from second tumors increased from 3% to 22% between 5 and 10 years and 20+ years.[9] In fact, Lawless and colleagues found SMNs to be more often the cause of death than was relapse of the primary tumor.[10] In their single-institution study, they found that SMNs were the leading cause of death (39%) in 15+-year survivors; greater than the rates for primary cancer (21%) and cardiac (16%) deaths. Increasingly, the data suggest that although specific exposures (whether to a particular chemotherapeutic agent or to ionizing radiation) might be linked to the occurrence of a new malignancy, the most important factor in the pathogenesis of many SMNs could well be the patient's genetic susceptibility. We will review the genetic and treatment factors that have been associated with the occurrence of SMNs and discuss the follow-up and evaluation of the successfully treated pediatric cancer patient.

Genetic Factors

The importance of genetic predisposition to the occurrence of a SMN has been demonstrated most clearly in patients with hereditary

retinoblastoma. Among 1604 1-year survivors of retinoblastoma in Boston and New York City between 1914 and 1984, 961 had the hereditary form of the disease.[11] The cumulative percentage of those who developed a SMN was 51.0% (±6.2%) 50 years after retinoblastoma diagnosis, compared with 5.0% (±3.0%) among those with nonhereditary retinoblastoma (Fig. 66-1A). Among patients with hereditary retinoblastoma, the cumulative percentage that developed SMNs was 58% among those whose treatment included radiation therapy (RT), compared with 26.5% among those whose treatment did not include RT (Fig. 66-1B). Kleinerman and colleagues[12] updated this series to focus on secondary sarcomas and found that there was a significantly increased risk of sarcomas within the RT field as well as an increased risk outside of the RT field, with a 13% cumulative risk of sarcoma 50 years after RT. Leiomyosarcomas were frequently diagnosed over 30 years later, indicating that older carriers remain at risk. Fletcher and colleagues[13] described the long-term risks of SMNs in retinoblastoma survivors born before 1950, a group that was not routinely treated with high-dose RT. The cumulative incidence of SMNs from age 25 to 84 was 69% in the hereditary cases and 48% in the sporadic cases, but the majority were epithelial cancers and not sarcomas. These studies indicate that retinoblastoma carriers have both an inherent risk of other SMNs and a RT-dependent risk of secondary sarcomas, which affects how these patients should be followed into adulthood.

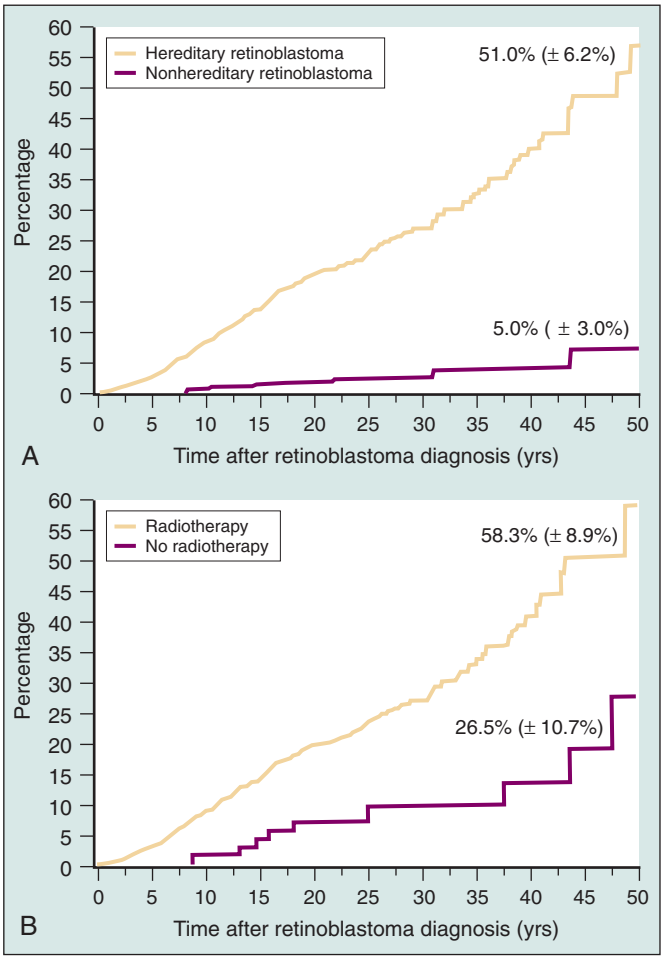

Figure 66-1 • **A,** The cumulative incidence of second malignant tumors is increased in children with familial retinoblastoma. **B,** The cumulative risk of second malignant tumors is increased in children with familial retinoblastoma who are treated with radiation therapy. (Data from Wong GL, Boice JD Jr, Abramson DH, et al: Cancer incidence after retinoblastoma: radiation dose and sarcoma risk. JAMA 1997;1262:278.)

Li-Fraumeni syndrome consists of sarcoma diagnosed in the proband before age 45 years, with additional cancers (frequently soft-tissue sarcoma or breast cancer) diagnosed in other children and young adults within the family.[14] The genetic defect in some families with the Li-Fraumeni syndrome was demonstrated to be a mutation within the p53 gene.[15–18] Because the pattern of first and second malignant tumors in some patients with SMNs resembles the distribution that is observed within some families with Li-Fraumeni syndrome, a series of patients with SMNs was evaluated for the occurrence of mutations at this locus. Mutations were identified in 5.1% of 59 patients who were examined.[19,20] Pediatric patients with cancer who have neurofibromatosis have a relative risk of 8.1 of developing a SMN compared with pediatric patients with cancer who do not have neurofibromatosis.[21] Future research could demonstrate that neurofibromatosis type 1 patients who develop SMNs have coexistent germline p53 mutations.

Treatment Factors

Surgery

Surgical procedures can increase the risk of subsequent malignancy. Adenocarcinoma of the colon has been reported in several patients after ureterosigmoidostomy. The incidence of adenocarcinoma in these patients was approximately 9.9 per 1000, compared with an incidence rate of 9.9 per 100,000 in the general population.[22] The majority of reported patients have undergone this procedure for treatment of exstrophy of the bladder. The median interval between ureterosigmoidostomy and the diagnosis of colon carcinoma was 22 years.[23]

Radiation Therapy

The risk of various SMNs has been linked to the use of both RT and chemotherapy.[8,24,25] As treatment of childhood malignancies has intensified over the past several decades, the cure rate has increased, but so has the risk of SMNs.[8] In the cohort of 13,136 patients from the Childhood Cancer Survivor Study, 59% of the nonbreast, nonskin, nonthyroid SMNs occurred within RT fields.[26] A European case-control study of 4581 survivors by Guerin and colleagues demonstrated a radiation dose-response for the excess risk of SMNs that best fit a linear model of 0.13 per Gy.[24] This study also noted that the relative risk of SMN was increased when chemotherapy and RT were delivered concomitantly.

Patients who receive neck irradiation for malignant diseases are at risk for the subsequent occurrence of thyroid malignancies. These have been reported after treatment of patients with medulloblastoma, acute lymphoblastic leukemia, and Hodgkin's disease (HD).[27–29] The incidence of thyroid cancer in survivors of HD was 0.8% (1 in 119) among children who were treated at Stanford University.[30] Malignant thyroid tumors occurred at lower RT doses than did benign lesions.[31] Ron and colleagues reported that a linear-exponential model fit the dose-response data for thyroid cancer after treatment for childhood cancer better than a linear model did.[32]

This finding is consistent with the data of Upton, who demonstrated that the dose-response relationship for some radiation-induced experimental tumors was quadratic rather than linear.[33] These data led Gray to hypothesize that the shape of the dose-response curve was the sum of two radiation-induced processes: mutation induction and cell death.[34] Radiation-associated SMNs in other sites, however, have been fit to linear models (see later discussion).

Central nervous system tumors, including meningiomas and gliomas, have been reported with increasing frequency after direct or incidental irradiation of the brain, which is not surprising when the occurrence of brain tumors in children treated with low doses of RT for tinea capitis is recalled. Neglia and colleagues[35] reported that the excess radiation-associated risk for secondary gliomas was 6.8 and

that for meningiomas was 9.9. There was a linear dose response, with a steeper slope for meningiomas (1.1) than for gliomas (0.3; Fig. 66-2). The excess risk for gliomas was greatest in children who were irradiated before age 5. Other researchers have confirmed the increased risk of central nervous system tumors in children whose treatment for acute lymphoblastic leukemia included cranial irradiation.[36] In children with neurofibromatosis type 1, there was a threefold relative risk of second nervous system tumors after RT for optic pathway gliomas compared to unirradiated patients.[37]

Genetic loci associated with the occurrence of Wilms' tumor have been identified on chromosomes 11, 17, and 19.[38–40] Some patients have germline mutations in WT1, the only Wilms' tumor-associated gene that has been sequenced.[41,42] Li and associates reported that the frequency of SMNs in a cohort of successfully treated Wilms' tumor patients was 6% 20 years after diagnosis.[43] SMNs were diagnosed only in irradiated patients. Breslow and colleagues reviewed the occurrence of SMNs among patients entered on the National Wilms Tumor Studies.[44] The cumulative risk of SMN was 1.6% 15 years after diagnosis (Fig. 66-3). The relative risk of developing SMN was increased in patients who had received RT, the relative risk increasing with increasing radiation dose. Administration of doxorubicin increased the relative risk at each level of radiation exposure.[44] Other researchers have reported a cumulative frequency of SMN after treatment for Wilms' tumor at 3.9% at 20 years, with a relative risk of 11.0.[45] Patients with bilateral Wilms' tumor were not at increased risk for SMNs, according to the National Wilms Tumor Study Group analysis.[44]

Sarcomas of bone have been reported both in patients with hereditary retinoblastoma and in those who survive other types of childhood cancer. The cumulative risk of SMN in bone was estimated to be 2.8% among 9170 patients who were evaluated but was 14.1% among those with retinoblastoma and 22.1% among those who had

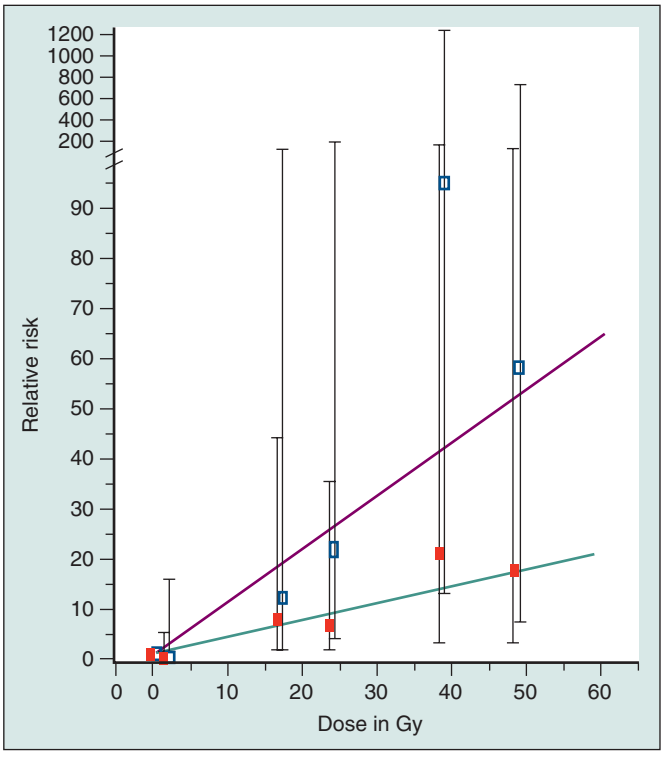

Figure 66-2 • The risk of subsequent glioma (*closed squares*, *purple line*) and meningioma (*open squares*, *blue line*) increases with radiation dose. (Data from Neglia JP, Robison LL, Stovall M, et al: New primary neoplasms of the central nervous system in survivors of childhood cancer: a report from the Childhood Cancer Survivor Study. J Natl Cancer Inst 2006;98:1528.)

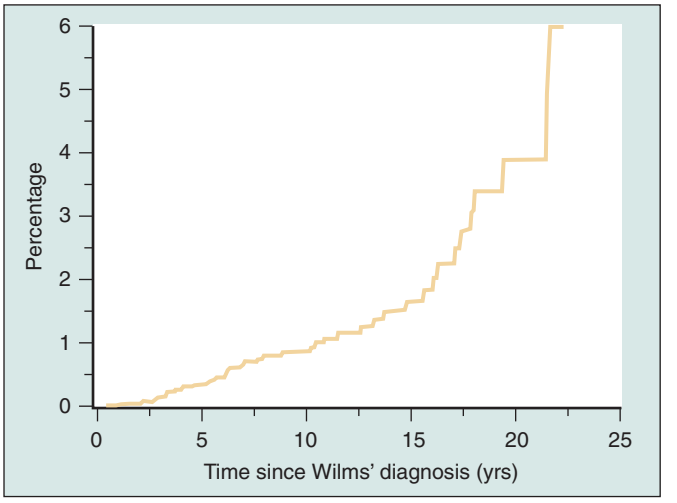

Figure 66-3 • Children who have been successfully treated for Wilms' tumor have a significant risk of developing a second malignant tumor. (Data from Breslow NE, Takashima JR, Whitton JA, et al: Second malignant neoplasms following treatment for Wilms' tumor: a report from the National Wilms Tumor Study Group. J Clin Oncol 1995;13:1851.)

been treated for Ewing sarcoma (ES) at 20 years after diagnosis (Fig. 66-4).[46] The relative risk was 2.7 among patients whose treatment had included RT; the relative risk increased with increasing RT dose and more intensive use of alkylating agents.[46] Other researchers reported a relative risk for osteosarcoma of 88–1515 in patients who had been treated for retinoblastoma; the relative risk rises to 800 after treatment for ES.[3,47] Hawkins and colleagues calculated the cumulative frequency of bone cancer in previously irradiated childhood cancer survivors as 0.5% among those who were not treated for retinoblastoma and as 7.2% among those who were treated for heritable retinoblastoma.[48] A dramatically high risk of sarcoma of bone after treatment of ES was observed in a multi-institutional study.[49] The cumulative frequency of a SMN in ES patients who were treated successfully was 9.2% at 20 years after diagnosis, and that of a secondary sarcoma was 6.5%. No secondary sarcomas developed in patients who had received less than 48 Gy.[49] A case-control study of bone sarcoma as a SMN found no difference in relative risk between patients treated with orthovoltage and megavoltage RT.[46] A decreased risk might have been expected because of the lower absorbed doses in bone after high-energy RT. Successfully treated patients are at risk of developing carcinomas (e.g., of the skin) within prior RT treatment volumes given at a very early age.[50]

Irradiation of breast tissue increases the risk of breast cancer, as was demonstrated in women who were exposed to diagnostic radiograph for pulmonary tuberculosis and survivors of the atomic bomb detonations in Hiroshima and Nagasaki.[51,52] The reported relative risks of breast cancer in girls who were treated for HD have varied widely. The largest study with the longest follow-up reported a relative risk of 11.5.[53] In this large, population-based study of 383 HD survivors, all 16 women who developed breast cancer had supradiaphragmatic irradiation. The cumulative risk of breast cancer at 25 years was 9.9% for all HD patients and 12.2% for those who were treated with supradiaphragmatic RT.

Total body irradiation, a component of most preparative regimens for allogeneic bone marrow transplantation for malignant diseases, is associated with a cumulative risk for the occurrence of a second solid neoplasm of 6.1% at 10 years after treatment.[54]

Hormone Therapy

Growth hormone (GH) treatment is necessary for the management of some children who received cranial irradiation as part of their

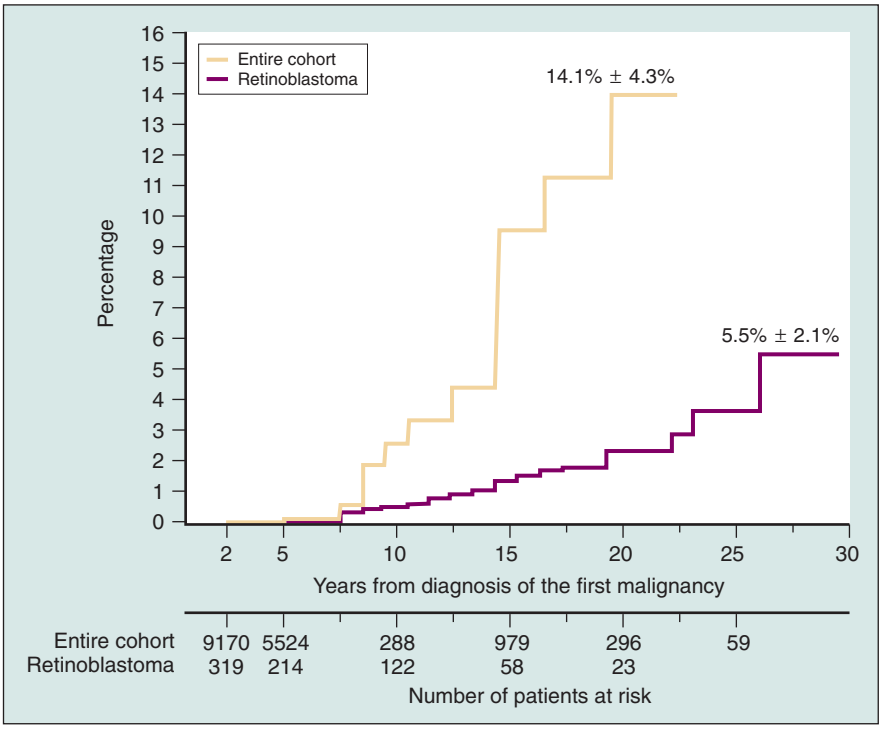

Figure 66-4 • The cumulative incidence of bone sarcoma as a second malignant tumor is increased in children who were treated for retinoblastoma compared with those who were treated for other forms of childhood cancer. (Data from Tucker MA, D'Angio GJ, Boice JD Jr, et al: Bone sarcomas linked to radiography and chemotherapy in children. N Engl J Med 1987:317:588.)

therapy for acute lymphoblastic leukemia or brain tumors. The question of whether use of GH increases the risk of second cancers was addressed in the Childhood Cancer Survivor Study cohort.[55] Using a time-dependent Cox multivariate model, the authors found that GH increased the risk of SMNs by 2.1, which was less than previous estimates. The majority of SMNs were intracranial, especially meningiomas. Although the use of radiation was taken into account in their model, the radiation dose was not, so it is possible that the need for GH was a surrogate for radiation dose. The possible risk identified by these two studies must be weighed in the context of the substantial benefits that accrue to these patients as the result of GH therapy, including improved linear growth and bone mineral accretion.

Chemotherapy

The significance of prior treatment with chemotherapy in the pathogenesis of SMNs was first evaluated in detail in cohorts of adults who had been treated successfully for HD. The risk factors for the occurrence of SMNs in pediatric patients after treatment for HD have been evaluated less thoroughly.

Bhatia and coworkers reported that the cumulative risk of developing any SMN after treatment for HD in childhood was 7% at 15 years after diagnosis.[56] The risk of developing non-Hodgkin's lymphoma (NHL) was 1.1%, and the risk of developing any type of leukemia was 2.8% at 15 years after diagnosis. The investigators found that the relative risk of leukemia was proportional to the alkylating agent dose score, that is, the cumulative dose of those drugs. The actuarial risk of developing acute myelogenous leukemia 10 years after diagnosis was 11% among pediatric patients treated at Stanford University with low-dose (2500 cGy) RT and MOPP (nitrogen mustard [M], vincristine [O], procarbazine [P], and prednisone [P]) chemotherapy, which has an alkylating agent dose score of 2.[57] The risk was 1.1% 15 years after diagnosis among pediatric patients treated with involved or extended field RT and various chemotherapy regimens that did not contain nitrogen mustard (vincristine, prednisone, doxorubicin, with or without procarbazine; cyclophosphamide, vincristine, prednisone, procarbazine, or methotrexate).[58]

Other investigators have studied the risk of developing SMNs after various chemotherapeutic agent exposures. Tucker and colleagues reported that prior treatment with an alkylating agent increased the risk of developing bone cancer or leukemia (Fig. 66-5) as SMN.[46] De Vathaire and coworkers demonstrated that dactinomycin increased the risk of a bone or soft tissue SMN (relative risk: 8.7).[59] Garwicz and associates reported that treatment with classical alkylating agents (nitrogen mustard, cyclophosphamide, lomustine), nonclassical alkylating agents (procarbazine), vinca alkaloids (vinblastine, vincristine), or prednisone each increased the relative risk of SMN.[21] Only procarbazine increased the relative risk of SMN when it was included in a two-factor multivariate model.[21] Klein and colleagues reported an increased relative risk for SMN with higher doses of several agents, including cyclophosphamide (RR 6.3 for doses >8000 mg/m^2), cisplatinum (relative risk: 2.8 for doses >435 mg/m^2), and 6-mercaptopurine (relative risk: 4.5 for doses >5000 mg/m^2).[60] Neglia and associates reported that treatment with an anthracycline (relative risk: 1.51 for doses of 101–300 mg/m^2; relative risk: 1.44 for doses >300 mg/m^2) or epipodophyllotoxin (relative risk: 2.78 for doses >4001 mg/m^2) did not demonstrate an increased relative risk with increasing alkylating agent dose score or cisplatinum exposure.[6]

The epipodophyllotoxins have been identified as important leukemogens. Pui and coworkers reported the risk of secondary acute myelogenous leukemia (AML) as 4.7% at 6 years after diagnosis among patients treated for acute lymphoblastic leukemia.[61] The risk was substantially higher (19.1%) among patients with T-cell leukemia. These investigators subsequently demonstrated that the risk of secondary AML in this population was related to the administration of epipodophyllotoxins, with the cumulative frequency of AML being 12.3% among those who were treated twice weekly and 12.4% among those who were treated weekly, compared with a frequency of 1.6% among those who were treated with the drug less frequently or not at all (Fig. 66-6).[62]

The risk of secondary leukemias after the treatment of solid pediatric tumors has been linked to treatment with radiation, epipodophyllotoxins, and vinca alkaloids.[25] The onset of secondary leukemia

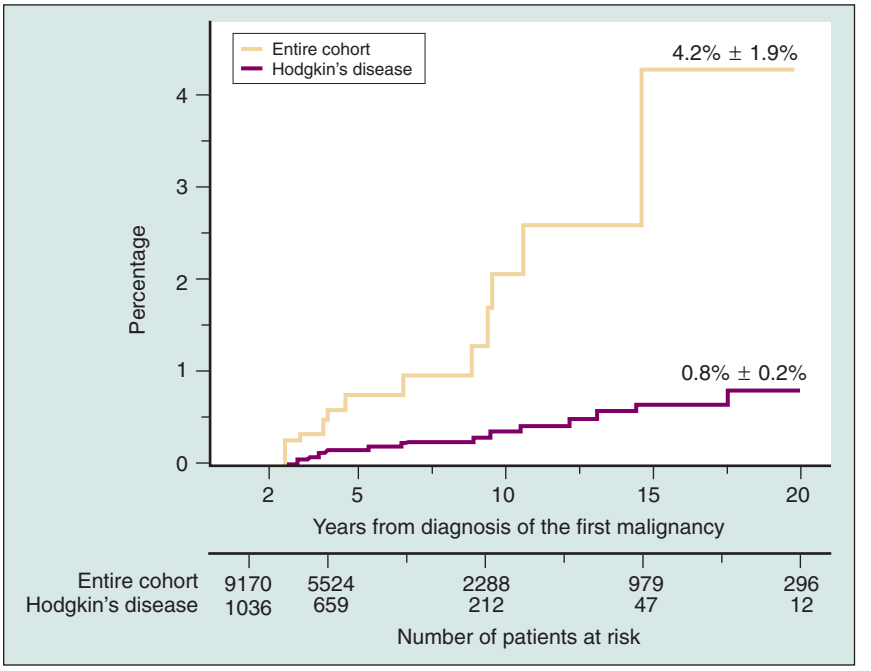

Figure 66-5 • The cumulative incidence of leukemia as a second malignant tumor is increased in children who were treated for Hodgkin's disease compared with those who were treated for other forms of childhood cancer. (Data from Tucker MA, Meadows AT, Boice JD Jr, et al: Leukemia after therapy with alkylating agents for childhood cancer. J Natl Cancer Inst 1987;78:459.)

is generally considered an early event, but Haddy and coworkers noted peaks in the first 10 years and again after 20 years.[25] The risk of secondary AML depends on the cumulative dose of drug administered and the schedule of administration; the frequency was reported to be 0% among germ cell tumor patients who were treated with less than 2000 mg/m^2, 5.9% among childhood acute lymphoblastic leukemia patients who were treated with 1800 to 9900 mg/m^2, 11.3% among germ cell tumor patients who received more than 2000 mg/m^2, and 18.4% among pediatric NHL patients who received 4200 to 5600 mg/m^2.[63–65] Hawkins and associates reported an increased risk of secondary leukemia with increasing cumulative dose of epipodophyllotoxin.[66]

The carcinogenic potential of the anthracycline doxorubicin was suggested by the results of a previous case-control study of risk factors for leukemia as a SMN. Increasing doxorubicin dose was found to be associated with an increasing relative risk of leukemia as a SMN after adjustment for the cumulative dose of alkylators given concomitantly.[67] More recently, prior treatment with anthracyclines or epipodophyllotoxins has been shown to increase the risk of therapy-related acute promyelocytic leukemia and of secondary leukemia or myelodysplasia.[68,69] Patients who received 1.2 to 6.0 g/m^2 of epipodophyllotoxin had a relative risk of developing leukemia of 3.9, whereas those who received more than 170 mg/m^2 of anthracycline had a relative risk of developing leukemia of 3.0.[68] This finding is of

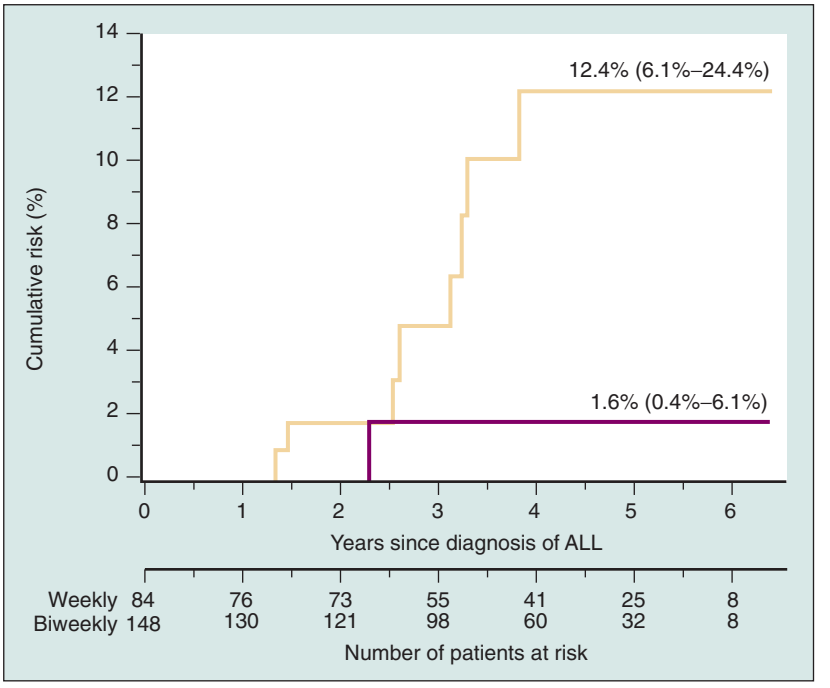

Figure 66-6 • The cumulative incidence of acute myelogenous leukemia after treatment for acute lymphoblastic leukemia is increased among children whose therapy includes weekly epipodophyllotoxin. (Data from Pui C-H, Behm FG, Raimondi SC, et al: Secondary acute myeloid leukemia. N Engl J Med 1989;321:136.)

interest, as doxorubicin is now known to have topoisomerase II as one of its targets—the same target as that of the epipodophyllotoxins. A case-control study of risk factors for bone sarcoma as a SMN did not identify any effect of doxorubicin therapy on the risk of developing such SMNs.[46] An analysis of risk factors for any SMN in a large cohort of pediatric patients with cancer demonstrated that treatment with doxorubicin was the only factor that was identified (other than treatment with carmustine) that increased the risk of a SMN. (This finding apparently extended the earlier suggestion that doxorubicin was leukemogenic.[2]) The evidence in adults will be reviewed later in the chapter.

The leukemogenicity of topoisomerase II inhibitors could be related to the high degree of specificity of these agents for specific DNA targets, including the myeloid-lymphoid leukemia gene and the acute myeloid leukemia 1 (AML1) gene.[70–72]

Although most studies of carcinogenicity of chemotherapeutic agents have focused on the development of leukemia after treatment, it is clear that solid tumor induction is also possible after exposure to one or more chemotherapeutic agents. The best example of this is the occurrence of solid SMNs in genetically predisposed retinoblastoma patients who were treated only with cyclophosphamide after enucleation.[73] As our ability to identify genetically predisposed patients improves, our understanding of the apparent anomaly of solid tumor induction after systemic exposure to a carcinogenic agent will increase.

Immune Suppression

Immune suppression is a component of allogeneic bone marrow transplantation. To prevent graft-versus-host disease, antithymocyte globulin can be administered to the recipient, or the bone marrow can be manipulated to remove T cells. These manipulations and bone marrow transplantation from an unrelated bone marrow donor increase the risk of Epstein-Barr virus-associated B-cell lymphoproliferative disorder. The cumulative incidence rates at 10 years after bone marrow transplantation were 11.3% among those who were treated with antithymocyte globulin, 11.4% among those who received T-cell-depleted bone marrow, and 2.3% among those who received bone marrow from unrelated donors.[74]

Recommendations

Survivors of childhood cancer are at increased risk of developing a new malignancy. The magnitude of this risk is modulated by several factors, including the patient's genetic susceptibility, the type of surgical procedure that is employed for removal of the tumor, the use of RT as part of the treatment plan, the chemotherapeutic agents that are employed, the severity of immune suppression present at the completion of all treatment, and environmental exposures.[75]

All former patients should remain under a physician's care indefinitely and should undergo frequent physical examinations, preferably by a physician or other health care worker who is familiar with the problem of therapy-induced malignancy.

Patients who have been irradiated should have plain radiographs obtained whenever local pain occurs in a previously irradiated bone. Patients who have received irradiation to volumes that include the breast, uterine cervix, or intestine should undergo routine evaluation with available screening tests, such as mammography, Pap smear, and stool examination for the presence of occult blood. Annual mammography should be initiated no later than 10 years after breast irradiation. Careful physical examination of irradiated patients will facilitate the early identification of thyroid nodules and skin cancer.

All patients who have been treated with an alkylating agent, procarbazine, or a topoisomerase II inhibitor should have a complete blood count every 6 to 12 months for a minimum of 12 years after diagnosis. The presence of macrocytosis and/or cytopenia should prompt evaluation of the bone marrow.

The adverse health consequences of tobacco use, including carcinogenesis, are well documented. Unfortunately, childhood cancer survivors are only slightly less likely to use tobacco.[76,77] Physicians should counsel childhood cancer survivors about the potential for the adverse effects of tobacco use to interact with the adverse effects of their prior therapy, such as irradiation of the oropharynx, esophagus, and/or lung.

ADULTS

Genetic Factors

Travis provides an excellent, comprehensive overview and update of research concerning SMNs focusing on solid tumors in the adult age group.[78] She stresses that several factors besides chemotherapy, RT, and their interplays need to be considered. For example, the complex potential interactions of alkylating agents, RT, and tobacco smoking are developed extensively in her discussion of lung cancers as SMNs, especially in HD patients. She points out the additional variable in HD patients (i.e., impaired immunologic responses), so that data derived from long-term survivors of HD cannot be extrapolated with confidence to patients with other SMNs. Studies of second cancers can help point to common genetic mechanisms. For example, a study of secondary pancreatic cancers showed an increased propensity of pancreas cancer to occur not only after tobacco-associated cancers, but also after breast cancer (male and female) and ovarian cancer, which are associated with BRCA2 mutations.[79]

The potential importance of immunodeficiency in the appearance of SMNs was the hypothesis explored by Hemminki and coworkers in an imaginative epidemiologic investigation.[80] They noted that skin cancers and NHLs were the most frequent malignant lesions to appear in immune-deficient patients (e.g., in renal transplant patients who were given needed post-transplant immune-suppressing agents). Using the Swedish nationwide database, they found 4301 secondary skin cancers and 1672 NHLs in a period of about 40 years among 10.2 million survivors of a primary cancer. The researchers found increased risks—up to 12-fold depending on patient sex and primary tumor site—for these two neoplastic entities. These results suggest that immunodeficiency could play a role in the appearance of SMNs.

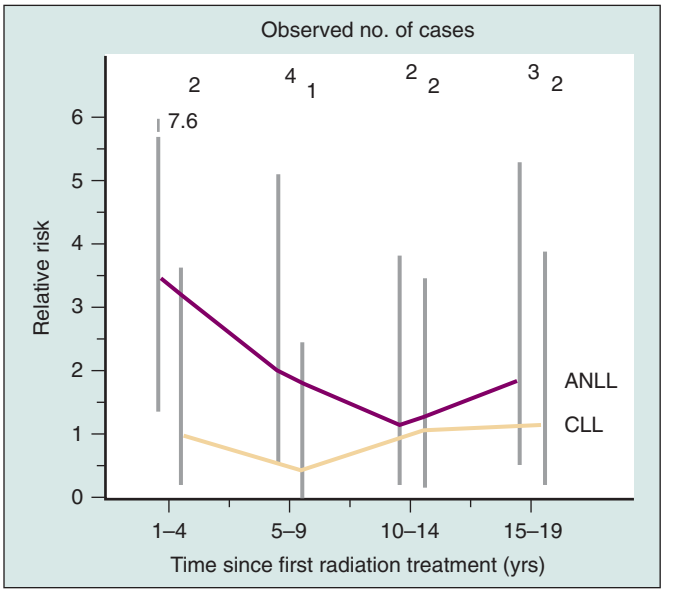

Figure 66-7 • Schematic illustration of risk factors for second primary cancers. ANLL, acute nonlymphoblastic leukemia; CLL, chronic lymphoblastic leukemia. (Data from Storm HH: Second primary cancer after treatment for cervical cancer. Later effects after radiotherapy. Cancer 1998;61:679.)

Several sites of primary tumors in both males and females were encompassed in their study, making therapy-induced immunosuppression unlikely. This conclusion points to possible underlying genetic factors as contributory influences (Box 66-1).

The importance of the Li-Fraumeni syndrome as a risk factor for cancer in young adults has been discussed previously.[75] Cancer families provide evidence supporting laboratory studies of the genetic bases of adult cancers. Cancer predisposition genes for breast cancer (BRCA1, BRCA2), colon cancer (MSH1, MSH2, APC, DCC), malignant melanoma (CDK2), and renal cell carcinoma (RCC) have all been identified.

Box 66-1. EVALUATION FOR PATIENTS AT RISK FOR SECOND MALIGNANT NEOPLASMS

Risk Factors
- Treatment with radiation therapy, an alkylating agent, and/or a topoisomerase II inhibitor
- History of hereditary retinoblastoma (unilateral with a positive family history or bilateral)
- Carrier of ataxia-telangiectasia
- Postsurgical chronic lymphedema
- Ureterosigmoidostomy
- Estrogen treatment

History
- Pain in any previously irradiated area
- Bruising
- Gum bleeding
- Pallor
- Easy fatigability
- Breast lump
- Cough
- Chest pain
- Hemoptysis
- Blood in stool
- Constipation
- Tenesmus
- Hematuria
- Increased urinary frequency/incontinence
- Difficulty voiding
- Intermenstrual bleeding

Physical Examination
- Pallor
- Petechiae
- Chronic skin ulceration
- Presence of lump (mobility, tenderness, consistency)
- Asymmetric breath sounds
- Nodule in prostate
- Abnormal uterine cervix

Evaluation
- Plain radiographs of any painful area or mass in a previously irradiated area
- Stool examination for occult blood (any patient who received any abdominal irradiation)
- Pap smear
- Urine cytology (in any patient with hematuria and a history of bladder irradiation and/or treatment with a cyclophosphamide or ifosfamide)
- Mammogram
- Additional tests as indicated by the history and physical examination

At the clinical level, carriers of the ataxia-telangiectasia gene (ATM) are more likely to develop cancer; Swift and colleagues estimate a 3 to 4 excess relative risk of cancer in male and female carriers.[81] Female breast cancer was the most frequent cancer reported (excess risk of about 5) and was more likely to occur in those exposed to ionizing radiation. Little and coworkers compared the relative risks of developing post-therapeutic irradiation SMNs to those among Japanese survivors of the atomic bomb blasts.[82] They found the relative risks of developing leukemia or lung, bone, or ovarian cancer to be higher among the Japanese survivors than among treated patients. Neither chemotherapy nor underlying genetic factors seemed to play a role in their results.

The cytogenetics of SMNs have been the subject of intensive investigation. Le Beau and associates described characteristic abnormalities of chromosome 5(del (5q)) and 7(del (7q)) in patients with treatment-associated acute myeloid leukemia.[83] (The terms *acute myeloid leukemia* [AML] and *acute nonlymphoblastic leukemia* will be used interchangeably in this discussion. In most cases, the term that is used will be the one employed by the authorities being cited.) Detourmignies and colleagues found t(15;17) in treatment-associated acute promyelocytic leukemia (t-APL) and the other forms of acute myeloid leukemia (t-AML), the same translocation as is found in those diseases de novo.[84] In addition, t(8;21), t(9;11) and inv[16] were found in t-APL and other t-AMLs. They tend to arise in patients with solid tumors, have short latent periods, and are associated with prior therapy with drugs that inhibit topoisomerase II. Cytogenetic evaluations of solid SMNs have demonstrated chromosome 22 deletions in meningiomas and deletions in chromosomes 10 and 17 in malignant astrocytomas.[85,86] These cytogenetic findings could have important implications regarding early identification and early treatment of SMNs.

Treatment Factors

Surgery

In adults, perhaps the most common SMN ascribed to surgery is angiosarcoma in a lymphedematous structure (Stewart-Treves syndrome), a complication that has been described most often after radical mastectomy.[87] The tumors tend to arise in the edematous arm rather than in irradiated areas.[88] Marchal and coworkers conducted a survey of breast angiosarcomas that develop in women who were treated with breast-conserving techniques.[89] They found 9 cases among almost 20,000 women but found no conclusive evidence linking therapy as a causative factor.

Radiation Therapy

Lindsay and colleagues have reviewed the factors involved in radiation carcinogenesis.[90] Breast, thyroid, bone, soft tissues, and organs and tissues that are prone to develop SMNs after RT given in childhood are also vulnerable to radiation oncogenesis when treatment is given during the adult years (Fig. 66-7). The dose-response relationship has classically been described as bell-shaped: an initial increase with low and moderate radiation doses to a peak followed by a rapid decrease at higher doses due to killing of the vulnerable cells. The observed rate for second cancers after radiation of Hodgkin's disease has been higher than predicted, and Sachs and Brenner proposed a model using normal cell repopulation to account for high cancer rates after higher radiation doses.[91] Precise RT dose-response relationships remain murky, in part owing to limited data about the true RT doses at observed SMN sites.

LYMPHOMA. Survivors of Hodgkin's disease are at increased risk for a variety of cancers, especially lung, colorectal, and breast cancer, all of which were more common in those who were treated with chemotherapy and radiation.[92] In fact, a leading cause of death among long-term survivors of HD is second cancer. Treatment of HD has served as a model for therapeutic radiation-induced carcinogenesis,

especially the risk for breast cancer.[91,93,94] Wendland and colleagues studied secondary breast cancers in 8036 females with HD from Surveillance, Epidemiology and End Results (SEER) registries. Second breast cancers were seen in 2.3%, and the standardized incidence ratio was 1.9 for women treated with RT.[94] Interestingly, the breast cancer-free survival curves crossed for irradiated and nonirradiated patients. There was a paucity of early breast cancers in the radiated group, but an increased incidence over time. This was modeled best with a nested proportional hazard model, possibly owing to a therapeutic effect on pre-existing tumors combined with induction of latent tumors. Travis and colleagues[93] studied 3817 female 1-year survivors of HD and noted an age- and dose-dependent cumulative risk of breast cancer development that was lower in patients who were treated with alkylating agents. In their model, women who were treated at age 25 would have an estimated cumulative absolute risk of breast cancer of 1.4% by age 35, 11% by age 45, and 29% by age 55. Projections from these studies should be taken with caution, however, owing to decreases in the dose and volume radiated in the modern era.

A SEER study of 77,876 patients with NHL showed that irradiated patients had a similar risk of SMNs compared with unirradiated patients (relative risk: 1.04).[95] The SMN types differed, with more sarcomas, breast cancers, and mesotheliomas occurring in irradiated patients. Younger patients had an increased relative risk for SMNs, which was more pronounced in irradiated patients.

BONE AND SOFT TISSUE. The largest follow-up study of second cancers in patients with soft-tissue sarcoma primaries (N = 6,671) comes from the Swedish Family-Cancer Database, which identified 650 second cancers (9.7%).[96] The median time to second cancer was 7 years, and the standardized incidence ratio was 1.42 (95% CI: 1.31 to 1.53). The most common second cancer was another soft-tissue sarcoma. Although 10 of 39 were at the same primary site, the majority occurred at different anatomic sites. A weakness of this database is the lack of treatment information, so Ji and colleagues did a reverse analysis, which showed an increased rate of second soft-tissue sarcomas after any primary tumor as well (1.92, 95% CI: 1.78 to 2.07).[96] This suggests that factors other than treatment, such as genetic predisposition and environmental risk, also play an important role.

Lagrange and coworkers reported 80 radiation-associated sarcoma cases collected by a consortium of French cancer centers.[97] The median dose of RT was 50 Gy (range: 9 to 110 Gy) delivered to adults (median age: 44 years) for a variety of primary diagnoses. Of the histologically proven secondary sarcomas, 70% were bone and 30% were soft-tissue sarcomas, osteosarcomas and malignant fibrous histiocytomas predominating among them. Unlike the earlier study by Tountas and colleagues,[98] these authors could not demonstrate a correlation with increasing dose. The outcomes were poor despite aggressive treatment based largely on surgical maneuvers.

HEAD AND NECK. In the head and neck, second primary tumors are commonly observed as a result of premalignant field changes due to environmental risk factors, such as tobacco. A multicentric, case-control study of laryngeal and hypopharyngeal cancers showed an average second cancer rate of 2.1% per year. A higher risk was associated with tobacco, alcohol, and butter consumption, whereas citrus fruit consumption was protective.[99] An attempt has been made to prevent second cancers with antioxidant therapy in a randomized, placebo-controlled trial.[100] Unfortunately, α-tocopherol did not lower the overall recurrence/second cancer rate and actually increased the rate in the first 3.5 years.

In an analysis of 326 consecutive patients with nasopharyngeal carcinoma who were treated with definitive RT, 5.2% developed second primary cancers at a rate of 1% per year.[101] Only about one third of these were in-field, and there was not an association with the total prescribed dose. The only second tumors that occurred after 5 years were within the radiation field, supporting the concept of a lag time for radiation-induced solid cancers.

GYNECOLOGIC. Storm reviewed the frequency of SMNs in a cohort of 24,970 Danish women with invasive cervical cancer and 19,470 who had carcinoma in situ followed for 30 or more years.[102] Taken together, there was an increased relative risk of 1.9 in irradiated patients who survived 30 or more years, representing an excess of 64 cases per 10,000 women annually (see Fig. 66-7). Werner-Wasik and coworkers analyzed the frequency and patterns of SMNs in women with cervical cancer and came to a different conclusion.[103] They found 11 SMNs among 10 of the 125 women with FIGO stage I and II cervical carcinoma who received RT in a recent 10-year period (1980 to 1990). All of the SMNs were outside the fields of irradiation, and none of the women had received chemotherapy. The researchers concluded that the increased relative risk of a SMN might be genetically based, as the administered treatments did not appear to be factors. The Werner-Wasik report again emphasizes the need to consider the multiple possible contributing factors to oncogenesis (see Fig. 66-7).

Sturgeon and associates found an excess of SMNs among women with vulvar or vaginal cancers.[104] Most of the SMNs were smoking-related (lung, upper airways) or in patients infected with the human papillomavirus, which is known to be associated with cancers of the genital tract. A related observation by Hemminki and Dong is of interest; they found an increase in anal cancers in both women with cervical cancer and their husbands, implicating human papillomavirus in the etiology of anal cancer.[105]

Hall and colleagues found an increased risk of ovarian cancer as a SMN in certain sets of women.[106] These were women younger than 50 years of age with melanoma or cancer of the colon, breast, cervix, uterine corpus, or ovary. The relative risks ranged from about 5 to almost 20.

Bergfeldt and coworkers could not substantiate a reputed increase in breast cancers among women with ovarian cancer.[107] Their case-control study from a pool of 5060 Swedish women led them to conclude that increased surveillance (mammography) of surviving patients with ovarian cancer was not warranted. Travis and associates likewise attributed secondary breast cancers to factors other than therapy, although they attribute soft-tissue, bladder, and rectal malignancies to RT and leukemia to chemotherapy.[108]

Buiatti and colleagues reported a population-based study of second primary cancers.[109] They considered only the 463 metachronous SMNs that developed among the 19,252 adults with primary cancers of the colon, rectum, lung, stomach, and female breast who constituted the study population. Significantly higher risks of developing another cancer were found in patients under 65 years of age. Associations of three types were found:

1. Between primary rectal and secondary kidney cancers
2. Between colon and later ovarian malignancies
3. Between female breast and subsequent rectal cancers, although cancer in the opposite breast constituted the highest risk in this group

No correlations were made between the treatments that were used for the primary tumor and the secondary cancer. This report, together with that of Werner-Wasik and associates,[103] highlights the fact that SMNs should not all be assumed to have an iatrogenic basis.

GENITOURINARY TRACT. The incidence of second neoplasms resulting from RT for prostate cancer is controversial. Movsas and associates found no increase in the risk of SMN among 543 of their patients when compared with a matched set of 18,135 men derived from the Connecticut Tumor Registry.[110] Most of the SMNs developed outside the RT fields and were associated with lifestyles that were predisposing to cancer. Johnstone and colleagues also found no definite increase.[111] Groups using the SEER database have found

conflicting results.[112–115] In comparison to patients who were treated only with surgery, there was a small but significantly increased risk of in-field tumors, especially bladder and rectal cancers, following RT.[112,113] However Moon and colleagues also found an increased risk of second cancers outside the field and in men who were treated with transurethral resection of prostate alone.[115] These results suggest the researchers did not adjust for all relevant factors. In fact, when Cox modeling was used and adjusted for attained age, no significant excess risk from RT was found.[114,116]

SMNs occurring in men with testicular cancers have been studied by several investigators. Wanderas and associates found an increased risk of second germ cell cancer, usually of the same histology, among 2201 patients, the risk being highest among men younger than 30 years of age at first diagnosis.[117] More SMNs than expected were found by Ruther and colleagues in their multicenter collection of men with pure seminomas.[118] These included both nontesticular and testicular SMNs. Other researchers, who have studied larger numbers of patients, have documented increased relative risks for gonadal and nongonadal carcinomas of 1.2 to 2.3. Higher risks were recorded for leukemia (relative risk: 2.4) and soft-tissue sarcomas (relative risk: 3.0).[119] The SMNs tended to develop in irradiated fields.

Travis and coworkers showed that men who were treated for testicular cancer had a persistent increased risk of second cancers (relative risk: 1.9) in a large cohort study of 40,576 survivors.[120] SMNs of the lung, colon, bladder, pancreas, and stomach accounted for almost 60% of the excess cancers. The risks of cancer 40 years after treatment were 36% for seminomas and 31% for nonseminomas compared to 23% for the general population to age 75. Richiardi and associates also found an elevated risk of second cancers with a standardized incidence ratio of 1.65 compared to population controls in a cohort of 29,511 patients with testicular cancer.[121] Interestingly, they found a markedly increased risk of myeloid leukemia, especially in nonseminomas that were diagnosed after 1990 (standardized incidence ratio: 38). The elevated risk in these patients could be due not only to genetic and environmental factors, but also to outdated RT techniques in which extended fields were used even for early-stage disease.[122]

BREAST CANCER. After a diagnosis of breast cancer, the risk of second cancers is increased in general in comparison to population controls. A study of 335,191 women with either invasive or noninvasive breast cancer revealed a second primary rate of 12% for women who were diagnosed before age 50 and 17% for women who were diagnosed over age 50.[123] Noteworthy is the fact that the standardized incidence ratios for second cancers actually decreased with age, suggesting that genetic mechanisms play a role. The patterns of second cancers, namely, second breast, bone, colorectal, sarcoma, leukemia, lung, ovarian and thyroid cancer, have a shared pattern of risks with BRCA1, BRCA2, p53, and PTEN mutations.[123] In a study of 491 female carriers of either BRCA1 or BRCA2 mutations, the risk of contralateral breast cancer was 29.5% at 10 years, with BRCA1 carrying a higher hazard than BRCA2.[124] Studies of second malignancies after male breast cancer have similarly shown increased rates compared to population controls, especially breast, gastrointestinal, and prostate cancers, but unlike female breast cancer, the risks increased over time.[125,126]

In women who had been treated uniformly with wide local excision, axillary dissection, and postoperative irradiation, the cumulative 10-year SMN rate was 16% in the 1253 women who were reviewed, about half of whom had second breast malignancies.[127] A 20-year analysis of 1801 similarly treated women showed a contralateral breast cancer rate of 15.4%, the majority (83%) of which were the invasive type.[128]

The contralateral breast does receive some radiation dose during breast RT. It is in the range that is known to be carcinogenic, especially in young women.[129] A case-control study of 41,109 women with breast cancer showed an attributable contralateral breast cancer risk of only 2.7% from prior irradiation.[130] Some of the more important variables that were considered in the analyses are shown in Table 66-1. An increase in relative risk was observed in irradiated women surviving 10 or more years, but only in those who had been treated when under 45 years of age (relative risk: 1.85). The risk among this sample increased with increasing RT dose, the analyzed range extending from 1.99 Gy to 4 Gy, and the relative risks from 1.54 to 2.35, respectively ($P = 0.003$).

The use of adjuvant RT appears to increase the risk of both contralateral breast and other cancers (skin, lung, colon, and esophagus) in some,[131–134] but not all studies.[135] Additional evidence for an increased risk of esophageal cancer after breast cancer has been found in population-based studies.[136,137] This may be attributable to the radiation field that was used to include the internal mammary nodes. Although the absolute risk from RT of breast cancer is small, the doses to the contralateral breast and mediastinum can and should be reduced by using modern RT techniques.

NERVOUS SYSTEM. Jones conducted an extensive retrospective analysis of brain tumors occurring in patients after RT for pituitary lesions, a unique group that receives relatively high doses of RT for nonmalignant lesions.[138] He concluded that the risk of RT oncogenesis in adults is low after small-field RT in the doses usually used for the control of pituitary disorders. When both irradiated and unirradiated adults with pituitary tumors who developed regional fibrosarcomas, gliomas, and meningiomas were compared, the role of therapeutic RT in the genesis of such SMNs became questionable. Erfurth and associates not only find no clear evidence implicating RT, but also again raise the possibility that underlying genetic factors are responsible.[139]

LEUKEMIA. The risk of secondary leukemia is greatest within the first several years after radiation, whereas the risk for solid tumors generally becomes evident thereafter. Although relatively rare, an excess absolute risk of AML was detected in patients who have been treated for HD.[140] The excess risk was greatest in the first 10 years after treatment and subsequently remained elevated. In cervical cancer patients, Storm described a significantly increased relative risk of acute nonlymphoblastic leukemia (relative risk: 3.5), manifest in the early postirradiation years but not of chronic lymphoblastic leukemia (CLL).[102] The relative risk decreased by the 10th year after diagnosis, and the incidence approximated that of the general population by the 15th year after diagnosis. This was unlike the experience with solid tumors, in which relative risks continued to increase with time.

Table 66-1 Relative Risk of Contralateral Breast Cancer after Radiation Therapy

Age at Treatment (10-Year Survivors)	No. Exposed	Total No.	Relative Risk (95% Confidence Interval)
<45 yrs old	45	143	1.85 (1.15–2.97)
>45 yrs old	55	298	1.08 (0.74–1.57)

Data from Boice JD, Harvey EB, Blettren M, et al: Cancer in the contralateral breast after radiotherapy for breast cancer. N Engl J Med 1992;326:781.

Intensity-Modulated Radiotherapy and Proton Radiotherapy

Technological advancements in RT over the past several decades have led to safer, more tolerable treatment. Intensity-modulated radiotherapy (IMRT) has been popularized in recent years owing to the ability to shape the irradiated volume in three dimensions. This permits both a limitation of doses to adjacent normal structures and an increase in the dose to critical diseased sites that need a boost, allowing for dose escalation opportunities. A disadvantage of IMRT is higher integral body doses, resulting both from the spreading of a low dose to a greater volume and from longer treatment times with the attendant increase in incidental irradiation due to machine head leakage. Higher integral doses have led to concerns about a possible increased risk of fatal SMNs; indeed, these have been calculated to be 1.7% for conventional treatment compared to 2.1% for IMRT.[141] These worries were echoed by Hall, who also pointed out a potentially increased risk of SMNs from proton RT due to neutron contamination of the proton beam.[142] Proton RT has the advantage of no exit dose, but the most common method of proton field generation, passive scattering, is associated with a higher level of neutron contamination. Active scanning proton RT has less neutron contamination than passive scattering and is predicted to deliver a lower integral dose than photon IMRT. Hall's neutron contamination calculations and SMN risk for passive scattering proton RT were widely criticized as being based on outdated equipment.[143] The point still stands, however, that active scanning proton RT may provide the best conformality with the lowest risk of SMNs, despite a very high price tag.[144]

Radionuclide Therapy

Unlike external beam RT that is aimed to a particular site, radionuclide therapy is delivered intravenously and any localization is a result of specific affinities. Although the use of radioimmunotherapy for lymphoma with radiolabeled anti-CD20 antibodies is on the rise, the most experience with radionuclide therapy has been with I-131 for thyroid cancer. In a pooled European cohort of patient with primary thyroid cancers, patients who were treated with I-131 were found to have an increased incidence of bone, soft-tissue, colorectal, and salivary gland cancers.[145] A multinational record linkage study of 39,002 patients with primary thyroid cancer demonstrated an increased risk of second cancers both after and before treatment for the thyroid cancers.[146] A similar observation was seen in both the SEER database and a cohort from Leiden University Medical Center, indicating that common genetic and environmental risk factors are probably more important than I-131 causation.[147,148]

Chemotherapy

LEUKEMIA–LYMPHOMA. Most of the SMNs reported after chemotherapy have been AML or NHL. The alkylating agents were the first to be implicated in the etiology of these SMNs and remain the most frequently implicated agents.[149,150] Subsequently, the leukemogenicity of the nitrosoureas was recognized.[151] Greene and colleagues estimated the increased relative risk of AML in patients with brain tumors who had been given carmustine to be about 25.[152] More recently, other agents have been associated with AML. These include the epipodophyllotoxins, the platinum compounds, and their combinations.[25,153]

AML that developed in women with ovarian cancer who had been given alkylating agents was one of the first iatrogenic chemotherapy-related SMNs to be reported in convincing numbers.[150] The relative risk reported by Reimer and associates was more than 170 for women who received alkylating agents compared with those who did not. That estimate was updated by Greene and colleagues, who found a relative risk of 110 and the excess risk of acute nonlymphoblastic leukemia to be 5.8 cases per 1000 women per year.[154] Melphalan and chlorambucil were the two agents that were most strongly implicated (relative risks of 122 and 159, respectively), the risk of leukemia being dose-related.

Kaldor and coworkers published an international case-control study in 1990 of women with ovarian cancer and reported increased risks of leukemia in those who had received cyclophosphamide, chlorambucil, melphalan, thiotepa, or dihydroxybusulfan (treosulfan) as single agents.[155] The relative risks, which increased with larger administered doses, ranged from 2.2 for low-dose cyclophosphamide to 23.0 for chlorambucil and melphalan and 33.0 for treosulfan in high doses as defined by the researchers. The risk estimates were relative to those of women who received only RT or surgery, no increased leukemia risk being identified in patients who had RT alone. The risk of leukemia was also increased in patients who were treated with the combination of doxorubicin and cisplatin. Kaldor and coworkers concluded that at least one of the two drugs was leukemogenic.[155] The controversies that are engendered by large-scale studies of this kind are reflected in the editorial that accompanied the article and the brisk correspondence that followed.[156,157]

Travis and associates underscore these issues by their findings regarding the 4402 10-year survivors among the 32,251 women with ovarian cancer on whom they collected data.[108] They found 1296 SMNs rather than the expected 1014 in such a cohort, the cumulative risk at 20 years of follow-up being 18.2% versus the 11.5% expected in the general population. Although leukemias appeared to be related to chemotherapy and cancers in infradiaphragmatic sites appeared to be related to RT, there were also increased risks of tumors in other sites—for example, breast cancer and ocular melanoma—that are not obviously related to the treatments that were used. Travis and associates therefore postulated genetic or other factors that predispose to ovarian cancer as being responsible.[108] In this way, they echo the surmises of Werner-Wasik and colleagues concerning the genetic bases of SMNs that develop in women with cervical cancer.[103]

Fisher and coworkers reviewed the extensive experience that had accumulated in women who were treated for breast cancer following the protocols of the National Surgical Adjuvant Breast and Bowel Project (NSABP).[158] Using data from the SEER registry for comparison, they reported a relative risk of 24.0 for AML among all patients who were treated with surgery and chemotherapy. The risk was found to be 39.3 among patients under 50 years of age compared with a relative risk of 19.9 among those age 50 or older. The relative risks of AML were 2.6 among all women who were treated with surgery only and 10.3 among those who were treated with surgery and RT. These data confirm the leukemogenicity of melphalan, the alkylating agent that was employed in the chemotherapy trials conducted by the NSABP.[155] Curtis and associates reported the relative risks for acute nonlymphoblastic leukemia or myelodysplastic syndrome of 10.0 and 17.4 among unirradiated and irradiated patients with breast cancer, respectively, who were treated with an alkylating agent.[159]

Greene reviewed the evidence concerning the carcinogenicity of cisplatin in animals and humans and provided a concise survey of the oncogenic potential of other chemotherapeutic agents that are in common use in adults with cancer.[153] He pointed out that cisplatin has many of the properties of an oncogene and is carcinogenic in animal systems, where its effects can be reversed by MESNA (2-mercaptoethane-sulfonate). The evidence implicating cisplatin as a leukemogene in humans is found in situations in which it has been used together with etoposide or doxorubicin. It is not clear whether cisplatin is a cofactor in leukemogenesis when used with other drugs or whether these other drugs, rather than cisplatin, are responsible.

AML, usually of French-American-British M5 morphology, which has a characteristic translocation that involves 11q23, has been detected in patients who were given topoisomerase II inhibitors.[160,161] The anthracyclines, epipodophyllotoxins, and dactinomycin are such inhibitors.[161] Detourmignies and colleagues implicated inhibitors of topoisomerase II in their report of therapy-associated acute promyelocytic leukemia (t-APL).[84] They pointed out that the same translo-

cation, t(15;17), can be identified in both de novo and treatment-related acute promyelocytic leukemias that develop after therapy with drugs of this class.

van Leeuwen provided an extensive analysis of AML and myelodysplasia that developed after cancer treatments of various kinds and at different ages.[162] In general, the findings authoritatively confirm the observations of others in that chemotherapy was found to be more leukemogenic than was irradiation, and the latent periods for the appearance of nonlymphatic leukemias after therapy with topoisomerase II inhibitors and with alkylating agents tended to be short (<5 years) and long (5 to 10 years), respectively. There has been a recent report of a 23-year interval between treatment of HD and the appearance of secondary erythroleukemia. This was attributed to the alkylating agents that were used as part of the HD therapy.[163] van Leeuwen's detailed analyses by original tumor type, treatments employed, and age factors are worthy of careful reading by students of this problem.[162]

SOLID TUMORS. Solid tumors are not often associated with anticancer drugs. Greene listed four breast carcinomas among the few solid tumors that appeared in cisplatin-treated women without there being a convincing causative relationship.[153] A dose-effect relationship between alkylating agent treatment and the occurrence of secondary bone sarcomas was identified in children, and there have been several reports of urothelial carcinomas in adults who were treated with cyclophosphamide.[164] Although the data of Fairchild and coworkers[165] and others[166] suggested that cyclophosphamide was not a significant etiologic factor for bladder cancer, Travis and associates reported a relative risk of 4.5 of bladder cancer among patients with NHL who were treated with cyclophosphamide.[167] The relative risk increased with increasing cumulative dose, being 6.3 for cumulative doses of 20 to 49 g and 14.5 for cumulative doses of 50 g or more. Topical nitrogen mustard has been held responsible for the appearance of skin cancers in patients with mycosis fungoides treated in that way.[168]

HODGKIN'S DISEASE. There is a voluminous literature concerning the leukemias, NHLs, and solid tumors that are encountered in adults with HD, often with conflicting reports. The major focus here will be placed on two recent comprehensive analyses of the solid tumor and leukemia risks.[169,170]

Dores and colleagues assessed the relative and absolute excess risks of site-specific SMNs in long-term HD survivors.[169] They analyzed data from 32,591 HD patients, including 1111 25-year survivors, and found 1726 solid tumors among those patients. Cancers of the lung, gastrointestinal tract, and female breast were the most frequently observed. The actuarial SMN rate among 25-year survivors was approximately 20%, the risk being about the same in all age groups. Of interest was an apparent decrease in SMN risk after the 25th year of survival. Brusamolino and coworkers reviewed the leukemia risk in HD survivors.[170] Their 1659-patient sample was analyzed according to age, splenectomy, combined modality therapy, and cumulative drug doses, especially of alkylating agents, including nitrosourea derivatives. The overall actuarial risk of leukemia at 15 years was 4.2%, with two peaks. These occurred at 3 and 8 years after initiation of therapy, and the curve flattened at 12 years. The risks after RT alone, chemotherapy alone, and combined modality treatments were 0.3%, 2.8%, and 5.4%, respectively. Risks were higher among patients who had received extended field RT, lomustine, or mechlorethamine. Neither age nor splenectomy proved to be a significant independent variable. No leukemias were found in patients who were treated with ABVD (adriamycin, bleomycin, vinblastine, dacarbazine).

SECONDARY NON-HODGKIN'S LYMPHOMA. The cumulative incidence rate of secondary NHL among HD patients increased during the first 5 years after treatment before reaching a plateau. These findings were not correlated with any specific treatment or combinations of therapies. Swerdlow and colleagues[171] suggest that immunosuppression could be a contributing factor to the occurrence of secondary NHL in HD patients, most if not all of whom have long been known to be immunologically impaired at diagnosis.[172]

Immunosuppression

Immunosuppressive drugs and the human immunodeficiency virus have been linked to lymphomas and other tumors.[173,174] Kinlen and associates were among the first to conduct a systematic study of cancers appearing in patients who had been given immunosuppressants.[173] In 1979, they reported an increase in the risk of NHL (especially in the brain) in renal transplant recipients (relative risk: 58.6). A large study of SMNs in patients with either primary or secondary NHL showed bidirectional effects with several potentially virally linked cancer sites, suggesting a role for immune suppression. Bone marrow transplantation entailing iatrogenic immunosuppression has also been linked to SMNs.[175–177] Curtis and colleagues[175] reported that bone marrow transplant survivors are at risk of developing solid tumors with the passage of time. Their analyses were based on 20,000 bone marrow transplant recipients; many different types of SMNs were encountered, including brain and thyroid tumors. These developed only in patients who had been given brain and total body irradiation. The highest risk was in young children (<10 years of age). In contrast, a smaller cohort of 926 patients with long follow-up showed that recipients over 40 years of age and those with female donors were at higher risk of SMNs, and there was no impact from total body irradiation.[176]

Hosing and associates discussed the risks of myelodysplastic syndrome and acute myelogenous leukemia (AML) after therapy.[178] They studied almost 500 patients with NHL who received high-dose chemotherapy and autologous stem cell transplantation and found 22 patients with myelodysplastic syndrome or AML. The risk was highest among patients who received total body irradiation together with cyclophosphamide and etoposide.

Prolonged immunosuppression is associated with the appearance of skin cancers. Liddington and coworkers reported cutaneous carcinomas (mostly of the squamous cell type) in renal transplant patients and estimated the increase in risk to be approximately 100-fold.[179]

Hormones

Hormones and hormonal manipulations have been held responsible for oncogenesis. Various second tumors have been reported in men with prostatic cancer who were treated with estrogens. These include breast cancers, hepatomas, and desmoids.[180–182] In women, the use of oral contraceptives that emphasize the estrogenic component has been held responsible for the subsequent appearance of endometrial cancer. Thus, female patients with cancer who are managed by hormonal manipulations or women who use hormone-based contraceptives may be at an increased cancer risk.[183]

Recommendations and Conclusions

The recommendations that were made previously for children apply equally to adults, suitably modified for the age group. In adults particularly, for whom the prognosis often is worse than that for children, the potential risk of a second malignant process should not lead to therapeutic compromises when treatment, often aggressive, is of known benefit. Further SMN research must take into fuller account possible contributory genetic, immunologic, environmental, and other factors beyond which drugs and what RT doses were used.

ACKNOWLEDGMENTS

The authors thank Mrs. Diane Piacente and Mrs. Lee Sucher for preparation of the manuscript.

H. SPECIAL POPULATIONS

67 Cancer in the Elderly: Biology, Prevention, and Treatment

Lodovico Balducci and Claudia Beghé

SUMMARY OF KEY POINTS

Incidence

- Cancer in the older person is increasingly common.
- Data on prevention and management of cancer in the older person are limited.

Epidemiology of Aging and Cancer

- The older population continues to expand as a result of reduced mortality and birth rates. Currently, 60% of all malignancies occur in persons aged 65 and older, and this proportion is expected to rise to 70% by the year 2030. Although cancer-related mortality is declining among younger persons, it is increasing among the oldest ones.
- Of special interest, cancer appears to affect mainly older persons who are otherwise healthy and would have lived longer were it not for the cancer.

Aging and Carcinogenesis

The association of cancer and age may be explained by three mechanisms that are not mutually exclusive:

1. Carcinogenesis is a time-consuming process, the end-product of which, cancer, is more likely to develop at an advanced age.
2. Aging is associated with molecular changes that mimic carcinogenesis; older cells are primed to the effects of environmental carcinogens.
3. Aging is associated with environmental phenomena such as immune senescence or proliferative senescence that favor the development of cancer.

Aging and Cancer Biology

The biology of common malignancies such as breast cancer, ovarian cancer, non-Hodgkin's lymphoma, and acute myelogenous leukemia (AML) may change with age. In some cases, the tumor may become more indolent, whereas in others, it becomes more aggressive. Two mechanisms underlie these changes:

1. The biology of the tumor cells (e.g., the prevalence of MDR1 in AML increases after age 60, associated with a worse prognosis).
2. The aging of the patient: An age-related increase in circulating concentrations of interleukin-6 (IL-6) may favor the growth of lymphomas, whereas hormonal senescence may inhibit the growth of breast cancer.

Assessment of the Older Person

- Aging involves a progressive shortening of life expectancy and reduction in the functional reserve of multiple organ systems.
- Personal and social resources to cope with stress may become more limited.
- Reduced life expectancy and reduced stress tolerance lessen the benefits and enhance the risks of medical intervention.
- A comprehensive geriatric assessment (CGA), evaluating the patient's function, comorbidity, cognition, nutrition, medications, and living resources, is a currently available, reliable instrument for predicting life expectancy and the risk of treatment-related complications.
- The CGA may unveil pre-existing situations or conditions such as undiagnosed disease, poor nutrition, depression, or lack of adequate social support that are remediable and may influence the outcome of treatment.
- A number of laboratory tests, including assays of circulating levels of IL-6 and D-dimer, and tests of physical performance may complement the CGA.

Cancer Prevention

- Older persons may be primary candidates for chemoprevention of cancer, but none of the current chemopreventive agents have demonstrated efficacy definitively.
- Screening asymptomatic patients for cancer of the breast and of the large bowel appears to be reasonable when the life expectancy is 5 years or longer.

Cancer Treatment

- *Surgery*: Age by itself, up to 100 years, does not appear to increase the surgical mortality rate, although the risk of surgical complications and length of postoperative hospitalization increase with age. Age is a definitive risk factor for death related to emergency surgery.
- *Radiation therapy*: Tolerance for radiation therapy seems to remain high, even for persons aged 80 and older.
- *Cytotoxic chemotherapy*: The main pharmacologic changes of age include decreased excretion of drugs and of their active metabolites from the kidneys; decreased volume of distribution of water-soluble drugs, which may in part be accounted for by anemia; increased susceptibility to myelodepression, mucositis, and peripheral and central neuropathy; and cardiomyopathy. The National Cancer Center Network (NCCN) has issued the following guidelines for the management of older cancer patients:
  1. Dose adjustment according to the individual patient's glomerular filtration rate (GFR), for persons aged 65 and older
  2. Prophylactic use of filgrastim or pegfilgrastim for patients aged 65 and older treated with combination chemotherapy of dose intensity comparable to that of the cyclophosphamide-doxorubicin-vincristine-prednisone (CHOP) regimen
  3. Maintenance of hemoglobin levels of 12 g/dL or greater

INTRODUCTION

The progressive aging of the population is an epidemiologic hallmark of our times. People 65 years of age and older represented 12% of the U.S. population in 1990; the percentage in this age group is expected to grow to 20% by 2030.[1] The segment of the older population undergoing the most rapid growth is that older than 85, the so-called oldest old.

Aging is the most important risk factor for cancer. The incidence of common malignancies increases with age—in fact, currently more than 60% of all neoplasms occur in persons aged 65 and older[2] (Fig. 67-1), and this proportion is expected to increase to 70% by 2030. Today, cancer is the main cause of death among persons up to the age of 85.[2] Clearly, improved cancer control involves effective management of cancer in older adults.

This chapter explores the association between cancer and aging, the influence of aging on cancer biology, and prevention and treatment of cancer in older persons, after reviewing the biologic and clinical aspects of aging. This information is presented as a frame of reference allowing the practitioner to estimate risks and benefits of preventive and therapeutic interventions in each patient.

BIOLOGY OF AGING

Molecular and Cellular Biology

Cellular aging observed in vitro (in the culture plate or test tube) is associated with a number of molecular events, of which some may favor and others may inhibit the development of cancer. Formation of DNA adducts, DNA hypermethylation, and point mutation[3] mimic the early stages of carcinogenesis, are associated with activation of oncogenes and inhibition of antiproliferative genes, and may prime the aging cell to the effects of environmental carcinogens, which explains, in part, the association between cancer and age. Other changes, including a progressive reduction in telomere length and telomerase activity[4] and activation of the *P14* antiproliferative gene, encoding the CDK16 inhibitor, are contrary to those observed in neoplastic cells.[5] Of special interest are age-related abnormalities in protein synthesis, with reduced activity of DNA-repairing and drug-metabolizing enzymes, which may both accelerate carcinogenesis and enhance the complications of cytotoxic chemotherapy in normal tissues.[6]

Paradoxically, proliferative senescence may enhance the risk of cancer, because the senescent cells lose the ability not only to replicate

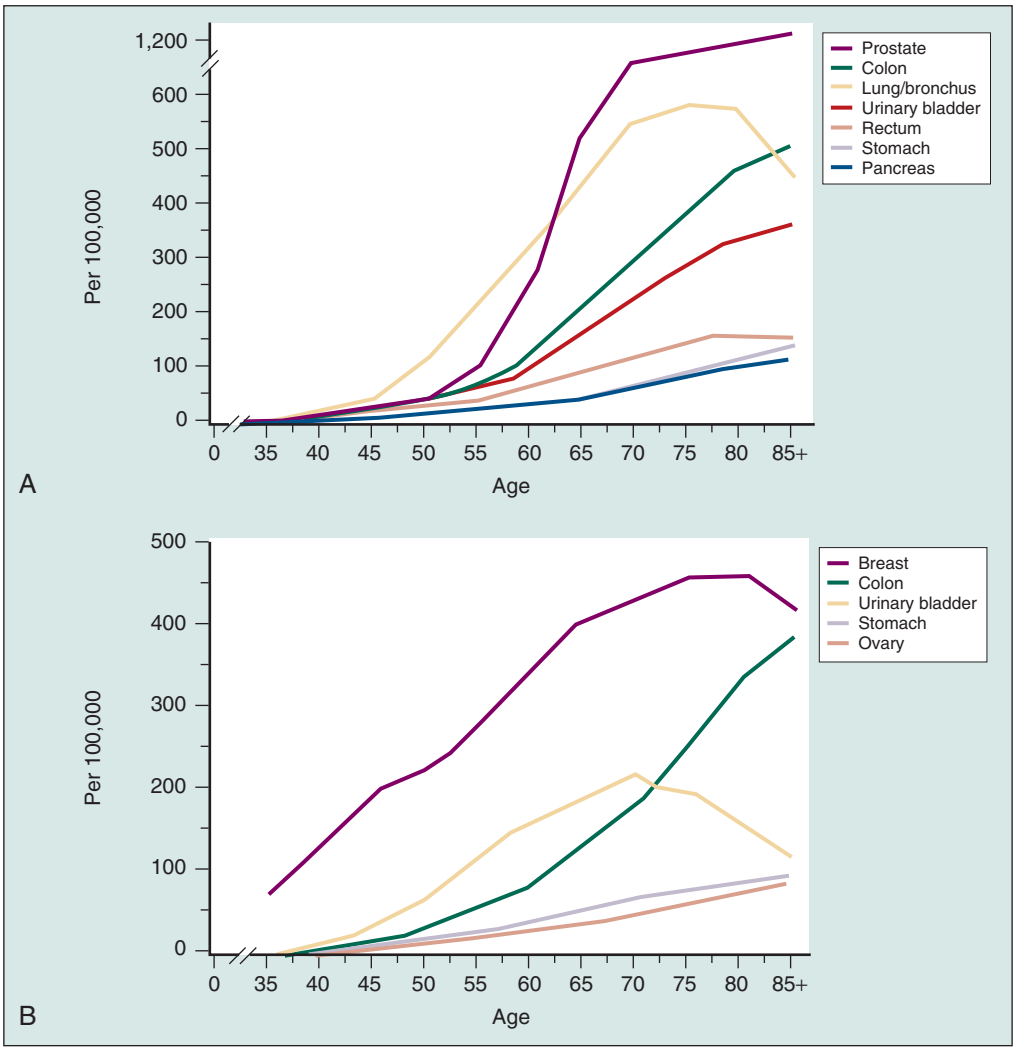

Figure 67-1 • Incidence of different neoplasms with age. **A,** Men. **B,** Women.

themselves but also to undergo apoptosis—thereby acquiring immortality and its inherent risks.[7,8] Proliferative senescence also is associated with the production of tumor growth factors and of proteolytic enzymes that may favor metastatic spread.[7,8]

Physiology of Aging

Aging involves a progressive reduction in the functional reserve of multiple organ systems, with reduced tolerance of stress, including cancer and cancer treatment. The mechanisms may include increased prevalence of chronic diseases[9]; progressive accumulation of catabolic cytokines, including the interleukins IL-6 and IL-10 and tumor necrosis factor in the circulation[10]; and reduction in the stem cell reserve of different tissues.[11] Catabolic cytokines appear to be pivotal in physiologic aging: Their accumulation is associated with increased prevalence of geriatric syndromes,[12] increased risk of mortality and functional decline,[11] and a generalized catabolic status.[13]

From the standpoint of cancer treatment, the most significant changes include gastrointestinal, renal, hepatic, hematopoietic, and mucosal changes, which may alter the pharmacokinetics of antineoplastic agents and may increase the risk of complications from cancer treatment.

BIOLOGIC INTERACTIONS OF CANCER AND AGING

Aging may affect tumor biology at two levels: carcinogenesis and tumor growth.

Aging and Carcinogenesis

The association of aging with carcinogenesis may be explained by at least three mechanisms: duration of carcinogenesis, increased susceptibility of aging tissues to environmental carcinogens,[3] and changes in body environment, including proliferative senescence[7] and immune senescence.[14] Both experimental and epidemiologic findings support the theory that aging tissues are more susceptible to environmental carcinogens. Several murine tissues, including cutaneous, hepatic, lymphatic, and nervous tissues, have been found to be more likely to develop cancer after exposure to carcinogens if they are obtained from older animals.[3] In humans, the incidence of some cancers, such as nonmelanomatous skin cancer and prostate cancer, increases geometrically with age, suggesting enhanced carcinogenesis.[2] In addition, the incidence of some neoplasms, including non-Hodgkin's lymphomas,[15] anaplastic astrocytomas, and glioblastoma multiforme,[16] has increased several-fold among older adults during the past 30 years, suggesting that older persons may be more susceptible than younger ones to new environmental carcinogens. In the Italian city of Trieste, Barbone and coworkers found that the incidence of lung cancer after exposure to environmental pollutants increased in relation to the patient's age at the time of exposure.[17] The increased susceptibility of older people to environmental carcinogens indicates that primary cancer prevention, including elimination of environmental carcinogens and chemoprevention, may be particularly effective in this population. This is a new concept, directly opposed to common wisdom, which has held that preventive interventions are less efficacious for older persons.

Aging and Tumor Growth

Aging may influence tumor growth at two levels, the neoplastic cell itself and the host environment in which the tumor grows. It is reasonable to expect a concentration of more indolent tumors among older persons (Fig. 67-2), by a process of natural selection. This is certainly the case with breast cancer, because the prevalence of well-differentiated, hormone receptor-rich tumors increases with age.[18]

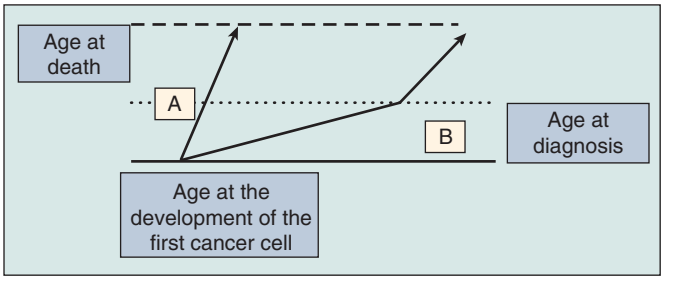

Figure 67-2 • The prevalence of more indolent tumors may increase with age for a process of natural selection. In this diagram, two persons start developing cancer, both at the age of 35 years. One cancer (A) is very aggressive and will manifest at age 37 and cause death at age 39. The other (B) is very indolent, will not manifest until age 65, and will not cause the patient's death until age 75. By a process of natural selection, by which the bearers of more aggressive tumors die earlier, a higher prevalence of indolent tumors can be expected among older persons.

The influence of the tumor host on cancer growth was demonstrated in a now-classic experiment by Ershler and coworkers, who demonstrated that the same loads of Lewis lung carcinoma and of B16 melanoma were associated with shorter survival and higher incidence of metastasis in younger animals than in older animals.[19] In successive studies, these investigators demonstrated that the tumor growth rate seemed to decrease for poorly immunogenic and increase for highly immunogenic tumors as the host age increased, highlighting the influence of immune senescence on tumor growth. In humans, Kurtz and colleagues demonstrated a reduction in the growth rate of primary breast cancer among older women, related directly to the degree of mononuclear cell reactions.[20] This observation suggested that immune senescence may mitigate tumor growth in poorly immunogenic tumors.

The clinical behavior of several human malignancies may change with the age of the patient.[21] Table 67-1 reveals that the biology of both the tumor cell and the tumor host may influence the change in prognosis. Another important observation is that in some instances, the prognosis becomes worse with age, in contrast with the generally held view. In any case, age by itself should not be considered a prognostic factor. If it is true that approximately 80% of breast cancers in women aged 70 and older are rich in hormone receptors, the converse also is true: 20% of cancers in women in this age group are not rich in hormone receptors, and appropriate treatment may require the use of cytotoxic chemotherapy. If MDR1 is present in 67% of patients older than 60 years with AML, it also is true that 33% of these patients have a disease responsive to chemotherapy and potentially curable. Each case should be treated on its own merits on the basis of an estimate of risks and benefits.

CLINICAL EVALUATION OF THE OLDER PATIENT

The benefit of cancer prevention and cancer treatment may be reduced and the risk enhanced in the older person, owing to a simultaneous reduction in life expectancy and in the tolerance of medical interventions. The basic questions of geriatric oncology include the following:

- Is the patient going to die with cancer or of cancer?
- Is the patient going to suffer the consequence of cancer during his or her lifetime?
- Is the patient able to tolerate cancer treatment?
- What are the long-term consequences of cancer and cancer treatment in older persons?

Table 67-1 Age and Changes in Cancer Prognosis

Neoplasm	Age-Related Changes in Prognosis	Mechanism(s)
Acute myelogenous leukemia[73]	Worse with age	Neoplastic cell
	Increased resistance to chemotherapy	Increased prevalence of MDR1-expressing cells
	Increased mortality during induction	Increased prevalence of stem cell leukemia
Non-Hodgkin's lymphoma[21]	Worse with age	Tumor host
	Decreased duration of complete remission	Increased circulating concentration of interleukin-6
Breast cancer[20]	More indolent disease	Neoplastic cell
		Increased prevalence of hormone receptor-rich, well-differentiated tumors
		Tumor host
		Decreased production of sex hormones
		Immune senescence
Celomic ovarian cancer[21]	Worse with age	Unknown
	Decreased remission duration	
	Decreased survival	
Non-small cell lung cancer[21]	Better prognosis with age	Unknown
	Presentation at an earlier stage	

The issue of long-term consequences has become highly relevant as the percentage of older cancer survivors has increased. For example, the Cancer Acute Leukemia Group B (CALGB) recently reported that the risk of adjuvant chemotherapy-related acute leukemia increases with age and may be as high as 1.7% for women 65 and older.[22]

The life expectancy and functional reserve of the older person may be estimated with a comprehensive geriatric assessment (CGA; Table 67-2) to determine the patient's level of functioning and to identify any coexisting medical conditions (e.g., comorbidity, geriatric syndromes, polypharmacy, malnutrition) and the social resources available to ensure compliance with and safety of cancer treatment.[23] In addition, the CGA may unearth unsuspected conditions that interfere with the treatment of cancer, including malnutrition, polypharmacy, cognitive and emotional disturbances, and inadequate social support.[23–25]

General Principles of Geriatric Assessment

In general geriatrics, the CGA has succeeded in reducing the rates of functional dependence and of admission to the hospital and to adult living facilities.[23,24] In geriatric oncology, the CGA may unearth conditions that may compromise cancer treatment. In a pilot study involving 15 women aged 70 and older with early breast cancer, the performance of the CGA resulted in, on average, an additional 17.2 interventions per patient.[26] Three studies exploring the effects of CGA in older cancer patients demonstrated some degree of functional dependence in approximately 70% of those patients; some degree of comorbidity in more than 70%; and dementia, malnutrition, and depression in approximately 20%.[27–29]

The CGA also helps the practitioner to make a gross estimate of the patient's life expectancy and expected tolerance of treatment. Life expectancy declines with the degree of functional dependence and also with the seriousness of comorbid conditions and geriatric syndromes.[30,31] One group of researchers have devised a "frailty index," based on functional deficit, comorbidity, and social support, from which they calculate the functional rather than chronologic age of each patient.[32] This instrument may become particularly useful for the classification of older patients with cancer enrolled in clinical theapy trials. Two studies demonstrated that the risk of chemotherapy-induced myelosuppression increased for patients who were dependent in some instrumental activities of daily living (IADLs).[33,34]

Thus, the CGA provides a common language for use in the classification of older patients undergoing cancer treatment or enrolled in clinical trials. A recurrent term that needs clarification is

Table 67-2 Comprehensive Geriatric Assessment and Clinical Implications

Assessment Component	Clinical Implication(s)
Functional status	
Activities of daily living (ADLs) and instrumental activities of daily living (IADLs)	Relation to life expectancy, functional dependence, and tolerance of stress
Comorbidity	
Number of comorbid conditions and comorbidity indices	Relation to life expectancy and tolerance of stress
Mental status	
Folstein Mini-Mental Status Examination	Relation to life expectancy and functional dependence
Emotional condition	
Geriatric Depression Scale (GDS)	Relation to life expectancy; may indicate motivation to receive treatment
Nutritional status	
Mini Nutritional Assessment (MNA)	Reversible condition; possible relationship to survival
Polypharmacy	Risk of drug interactions
Geriatric syndromes	
Delirium, dementia, depression, falls, incontinence, spontaneous bone fractures, neglect and abuse, failure to thrive, vertigo	Relation to survival and functional dependence

frailty, which commonly is associated with aging. At a recent consensus conference supported by the National Institute on Aging and the American Geriatrics Society, frailty was defined as a syndrome with multiple causes and involving multiple organ systems, characterized by increased vulnerability to stress and associated with sarcopenia, increased concentration of inflammatory cytokines in the circulation, and decreased motility and decreased ability to perform complex movements.[35] The conference recognized the existence of multiple signs of frailty and agreed to adopt for the time being the definition of the frail phenotype that emerged in the Cardiovascular Health Study (CHS).[36] On the basis of five parameters: weight loss of at least 10 pounds over 6 months, reduced energy levels, difficulty in initiating movements, reduced gait speed, and decreased strength of the hands, the CHS recognized three phenotypes with different life expectancy and risk of functional dependence. These phenotypes are (1) *fit*, with no abnormalities; (2) *pre-frail*, with one or two abnormalities; and (3) *frail*, with three or more abnormalities. It is worthy of emphasis that the definition of frailty will evolve with better insight in the biology of this syndrome. In the meantime, the CHS classification also may be helpful for classification of patients enrolled in clinical trials.

CLINICAL ASPECTS OF GERIATRIC ASSESSMENT

Function

Function is assessed on the basis of performance status (PS), activities of daily living (ADLs), and IADLs. The ADLs include transferring, bathing, dressing, eating, toileting, and continence; dependence in one or more of these functional areas, with the exception of continence, is associated with a 2-year mortality rate of approximately 40%.[23–25,37] The IADLs are those activities necessary to maintain an independent life, including use of transportation, shopping, and the ability to take medications, to provide one's own meals, to use the telephone, to manage personal finances, and to take care of laundry and housecleaning. Dependence in one or more IADLs (with the exceptions of laundry and housecleaning) is associated with a 2-year mortality rate of 16%[23–25,37] and a 50% risk of developing dementia within 2 years.[38] In addition, dependence in IADLs is associated with increased risk of neutropenia from cytotoxic chemotherapy.[33,34] In two prospective studies, functional dependence and PS appeared poorly correlated; consequently, it is recommended that they be evaluated independently.[27,28]

Comorbidity

Comorbidity is an independent cause of mortality for older patients with cancer[9] and may be associated with reduced tolerance of cancer treatment. The best way to assess comorbidity is still being investigated. Satariano and Ragland identified seven conditions associated with reduced life expectancy and demonstrated that the risk of mortality increased with the number of comorbid conditions.[39] Other investigators have devised comorbidity scales that take into account the degree of severity of each condition. Of these, the Cumulative Index of Related Symptoms–Geriatrics (CIRS-G) proved in some studies to be the most sensitive.[40] Another advantage of the CIRS-G is that its final score may be translated into the score of another scale in common use in epidemiologic studies, Charlson's scale.

Anemia is of special interest among the comorbid conditions[41] because its incidence and prevalence increase with age. Anemia is an independent risk factor for death and for myelosuppression from cytotoxic chemotherapy,[42] is a main cause of fatigue and functional dependence,[41] and may be associated with congestive heart failure and dementia.[41] An unsolved question is what level of hemoglobin defines anemia. Of special interest is the finding by the Women's Health and Aging Study that hemoglobin levels lower than 13.4 g/dL were an independent risk factor for death among 556 home-dwelling women aged 65 and older, evaluated on a prospective basis for a period of 8 years.[43] Similar findings were reported in the CHS.[44] In patients with cancer, anemia was associated with reduced survival and increased risk of functional dependence.[45]

Geriatric Syndromes

Geriatric syndromes include a number of conditions typical, if not specific, of aging, such as dementia, depression, delirium, incontinence, vertigo, falls, spontaneous bone fractures, failure to thrive, and neglect and abuse. Geriatric syndromes are associated with reduced life expectancy.[23–25] To be considered a geriatric syndrome, the condition must interfere with the affected person's daily life. Dementia must be moderate to severe; delirium must occur as a result of medications or organic diseases that do not commonly affect the central nervous system (e.g., urinary or upper respiratory infections); incontinence must be complete and irreversible; and falls must occur at least three times a month, or the fear of falling must prevent regular activities such as walking. Depression is of special interest because it is associated with decreased life expectancy, even when it is subclinical.[46] Depression also interferes with treatment compliance and in many cases may be fully reversible by medication. A simple 15-item questionnaire, the Geriatric Depression Scale 15 (GDS 15), speedily and reliably identifies persons with subclinical depression and is part of the CGA.[46]

Social Resources

Pivotal among the social resources ideally available to the older patient is the home caregiver. The ideal caregiver should be able to recognize and manage emergencies, to support the patient physically and emotionally, to mediate conflicts among family members, and to act as spokesperson for the family with the health care provider.[47] Under the best circumstances, the caregiver is the practitioner's best ally in ensuring compliance with treatment and smooth interactions with the patient. For this reason, it behooves the practitioner to participate in the selection, training, and support of the caregiver. In reality, the caregiver of an older person often is an older spouse with health problems of his or her own, or a married daughter who needs to balance her caregiving duties with other family and work responsibilities.

Nutrition

The prevalence of protein-calorie malnutrition increases with age. Isolation, depression, economic restriction, and reduced appreciation of hunger may all contribute to insufficient food intake, and chronic diseases and inflammatory cytokines may impede the synthesis of new proteins.[35] The Mini Nutritional Assessment (MNA) is a simple nutritional screening test used worldwide that identifies patients who are malnourished and those at risk of becoming malnourished, thereby permitting the prevention and early reversal of malnutrition.[48]

Polypharmacy

The prevalence of polypharmacy increases with age and, among cancer patients aged 70 and older, has been found to be as high as 41%.[23–25] The problem of polypharmacy exemplifies a common problem of elderly patients in developed countries: the absence of a primary care provider.[49] According to a recent study, more than 50% of people 70 years of age and older in the United States, Canada, and Israel, although attending multiple specialty clinics, lacked a primary care physician.

Other Forms of Geriatric Assessment

The CGA is the standard form of geriatric assessment, but it may be complemented by laboratory data and by so-called proofs of physical performance levels (Box 67-1).

Box 67-1. ASSESSMENT OF OLDER PERSONS: SCREENING TESTS

The comprehensive geriatric assessment (CGA) is time-consuming. A number of provisions that save office time may render its use more cost-effective. Proposed strategies include the following:

- Home assessment, in which questionnaires are mailed to the patient at home and completed before the office visit. The advantage is reduction of the visit time. Disadvantages include dependence on self-reported function and comorbidity, inability to self-assess cognition, and, in a significant proportion of patients, inability to complete the questionnaire.
- Administration of screening tests before the visit, with a more complete CGA then performed for patients for whom screening gives a positive result. The Vulnerable Elderly Survey 13 (VES 13), one of the best-validated screeing tests, can be completed in less than 1 minute. This is our favorite approach because it saves time and has been validated with functional and survival outcomes. Potential disadvantages include disagreement among clinicians on a cutoff score above which the result is considered positive and lack of a way to provide information about comorbidity, nutrition, cognition, and emotional disorders.
- Use of laboratory tests or physical performance tests to identify patients at risk for death and disability. This approach is promising but needs validation and should be considered at present to be in clinical trials.
- An additional issue is the age at which screening should begin. We have selected the age of 70 years, because previous studies have shown that the steepest increase in prevalence of age-related changes is seen between the ages of 70 and 75.

Laboratory Markers of Aging

The recognition that the concentration of catabolic cytokines in the circulation increases with age and usually is correlated with the presence of geriatric syndromes prompted a number of studies aimed at establishing whether these substances may predict functional dependence and decreased survival. In a recent study, Cohen and coworkers demonstrated that increased concentrations of either IL-6 or D-dimer were associated with a 50% increase in the risk of functional dependence and death.[50] When the concentration of both substances was elevated (with values in the upper quartile), however, the risk increased more than threefold.

Tests of Physical Performance

Difficulty in performing some activities is considered a predictor of functional dependence and disability. Of particular interest, a study has shown that the risk of mortality and functional dependence in older persons can be predicted by the "get up and go" test.[51] In this test, the patient is asked to get up from an armchair and walk 10 feet forward and then back to the chair. Both inability to get up without using the chair arms and requiring more than 10 seconds to walk the distance are highly predictive of functional decline.

Issues Related to Geriatric Assessment

A number of issues related to the application of the CGA in clinical practice merit further study. Among these are the questions of which patients should undergo a CGA, who should perform the test, and whether the complete test is always necessary.

Who should undergo a CGA? In three prospective studies of patients with cancer aged 70 and older, the CGA unearthed a number of conditions that were reversible and could interfere with cancer treatment.[27–29] On the basis of these findings, the NCCN recommended some form of CGA for all patients with cancer aged 70 and older.[25]

Who should perform the CGA? Ideally, the CGA should be performed by a primary care provider at periodic intervals, and the results should be part of the patient's permanent record. Any physician involved in the management of older patients should be familiar with the principles of CGA and its interpretation.

Is a full CGA necessary in all patients? Because the CGA is time-consuming, more cost-effective alternatives have been explored. Their value has not yet been determined. These include the use of a screening instrument to identify patients at high risk for functional dependence,[25] including questionnaires and tests of physical functioning.[1] The problem with both of these, however, is that they do not provide any direct assessment of comorbidity, depression, cognition, and social resources. Another interesting approach, proposed by Ingram and coworkers, involved sending to the patient's home a package including questionnaires about function, comorbidity, depression, and social resources.[29] The CHS assessment appears to be one of the most suitable ways to classify older patients involved in clinical trials: It is simple to execute, time-saving, and widely accepted and has been validated in a population of 8500 subjects.[37] For persons classified as prefrail and frail, a more in-depth assessment may be in order.

CANCER PREVENTION IN OLDER PERSONS

Some aspects of aging favor and others interfere with cancer prevention. Because the incidence of cancer increases with age, the elderly presumably would be the population most likely to benefit from cancer prevention. At the same time, reduced life expectancy and decreased tolerance of chemopreventive therapy may lessen the benefits of some types of prevention. The study of cancer prevention in older persons is complicated by a lack of general agreement on what represents a meaningful endpoint: Should it be reduction in cancer-related mortality, as commonly accepted in prevention trials, or should it instead be an improvement in quality of life, in view of the limited life expectancy for this population?[52] This section provides a brief review of the evidence supporting chemoprevention and early detection of cancer among older persons.

Chemoprevention

At least three groups of substances, the selective estrogen receptor modulators (SERMs), the retinoids, and the nonsteroidal anti-inflammatory drugs (NSAIDs), have demonstrated cancer preventive activity in randomized clinical trials,[53] but these substances are used to only a limited degree in current clinical practice for cancer prevention. The SERM tamoxifen has a number of potential adverse side effects, including endometrial cancer, deep vein thrombosis, strokes, and vasomotor and genitourinary manifestations of menopause, the incidence of which increases with age.[53] In a decision analysis, Gail and coworkers calculated that tamoxifen may be beneficial for women aged 70 if their risk of developing breast cancer over 5 years is as high as 7% and if they do not present other contraindications to the drug; the threshold of risk at which this agent may be beneficial increases with the age of the patient.[54] Recently it was shown that raloxifen was as effective as tamoxifen in preventing breast cancer and had fewer side effects.[55]

Older persons may be ideal candidates for inclusion in future studies of chemoprevention in view of their increased risk of cancer, but none of the current options for chemoprevention appear to be optimal.

Screening and Early Detection

Because the prevalence of common cancers increases with age, the positive predictive value of screening tests might be expected to

increase as well.[52] At the same time, older persons have in general undergone screening for common cancers earlier in life. Previous examinations may have eliminated all prevalence cases and minimized the diagnostic yield of subsequent examinations.

Breast Cancer

Most of the randomized controlled studies on breast cancer detection have established that serial mammograms reduce by 20% to 30% the cancer-related mortality rate among women aged 50 to 70.[56] The benefits of mammography after age 70 have been suggested by three reports. A historically controlled cohort study, the Nijmegen study, showed a reduction in cancer-related mortality up to age 75[57]; a retrospective study of the Survey Epidemiology and End Results (SEER) data showed a more than twofold decrement of breast cancer-related mortality for women aged 70 to 79 who had undergone at least two mammograms after age 70[58]; and another retrospective analysis of the same data showed that women older than 70 who had not undergone screening mammography presented with breast cancer at a more advanced stage than that typical for women who had been screened.[59]

An important question is the role of clinical examination of the breast (CBE). The Canadian study suggested that CBE may be as effective as screening mammography in women aged 50 to 60,[60] and the Breast Cancer Detection Demonstration Project (BCCDP) showed that mammography was superior to CBE only in the diagnosis of ductal carcinoma in situ (DCIS).[61] The CBE appears particularly attractive for older women who undergo multiple clinic visits in the course of the year, because it may be performed with no additional cost and inconvenience.

Colorectal Cancer

Early detection of cancer of the large bowel reduces cancer-related mortality among persons aged 50 to 80, but controversy lingers concerning the most appropriate screening strategy.[52] According to a decision analysis by Frazier and associates, full colonoscopy every 10 years is more cost-effective than yearly examination of the stool for fecal occult blood or more frequent flexible rectosigmoidoscopy.[62] A more recent decision analysis by Lin and colleagues[63] claiming that colonoscopy in persons aged 80 and older has negligible benefit may be misleading: These researchers failed to take into account individual life expectancy and functional reserves, which are highly diverse at that age. Virtual colonoscopy, which appears to be as sensitive as endoscopy, may be a more comfortable alternative for older persons.

Prostate Cancer

The value of screening asymptomatic men for prostate cancer with serial determinations of prostate-specific antigen (PSA) level, and the most cost-effective screening strategies, are controversial.[53] If screening is instituted, it should be continued up to age 75, because a Swedish study has demonstrated that radical prostatectomy reduces prostate cancer-related mortality in men up to age 75.[64]

Other Cancers

No benefits of screening women older than 60 for cervical cancer have been recognized if the women have undergone regular Papanicolaou examinations of the cervix earlier in life[53] and have had normal results. Interest in screening ex-smokers for lung cancer has been renewed by the demonstration that helical (spiral) computed tomography is able to detect small and curable cancers.[52] This approach remains controversial but may be of particular interest in older persons, because the incidence of lung cancer is increasing after age 80, probably because smoking cessation has resulted in a decrease in early coronary deaths and an increase in indolent lung cancers.[65]

Clearly, early detection of breast and colorectal cancer may reduce mortality among older persons and may improve their quality of life. It appears reasonable to institute some form of screening for persons whose life expectancy is 5 years or longer, because the initial benefits of screening are seen after 5 years.

CANCER TREATMENT

Surgery

Although surgical mortality and the risk of other surgical complications increase with the age of the patient, elective surgery appears to be safe in general, even in patients older than 80 years.[66] Persons 70 years of age and older are substantially more vulnerable to the complications of emergency surgery, especially surgery related to the digestive tract. In this population, regular screening for colorectal cancer may minimize the incidence of emergency surgery. A number of recent advances in surgery and anesthesia have rendered cancer surgery even safer for older persons. These include more limited surgical excisions (e.g., transanal resection of rectal cancer) and the use of anesthetic agents with a shorter half-life and minimal respiratory suppression.[67]

Radiation Therapy

Two large patient series from Europe and one from the United States attest to the feasibility and safety of radiation therapy in patients of all ages.[68–70] Combined chemotherapy and radiation therapy in the management of cancers of the head and neck, the esophagus, the bladder, and the lung also appear to be well tolerated up to the age of 80 at least. Among the newer radiation techniques, brachytherapy and high-dose intraoperative irradiation are of special interest for treatment in older patients: Brachytherapy minimizes the risk of complications to normal tissues, and intraoperative radiation eliminates the inconvenience of serial visits. Data on use of hyperfractionated radiation in older patients are wanted. Among the complications of radiation therapy, mucositis is of special concern in older patients, because age is associated with a more limited reserve of mucosal stem cells and increased proliferation of epithelial superficial cells[71]—two conditions that predispose older persons to more prolonged and severe mucositis. With cancer of the upper airway or upper digestive tract, in which the risk of mucositis is highest, nutritional management is essential and may involve prophylactic insertion of a percutaneous endoscopic gastrostomy tube.[70]

Cytotoxic Chemotherapy

Age is associated with changes in the pharmacokinetics and pharmacodynamics of cytotoxic drugs and increased susceptibility of certain organ systems to therapeutic complications.[71] The pharmacokinetic changes of major interest involve absorption, renal excretion, and volume of distribution of drugs.

The intestinal absorption of nutrients decreases with age, secondary to a reduction in the absorbing surface area, in the splanchnic circulation, and in gastric motility and secretions,[72] but the bioavailability of oral agents (e.g., capecitabine) does not appear to be compromised. Oral drugs are particularly appropriate for older patients because of the convenience of administration and adjustability of doses.

A progressive reduction in GFR is an almost universal consequence of aging, and it may lead to a more prolonged half-life of medications that are excreted from the kidneys (e.g., methotrexate, bleomycin, carboplatin) and of active and toxic metabolites of drugs excreted through other avenues.[71] These metabolites include daunorubicinol and idarubicinol, responsible for approximately 80% of the activity of the parent compounds,[71] and arauridine, responsible for the cerebellar toxicity of high-dose cytarabine.[71] Dose adjustment of these agents to the patient's GFR may improve tolerability.

The volume of distribution (Vd) of a drug is determined by the body composition and the concentrations of serum albumin and of hemoglobin.[71] Hemoglobin is important because most antineoplastic

agents are bound to red blood cells. In the presence of anemia, the free concentration in plasma and toxicity of these substances in the circulation increase.[43] Correction of anemia may then ameliorate the toxicity of chemotherapy. Among the pharmacodynamic changes associated with age, the most significant are the increased prevalence of multidrug resistance, abnormal intracellular metabolisms of drugs, and abnormal repair of DNA damage. Multidrug resistance may be caused by increased expression of the *MDR1* gene, as is the case in acute myelogenous leukemia[73]; increased prevalence of anoxic tumor cells; and resistance to apoptosis.[71] Abnormal drug metabolism and delay in DNA repair may enhance the toxicity of these agents.[6]

Myelosuppression and mucositis are particularly common and severe complications of cytotoxic chemotherapy. The risk of neutropenia and neutropenic infections with moderately toxic chemotherapy (such as the CHOP regimen—cyclophosphamide, doxorubicin, vincristine, and prednisone) increases with age and appears to be particularly marked after age 70; fortunately, hematopoietic growth factors in pharmacologic doses prevent this complication in 50% to 75% of people older than 70 years of age.[74] Neutropenic infection is potentially fatal and may occur after the first course of treatment—a fact that prompted the recommendations to use growth factors prophylactically in patients aged 65 and older.[75]

The risk of mucositis also increases with age, and this complication may be fatal if not treated promptly.[76] A keratinocyte growth factor, undergoing clinical trials, appears promising for the prevention of mucositis.[77] Other interventions to ameliorate this complication include substitution for intravenous fluorinated pyrimidines by capecitabine, which is associated with a lower risk of mucositis, and ensuring adequate hydration for older people in whom diarrhea or severe dysphagia develops.

Targeted Treatment

Treatments targeted to specific tumor components or tumor functions have substantially reduced the risk of therapeutic complications in older patients with cancer.[78] Some words of caution are in order, however:

- In many cases, these compounds are more a complement of than an alternative to cytotoxic chemotherapy. The most noticeable exceptions to this rule are imatinib, desatinib, and nilatinib.
- A number of complications of these agents may be particularly burdensome to older patients, including the risk of hypertension with bevacizumab; the risk of skin reactions with cetuximab, panitumab, and most small molecule inhibitors of receptor tyrosine kinase; and the risk of myelotoxicity related to lenalidomide and radioimmunotherapy.

Hormonal Treatment

Overall, hormonal treatment of cancer is considered much safer than cytotoxic chemotherapy, and the ongoing tendency is to institute chemical castration for PSA "relapses" in prostate cancer. This approach, however, may have a multiple unwanted effects in older men, including osteoporosis, bone fractures,[79] fatigue, anemia, diabetes, and coronary artery disease.[80]

PRACTICAL DECISIONS RELATED TO THE MANAGEMENT OF OLDER PATIENTS

Informed decision making is the key to effective and safe treatment of older patients with cancer. Any oncologic decision has two components: the person and the neoplasm. For example, cytotoxic chemotherapy is rarely indicated in a woman aged 90 or older with stage 1 or 2 breast cancer, in view of the negligible benefit and the substantial risk of treatment. Extermann and coworkers demonstrated that adjuvant chemotherapy is beneficial to an 80-year-old woman when her chances of dying of breast cancer are only about 30%, if a 1% reduction in breast cancer-related mortality is desirable; in a 90-year-old woman, however, the risk of dying of breast cancer must be close to 70% to justify the use of chemotherapy.[81] Chemotherapy seems definitively indicated if the same patient has a chemotherapy-responsive disease that may shorten her survival, such as large cell non-Hodgkin's lymphoma. The algorithm presented in Figure 67-3 depicts a useful frame of reference for the use of chemotherapy in older patients. The two points that deserve emphasis are (1) the rapidly evolving classification of older patients with cancer and (2) the likelihood that chemotherapy may represent the best option for palliation in frail patients. Several agents with minimal toxicity, including capecitabine at low doses, weekly taxanes, gemcitabine, and vinorelbine, may be used safely in these patients.[35]

NATIONAL AND INTERNATIONAL INITIATIVES RELATED TO CANCER AND AGE

The issues of cancer in the older person have been well recognized throughout the Western world and have prompted a number of important responses.

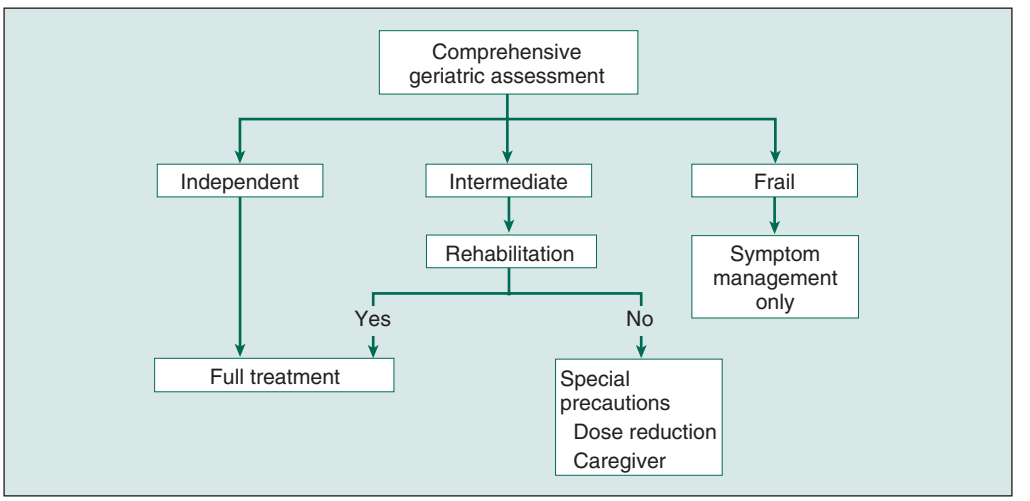

Figure 67-3 • Treatment algorithm for the use of chemotherapy in older persons with cancer.

Governmental Responses

The National Cancer Institute, in cooperation with the National Institute on Aging, has held a number of conferences related to cancer and aging. As a consequence of these conferences, six to eight program grants (P20) for the development of geriatric programs within comprehensive cancer centers have been offered. In addition, a number of requests for proposals for the study of management of cancer in the older person have been offered.

All major cooperative groups in the United States and Europe now have a committee or subcommittee whose aim is promotion of enrollment of older patients with cancer into existing clinical trials and promotion of clinical trials devoted to older persons.

Professional Associations and Private Foundations

The American Association for Cancer Research (AACR), the American Society of Clinical Oncology (ASCO), and the European Society of Medical Oncology (ESMO) have dedicated special scientific and educational sessions to the issues of cancer and aging. ASCO also has developed a special curriculum on cancer and age. Of the private foundations, the Hartford Foundation merits special mention: This body has founded, through ASCO, 12 3-year fellowships for special training in geriatric oncology.

A number of industry-funded cooperative efforts for studying the management of cancer in the elderly also have been developed, including the Geriatric Oncology Consortium in the United States, the Geriatric Radiation Oncology Group (GROG) in Italy, and the Italian Group of Geriatric Oncology (GioGER), which, although it originated in Italy, incorporates the effort of several European countries.

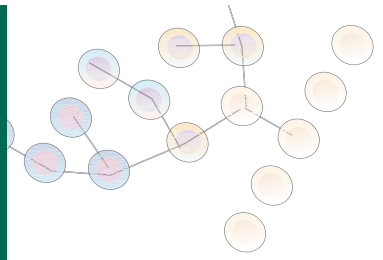
Practice Guidelines

In 1999 the NCCN established a panel for the issuance of guidelines for the management of older patients with cancer. The first set of guidelines (Table 67-3) was published in 2000.[52] These guidelines are based on the available clinical evidence, reviewed in this chapter, and are intended to be used as a frame of reference for clinical practice and as a building block to accommodate emerging data. Other associations, including the EORTC and the Canadian Cancer Institute, are preparing their own guidelines.

Table 67-3 Guidelines for Management of the Older Person with Cancer Established by the National Cancer Center Network

1. All patients aged 65 and older should undergo some form of geriatric assessment before institution of treatment.
2. With compounds that are excreted through the kidneys, or that give origin to active and toxic metabolites excreted through the kidneys, the dose should be adjusted to individual GFRs in persons aged 65 and older. Dose escalation can begin if no evidence of toxicity is encountered.
3. Patients aged 65 and older undergoing moderately toxic chemotherapy (of dose intensity comparable to that of CHOP) should receive prophylactic growth factors (G-CSF or pegylated G-CSF).
4. Hemoglobin levels should be maintained at 12 g/dL or greater with epoietin.
5. Patients aged 65 and older experiencing grade 3 or 4 mucositis should be hospitalized for aggressive fluid resuscitation.

CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; G-CSF, granulocyte colony stimulating factor; GFR, glomerular filtration rate.



CONCLUSIONS

The scope of geriatric oncology includes changes in tumor and patient biology as well as comprehensive evaluation of the older person aimed at establishing life expectancy, treatment tolerance, risk of cancer-related complication, and need for rehabilitative intervention. Biologic changes and CGA are the two poles of preventive and therapeutic interventions. Treatment-related guidelines may help establish a uniform approach to older cancer patients and thus facilitate the interpretation of clinical data. A number of initiatives developed during the past 5 years promote clinical research in older patients with cancer and promise to fill the current gaps in clinical evidence. In no circumstances does age alone represent a contraindication to effective cancer treatment.

68 Special Issues in Pregnancy

Andrew Grigg

SUMMARY OF KEY POINTS

- Cancer complicates 1 in 1000 pregnancies; the most common malignancies are breast and cervical cancer, lymphoma, and melanoma.
- There is no evidence that pregnancy alters the clinical behavior of cancer, but cancer often is advanced at diagnosis owing to the overlap of symptoms with those of a normal pregnancy.
- Important factors in management include assessment of gestational age, maternal staging with limited exposure to ionizing radiation, the urgency for therapy, and the impact of therapy on maternal prognosis and fetal outcome.
- Physiologic changes in pregnancy affect the metabolism of chemotherapy drugs, but there are few practical guidelines about how dosing should be adjusted to take this into account.
- Alkylators and antimetabolites should be avoided in the first trimester, but these agents and other cytotoxics are generally not contraindicated in the second and third trimesters.
- The scheduling of chemotherapy should be planned to minimize the risk of complications at the time of delivery.
- There is no evidence that exposure to chemotherapy results in long-term adverse effects on physical or intellectual development, and there is no increased risk of malignancy in surviving children.
- Therapeutic radiation jeopardizes fetal outcome and should be reserved for the postpartum period when possible.
- Subsequent pregnancy after cancer diagnosis and effective therapy is usually possible.

INTRODUCTION

This chapter focuses on the issues related to the care of cancer diagnosed during the gestational period. Cancer is the second leading cause of death in women between the ages of 20 and 39 and complicates 1 in 1000 pregnancies. The most common cancers diagnosed in pregnant patients are those that are seen in nonpregnant women of similar age: breast, cervix, lymphoma, and melanoma.[1] Although pregnancy is associated with immunologic tolerance, there is no evidence of an increased incidence of cancer or of more aggressive behavior of malignancies that are diagnosed during pregnancy. However, many cancers in pregnancy are diagnosed at an advanced stage, often because symptoms of the malignancy overlap with those that are experienced in a "normal" pregnancy.

FETAL DEVELOPMENT AND PHYSIOLOGY

The three phases of fetal development are implantation, organogenesis, and growth. The implantation phase lasts from conception to 2 weeks and often ends in a spontaneous abortion after exposure to a toxic stimulus. Organogenesis occurs between 2 and 7 to 12 weeks; noxious stimuli at this time may lead to organ dysgenesis, resulting in fetal malformation or death. The growth phase occurs from the second trimester to term; toxic stimuli to the mother and fetus may result in fetal growth retardation, which can be associated with abnormal brain development and subsequent learning difficulties. However, as will be discussed, this has not been demonstrated to be a significant clinical concern in women receiving chemotherapy during the second and third trimesters.

As most chemotherapy drugs are uncharged, lipophilic, of low molecular weight, and minimally protein bound, they cross the placenta to the fetal circulation. The placenta is the primary portal of exit of waste products and toxins from the fetus. However, the metabolites are generally more polar than is the parent compound, might not cross the placenta as easily, and hence may accumulate in fetal tissues or amniotic fluid. The fetal liver can metabolize drugs as early as 7 to 8 weeks of pregnancy, but the extent to which fetal liver and kidneys participate in drug elimination is minimal.[2]

MATERNAL PHYSIOLOGY: RELEVANCE TO CHEMOTHERAPY AND SURGERY

Pregnancy induces a number of important physiologic changes that cause significant alterations in the metabolism and efficacy of commonly used medications (Box 68-1). However, few data exist to guide physicians in adjustment of drug dosing (see the section on chemotherapy dosing).

Physiologic changes in pregnancy also affect surgical treatment and planning. Pregnancy is accompanied by increased plasma volume and dilutional anemia, reduced mean arterial pressure, increased oxygen consumption, and a narrow respiratory reserve. Cardiac output is increased by 30% to 50% as early as the second trimester, but in the supine position, the gravid uterus can compress the inferior vena cava, resulting in decreased venous return and reduction in cardiac output. Fetal development or viability may be jeopardized by hypotension and hypoxemia. Nevertheless, surgery can usually be performed safely during pregnancy; there is a small but increased risk

Box 68-1. PHYSIOLOGIC CHANGES IN PREGNANCY THAT MAY AFFECT THE METABOLISM AND EFFICACY OF CHEMOTHERAPY AGENTS

- Alteration of drug absorption due to delayed gastric emptying and gastrointestinal mobility
- Increased plasma volume leading to dilutional anemia, increased volume of distribution, and decreased peak plasma concentration of drugs
- Increased enterohepatic circulation leading to increased drug bioavailability
- Enhanced hepatic oxidation enhancing drug clearance
- Altered levels of plasma proteins altering the pharmacokinetics of drugs with significant protein binding
- Increased glomerular filtration resulting in enhanced drug clearance

of low birth weight and spontaneous abortion but no increased risk of fetal malformation.

DIAGNOSTIC RADIOLOGY FOR STAGING

The practitioner who is responsible for the radiologic examination must take all reasonable steps beforehand to advise the pregnant patient of the potential risks to the embryo or fetus that are associated with in utero exposure.

Radiation can be divided into ionizing and nonionizing radiation. Ionizing radiation has the ability to penetrate tissue and damage cellular DNA, resulting in mutation and ultimately affecting the development and viability of the fetus. Numerous studies of radiation exposure after atomic bomb detonations in Japan confirmed that this effect is dependent on dose and stage of fetal development at the time of exposure (Table 68-1).[3] Fetal abnormalities after exposure to excessive ionizing radiation include microcephaly, eye malformation, and growth retardation.[4] The American College of Obstetricians and Gynecologists has published recommendations for imaging during pregnancy that state that 5-cGy exposure to the fetus is not associated with any increased risk of fetal loss or birth defects.[5] Radiation exposure is well below this for most procedures except for the maximum dose with CT scanning of the abdomen and pelvis (Table 68-2). A more relevant concern is an increased risk of childhood cancer. After a gestational age of 3 to 4 weeks, the number of excess cancer cases (leukemia and solid tumors) up to age 15 years following radiation in utero is estimated to be 1 in 17,000 per 0.1 cGy. The baseline cancer risk in the first 15 years is about 1 in 650, so a fetal dose of 2.5 cGy will approximately double the risk; however, this represents an excess lifetime fatal cancer risk of less than 0.5%.

Table 68-2 Typical Ranges of Fetal Doses Following Common Diagnostic Procedures

Examination	Mean Dose (cGy)	Maximum Dose (cGy)
CONVENTIONAL X-RAY		
Abdomen	0.14	0.42
Chest	<0.01	<0.01
Cervical spine	<0.01	<0.01
Lumbar spine	0.17	1.0
Pelvis	0.11	0.4
Thoracic spine	<0.01	<0.01
COMPUTED TOMOGRAPHY		
Abdomen	0.8	4.9
Pelvis	2.5	7.9
Chest	0.006	0.096
Cervical spine	<0.01	
Brain	<0.005	<0.005
NUCLEAR MEDICINE		
99m Tc bone scan (phosphate)	0.33	0.46
67 Ga tumors and abscesses	—	1.2
131 I thyroid metastases	—	2.2

The radiation doses have been estimated from surveys conducted in the United Kingdom for a range of diagnostic radiology.

Ultrasound and Magnetic Resonance Imaging

Ultrasound is accepted as being safe in pregnancy and can be particularly useful in assessing the breasts and liver. Magnetic resonance imaging (MRI) does not expose the patient to ionizing radiation, and there has been no indication that MRI during pregnancy has produced deleterious effects. Hence, MRI may be used in pregnant women if other nonionizing forms of diagnostic imaging are inade-

Table 68-1 Estimates of Threshold Doses for Effects Following Fetal Radiation in Utero

	Minimal Dose (mGy)		
Age (in weeks)	**Death**	**Gross Malformations**	**Mental Retardation**
0 to 1	No threshold at day 1; 100 thereafter	No threshold at day 1?	Analysis of Japanese data suggest a dose related reduction of about 3 IQ points per 10 cGy for children irradiated in utero from 8 to 15 weeks post fertilization. The threshold is ill defined and may lie between 6 and 30 cGy
2 to 5	250 to 500	200	
5 to 7	500	500	
7 to 21	>500	Very few observed	
To term	>1000	Very few observed	

quate or if the examination provides important information that would otherwise require exposure to ionizing radiation (e.g., fluoroscopy, CT). Contrast agents such as gadolinium cross the placenta and are contraindicated. MRI of the abdomen is limited by motion artifact of the bowel.

Position Emission Tomography Scanning

Pregnancy is a relative contraindication to positron emission tomography (PET) scanning but termination is not generally recommended if a patient is found to be pregnant after a PET scan. After a PET/CT scan, a representative dose is 8 mGy (PET) and 0.3 cGy (CT). The dose to the fetus may be higher owing to close proximity of the mother's bladder, where fluorodeoxyglucose is excreted.

TERATOGENICITY OF CHEMOTHERAPY

The U.S. Food and Drug Administration (FDA) has defined risk categories for all drugs based in part on the evidence in animals of fetal harm (Table 68-3). The majority of chemotherapeutic agents are Category D. Extrapolation of teratogenic and mutagenic effects of chemotherapeutic agents from animals to human organogenesis is difficult, however, because of differences in susceptibility between species.[6] The timing of fetal drug exposure is critical. Drugs that are administered with one week of conception may produce a spontaneous abortion or a healthy fetus. During the first trimester, when organogenesis occurs, drugs may produce congenital malformations and/or result in spontaneous abortion. Other factors that may influence the probability of teratogenesis include the frequency of drug administration, duration of exposure, synergistic effects of multiple drugs, radiation, and individual genetic susceptibility.

Most human data about chemotherapy during pregnancy involve small series or case reports, which are prone to reporting bias. There is limited specific or systemic information about the teratogenicity of individual cytotoxics or modern multiagent chemotherapy regimens, particularly in the first trimester. Many reported malformations have occurred after exposure to multiple agents, making it difficult to apportion blame to a single causative agent. Interpretation of these data should be tempered by the reality that the overall incidence of major congenital malformations is approximately 3% of all births, the incidence of minor malformations may be as high as 9%, and between 10% to 15% of all pregnancies result in a miscarriage or spontaneous abortion.[7] Extrapolation from older data might also not be appropriate, as many of these drugs (e.g., alkylating agents such as nitrogen mustard and busulfan and antimetabolites such as aminopterin) are now rarely used. Limited experience in the first trimester with regimens such as adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD) and cyclophosphamide, adriamycin, vincristine, and prednisolone (CHOP) suggests low rates of teratogenicity.[8] In the second and third trimesters, drugs extremely rarely cause significant malformations but could impair fetal growth and development, probably mainly indirectly due to maternal ill-health. The available literature suggests that learning or behavioral problems (functional teratogenesis) do not result from chronic prenatal chemotherapy exposure. Overall, the use of systemic antineoplastic therapy alone appears to be accompanied by significantly lower risk than is commonly appreciated.

SPECIFIC CHEMOTHERAPY DRUGS

Table 68-4 details the available experience on the use of some of the more commonly used chemotherapy drugs in animals and at various stages of pregnancy, in humans, together with the FDA category.[9–34] The recommendations are those published by Briggs and colleagues,[9] with some additional comments from the author. An excellent review by Cardonick and Iacobucci is recommended.[35]

Antimetabolites

Methotrexate is widely distributed, including into fluid spaces such as amniotic fluid, and is closely associated with fetal abnormalities when given during the first trimester, characterized by cranial dysostosis, hypertelorism, micrognathia, limb deformities, and mental retardation.[20] However, methotrexate does not uniformly cause malformations, and there may be a critical dose above which fetal malformations occur.[21] Exposure to methotrexate in the latter trimesters has not been associated with significant malformations,[9] but its elective use at this time, particularly in high dose, is still not recommended.

5-Fluorouracil (5-FU) was associated with multiple congenital malformations in the fetus of a patient who was found to be pregnant at week 14 after she began receiving chemotherapy for colon cancer at week 12 and hence is not recommended for use during the first trimester.[36] Cytosine arabinoside, alone and in combination with other drugs, during the first trimester has also been associated with congenital anomalies.[18]

Alkylating Agents

Alkylating agents are commonly used in the treatment of lymphoma, acute lymphocytic leukemia, and breast cancer. Among 47 at-risk pregnancies, six malformations were reported when alkylating agents were used in the first trimester, usually as part of combination

Table 68-3 Food and Drug Administration Risk Categories for Drugs Administered During Pregnancy

Category	Description
A	Controlled studies in women do not show risk to the fetus during the first trimester; there is no evidence of risk in late trimesters, and the possibility of fetal harm is remote.
B	Animal reproduction studies have not shown a fetal risk, but there are not controlled studies in pregnant women; or animal reproduction studies have shown an adverse effect (other than a decrease in fertility), but this has not been confirmed in controlled studies in women in the first trimester (no evidence of a risk in later trimesters).
C	Studies in animals have revealed adverse effects on the fetus (teratogenic, embryocidal, or both), and there are no controlled studies in women, or studies in animals and women are unavailable. Drug should be given only if potential benefit justifies the risk to the fetus.
D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (if the drug is needed in a life-threatening situation for which other safer drugs are not available).
X	Studies in humans and animals have shown fetal malformations; there is evidence of fetal risk based on human experience or both. The risk of use in a pregnant woman clearly outweighs any potential benefit. This drug is contraindicated in women who are or may become pregnant.

Table 68-4 Summary of and Recommendations[9] for Chemotherapy Drug Experience in Pregnancy

Drug	First Trimester	Second Trimester	Recommendations	Risk Category	Author Comment
Alkylators in general[10]	Inadequate data; teratogenic in animals	Case reports without apparent fetal harm	Contraindicated in first trimester	D	
Anthracyclines	Teratogenic in rats; little human data as single agent	No reports of specific fetal abnormalities; idarubicin associated with neonatal cardiomyopathy[11]	Contraindicated in first trimester	D	Doxorubicin preferred
Bleomycin	Teratogenic in rats; use in combination not associated with fetal malformations	Use in combination has not been clearly associated with fetal abnormalities	Not specified	D	Oxygen during delivery may aggravate pulmonary toxicity[12]
Cisplatin	Teratogenic in animals; little human data	Case reports suggest safety[13,14]	Contraindicated in first trimester	D	
Corticosteroids	Associated with nonsyndromic orofacial clefts[15]	Repeated exposure to dexamethasone may increase leukomalacia and neurodevelopmental abnormalities[16]	Potential maternal benefit outweighs embryo/fetal risk	C: second/third trimester D: first trimester	
Cyclophosphamide	Yes: cyclophosphamide embryopathy[17]	Main concern is neonatal myelosuppression	Contraindicated in first trimester	D	
Cytarabine	Yes: limb abnormalities[18]	Main concern is maternal myelosuppression and sepsis with secondary effects on the fetus	Not specified; relatively contraindicated in first trimester	D	
Etoposide	Teratogenic in animals; no human data	IUGR and myelosuppression when used in aggressive combination regimens	Not specified	D	
Imatinib	Limited data; malformations reported[19]	Limited data suggest safety	—	D	Consider in second or third trimester if poor disease control
Methotrexate	Yes: methotrexate embryopathy;[20] minimal risk at 6 to 8 weeks post-conception at doses ≥10 mg/week[21]	Neonatal myelosuppression; accumulates in ascitic fluid	Contraindicated at all stages	X	
Rituximab	Not teratogenic in animals; limited data suggest no adverse effects[22,23]	Limited case reports suggest safety[24–28]	—	C	Benefit outweighs risk in most circumstances
Taxanes	Teratogenic in animals; no human data	Reports suggest no significant risk to the fetus[29,30]	Not specified		Consider in second/third trimester if clear maternal benefit
Trastuzumab	No fetal harm in monkeys	One report of reversible anhydramnios[31]	—	B	Not contraindicated but use with caution
Vinca alkaloids	Teratogenic in rats, but limited human data suggest relatively safe[8,32–34]	No reports of specific fetal abnormalities	Not specified	D	Vinblastine has been recommended as single agent in HL in first trimester

Briggs GG, Freeman RK, Yaffe ST: Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk, 7th ed. Philadelphia, Lippincott Williams and Wilkins, 2005.

therapy.[10] Cyclophosphamide is clearly teratogenic in animals, with similar malformations noted in different species. A distinct and similar embryopathic phenotype in humans has been described after exposure to cyclophosphamide as a single agent, with one dose (20 mg/kg) during the sixth week after conception.[17] Second- and third-trimester exposure has not been associated with malformations. Other alkylating agents, such as thiotepa and dacarbazine, are teratogenic at high doses in rats, but little is known about their effects in humans apart from case reports of lack of side effects when used in the second trimester or beyond. Exposure to chlorambucil during the first trimester has been reported to cause renal aplasia, cleft palate, and skeletal abnormalities.[37]

Platinum

A number of case reports documenting platinum use after the first trimester have not noted any congenital malformations.[13,14]

Vinca Alkaloids

Although vinblastine is highly teratogenic in animal models, the literature suggests that its use in the first trimester may be relatively safe. No congenital malformations were reported in 11 pregnancies that were exposed to vincristine, three being in the first trimester.[32] Vinorelbine, vinblastine, and vincristine had been used during the latter trimesters without fetal harm.[8,31,34]

Anthracyclines

There is little information about the effects of these drugs in pregnancy as single agents; malformations have been reported when they are used in combination regimens in the first trimester. Idarubicin is more lipophilic, which favors placental transfer, and has been associated with neonatal cardiomyopathy.[11]

New Agents

There are minimal human data with respect to the following:

- Topoisomerase-1 inhibitors such as topotecan (used in ovarian and small cell lung cancer) and irinotecan (used for colorectal cancer and non-small-cell lung cancer)
- Ertotinib, an epidermal growth factor receptor tyrosine kinase inhibitor that is used in metastatic lung and pancreatic cancer
- Bevacizumab, a humanized monoclonal antibody with an antiangiogenic effect that is used for metastatic colorectal cancer. Because it is teratogenic in rabbits (according to Roche product information), consistent with a crucial role of angiogenesis during normal fetal development, bevacizumab should not be administered to pregnant women.
- Oxaliplatin. This is embryotoxic in animals, classified as a Category D drug and is not recommended for use in pregnancy.
- Capecitabine is an oral drug akin to 5-FU used in bowel and breast cancer. This is embryotoxic in animals, classified as a Category D drug, and is not recommended for use in pregnancy.

Miscellaneous Agents

Granulocyte colony-stimulating factor (G-CSF) is not teratogenic in rats, and no congenital malformations or toxicities attributable to G-CSF have been reported in humans.[9] G-CSF is a Category B drug and should not be withheld in pregnancy if there is a significant potential benefit to the mother.

5-Hydroxytryptamine-3 (5HT3) antagonists, such as ondansetron, are widely used to prevent and treat chemotherapy-induced nausea and vomiting. These drugs are not teratogenic in animals, and the small number of reports of ondansetron for hyperemesis gravidarum and chemotherapy in pregnancy suggest effectiveness and safety. 5HT3 antagonists have been classified as Category B drugs in pregnancy.[9] Aprepitant (Category B) is an effective antiemetic for delayed nausea after chemotherapy. Animal studies have not revealed harm to the fetus after exposure to aprepitant (according to Merck, Sharp and Dohme product information), but there are no data on its use in pregnant women.

Recombinant human erythropoietin (Category C) does not cross the human placenta and does not appear to present a major risk to the fetus,[9] and the benefit of its appropriate use for maternal anemia appears to outweigh any known or potential risks.

CHEMOTHERAPY IN PREGNANCY: OVERVIEW

An overview of the approach to treatment is detailed in Figure 68-1.

First Trimester

Patients should be counseled that the incidence of teratogenicity as a result of exposure to a particular chemotherapy drug or a drug combination in the first trimester is not well established. Counseling regarding the effects of chemotherapy needs to be performed using as much information as possible, which may involve asking the relevant pharmaceutical company for updated information. In addition, for many malignancies, there is no evidence either way that delaying chemotherapy from the first trimester until the completion of fetal organogenesis early in the second trimester adversely affects the

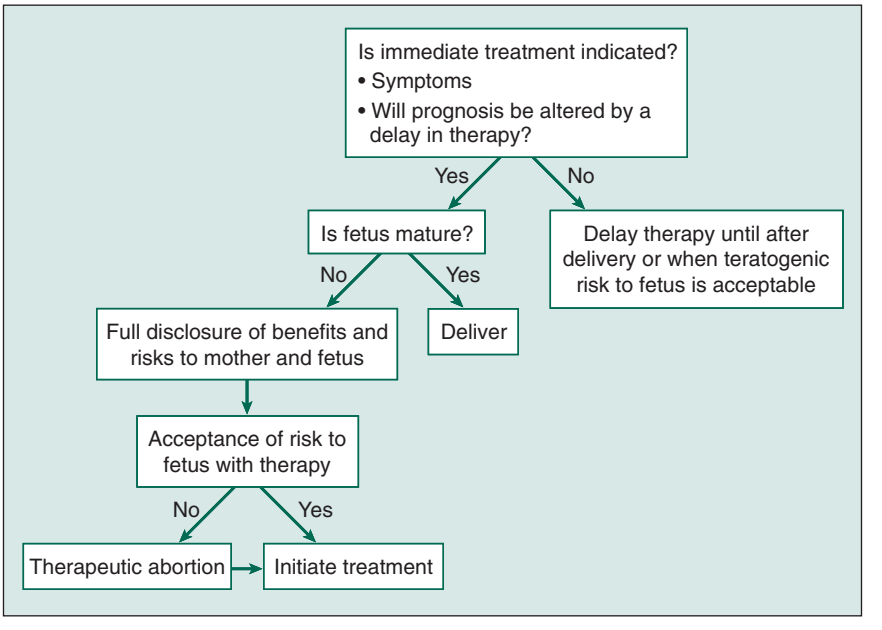

Figure 68-1 • Overview of the treatment approach to cancer in pregnancy.

ultimate outcome. A therapeutic abortion is usually recommended for cancers diagnosed in the first trimester that require urgent multiagent chemotherapy. There are multiple factors, such as desire to avoid termination, risk of delay, and interim use of truncated chemotherapy protocols with drugs with a low probability of teratogenicity, that need to be considered in each patient.

Second and Third Trimesters

The administration of most chemotherapeutic agents in the second and third trimesters has not been associated with specific adverse effects on the fetus; hence, in general, chemotherapy-based treatment of the underlying malignancy at this stage of pregnancy should not be delayed and should follow the same guidelines as for nonpregnant women. The main risk to the fetus appears to be secondary to neutropenic sepsis, anemia, and nutritional deficiency in the mother.[35] The parents can be assured that long-term studies have shown that in the absence of chemotherapy-embryopathy, children who are exposed to chemotherapy in utero are not different physically or intellectually from matched controls, and there is no suggestion of a significantly increased risk of malignancy in the neonate (i.e., transferred from the mother) or in long-term follow-up.[8]

Chemotherapy Dosing

An anecdotal observation of fewer chemotherapy-related side effects during antenatal treatment compared with identical chemotherapy postpartum has been reported,[35] consistent with physiologic changes in pregnancy leading to lower plasma levels and reduced area under the concentration × time curve. Pharmacokinetic studies have not been done. Accordingly, particularly when given with curative intent, chemotherapy doses should not be empirically dose-reduced. A practical approach, particularly in curable hematologic malignancies such as Hodgkin's lymphoma in which low hematotoxicity is an independent prognostic factor for a poorer treatment outcome, may involve regular blood counts with individualized dose adjustments (up or down) according to the level of myelosuppression.[38]

SPECIFIC MALIGNANCIES

Breast Cancer

The incidence of breast cancer during pregnancy is estimated to be 1 in 3000.[39] Women with a genetic predisposition to breast cancer, particularly BRCA2 mutations, might be overrepresented in this group.[40] Despite its long-term protective effect on the development of breast cancer, pregnancy itself may temporarily increase the risk of disease, again particularly in women with BRCA2 mutations. Breast cancer in pregnancy is more likely to be advanced (almost 50% stage IV, with lymph node involvement in 65%), is thought to reflect a delay in diagnosis as the physiologic breast changes of pregnancy may mask a malignant mass, and possibly involves a higher incidence of Her-2/neu positivity and a lower incidence of estrogen receptor positivity (there is conflicting literature) than breast cancer in nonpregnant women.[40–42] The majority are poorly differentiated infiltrating ductal adenocarcinomas. However, stage-specific survival is similar to that of nonpregnant patients.[43,44] Placental metastases of breast cancer have been reported, but rarely, and there are no reports of fetal involvement.[45]

The principles of diagnosis are similar to those for nonpregnant women. Mammography is safe, as there is negligible radiation dose to the fetus with abdominal shielding, but may be associated with high false-positive rates. Ultrasonography can distinguish solid from cystic masses. Gadolinium-enhanced MRI of the breast is contraindicated. Fine needle aspiration biopsy is acceptable, but accurate interpretation requires an experienced pathologist who is aware that the woman is pregnant. If nondiagnostic, solid masses should be subject to excisional biopsy. Safe staging procedures include a chest x-ray and MRI without contrast. A chest CT scan is not contraindicated (see the section on radiology), but a MRI of the thorax is preferred. Bone evaluation if required, can be with a modified bone scan with maternal hydration and frequent voiding to limit fetal radiation exposure from radionuclides in the adjacent maternal bladder.[46] The serum alkaline phosphatase level rises physiologically during pregnancy and is not useful as an indicator of bony secondaries.

National Comprehensive Cancer Network Guidelines for the treatment of nonmetastatic breast cancer during pregnancy are available and are reproduced in Figure 68-2. International expert recommendations have also been published recently.[47] Treatment should not be unnecessarily delayed, as delay may result in significantly worse disease-free survival. Therapeutic abortion does not appear to alter maternal survival.

Considerations and selection of optimal local therapy are similar to that recommended in non-pregnancy-associated breast cancer. Breast and axillary surgery during any trimester appears to be reasonably safe for the mother and associated with minimal fetal risk. Axillary lymph node dissection is important, as nodal metastases are common and nodal status affects the choice of adjuvant therapy. At present, sentinel lymph node biopsy has not been systematically evaluated and is not generally recommended.[47] Therapeutic radiation has been contraindicated during pregnancy, as this is calculated to expose the fetus to 10 cGy in early pregnancy and 200 cGy in late pregnancy, which are above the acceptable limits;[39] however, this view has recently been questioned.[48] Accordingly, mastectomy is a consideration in early gestation when radiation therapy is significantly delayed. Breast-conserving surgery is an option in the second or early third trimester with neoadjuvant chemotherapy or by itself late in the third trimester.

Adjuvant chemotherapy should be delayed to beyond the first trimester. FAC (5-FU, adriamycin, cyclophosphamide) during the second or third trimesters has not been associated with spontaneous abortions or fetal abnormalities; methotrexate is usually avoided.[49] Tamoxifen is contraindicated owing to its association with spontaneous abortion, birth defects, fetal death, and, in pregnant rats, breast cancer in female offspring.[47] International guidelines suggest avoiding taxanes and dose-dense anthracyclines during pregnancy owing to the paucity of data, although the limited literature has not demonstrated any adverse fetal effects with taxanes that are administered beyond the first trimester.[29,30] Trastuzumab (herceptin), a pregnancy category B drug, is a monoclonal antibody that blocks the human epidermal growth factor receptor Her-2/neu and that in combination with adjuvant chemotherapy has been shown to improve disease-free and overall survival for early-stage Her-2 positive breast cancer.[49] Reports have demonstrated either no adverse effect or reversible anhydramnios in women who are exposed to trastuzumab in the first trimester.[31,50,51] Consideration should be given to the use of trastuzumab and/or taxane compounds beyond the first trimester if there is a strong likelihood of maternal benefit.

There is no evidence that a future pregnancy worsens the prognosis with respect to recurrence; in fact, on early follow-up, pregnancy may lower the risk of death.[52] However, most oncologists advise women to wait two to three years before another pregnancy, as the risk of recurrence is highest during this time. Recent literature has highlighted the impact of chemotherapy regimen, age, and time since treatment on ovarian function after breast cancer treatment in premenopausal women.[53]

Cervical Cancer

Cervical cancer is the most common malignancy diagnosed during pregnancy (1 in 750) probably owing to routine Papanicolaou screening.[54] Unlike other malignancies in pregnancy, cervical cancer is often detected early because of this; advanced cervical cancer is rarely encountered. Symptoms such as vaginal bleeding or discharge may overlap with those of pregnancy. Human papillomavirus is involved

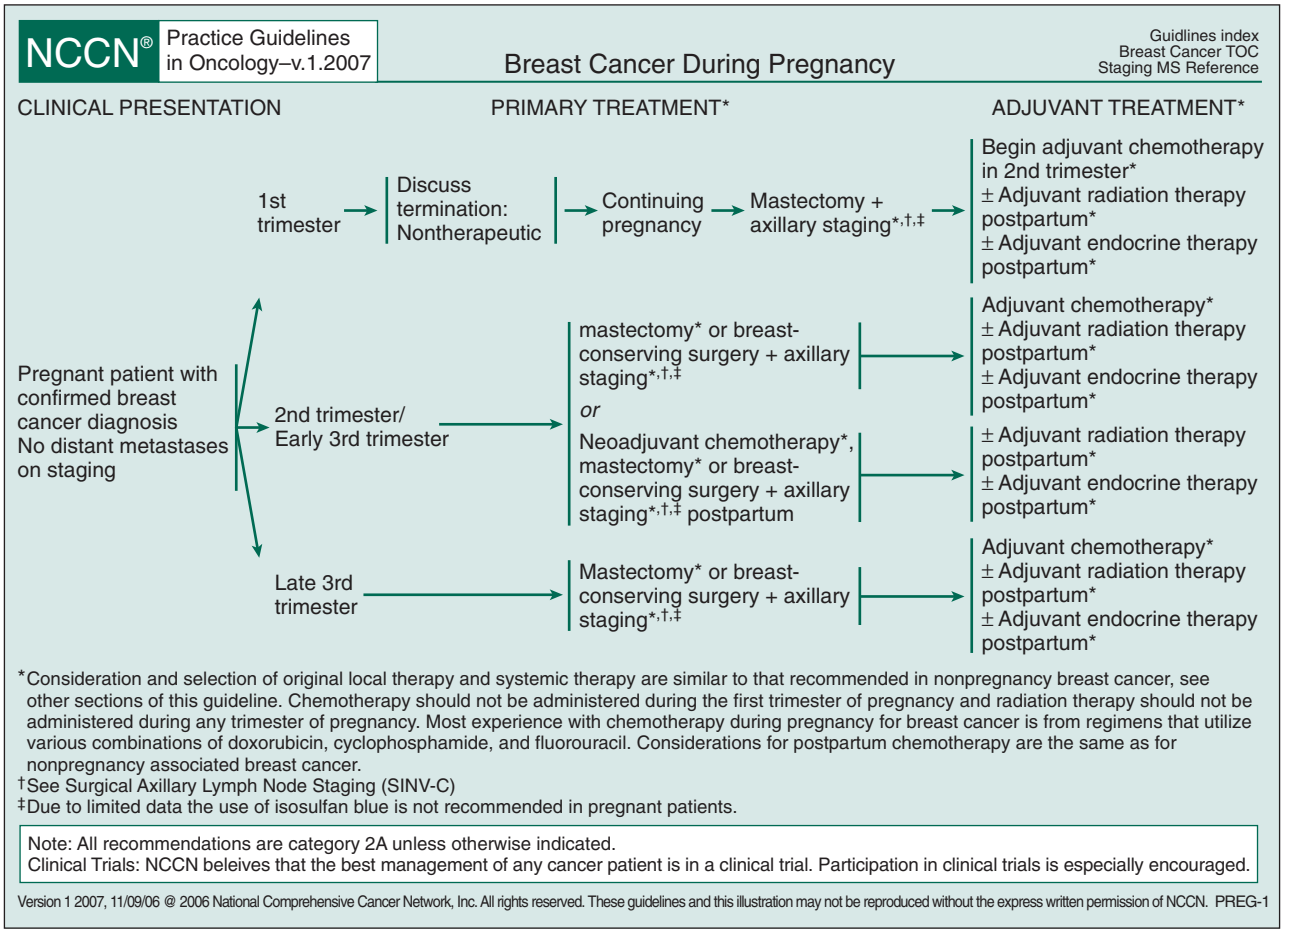

Figure 68-2 • National Comprehensive Cancer Network Guidelines for the treatment of nonmetastatic breast cancer during pregnancy. (Reproduced with permission from The NCCN 1.2007 Breast Cancer During Pregnancy Clinical Practice Guidelines in Oncology. Available at: www.nccn.org. Accessed December 2006. To view the most recent complete version of the guidelines, go online to www.nccn.org.)

in most cervical cancers. There is no evidence that the relative immunosuppressive state of pregnancy modifies the aggressiveness of human papillomavirus infection.[55] Cone biopsies may result in significant hemorrhage and fetal death and should be done only if necessary for diagnosis of invasive malignancy.[56]

Management recommendations differ according to disease stage. There is evidence that delay of treatment of early-stage cancer until fetal maturity in a desired pregnancy is not deleterious to the mother. An algorithm of treatment options for early-stage cancer at less than 20 weeks gestation has been described.[55] If advanced disease is diagnosed and the fetus is viable, then delivery by cesarean section is recommended, followed by commencement of therapy. Neoadjuvant chemotherapy is a consideration if treatment needs delay for fetal indications. If the fetus is not viable and stage IIB–IVA disease is detected, treatment should be directed with curative intent. Chemoradiation should be initiated promptly, which will lead to abortion of the fetus.

Melanoma

While overall there is a male preponderance, age-specific incidence rates are higher among females until age 40 years, leading to speculation that some causes may be hormonally driven.[57] However, there is no clear evidence that exogenous hormone use increases the risk,[58] that the incidence of melanoma is higher in pregnancy,[59] or that pregnancy influences the prognosis.[60] Treatment principles are similar to those for the nonpregnant patient. An approach to the management of pregnant women with high-risk melanoma has been published.[61] Melanoma is the most common malignancy associated with transplacental metastases to the fetus. With placental involvement, the fetal risk of melanoma metastasis is approximately 22%, with a high fatality rate in affected infants.[62]

Ovarian Cancer

Invasive epithelial ovarian cancer is uncommon during pregnancy, the majority of cases being diagnosed early owing to frequent use of pelvic ultrasound and generally having germ cell or low malignant potential histology.[63,64] Surgical staging and treatment of ovarian neoplasms include debulking surgery, including omentectomy, lymph node and peritoneal biopsy, and assessment of peritoneal washings. Germ cell tumors are typically treated with bleomycin, etoposide, and cisplatin; experience with these agents in the latter trimesters of pregnancy with this combination is limited but has been associated with prematurity and ventriculomegaly in one report.[65] Low malignant potential neoplasms are treated with surgery alone. Invasive epithelial ovarian cancer is treated with postoperative chemotherapy consisting of platinum and paclitaxel; the safe use of this combination in the second trimester has been reported.[13,66]

Gestational Choriocarcinoma

Gestational choriocarcinoma is a highly malignant vascular neoplasm of the cytotrophoblast and syncytiotrophoblast that readily

metastasizes. Choriocarcinoma can be preceded by any gestational event; most arise after a hydatiform mole or a spontaneous abortion or after a normal pregnancy. Diagnosis concurrent with a normal pregnancy is extremely rare.[67] A scoring and risk factor system for gestational choriocarcinoma from the International Federation of Gynecology and Obstetrics (FIGO) has been published; chemotherapy recommendations depend on the FIGO risk score.[68] In tumors that are diagnosed after pregnancy, a high cure rate can be achieved with single-agent chemotherapy (usually methotrexate) for low-risk disease, but responses are lower in high-risk disease, for which multiagent chemotherapy is the treatment of choice.[69] However, the cure rate for choriocarcinoma concurrent with pregnancy is poor. Simultaneous choriocarcinoma in the mother and infant is rare but may be curable in both if recognized and treated early.[70]

Colorectal Cancer

About 300 cases of colorectal cancer during pregnancy have been reported; underlying risk factors such as hereditary or familial syndromes and long-standing inflammatory bowel disease are likely to be particularly relevant in this younger age group.[71] Unlike the general population, in which only 20% to 25% of colon cancers occurs in the rectum, a higher incidence of rectal presentation may result from increased local symptoms from rectal compression by the pregnant uterus or more frequent rectal or pelvic examinations. Sigmoidoscopy is safe. While the safety of colonoscopy during pregnancy is not well established, the limited literature suggests no increase in adverse outcome to the mother or children.[71] Abdominal ultrasound is safe, but CT scanning of the abdomen and pelvis, especially in the first trimester, is problematic (see the section on radiology). Of note, ovarian metastases occur in 25%,[71] and serum BHCG may be elevated owing to ectopic production by the cancer cells.[72]

Surgical recommendations are complex and are well summarized in a recent review.[71] Adjuvant chemotherapy with 5-FU or related drugs such as capecitabine is contraindicated in the first trimester. Later trimester exposure to 5-FU has not been associated with increased fetal loss or development abnormalities but with intrauterine growth retardation and prematurity. Delaying adjuvant chemotherapy is an option, but whether the beneficial effect is maintained is unclear. Preoperative or postoperative radiotherapy is contraindicated during pregnancy. Survival is generally poor, owing to late presentation and advanced pathologic stage, but is no different from that in the general population when stratified for pathologic stage.[73]

Thyroid Cancer

The most common presentation is that of an asymptomatic nodule. The outcome does not appear to be affected by pregnancy.[74] Recommendations include delaying surgery to the second trimester for tumors that are diagnosed early in pregnancy and, if required, administration of radioiodine after delivery, as it might cause cretinism in the fetus.[75] Conventional chemotherapy is not particularly effective in resistant disease.

Other Cancers

Gastrointestinal pancreatic and hepatic cancers are very rare in pregnant women, except for gastric cancer in Japan. Delays in diagnosis are common. A detailed review of these malignancies in pregnancy has recently been published.[76]

Genitourinary malignancies are rare, although the risk of renal cell cancer may be increased by pregnancy.[77] Lung cancer has a poor prognosis in pregnancy,[14] and metastasis of small cell carcinoma from mother to fetus has been reported.[14,78] Sarcomas are rare in pregnancy. There appears to be no interaction between pregnancy and the natural history of osteogenic carcinoma.[79] Successful delivery of chemotherapy to the mother has been reported for Ewing's sarcoma.[80]

HEMATOLOGIC MALIGNANCIES

Hodgkin's Lymphoma

Hodgkin's lymphoma, with an incidence of 1 : 1000 to 1 : 6000, is the most common lymphoma in pregnancy.[81] Reasonable options for staging in pregnancy include a CT scan of the neck and chest with MRI of the abdomen and pelvis.

The majority of patients who are found to have Hodgkin's lymphoma during pregnancy do not require immediate intervention. Asymptomatic or minimally symptomatic patients can be followed carefully, with treatment reserved for threatening or more symptomatic disease; many patients can carry the pregnancy to term without any treatment becoming necessary.[34]

Options for symptomatic disease that is diagnosed in the first trimester include single-agent chemotherapy or multiagent chemotherapy with or without a prior therapeutic abortion. There are no large studies of the teratogenic effects in the first trimester of commonly used regimens such as ABVD, although the limited literature has not demonstrated any adverse effect.[8,35] Vinca alkaloids, anthracyclines, bleomycin, and steroids appear to be relatively safe in the first trimester, but alkylators such as cyclophosphamide and dacarbazine may be teratogenic. Options that have been proposed include ABV or vinblastine alone.[34,35] Mantle field radiotherapy for supradiaphragmatic disease has not been associated with adverse fetal effects, as the estimated fetal dose after uterine shielding is below the threshold for major congenital malformations.[81] Nevertheless, it is rarely indicated, and its use during pregnancy cannot be considered standard, as there is a lack of reliable clinical data on late effects.

Multiagent chemotherapy such as ABVD appears to have minimal fetal risk when administered during the second or third trimester, with only one minor malformation in 10 patients treated with ABVD ($n = 9$) or ABV ($n = -1$) (E. Cardonick, personal communication).[35] An option is single-agent vinblastine, which almost always induces some disease regression and allows disease control until after delivery, at which time multiagent chemotherapy can be delivered.[34] These alternatives—that is, (1) prompt potentially curative chemotherapy with protocols such as ABVD after counseling that there does not seem to be an increased risk of congenital birth defects or of significant long-term neurologic sequelae or (2) minimizing fetal risk by delay of definitive therapy until after delivery—need to be discussed in each case, considering factors such as symptoms and aggressiveness of the tumor. Supradiaphragmatic radiation is problematic in the third trimester, as fetal exposure is increased owing to uterine proximity.

The role of allogeneic stem cell transplantation for Hodgkin's lymphoma is controversial, but this approach is occasionally used in patients with relapsed disease after an autograft. In the absence of a histocompatible sibling, alternative sources of allogeneic stem cells include marrow, peripheral stem cells, or cord blood from an unrelated donor. Cryopreservation of umbilical cord blood at delivery is an issue that might need to be addressed in some patients with high-risk disease.[82]

Non-Hodgkin's Lymphoma

Aggressive non-Hodgkin's lymphoma (NHL) in pregnancy is rare, with an incidence of approximately 1 in 100,000. Indolent NHL usually does not require immediate therapy.[82] The NHL that is most likely to require treatment in pregnancy is CD20 positive diffuse large B cell NHL. These lymphomas are usually aggressive and advanced at diagnosis in pregnancy with a higher incidence of breast, uterine, cervical, and ovarian involvement, perhaps related to increased vascularity.[81] The current standard therapy is CHOP-rituximab, with consideration of the addition of involved field radiotherapy for localized disease.[83]

Treatment delay is rarely advisable in the first trimester but may be a consideration in some patients with relatively indolent disease

clinically. A recommended option has been a therapeutic abortion followed by standard chemotherapy.[81] However, experience with CHOP-based regimens in the first trimester suggests the risk of teratogenicity is low; Aviles reported no adverse fetal outcome 17 mothers with aggressive NHL treated in the first trimester with CHOP-bleomycin or similar regimens.[8] This suggests that CHOP-based chemotherapy, preferably without an alkylator initially, is a reasonable consideration during the first trimester when treatment is required without delay and termination is not acceptable. Prompt administration of CHOP-rituximab chemotherapy is recommended in the second trimester. Reduced intervals between cycles (e.g., each 2 weeks versus the standard 3 weeks) is commonly used in nonpregnant women[84] but is not currently advised in pregnancy, as there are no data on this approach.

An important issue is the safety of rituximab during pregnancy. This agent has been shown in a number of randomized studies to improve outcome in aggressive CD20+ NHL and represents a major therapeutic advance.[83] Administration of rituximab during organogenesis in monkeys had no obvious adverse effect on embryo or fetal development apart from the expected pharmacologic effect of B cell depletion, as IgG is known to cross the placental barrier.[85] The available literature in human pregnancy is limited. Two reports of exposure to rituximab without chemotherapy in the first trimester have described delivery of healthy, normal babies with no immunologic deficits.[22,23] Four reports of CHOP (or CHOP-like)-rituximab chemotherapy in the second trimester described delivery in all cases of healthy babies with subsequent normal immunologic reconstitution.[24–27] Two babies had detectable rituximab levels at birth with severe B lymphopenia but subsequently achieved normal immunologic status at 3 to 4 months without infectious sequelae in the interim.[26,27] One report of rituximab in the third trimester described no toxicity apart from asymptomatic transient neonatal neutropenia.[28] The approved product information states that rituximab should not be given to a pregnant woman unless the potential benefit outweighs the potential risk. A reasonable position is to recommend rituximab as part of combination chemotherapy during pregnancy, as in the author's opinion, the available evidence suggests that the maternal benefits outweigh the fetal risk.

Acute Leukemia

The presence of acute leukemia and/or its treatment has been associated with increased incidence of premature birth, stillbirths, and intrauterine growth retardation, particularly early in pregnancy.[35] Contributing factors other than chemotherapy include sepsis, anemia, and disseminated intravascular coagulation. Treatment is generally required without delay, irrespective of gestational age, as delay may increase both fetal and maternal mortality.

The most common acute leukemia in adults is acute myeloid leukemia, for which the usual chemotherapy is cytarabine (with at least one high-dose course) and an anthracycline such as daunorubicin or idarubicin. Acute lymphoblastic leukemia in adults is less common; induction treatments are less standard and more complex than in acute myeloid leukemia but generally include cyclophosphamide, vincristine, adriamycin, and steroids. Consolidation treatments in acute lymphoblastic leukemia characteristically include high-dose methotrexate. The risk of teratogenicity appears to be confined to the first trimester, particularly with methotrexate, other antimetabolites, thioguanine, and alkylating agents.[35] Cytarabine has been associated with limb malformations after first trimester exposure.[18] Other chemotherapy drugs such as vincristine, anthracyclines, and prednisolone appear to be relatively safe. Aviles and colleagues reported the outcome of 29 pregnancies that were complicated by acute leukemia: acute myeloid leukemia in 19 patients and acute lymphoblastic leukemia in the remainder.[8] All were treated with standard antileukemic protocols; 11 received chemotherapy during the first trimester. No congenital abnormalities were observed, there was no evidence of intrauterine growth retardation, and no excess of complications was seen in long-term follow-up in the children.

General principles of management include the following:

- In the first trimester, a therapeutic abortion is probably the recommendation of choice, particularly in acute myeloid leukemia, owing to concern of the teratogenicity of the optimal chemotherapy. Methotrexate is absolutely contraindicated.
- In the second and third trimesters, it is reasonable to treat with standard regimens without inducing an abortion, as there are no convincing data that the relevant chemotherapy is teratogenic at this time. However, the mother needs to be counseled about the fetal risks from maternal sepsis, anemia, and coagulopathy. High-dose methotrexate is inadvisable, and the administration of high-dose cytarabine is arguably best deferred until after birth, as there is minimal experience with this schedule during pregnancy.
- If possible, delivery should be scheduled not to coincide with severe neutropenia and thrombocytopenia. It is recommended to maintain platelets at greater than 30 to 50×10^9/L, especially around time of delivery, to allow for regional anesthesia and to maintain hemoglobin at greater than 9.8 g/dL, as perinatal complications increase as the hemoglobin declines.[82,86] Neonatal blood counts should be checked at delivery. Neonates are at risk of transient myelosuppression and cardiomyopathy after administration of idarubicin.[11]

- Following are some specific points:
  - Use of prednisolone rather than dexamethasone is recommended owing to concern of repeated fetal exposure to dexamethasone and adverse neurologic sequelae.[82] Steroids may increase the risk of diabetes owing to increased insulin resistance in pregnancy.
  - L-Asparaginase is commonly used in acute lymphoblastic leukemia protocols. Limited experience suggests this drug does not pose a major risk to the fetus when used beyond the first trimester. However, L-asparaginase has been associated with thromboembolism related to reduced levels of antithrombin III.[87] The risk may be higher in pregnancy, which is a hypercoagulable state. Consideration should be given to prophylactic infusion of antithrombin III concentrates if L-asparaginase is administered during pregnancy or in the first 6 weeks thereafter.
  - Acute promyelocytic leukemia is optimally treated with all-*trans*-retinoic acid, usually in combination with an anthracycline.[88] Retinoic compounds are teratogenic in animals, which has led to FDA approval of a centralized pregnancy risk management program for isoretinoin preparations. First trimester acute promyelocytic leukemia should be managed with a therapeutic abortion followed by chemotherapy that includes all-*trans*-retinoic acid. However, there are a number of reports of safe and effective use of all-*trans*-retinoic acid in the second trimester and beyond.[89,90] Arsenic is another agent active in acute promyelocytic leukemia. There are no data on the effect of therapeutic doses of arsenic in pregnancy, but epidemiologic studies in women with chronic exposure to arsenic found in drinking water reported an increase in stillbirths and an increase in spontaneous abortions.[91] These observations would argue strongly against the use of arsenic in pregnancy at any stage.

Chronic Leukemias

Of the chronic leukemias, chronic myeloid leukemia (CML) is the condition that is most likely to require treatment in pregnancy. Imatinib is now the treatment of choice in newly diagnosed CML.[92] Imatinib is teratogenic in rats (but not rabbits) during organogenesis at ≥100 mg/kg, doses that are equivalent to >800 mg/day in adults based on body surface area.[93] Defects include exencephaly, encephalocele, and skull bone abnormalities with fetal loss in all animals. Postimplantation loss occurred at doses ≥45 mg/kg, approximately

equivalent to 400 mg/day. The product information from Novartis recommends that imatinib not be used in pregnancy.

A recent publication reported on 180 cases of women who were exposed to imatinib during pregnancy.[17] Timing of exposure by trimester was known in 146 cases; of these, 71% involved exposure in the first trimester. Outcome data were known for 125 cases (63%): normal live infant ($n = 63$; 50%), elective termination ($n = 35$; 28%, including three following identification of fetal abnormalities), fetal abnormality ($n = 12$; 10%), and spontaneous abortion ($n = 18$; 14%). The fetal abnormalities included bony defects similar to those seen in animal models as well as an excess incidence of exomphalos. No data was presented on crucial issues such as the relationship of dose to the incidence and nature of fetal abnormalities or whether abnormalities were confined to first trimester exposure.

The MD Anderson group reported the outcome of CML in 10 women in whom imatinib was discontinued immediately after pregnancy was identified.[94] Six patients had an increase in Philadelphia-positive metaphases during pregnancy. All resumed imatinib after the abortion or birth, and nine achieved complete hematologic remission with varying levels of cytogenetic response with a median follow-up of 18 months (5 to 40 months).

Within the caveats of this limited experience, the following guidelines are suggested:

- In the first trimester, cease imatinib immediately. Counsel that there might be an increased risk of spontaneous abortion and fetal abnormalities, although the risk is probably not high enough at 400 mg/day to recommend termination of the pregnancy. There is no meaningful experience at doses in excess of 400 mg/day. Monitor CML, and institute treatment with leukapheresis or interferon if therapy is required. Interferon is thought to be safe in all trimesters.[95] Hydroxyurea is teratogenic at high doses in animals but has not been associated with major malformations in human pregnancies, even with first trimester exposure.[96] Consider reintroduction of imatinib at 400 mg/day in the second and third trimesters if CML is poorly controlled with these other measures and the mother's health is compromised.
- In the second and third trimesters, cease imatinib and commence interferon if therapy is required, but consider resumption as described previously.
- Postpartum, resume imatinib as quickly as practical. It should not be administered to women who are breast-feeding.

OTHER CONSIDERATIONS

Therapeutic Abortion

The decision by the mother or parents whether to continue with the pregnancy or to have a therapeutic abortion will depend on ethical, moral, and religious issues as well as the medical situation. Some of the parental considerations include willingness to assume a possible risk of fetal toxicity either directly from chemotherapy or radiation or indirectly from maternal complications of therapy, the impact on prognosis of delaying effective chemotherapy until the second trimester if a termination is not performed and there is unwillingness to accept risks to the fetus of chemotherapy in the first trimester, overall maternal prognosis and the ability to care for the child, and the effect of treatments on future fertility.

Therapeutic Radiation

Radiation therapy is commonly used in the treatment of patients with breast cancer, cervical cancer, and lymphoma, and systemic iodine 131 is often used for treatment of thyroid cancer. The use of radiation therapy is addressed in the sections devoted to these cancers. Radiation is extremely important for palliation of cancer-related symptoms and has been carefully used during pregnancy without fetal harm.

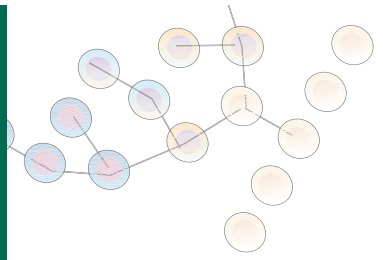
Subsequent Pregnancy

There is no evidence that a subsequent pregnancy increases the risk of recurrence of any malignancy in the mother, including hormone-responsive breast cancer, or the risk of fetal anomalies. Standard practice has been to defer pregnancy for 2 to 3 years, as the relapse risk is highest during this period, but recommendations need to be individualized on the basis of each patient's circumstances.

Transfer of Maternal Disease to the Fetus

Placental involvement has been documented, albeit rarely, in a variety of malignancies, but only a handful of cases of active transfer of malignancy to the fetus have been described; most have been melanoma. It is reasonable to counsel the mother that, apart perhaps from melanoma, the risk is minimal.

CONCLUSION



The care of the pregnant woman with cancer is complicated by unique issues such as the teratogenicity of staging procedures as well as chemotherapy and radiotherapy, the altered maternal physiology affecting drug metabolism, the impact of treatment on subsequent fertility, and the emotional trauma experienced by the mother (and her partner) in making decisions about the well-being of herself and the unborn child. Appropriate management of these issues necessitates the coordinated effort of a multidisciplinary team including hemato-oncologists, surgeons, nurses, psychologists, obstetricians, and pediatricians.

69 HIV-Associated Malignancies

Richard F. Ambinder and Nina D. Wagner-Johnston

SUMMARY OF KEY POINTS

Incidence

- Non-Hodgkin's lymphoma, Hodgkin's lymphoma, and Kaposi's sarcoma (KS) all occur with increased incidence in human immunodeficiency virus (HIV)-infected patients.
- KS occurs in HIV-infected patients who also are infected with KS herpesvirus (KSHV). Outside of Africa and some Mediterranean populations, KS occurs mainly in men who have sex with men.
- Lymphoma (non-Hodgkin's and Hodgkin's) occurs in all HIV risk groups. These neoplasms tend to be aggressive and extranodal and to manifest at an advanced stage. Burkitt's and Hodgkin's lymphomas tend to occur in patients with higher $CD4^+$ counts (typically greater than 200/mm^3), whereas primary central nervous system lymphoma tends to occur in patients with very low $CD4^+$ counts (typically less than 50/mm^3).

Etiology and Pathogenesis

- KS is always associated with KSHV; immunocompromise, inflammatory cytokines, and perhaps the HIV TaT protein contribute to pathogenesis.
- Lymphoma in HIV-infected patients is associated with Epstein-Barr virus (EBV) in approximately half of the cases; immunocompromise, chronic antigen stimulation, and perhaps inflammatory cytokines and chemokines contribute to pathogenesis.

Evaluation of Patients with Kaposi's Sarcoma

- Determination of $CD4^+$ T-cell count and HIV load is the first step in evaluation.
- Biopsy is indicated to confirm diagnosis.
- Computed tomography (CT) scan of chest and abdomen also is indicated.
- Gastrointestinal endoscopy is performed if clinically indicated

Treatment of Kaposi's Sarcoma

- Highly active antiretroviral therapy (HAART) and treatment of opportunistic infections sometimes are associated with regression of KS.
- If disease is symptomatic or rapidly progressive, or with visceral involvement, systemic therapy with liposomal anthracycline or paclitaxel is instituted; all patients should be receiving *Pneumocystis* prophylaxis. Hematopoietic growth factors and antifungal and anti-herpesvirus prophylaxis or treatment also are appropriate for most patients receiving cytotoxic chemotherapy.
- If disease is indolent and antiretroviral therapy has just been initiated or major changes have been made, observation may be appropriate.
- For a few lesions, topical therapy, injection of lesions, or radiation therapy may be adequate treatment.
- For systemic disease, interferon, thalidomide, or experimental therapy should be considered.

Evaluation of Patients with Lymphoma

- Determination of $CD4^+$ T-cell count and HIV load is the first step in evaluation.
- Assessment for signs of tumor lysis also is indicated.
- Extranodal presentations of lymphoma are common, as are constitutional symptoms (especially with Hodgkin's lymphoma).
- Staging for systemic lymphoma should include testing lactate dehydrogenase levels; imaging of chest, abdomen, and brain; bone marrow biopsy; and lumbar puncture.
- Positron emission tomography (PET) scans with fluorodeoxyglucose (FDG) labeling should be interpreted with extreme caution because HIV infection, inflammation associated with opportunistic infection, and immune reconstitution syndrome all are associated with FDG activity.

Treatment of Lymphoma

- Allopurinol and hydration constitute the first step in treatment, even before staging is complete.
- Chemotherapy (with cyclophosphamide, hydroxydaunomycin (doxorubicin), vincristine (Oncovin), and prednisone (CHOP) plus rituximab or etoposide, Oncovin, doxorubicin, cyclophosphamide, and prednisone (EPOCH) plus rituximab for non-Hodgkin's lymphoma, and doxorubicin (Adriamycin), bleomycin, vincristine, and dacarbazine (ABVD) or the Stanford V regimen for Hodgkin's lymphoma) is standard treatment.
- Intrathecal prophylaxis is appropriate for patients with Burkitt's or Burkitt's-like lymphoma, for patients with bone marrow involvement of non-Hodgkin's lymphoma, and for patients with EBV-associated non-Hodgkin's lymphoma. Either cytarabine or methotrexate can be used for this purpose.

Cytotoxic Therapy for Cancer

- *Pneumocystis* prophylaxis is given regardless of $CD4^+$ count.
- Antifungal and anti-herpesvirus infection prophylaxis or treatment also is indicated.
- In HAART-naive patients, antiretroviral therapy should be initiated shortly after cytotoxic chemotherapy begins when associated nausea is controlled.
- Patients with relapsed lymphoma may be appropriate candidates for high-dose therapy with stem cell rescue.

INTRODUCTION

In 1981, the first cases of *Pneumocystis carinii* pneumonia in gay men were reported.[1] Shortly thereafter, KS, primary central nervous system lymphoma, and Burkitt's lymphoma also were recognized in gay men. In 1983 human immunodeficiency virus (HIV-1) was cultured from the lymph node of a patient.[2] The origins of the HIV/AIDS (acquired immunodeficiency syndrome) epidemic remain obscure, but by 2006, the impact of the epidemic was staggering. Nearly 40 million people worldwide were infected with HIV, and the annual death rate was approximately 3 million, making HIV the fourth leading cause of death worldwide.[3] In North America, approximately 1.4 million people are infected, and almost half a million have died. Among patients with access to antiretroviral therapy, however, AIDS-related mortality has dramatically declined. This chapter reviews aspects of HIV infection and the diagnosis and management of KS, AIDS-associated lymphoma, and Hodgkin's lymphoma.

HIV INFECTION

The virus is transmitted sexually, parenterally, and vertically.[4] Worldwide, heterosexual transmission is most common. Condoms reduce the risk of transmission, and male circumcision reduces the risk of female-to-male HIV transmission.[5] The highest risk of sexual transmission is associated with receptive anal intercourse. In the United States, men who have sex with men are the largest HIV risk group. Injection drug use also is a major contributor to the epidemic. Health care workers are at risk, but barrier precautions, safer needle devices, attention to safe practices, and related technical innovations have reduced exposure.[6]

HIV is associated with a spectrum of disease from asymptomatic to profoundly immunocompromised. HIV RNA levels are important predictors of the rate of progression, whereas $CD4^+$ T-cell counts are markers of immunologic status. In patients who do not receive treatment, the plasma HIV load reaches a fairly constant level within about 6 months of primary infection. The host cytotoxic T-cell response is one determinant of this "set point." Some diseases are specifically associated with low $CD4^+$ T-cell counts. For example, *Pneumocystis* pneumonia typically occurs in patients with counts of less than 200 cells/mm^3, and primary brain lymphoma typically is diagnosed in patients with counts of less than 50 cells/mm^3.[7]

A variety of constitutional signs and symptoms are common in HIV-infected patients, even in the absence of opportunistic infection or malignancy. These include anorexia, nausea, vomiting, and weight loss. Persistent fever, however, always requires a search for opportunistic infections. Typically this investigation involves a chest radiograph, sinus CT scan, blood cultures for bacteria and atypical mycobacteria, and serum cryptococcal antigen test. Neurologic problems include AIDS dementia complex, HIV myelopathy, and various peripheral neuropathies.

Opportunistic infections that commonly occur in HIV-infected patients include *Pneumocystis* pneumonia (the agent of which is now called *Pneumocystis jiroveci*), chronic sinusitis, oral and esophageal candidiasis, herpes simplex infections, shingles, cytomegalovirus retinitis, and enterocolitis associated with *Campylobacter*, *Salmonella*, *Shigella*, adenovirus, cytomegalovirus, or any of various protozoans (*Cryptosporidium*, *Entamoeba histolytica*, *Giardia*, and others). A variety of infections manifest in the central nervous system, including toxoplasmosis, progressive multifocal leukoencephalopathy, and cryptococcal meningitis. Skin infections with molluscum contagiosum and dermatophytic fungi also are common. Several of these infections can be prevented with appropriate prophylaxis[8] (Table 69-1).

Antiretroviral therapy generally is recommended for all patients with acute HIV infection or within the first 6 months after seroconversion.[9–11] In addition, antiretroviral therapy is recommended for all patients with symptomatic AIDS, thrush, or unexplained fever and patients with $CD4^+$ T-cell counts below 200/mm^3. For asymptomatic patients with $CD4^+$ T-cell counts above 200/mm^3, many clinicians would initiate therapy only in those with higher viral loads. Drugs approved for the suppression of viral replication include nucleoside analog reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, protease inhibitors, and an inhibitor of fusion of the viral envelope with $CD4^+$ T cells.[12] In parallel with the treatment of chemotherapy-responsive malignancies, combination antiretroviral therapy with two or more agents appears to be the most effective way to suppress viral replication and to reduce the emergence of resistant virus. Use of non-nucleoside reverse transcriptase inhibitors is associated with rapid mutations to high-level resistance, so these agents should never be used alone. Use of protease inhibitors sometimes is associated with lipodystrophy, a disorder associated with fat redistribution. The only available envelope fusion inhibitor, enfuvirtide, is a parenteral drug and approved solely for resistant virus. A convenient guide to the medical management of HIV infection, which is updated regularly, can be found at the Johns Hopkins AIDS Service website (http://hopkins-aids.edu/publications/publications).

Table 69-1 Prophylaxis of Opportunistic Infections

$CD4^+$ T-Cell Count	Indicated Prophylaxis
Less than 200/mm^3	*Pneumocystis* pneumonia (PCP)* prophylaxis with TMP-SMX, dapsone, or aerosolized pentamidine.
Less than 100/mm^3	Toxoplasmosis prophylaxis in patients who are seropositive for *Toxoplasma gondii*. TMP-SMX administered for PCP prophylaxis also protects against toxoplasmosis. A variety of other agents are available for use in patients not receiving TMP-SMX.
Less than 50/mm^3	*Mycobacterium avium* complex (MAC) infection prophylaxis. The drug of choice is either clarithromycin (daily) or azithromycin (weekly).

TMP-SMX, trimethoprim-sulfamethoxazole.
*I.e., *Pneumocystis jiroveci* infection.

KAPOSI'S SARCOMA

Epidemiology

Before AIDS, KS was a rare disease recognized in older men of Eastern European or Mediterranean descent, in parts of Africa where it often occurred in children, and in organ transplant recipients.[13] Among AIDS patients, KS is the most common cancer. The risk of development of KS for an HIV-infected patient in the pre-HAART era was estimated to be greater than 1000 times the risk in the HIV-uninfected population.[14] With antiretroviral therapy, the incidence has diminished substantially.[15,16] The risk of KS is not evenly distributed among HIV risk groups. KSHV, also referred to as human herpesvirus-8 (HHV-8), is a required cofactor.[13] In contrast with most human herpesvirus infections, which are ubiquitous, KSHV infection is uncommon in most populations worldwide. Rates of infection are higher in central and southern Africa and intermediate in Mediterranean and Eastern European countries.

Men who have sex with men are at especially high risk for acquiring KSHV infection.[17] Sexual transmission may be inferred from several studies, but the precise mode of transmission remains poorly understood. By contrast, patients who acquire HIV infection through nonsexual blood-borne exposure (from intravenous drug use or transfusion of blood or blood products) are at lower risk for KSHV infection and for the development of KS. Among persons who are seropositive for KSHV and HIV, the sequence of exposure is an

important risk factor for the development of KS.[18] When KSHV seroconversion follows HIV seroconversion, the risk of developing KS is higher. Presumably this reflects the impact of HIV on establishing an effective primary immune response to KSHV.

Pathogenesis

KS lesions are composed of spindle-shaped cells between collagen bundles, neovascular slit-like spaces, extravasated erythrocytes, hemosiderin-laden macrophages, and an infiltrate of plasma cells, lymphocytes, and other inflammatory cells.[19] Spindle cells show nuclear pleomorphism in the later stages. Lesions begin in the dermis and progress from macular to plaque to tumor stage. In the early macular stage, spindle cells form irregular slits and clefts. Nuclear atypia and mitoses are absent. In the plaque stage, the entire dermis is involved, and extravasated erythrocytes and hemosiderin-laden macrophages appear. With progression to the tumor stage, spindle cells come to predominate. Nuclear atypia and mitoses are present.

Spindle cells probably are of lymphatic endothelial origin. KS may begin as a polyclonal inflammatory lesion and only sometimes progress to clonal neoplasia. Immunohistochemistry and in situ hybridization studies show that KSHV is present in spindle cells and some of the cells of the inflammatory infiltrate. KSHV is invariably present in KS lesions.[20] Electron microscopy shows evidence of viral production in some cells in KS lesions (Fig. 69-1), but spindle cells generally are latently infected (Fig. 69-2). Several viral genes are implicated in aspects of regulation of cellular growth, apoptosis, immune regulation, and angiogenesis.[21] Curiously, many of the genes with functional properties suggesting that they may play a role in transformation are lytic cycle genes and are not expressed in most of the spindle cells of KS lesions. These include the viral interferon regulatory factors (v-IRFs), an antiapoptotic protein viral Bcl-2 (v-Bcl-2), viral interleukin 6 (v-IL-6), a G protein-coupled receptor (GPCR), and K1, a transmembrane glycoprotein with transforming properties. The viral proteins that are expressed in latently infected spindle cells are LANA (latency-associated nuclear antigen), a nuclear protein required for maintenance of the viral episome; v-CyC, a cyclin-D homolog that may disrupt usual pathways of cell cycle inhibition; and v-FLIP (viral FLICE-like inhibitory protein—FLICE being Fas-associated protein with death domain [FADD]-like interleukin-1α–converting enzyme), an antiapoptotic protein that blocks death signals and may induce survival signals. KSHV LANA may recruit de novo DNA methyltransferases, an integral feature in the development of cancer.[22] The molecular biology of the virus and its role in transformation are discussed further in Chapter 11.

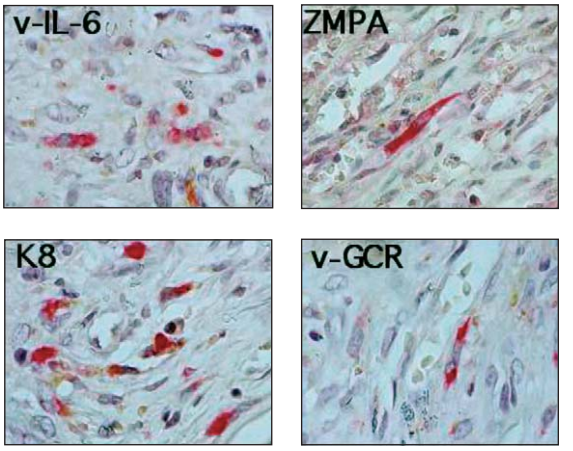

Figure 69-2 • Kaposi's sarcoma herpesvirus (KSHV) antigens in spindle cells of a nodular KS lesion. Immunohistochemical studies show punctate nuclear LANA *(brown spots)* in many cells, with v-GPCR expression *(red cytoplasm)* in a few scattered lytic cells with nuclei that are devoid of LANA. LANA, latency-associated nuclear antigen; v-GPCR, viral G protein-coupled receptor; v-IL-6, viral interleukin-6.

The immune system seems to play a determining role in the pathogenesis of KS. In organ transplant recipients, reduction or withdrawal of immunosuppression is often associated with tumor regression.[17] The virus itself expresses a number of genes that modify immune function. Viral genes modulate the actions of interferon and downregulate the display of major histocompatibility complex (MHC) class I and natural killer (NK) cell receptor ligands.[23–25] Cytotoxic T-cell responses to viral lytic antigens are readily detected in KSHV-seropositive individuals but are diminished in HIV-infected persons.

Cytokine dysregulation associated with HIV infection may specifically enhance the proliferation of this neoplasm. In vitro interleukin-6, tumor necrosis factor-α, interleukin-1β, interleukin-8, and various chemokines will stimulate proliferation of KS-derived cells. The HIV TaT protein may activate the RAS/ERK MAPK and JAK/STAT pathways, leading to lytic cycle replication of KSHV.[26,27] Opportunistic infections often precede the presentation or an exacerbation of KS. Although both phenomena may reflect a deterioration of underlying immune status, several investigators have suggested that altered cytokine and inflammatory mediator production in association with opportunistic infection may have a direct impact on KS pathogenesis.[28]

Clinical Aspects

KS lesions typically arise on the skin or mucous membranes as flat deep purple plaques (Fig. 69-3). These plaques may progress to form nodules. Many parts of the body may be involved, and the clinical problems associated with KS vary as a function of location. Lesions generally are not pruritic or painful (except occasionally when they involve the plantar surface of the feet). The most frequent sites of disease are the skin, mucous membranes, lymph nodes, and gastrointestinal tract. Skin lesions most commonly appear on the legs and face (especially the nose and ears) and often are symmetrically distributed. The oral hard palate also is commonly involved. KS virtually never involves brain parenchyma.

KS lesions have a distinctive appearance that is highly suggestive with regard to diagnosis. Other entities, however, occasionally are confused with KS. Among them is bacillary angiomatosis, a benign

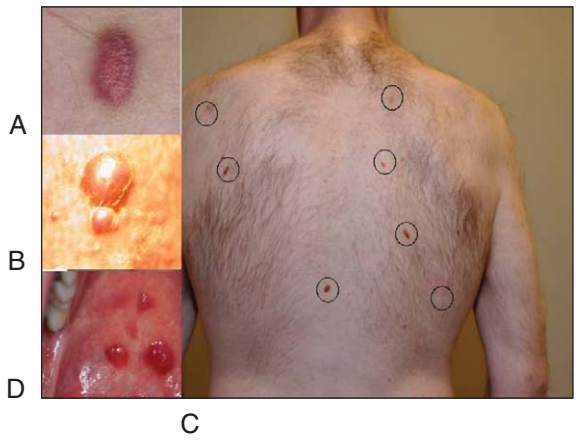

Figure 69-3 • Kaposi's sarcoma lesions. **A,** Plaque lesion. **B,** Nodular lesions. **C,** Near-symmetrical distribution of lesions on the trunk. Lesions are circled. **D,** Lesions on the hard palate.

disease associated with a slow-growing, fastidious, gram-negative bacillus and treated with antibiotic therapy.[29] Bacillary angiomatosis often is associated with systemic symptoms such as fever, chills, and headache. Therefore, a biopsy generally is indicated to confirm the diagnosis. This most commonly is a punch biopsy of a skin lesion, but at times lymph node biopsy, transbronchial or other endoscopic biopsy, or pleural biopsy is required. Once the diagnosis has been established, visualization of a characteristic lesion by bronchoscopy without biopsy or characteristic CT findings (flame-shaped hemorrhages) generally are regarded as adequate to diagnose pulmonary KS (Fig. 69-4). Gallium scan may be useful in differentiating pulmonary KS from *Pneumocystis* pneumonia, because the inflammatory infiltrates in *Pneumocystis* pneumonia are gallium-avid and KS lesions are not. On the other hand, KS lesions usually are thallium-avid.

Lesion location is an important determinant of symptoms. Facial lesions are particularly likely to be cosmetically disturbing. Lesions of the lower extremities often lead to lymphatic obstruction with painful edema. Pulmonary lesions often are associated with dyspnea (but rarely with hemoptysis). Gastrointestinal lesions may be associated with pain, cramping, diarrhea, and bleeding or may be entirely asymptomatic.

Staging and Prognosis

Standard tumor-node-metastases (TNM) staging has not proved particularly useful for KS, partly because KS is a multicentric disease and partly because the status of HIV disease is of overriding importance.

Figure 69-4 • Computed tomographic scan of the chest shows a nodular lesion with characteristic flame-like appearance adjacent to the right upper bronchus. (Courtesy of Elliot Fishman.)

The AIDS Clinical Trials Study Group (ACTG) developed a staging system specifically for KS occurring in HIV-infected persons.[30] Devised in the era before the introduction of HAART, this system classified patients as "good risk" or "poor risk" according to the extent of tumor (confined to skin or minimal disease versus edema, ulcers, and extensive oral, visceral, or gastrointestinal invasion), immune status as measured by $CD4^+$ T-cell count ($\geq 200/mm^3$, $<200/mm^3$), and evidence of HIV-associated systemic symptoms; it proved to be a reasonable predictor of survival. When the ACTG staging system was re-evaluated in patients receiving HAART, immune status was no longer associated with an increased risk of death, even when the $CD4^+$ cutoff point was lowered to $100/mm^3$ or less.[31]

Suppression of HIV replication with antiretroviral therapy sometimes is associated with remission.[32,33] It has been noted that some protease inhibitors have direct antiangiogenic effects, but regimens that do not include protease inhibitors appear equivalent with regard to clinical outcome of antiretroviral-naive HIV-infected patients with KS.[34] KSHV copy number does not correlate well with clinical response in patients receiving liposomal doxorubicin.[35]

Therapy

Management of HIV and Opportunistic Infection

HAART has profoundly altered the survival of patients with KS. The Multicenter AIDS Cohort Study showed an 81% reduced risk of death for patients with KS who received HAART.[33] The only form of KS clearly implicated in directly causing the death of patients is pulmonary KS. In the era before HAART, KS was associated with a 90% mortality rate attributable to disease progression. In patients receiving HAART, KS is associated with a 47% mortality rate.[36]

The impact of antiviral therapy may be multifaceted. Restoration of immune function must be of major importance, but antiviral therapy also may reduce exposure to HIV proteins such as TaT and a variety of inflammatory cytokines associated with opportunistic infections also thought to play a role in KS progression. Thus, therapy begins with ensuring that the antiretroviral regimen has been optimized and that opportunistic infections have been treated (Box 69-1). In the absence of rapidly progressing disease (more than 10 new lesions in the past month), lymphedema, or symptomatic visceral or cosmetically disfiguring disease, it often is appropriate to wait several months to assess the full impact of the initiation of antiretroviral therapy before systemic therapies are instituted.

Systemic Therapy

Interferon-α is active in a subset of patients.[37] The mechanism of action may involve antiviral, immune modulatory, antiproliferative,

Box 69-1. TREATMENT OF KAPOSI'S SARCOMA

- *Treatment with liposomal anthracycline*: Liposomal doxorubicin is administered at a dose of 20 mg/m^2 intravenously every 2 to 3 weeks. Granulocyte colony stimulating factor (G-CSF) is used as needed. Once a maximum response is attained, treatment is discontinued.
- *Treatment with paclitaxel*: Paclitaxel is administered at 100 mg/m^2 infused over 3 hours every 2 weeks. G-CSF is routinely used. Once a maximum response is attained, treatment is discontinued.
- *Treatment with interferon-α*: Therapy begins at 1 million units/per day, with dose escalation as tolerated up to 9 million units per day over a period of 2 months. Interferon treatment is associated with flu-like symptoms of fevers, chills, myalgias, and fatigue. These symptoms typically diminish and tolerance improves with time. Night-time administration and adjuvant use of acetaminophen and nonsteroidal anti-inflammatory medications improve the tolerability of the regimen. Patients who respond or whose disease is stable are continued on treatment until disease progression.

or antiangiogenic properties. Uncertainties with regard to mechanism notwithstanding, interferon-α has demonstrated beneficial activity in the treatment of KS. In combination with protease inhibitor-based antiretroviral therapy, interferon can be safely administered at 5 million IU per day.[38] Dose-limiting toxicities are neutropenia and malaise. Time to interferon response of 8 to 12 weeks precludes its use in patients with very symptomatic or aggressive disease. On the other hand, responses often are long-lasting, particularly complete responses (CRs). This period is longer than the response duration typically associated with cytotoxic chemotherapy. Furthermore, even patients with widespread disseminated disease can have complete clinical responses.

Although a variety of single agents and combinations of agents have been studied in the past, single-agent therapy with a liposomal anthracycline or with paclitaxel is now the standard of care. Liposomal formulation of anthracyclines leads to altered pharmacokinetic profiles. Thus, liposomal doxorubicin has a prolonged plasma half-life and achieves increased concentration in tumor tissues and decreased concentration in normal tissues.[39] In phase III trials, liposomal doxorubicin and liposomal daunorubicin have been shown to be at least as effective as and less toxic than combination regimens including nonliposomal anthracyclines.[40,41] Liposomal anthracyclines generally are well tolerated, with myelosuppression as the major limiting toxicity. A "hand-foot" syndrome occasionally is seen and often responds to steroids.[42] Alopecia is rare, and cardiotoxicity is very rare.

Paclitaxel is an active agent for treatment of refractory KS.[43–45] In an initial trial, patients with advanced KS received 135 mg/m^2, escalated to 175 mg/m^2 every 3 weeks. The response rate was 71.4%. Responses were seen in all four assessable patients who had previously received anthracycline therapy for KS and in patients with pulmonary KS. In a subsequent study, patients in whom one or more chemotherapy regimens, including combination chemotherapy and chemotherapy with liposomal daunorubicin, had failed to provide benefit, received treatment with paclitaxel 100 mg/m^2 every 2 weeks.[45] Of these patients with poor prognosis, in whom the median CD4$^+$ T-cell count was 5/mm^3, 53% responded. The same regimen in treatment-naive patients yielded an overall response rate of 70%. Alopecia, nausea, vomiting, myalgias, and myelotoxicity often requiring growth factor support are common toxicities.

Thalidomide also shows activity against KS.[46,47] Regimens studied include daily doses of 100 mg for 8 weeks, dose escalation beginning at 200 mg daily to tolerance, and treatment with 200 to 600 mg daily.[48,49] Sedation, depression, fever, rash, and neurologic toxicity have all been reported. The antineoplastic activity of thalidomide is poorly understood. Thalidomide inhibits tumor necrosis factor (TNF) production, alters T-cell response, and modulates T_H1 cytokine production. Although only a minority of patients respond, its oral availability and toxicity profile make it an attractive alternative for patients who do not require immediate responses and in patients who cannot tolerate myelosuppressive regimens.

Several other agents have been reported to have promising results. Administration of interleukin-12 to patients whose KS was progressing despite antiretroviral therapy led to partial response or CR in 71% of patients in a phase I pilot study.[50] Two oral therapies have also been reported to be active against KS in small series: Imatinib induced regression of tumor in HIV-infected patients,[51] whereas substitution of rapamycin therapy for other immunosuppression modalities was associated with regression in renal transplant recipients.[52]

Local Therapies

Local therapies are appropriate for patients with a few lesions and slowly progressive disease. For example, a patient with maximally suppressed HIV-1 infection and indolent but cosmetically disturbing facial lesions may benefit from local treatment. Local therapy avoids immunosuppression associated with cytotoxic chemotherapy but does nothing to interrupt or slow systemic progression and the appearance of new lesions. Alitretinoin (9-*cis*-retinoic acid) is administered as a topical gel.[53] Four to 8 weeks of therapy typically are required before responses are seen. Responses occur even in patients with low CD4$^+$ T-cell counts. Irritation at the site of gel application is common. Intralesional injections with vinblastine, interferon, and sodium tetradecyl sulfate all have a high response rate, but regrowth is common.[54,55] Similarly, liquid nitrogen is effective for the treatment of small lesions, particularly on the face.[56] Radiation therapy is an effective and widely used local treatment.[56–59] Response rates generally are between 80% and 90%. A variety of dosing schedules have been used. In a randomized study, three radiation regimens were compared: 8 Gy delivered in 1 fraction, 20 Gy in 10 fractions, and 40 Gy in 20 fractions. Each treatment scheme led to flattening of lesions. As might be expected, the highest dose was associated with the greatest chance for complete clearing of lesions and the longest duration of benefit. Thus, single fractions are most appropriate for patients with very short life expectancy and to provide symptomatic rather than cosmetic relief. The conjunctiva, oral pharynx, and other sensitive tissues require different doses and fractionation schemes than those used with most cutaneous lesions.

Antiherpesvirus Agents

In vitro ganciclovir and foscarnet are active in inhibiting lytic KSHV replication.[60] Several studies have demonstrated a decreased incidence of KS in patients with HIV who received either ganciclovir or foscarnet regimens but not acyclovir.[61–64] Thus, of potential interest to researchers is the possibility that agents with similar in vitro activity may block the development of KS. By contrast, these agents appear to have no activity in the treatment of established KS.[65] Presumably, the resistance of established KS to such treatments reflects the predominantly latent state of the viral genome in tumors.

LYMPHOMA

Epidemiology

Both non-Hodgkin's and Hodgkin's lymphomas occur with increased incidence in patients with HIV infection, although the increase in non-Hodgkin's lymphomas is much greater, and only aggressive B-cell non-Hodgkin's lymphomas have been formally recognized as AIDS-defining illnesses. In contrast with the situation with KS, lymphomas occur in all HIV-infected populations and show no marked predilection for men who have sex with men or other particular risk groups. Early data from cancer and AIDS registries in the United States showed that the relative risk of development of non-Hodgkin's lymphoma within 3.5 years of another AIDS diagnosis was 165-fold compared with that in persons without AIDS.[66] Particular types of lymphoma showed a much more dramatic increase in incidence. Thus, brain lymphoma was increased 3600-fold in comparison with the general population.[67] The risks for high-grade diffuse immunoblastic and Burkitt's lymphomas were increased 652-fold and 261-fold, respectively. The risk for Hodgkin's lymphoma in HIV-infected persons is increased 5- to 10-fold.[68–70]

With HAART, the overall incidence of lymphoma is decreasing, with the most marked decrease occurring in primary brain lymphoma.[71–74] The length of time with HIV infection before diagnosis of lymphoma is increasing, as is the CD4$^+$ T-cell count at the time of diagnosis. Of interest, the incidence of Hodgkin's lymphoma has increased in the past decade beginning with the availability of HAART.[68,75,76]

Histology and Pathogenesis

The spectrum of lymphomas in the general population includes indolent and aggressive, follicular and diffuse, B- and T-cell tumors, and Hodgkin's and non-Hodgkin's histologic types. In patients with

HIV infection, the increased incidence of lymphomas is mainly an increase in aggressive B-cell tumors with diffuse architecture and in Hodgkin's lymphoma.[73,77] Diffuse immunoblastic, Burkitt's (and Burkitt's-like), and diffuse large B-cell lymphomas each account for approximately one third of the total of non-Hodgkin's lymphomas. Polymorphic lymphoproliferative disorders such as those seen in transplant recipients also have been described.[78] Surface markers characteristic of B cells (CD19, CD20, CD22) generally are expressed, with the notable exception of primary effusion lymphomas. The latter often exhibit an indeterminate phenotype with expression of lymphoid activation markers.[77] Mixed cellularity is the most common Hodgkin's lymphoma subtype in the HIV-infected population, whereas lymphocyte-predominant Hodgkin's lymphoma is quite rare.[70,79–81]

The Epstein-Barr virus (EBV) genome is present in approximately half of lymphomas that arise in HIV-infected patients. In contrast with KSHV, EBV is a ubiquitous virus. EBV has a tropism for B lymphocytes and mediates growth transformation of primary B cells into long-term-proliferating lymphoblastoid cell lines. It is associated with lymphoma across the spectrum of immunocompromised patients, including patients with congenital immunodeficiency and transplant recipients. The molecular biology of the virus and its role in transformation are discussed further in Chapter 11. Particular anatomic sites and particular histologic types are especially likely to be EBV-associated. Primary brain lymphomas and lymphomas with central nervous system involvement are virtually always EBV-positive in patients with AIDS[82–84] (Fig. 69-5). Lymphomas with immunoblastic features, primary effusion lymphomas, plasmablastic oral lymphomas, and Hodgkin's lymphoma usually also are EBV-associated.[77,79] Curiously, although EBV was discovered in African Burkitt's lymphoma and nearly 100% of endemic Burkitt's lymphomas are EBV-associated, AIDS-associated Burkitt's or Burkitt's-like lymphoma is the histologic type least frequently associated with EBV (20% to 30%).[77]

Burkitt's lymphomas occur earlier in the course of HIV disease than do diffuse immunoblastic or diffuse large cell lymphomas.[73] In one series, the median $CD4^+$ T-cell count in patients with Burkitt's lymphoma was 270/mm^3, whereas it was 99/mm^3 for diffuse immunoblastic and diffuse large cell lymphomas.[85] Among patients with lymphoma as an AIDS-defining event, Burkitt's lymphoma accounted for 47% of lymphomas occurring as the first manifestation of AIDS, whereas it accounted for only 13% of non-Hodgkin's lymphomas that developed after another AIDS-related event. Isolated extranodal lymphomas were histologically diffuse immunoblastic or large cell types (97%) and were associated with a median $CD4^+$ T-cell count of 70/mm^3. Primary central nervous system lymphomas represent the extreme end of this spectrum and are associated with a particularly low $CD4^+$ T-cell count.[83] It has been suggested that HAART has changed the character of lymphomas occurring in HIV-infected patients, with a shift away from lymphomas of postgerminal center origin.[86]

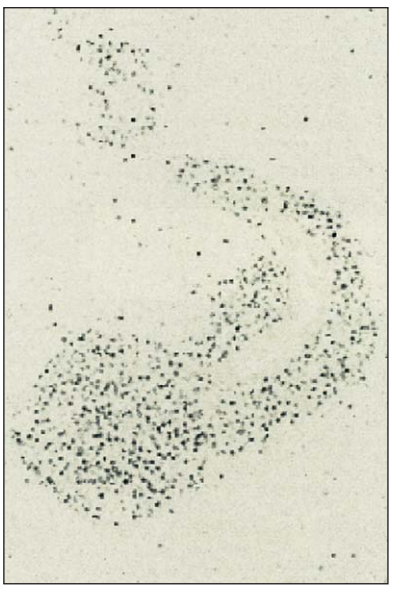

Figure 69-5 • In situ hybridization demonstrating the presence of Epstein-Barr virus (EBV) RNA in brain lymphoma. Tumor cells are clustered around a vessel.

Clinical Aspects

Advanced stage, extranodal disease, and constitutional symptoms frequently are seen in patients with HIV-associated lymphoma.[87–89] Approximately 90% of patients have some extranodal involvement, and in 30%, all disease is extranodal. The gastrointestinal tract is a particularly frequent site of extranodal involvement. Sites not generally involved by lymphoma, such as heart, common bile duct, and rectum, exhibit such involvement in patients with AIDS. Similarly, brain and skin may be involved by Hodgkin's lymphoma at presentation in HIV-infected patients. Pleural, pericardial, or peritoneal cavities may harbor lymphomatous effusions in the absence of any "solid" tumor mass.

Constitutional symptoms are much more common in association with lymphoma in HIV-infected patients than in other patients. As in patients with KS, the presence of such symptoms in patients with lymphoma should prompt a search for opportunistic infections. In contrast with the KS situation, however, even after opportunistic infections are excluded, constitutional symptoms are common. Biopsy is required for the diagnosis of lymphoma, with the possible exception of primary central nervous system lymphoma, as discussed later.[90] CT or magnetic resonance imaging (MRI) of the chest and abdomen often is useful in identifying lesions likely to yield diagnostic material. Gastrointestinal tract lesions occasionally will be detected only by endoscopy. Persistent generalized lymphadenopathy is common in patients with HIV infection, but asymmetrically enlarged nodes should always be biopsied. A finding of benign hyperplasia on biopsy and examination of an enlarged node does not exclude the possibility of lymphoma elsewhere, and several biopsies may be required to establish a diagnosis. Even in the absence of cytopenias, bone marrow biopsy sometimes will yield a diagnosis (Fig. 69-6). Bone marrow-only presentations of Hodgkin's lymphoma are not uncommon.

The location of the pathologic lesion is important in determining the type of biopsy to be performed. Lesions in the brain or other organs devoid of lymphoid tissue are adequately assessed by needle biopsy. Lymph nodes are best assessed by excisional biopsy, which allows assessment of architecture. Failure to identify a clonal population by flow cytometry or other molecular diagnostic techniques does not exclude lymphoma. Clonality could not be demonstrated in a sizable percentage of lymphomatous lesions in a San Francisco series; whether its absence reflected technical artifact or distinctive pathogenesis was not clear.[91]

Staging of non-Hodgkin's lymphomas in patients with AIDS requires that the brain be imaged by MRI or CT. In addition, in patients with EBV-positive tumors and in patients with Burkitt's, Burkitt's-like, or immunoblastic lymphomas, a diagnostic lumbar puncture is indicated. An initial dose of an appropriate agent for prophylactic intrathecal chemotherapy (cytosine arabinoside or methotrexate) often is administered at the time of the diagnostic lumbar puncture.

Although brain lymphomas are common in patients with HIV infection, toxoplasmosis is the most common cause for an intracranial mass lesion.[92] Ring-enhancing unifocal or multifocal lesions are

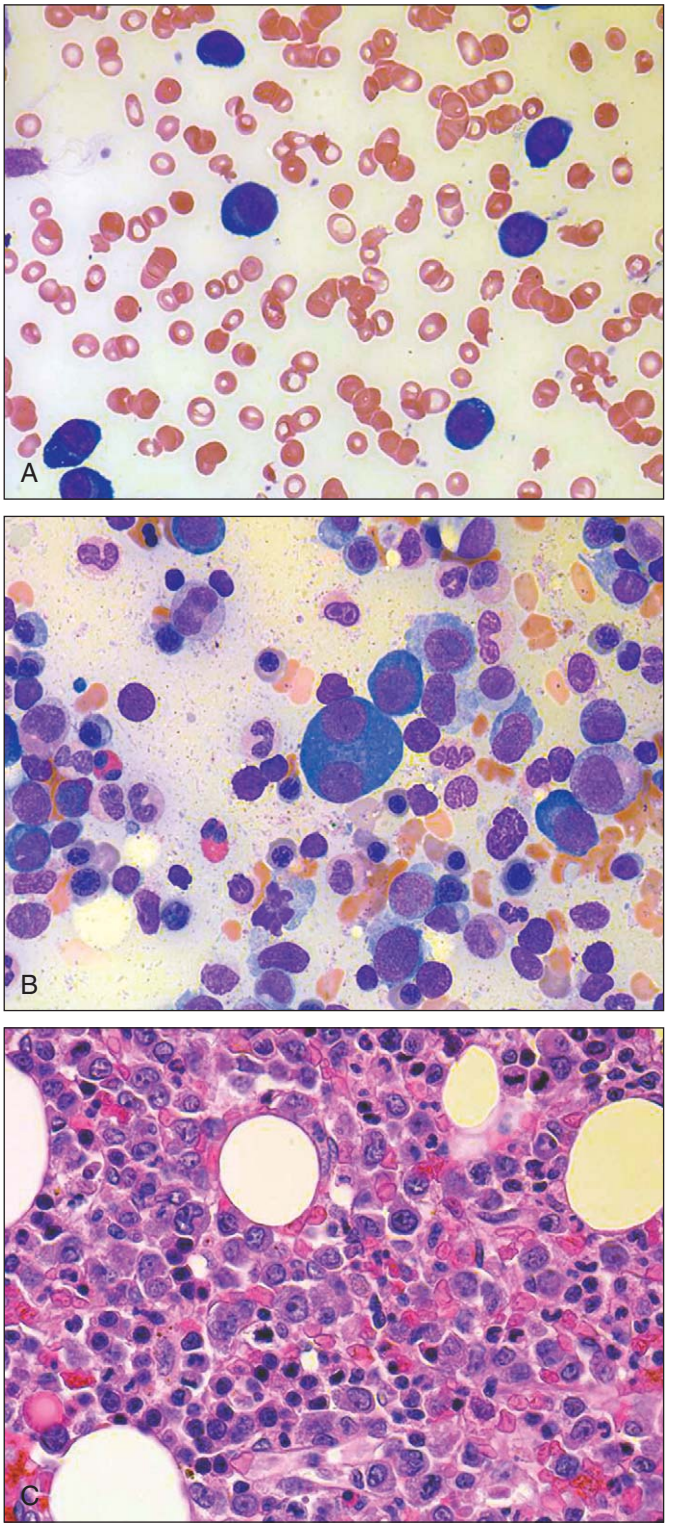

Figure 69-6 • Plasma cell leukemia in a patient with human immunodeficiency virus infection. **A,** Peripheral blood smear. **B,** Aspirate. **C,** Bone marrow biopsy.

common in both diseases. Yet biopsy sometimes is associated with morbidity and even death, particularly in patients with lymphoma.[93] Thus, rather than prompt biopsy of suspicious lesions, empirical treatment for presumed toxoplasmosis is standard in seropositive patients. Biopsy is pursued only if a patient fails to respond to toxoplasmosis therapy or if evidence of progression is observed over a 2-week therapeutic trial.

A variety of approaches to differentiate neoplastic from non-neoplastic lesions have been explored.[94–98] Recent studies of diffusion-weighted MRI have shown significant overlap in apparent diffusion coefficients between lymphoma and toxoplasmosis lesions, thereby limiting its utility in distinguishing between the two entities.[99,100] PET with [^{18}F]fluoro-2-deoxyglucose (FDG) seems promising in accurately differentiating between lymphoma and infectious intracranial lesions, although the literature is not recent and includes relatively few cases.[101] Single-photon emission computed tomography (SPECT) with thallium 201 generally correctly identifies patients with primary central lymphoma but occasionally mislabels patients with infectious lesions as having such neoplasms.[96–98]

A nonradiographic approach to diagnosis of primary brain lymphoma involves polymerase chain reaction (PCR) assay for EBV DNA in cerebrospinal fluid.[102,103] Although PCR analysis occasionally will detect EBV DNA in cerebrospinal fluid in other settings, such as acute infectious mononucleosis with neurologic manifestations, viral DNA rarely is detected in the cerebrospinal fluid of HIV-infected patients without lymphoma.

The established International Prognostic Index (IPI) factors of age, tumor stage, lactate dehydrogenase level, together with Eastern Cooperative Oncology Group (ECOG) performance status and number of extranodal sites, are confirmed to be significant variables in AIDS-related non-Hodgkin's lymphoma in the era of HAART.[104,105] Failure to attain complete remission also has been shown to predict shorter survival. $CD4^+$ cell counts below 100/mm^3 also were prognostic for poor outcome when analyzed prospectively; of interest, however, in a retrospective analysis, $CD4^+$ counts less than 100/mm^3 predicted shorter survival only in the pre-HAART era. The response to antiviral therapy has emerged as the most important prognostic factor.[74]

Therapy

Patients with HIV infection often have very aggressive, rapidly proliferating tumors. Attention to the possibility of tumor lysis syndrome with prompt assessment of renal function, serum electrolytes, and hyperuricemia is critical. Patients should always be started on allopurinol and aggressively hydrated, even before the staging evaluation is complete (Box 69-2). Rapid assessment and treatment can be critically important in patients with aggressive lymphomas.

Before the routine use of *Pneumocystis* prophylaxis and hematopoietic growth factors, lymphoma regimens in AIDS patients were associated with a high treatment-related mortality rate.[106]

Box 69-2. TREATMENT OF NON-HODGKIN'S LYMPHOMA

- Treatment is with standard-dose CHOP: cyclophosphamide (750 mg/m^2), doxorubicin (50 mg/m^2), vincristine (Oncovin; 1.4 mg/m^2), prednisone (100 mg/day for 5 days)—repeated every 3 weeks. A maximum of six cycles are given. Granulocyte colony stimulating factor is routinely prescribed. Dose adjustments are made for toxicity.
- Patients with Epstein-Barr virus-associated lymphoma, except Hodgkin's lymphoma, or with Burkitt's or Burkitt's-like lymphoma receive intrathecal prophylaxis with 12 mg of methotrexate and 100 mg of hydrocortisone administered five times during the first two cycles of systemic chemotherapy.
- Patients with lymphomatous meningitis receive whole-brain irradiation and intrathecal chemotherapy (three times per week until clear; the interval of treatments is then tapered to once a week for a month and then once a month for a total of 6 months), until the cerebrospinal fluid (CSF) demonstrates clearance of lymphoma.

A randomized trial of standard versus reduced-dose therapies showed that reduced-dose therapies did not compromise overall or disease-free survival but were associated with a decrease in the percentage of patients in whom severe toxicities developed.[107] In profoundly immunocompromised patients, the antitumor effects of cytotoxic chemotherapy had to be balanced against associated myelosuppressive and immunosuppressive effects. With the advent of improved prophylaxis of opportunistic infections, highly effective antiretroviral therapy, and perhaps some change in the character of the tumors emerging in such patients, the outlook for these patients has improved significantly.

A first question addressed in the era of HAART was the safety of the combination of antiretroviral therapy and cytotoxic chemotherapy. Data from retrospective series and from trials combining cytotoxic chemotherapy regimens with antiretroviral regimens have been published.[108,109] Although some interactions have been reported with altered clearance rates of serum concentrations of cyclophosphamide, doxorubicin, and indinavir, adverse interactions have been modest, with the exception of regimens that include zidovudine. Additional studies have suggested increased toxicity with the combination of chemotherapy and some of the protease inhibitors, known potent inhibitors of the cytochrome P-450 system. When saquinavir was combined with an infusional regimen of cyclophosphamide, doxorubicin, and etoposide (CDE), mucositis was observed in 67% of patients, a significantly higher rate than that seen with didanosine plus CDE.[108,110] Decreases in day 10 and day 14 neutrophil counts in patients receiving CDE with protease inhibitor-containing HAART compared with those who received HAART without protease inhibitors also are described, with grade 3 and 4 infections requiring hospitalization occurring in 48% versus 25% of patients, respectively.[111] Infusional regimens have attracted a great deal of interest. CDE administered as a 96-hour infusion combined with HAART has yielded impressive results in a multi-institutional study.[112] Of 98 analyzable patients, those who received the infusional therapy and HAART had a median overall survival time of almost 14 months, whereas those who received the same infusional therapy and only a single antiretroviral agent (didanosine) had a median survival time of approximately 7 months. Combination of the regimen with rituximab yielded a CR rate of 70% and a significant increase in estimated overall survival rate (64% at 2 years).[113] This study and another trial evaluating rituximab combined with CHOP (i.e., cyclophosphamide, vincristine, doxorubicin, and prednisone) chemotherapy have raised concerns that rituximab may increase the risk of severe and life-threatening infection.[114] Further evaluation of this strategy should proceed with caution. A different continuous infusion regimen used in a single-institution study also yielded impressive results.[86] The EPOCH chemotherapy regimen (i.e., cyclophosphamide, doxorubicin, etoposide, vincristine, and prednisone) given by continuous infusion yielded a 92% disease-free survival time of 53 months. These survival outcomes represent a dramatic improvement over what was reported in cooperative group trials from the pre-HAART era. Whether the improved survival reflects changing pathogenesis of lymphoma in HIV-infected patients, improved antiretroviral therapy following lymphoma therapy, the use of continuous infusion, or the particular choice of agents is not clear.

One of the complexities of infusional chemotherapy relates to possible metabolic interactions with antiretroviral agents. The possibility of important, possibly adverse interactions led the investigators studying one of the infusional therapies to not initiate antiretroviral therapy until the conclusion of cytotoxic chemotherapy.[86] Viral load increased modestly during therapy and plateaued between cycles 4 and 6. At 3 months after starting or restarting antiretroviral therapy, viral loads declined to below baseline. There was no evidence that therapy led to the emergence of antiviral resistance. To the contrary, resistance mutations became transiently undetectable during therapy. $CD4^+$ T-cell counts decreased but recovered to baseline within 6 to 12 months. *Pneumocystis* prophylaxis probably should be administered to all patients undergoing intensive chemotherapy regardless of $CD4^+$ T-cell count, whereas *Mycobacterium avium* complex prophylaxis is administered only to patients with $CD4^+$ T-cell counts below 50/mm^3.[87]

Most patients with HIV infection and Hodgkin's lymphoma present with advanced-stage disease. Thus, combination chemotherapy is virtually always the mainstay of therapy (Box 69-3). The ABVD regimen (i.e., doxorubicin, bleomycin, vinblastine, and dacarbazine) was studied by the AIDS Clinical Trials Group in the era before HAART.[115] With the advent of HAART, the CR rate has nearly doubled. In a recent retrospective series of 62 patients with advanced Hodgkin's lymphoma treated with ABVD and HAART, 54 (87%) achieved a CR with 5-year event-free survival (EFS) and overall survival (OS) probabilities of 71% and 76%, respectively.[116] The Stanford V regimen[117] with concomitant HAART was evaluated in a phase II study. Of 59 patients subjected to this regimen, 81% achieved a CR. At a median follow-up of 17 months, the estimated 3-year disease-free survival (DFS) and OS rates were 51% and 68%, respectively.[118]

A variety of salvage therapies have been evaluated, often with disappointing results.[88] ESHAP (etoposide, methylprednisolone, cisplatin, and high-dose cytarabine) chemotherapy is a commonly used regimen.[119] Increasingly, high-dose therapy with autologous peripheral stem cell transplantation is being used as consolidation.[120,121] Time to engraftment, infectious complications in the post-transplantation period, and conditioning regimen complications are similar to those seen in patients without HIV infection. High-dose therapy with peripheral stem cell transplantation is rapidly becoming established as the appropriate salvage strategy for patients with chemotherapy-responsive relapse of either Hodgkin's or non-Hodgkin's lymphoma.

What should be regarded as "standard therapy" for AIDS-associated lymphoma? Except in the most immunocompromised patients, standard-dose lymphoma therapy including doxorubicin is appropriate. Among the chemotherapy regimens that might be considered as standard are CHOP, CDE, and EPOCH. Rituximab has been almost universally added to these regimens.[113,114,122,123] One study suggested that rituximab therapy may be associated with an increased incidence of fatal bacteremia, but this has not been confirmed by other studies.[114] The optimal integration of antiretroviral therapy with chemotherapy remains uncertain, but long-term lymphoma-free survival can be achieved with concomitant or delayed antiretroviral therapy. Patients who experience relapse and are in good condition are appropriate candidates for salvage and may benefit from high-dose therapy with stem cell rescue or other aggressive interventions.

Whole-brain radiation therapy has been the mainstay of treatment for brain lymphomas (Box 69-4).[124,125] Retrospective studies show tumor responses, improvement in quality of life, and longer survival with treatment, but long-term survival is rare. Small series with high-dose methotrexate or ganciclovir and zidovudine have been reported.[126–128] In a retrospective analysis of the impact of HAART on survival in patients with primary central nervous system lymphomas, 6 of 7 patients who received HAART were alive, versus 0 of 18 patients who received no treatment, at a median follow-up time of 667 days ($P = 0.0007$).[129]

Box 69-3. TREATMENT OF HODGKIN'S LYMPHOMA

- Treatment is with standard-dose ABVD—doxorubicin (Adriamycin; 25 mg/m^2), bleomycin (10 units/m^2), vinblastine (6 mg/m^2), dacarbazine (375 mg/m^2)—administered on days 1 and 15.
- A maximum of six cycles are given. G-CSF is routinely prescribed.
- Dose adjustments are made for toxicity.

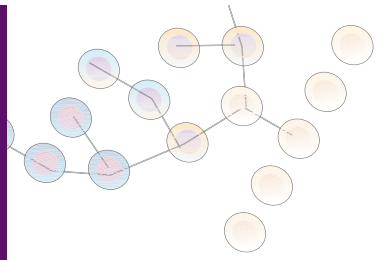
Box 69-4. APPROACH TO PATIENTS WITH AIDS-ASSOCIATED BRAIN LYMPHOMA

- In the presence of characteristic lesion(s) on magnetic resonance imaging and thallium or positron emission tomography studies, detection of Epstein-Barr virus DNA by polymerase chain reaction assay in cerebrospinal fluid is diagnostic of brain lymphoma. In patients in whom lumbar puncture is contraindicated, brain biopsy is required for diagnosis.
- Treatment is with radiation therapy.

OTHER MALIGNANCIES IN PATIENTS WITH HIV INFECTION

With HAART, the spectrum of malignancies in HIV-infected patients has been changing.[130] Non-AIDS-defining cancers have been reported with increased incidence, including those most common in the general population (lung cancer, colon cancer, skin cancers) as well as multiple myeloma and related plasma cell disorders, anal cancer, and cervical cancer. Lung and colon cancers may be indistinguishable from those appearing in the general population. Plasma cell dyscrasias in this population are quite distinctive, however. They are EBV-associated and often manifest with visceral or leukemic involvement.[131] Although cervical cancer has been recognized by the Centers for Disease Control and Prevention as an AIDS-defining illness, an excess of cervical cancer attributable to HIV infection remains to be conclusively demonstrated.[87,132] Some evidence, however, suggests that HIV-infected women with cervical cancer are more likely than non-HIV-infected women to have advanced disease at presentation and exhibit a higher recurrence rate. Furthermore, cervical intraepithelial neoplasia occurs more frequently in women with HIV infection. Anal cancer occurs with a 40- to 80-fold excess in people with AIDS compared with the general population. Receptive anal intercourse also is a well-established risk factor for this cancer, and the relative contributions of HIV infection and behavior have not been fully defined. Leiomyosarcomas in visceral organs occur with dramatically increased frequency in patients with HIV infection, particularly pediatric patients, but remain rare. The approach to treatment of these disorders does not differ from that in the non-HIV-infected population or has yet to be defined, although clearly, cognizance of the special risks associated with chemotherapy is important.

CURRENT OUTLOOK



With an improved prognosis for patients with HIV infection as a result of advances in supportive care and antiretroviral therapy, the neoplastic complications of HIV infection grow in importance. In the early days of the epidemic, the treatment of malignancies with curative intent might have been regarded as only marginally important in patients who were otherwise doomed to a short survival by virtue of their retroviral infection. For an increasing number of patients, however, HIV infection is most appropriately viewed as a chronic disease that requires a collaborative and multidisciplinary effort on the part of primary care and subspecialty providers, and the nihilism of the past should be replaced by a cautious optimism. It is now clear that durable remissions will translate into long-term survival in patients whose HIV load can be suppressed to very low or undetectable levels. The challenge that remains is to further develop specific therapies for HIV-associated malignancies and to integrate these approaches with the growing armamentarium of antiretroviral therapies.

70 Cancer of the Central Nervous System

Amit Maity, Amy A. Pruitt, Kevin D. Judy, Peter C. Phillips, and Robert Lustig

SUMMARY OF KEY POINTS

Incidence

- An estimated 43,800 new primary tumors of the central nervous system (CNS) were diagnosed in the United States in 2005, of which 18,500 were malignant.
- Approximately 85% of all primary CNS tumors are intracranial; the remainder occur in the spinal axis. An estimated 3410 new childhood (ages 0 to 19 years) primary benign and malignant brain tumors were diagnosed in 2005.
- Primary CNS malignancies account for 1% of all adult cancers and 2% of all adult cancer deaths. Among children 14 years of age or younger, primary CNS malignancies account for approximately 23% of all cancers and 26% of deaths due to cancer.

Pathology and Classification

- Taking all age groups into account, histologic types of CNS tumors include meningiomas (30%), glioblastomas (20%), other astrocytomas (9%), nerve sheath tumors (8%), pituitary adenomas (6%), oligodendrogliomas (4%), ependymomas (2%), and embryonal tumors including medulloblastomas (2%).
- Among children 14 years or younger, histologic tumor types include pilocytic astrocytomas (21%), glioblastomas (3%), other astrocytomas (11%), ependymomas (7%), oligodendrogliomas (2%), embryonal tumors including medulloblastomas (19%), craniopharyngiomas (3%), and germ cell tumors (4%).
- Most brain tumors are supratentorial; notable exceptions include brainstem gliomas, cerebellar pilocytic astrocytomas, medulloblastomas, and ependymomas that involve the posterior fossa.
- Glioblastoma (World Health Organization [WHO] grade IV astrocytoma) and brainstem gliomas in children carry the poorest prognosis. Pilocytic astrocytomas carry the best prognosis.

Clinical Manifestations

- *General signs and symptoms:*—from mass effect, increased intracranial pressure (ICP), edema, or shift or destruction of surrounding brain tissue—may include changes in personality and cognitive function, headaches, nausea, vomiting, seizures, and papilledema.
- *Focal signs and symptoms* may include focal seizures, visual changes, speech abnormalities, gait abnormalities, and cranial nerve deficits.
- Posterior fossa tumors often compress the fourth ventricle, causing hydrocephalus, and frequently manifest with ataxia and intractable nausea and vomiting.
- Brainstem gliomas often manifest with a combination of cranial nerve palsies and "long tract" signs such as hemianesthesia or hemiparesis coupled with ataxia in cases with cerebellar involvement.
- Pineal region tumors (germ cell tumors, pineocytoma, and pineoblastoma, as well as gliomas of this region) may compress the aqueduct of Sylvius, causing hydrocephalus. Compression of the pretectal area produces Parinaud's syndrome, with paralysis of upgaze, ptosis, and loss of pupillary light reflexes, along with retraction-convergence nystagmus.

Diagnostic Studies

- Magnetic resonance imaging (MRI) with gadolinium contrast is the most sensitive technique.
- Computed tomography (CT) scanning is good for visualizing intratumoral calcifications and bone erosion but poor at visualizing the posterior fossa.
- Positron emission tomography (PET) may help discriminate between tumor recurrence and radiation necrosis.
- Magnetic resonance (MR) spectroscopy may help distinguish high-grade tumor from low-grade tumor or radiation necrosis.

Therapy

- For most brain tumors, tissue diagnosis is required (an exception may be selected brainstem gliomas).
- Treatment for brain tumors is highly dependent on histologic type. For many tumors (e.g., gliomas, meningiomas, primitive neuroectodermal tumors [PNETs], ependymomas), maximal surgical resection that is safely feasible is the primary treatment.
- For some tumors (e.g., glioblastomas, PNETs, germ cell tumors), radiation therapy is an essential adjunct treatment after surgery.
- For some tumors (e.g., acoustic neuromas, glomus tumors), either irradiation or surgery can offer successful control; the decision between the two is based on assessment of side effects.
- Chemotherapy is assuming an increasingly important role in the management of many brain tumors (e.g., glioblastomas, germ cell tumors, anaplastic oligodendrogliomas, PNETs, CNS lymphomas).

INTRODUCTION

The different histologic types of CNS tumors are shown in Table 70-1. Meningiomas, glioblastomas, and astrocytomas constitute more than half of all CNS tumors. The frequency of different histologic tumor types varies with age, as shown in Figure 70-1. The incidence of all brain tumors is highest in the 75- to 84-year-old group. The incidence of meningiomas increases with increasing age, whereas for gliomas and pituitary adenomas, the incidence increases with age but then declines at the highest age category (see Fig. 70-1A). Certain histologic types, such as germ cell tumors, medulloblastomas, and pilocytic asctrocytomas, are far more common in children than in adults (Table 70-2; see Fig. 70-1B).

For most patients with primary CNS tumors, the initial therapy usually is operative. Radiation therapy often is an important component of treatment after surgery, but for management of malignant disease, chemotherapy has had an expanding role. A great deal of knowledge has been amassed over the past 2 decades regarding the biology of brain tumors, which with time should lead to improved treatments.

EPIDEMIOLOGY

An estimated 43,800 new cases of primary CNS system tumors were diagnosed in the United States in 2005.[1] Approximately 18,500 were malignant, representing 1.35% of all cancers diagnosed that year.[2] Malignant CNS tumors caused approximately 13,000 deaths in 2005.

On the basis of data provided by the Surveillance, Epidemiology, and End Results (SEER) Program, Deorah and colleagues[3] found that the incidence of brain cancer increased until 1987, when the annual percentage of change reversed direction. The elderly experienced an increase in brain cancer until 1985, but their rates were stable thereafter. Overall, however, the incidence of glioblastoma has been increasing, with survival unchanged over the past 2 decades.

Ionizing radiation is one of the few factors shown to have a strong association with the development of brain tumors. Exposure to ionizing radiation represents the most important exogenous risk factor for childhood brain tumors. Prenatal diagnostic x-ray exposure increases the risk of childhood brain tumors,[4] and various reports describe the occurrence of gliomas, meningiomas, and other brain tumors in children who received radiation therapy to the head for tinea capitis and for prior malignancies.[5–8] A dose of 1 to 2 Gy of radiation, used to treat tinea capitis in Israeli children, was associated with an increased risk of developing brain tumors—specifically, meningiomas, gliomas, and nerve sheath tumors.[9] A dose-response correlation in the induction of brain tumors was seen with a relative risk of 3.0 at a dose of 1 Gy. Tumors developed at least 6 years after irradiation, with a mean interval greater than 15 years. Even lower doses of radiation delivered with ^{226}Ra used to treat hemangiomas in Swedish infants (mean dose to brain of 7 cGy) were found to be associated with an excess risk of intracranial tumors, including pituitary adenomas, gliomas, meningiomas, and nerve sheath tumors.[10]

A large amount of data has been accumulated on the incidence of brain tumors in patients who received cranial irradiation for the treatment of acute lymphoblastic leukemia (ALL). The estimated cumula-

(Data from Central Brain Tumor Registry of the United States [CBTRUS]: Primary Brain Tumors in the United States Statistical Report, 2005–2006. Hinsdale, IL, CBTRUS, 2006. Data were collected between the years 1998 and 2002.)

Table 70-1 Primary Central Nervous System Tumors: Cell of Origin and Distribution by Histologic Type

Histologic Tumor Type	Cell of Origin	Frequency (%) In All Age Groups*	Frequency (%) Among Young Adults†
Meningioma	Arachnoidal fibroblast	30.1	13
Glioblastoma	Astrocyte	20.3	5.9
Other astrocytomas	Astrocyte	9.8	17.7
Ependymoma	Ependymocyte	2.3	4.6
Oligodendroglioma	Oligodendrocyte	3.7	8.9
Embryonal tumors, including medulloblastoma	Embryonal	1.7	2.8
Pituitary adenoma	Pituitary	6.3	13
Craniopharyngioma	Cells from Rathke's pouch	0.7	1.3
Nerve sheath	Schwann cell	8.0	9.4
Lymphoma	Lymphocyte	3.1	2.8
All others		13.9	20.8
Choroid plexus papilloma or carcinoma	Choroid epithelial cell		
Hemangioblastoma	Endothelial cell		
Germ cell tumor	Primitive germ cell		
Pineocytoma	Pineal parenchymal cell		
Chordoma	Notochordal remnant		

*Frequency among all patients with primary brain and CNS tumors ($N = 63,698$). Gliomas (glioblastomas, astrocytomas, oligodendrogliomas) and ependymomas and neuroepithelial tumors account for 40% of all tumors and 78% of malignant tumors.

†Frequency among young adults (20 to 34 years of age) with primary brain and CNS tumors ($N = 5741$).

Data from Central Brain Tumor Registry of the United States (CBTRUS), 2005–2006.[1]

tive risk of secondary malignant brain tumors after childhood ALL therapy is 0.5% at 10 years after completion of therapy.[11] In a study from St. Jude's Children's Hospital, the actuarial 20-year probability of developing a brain tumor in these patients was 1.4%.[12] The probability of developing a high-grade glioma was greater in children younger than 5 years of age at diagnosis than in those 6 years of age or older (1.08% versus 0.45%; $P = 0.045$). An apparent dose-response correlation was observed: The 20-year risk of developing a brain tumor was 3.2% in patients who received greater than 30 Gy, versus 1.03% in those who received 21 Gy or less ($P = 0.015$). No CNS malignancies were seen in patients who did not receive cranial irradiation. The latency between irradiation and the diagnosis of a brain tumor ranged from 5.9 to 29 years (median, 12.6) but was longer for meningiomas (median, 19 years) than for high-grade gliomas (median, 9.1 years). Very similar results regarding the frequency of brain tumors, latency, and dependence on prior cranial irradiation were seen in studies from the German BFM (Berlin-Frankfurt-Munster) group[13] and the Children's Cancer Study Group (CCSG).[14] The types of brain tumors that have been reported in these series include gliomas, meningiomas, and medulloblastomas. Patients who received cranial irradiation for ALL also often received intrathecal chemotherapy. It has been suggested that cranial irradiation and intrathecal chemotherapy may work synergistically to increase the incidence of glial tumors.[15,16]

Table 70-2 Primary Central Nervous System Tumors of Childhood: Distribution by Histologic Type

Histologic Tumor Type	Frequency (%) Age 0–14 Years ($N = 4214$)	Frequency (%) Age 15–19 Years ($N = 1241$)
Pilocytic astrocytoma	20.9	14.0
Glioblastoma	2.8	3.2
All other astrocytomas	10.5	11.4
Ependymoma	7.0	4.6
Oligodendroglioma	2.0	4.0
Embryonal tumors, including medulloblastoma	16.8	6.7
Pituitary adenoma	0.8	10.1
Craniopharyngioma	3.1	2.7
Germ cell tumor	3.9	6.8
All others	32.1	36.6

Gliomas account for 56% of all tumors and 67% of all malignant tumors in children 0 to 14 years of age and for 45% of all tumors and 68% of all malignant tumors in those 15 to 19 years of age.

Data from Central Brain Tumor Registry of the United States (CBTRUS) 2005–2006.[1]

Viruses can induce brain tumors in animals in the experimental setting; however, no conclusive data point to viruses as a cause of brain tumors in humans (reviewed by Berleur and Cordier[17]). Although many chemicals can induce brain tumors in laboratory animals, no definitive associations have been found in humans. For example, *N*-nitroso compounds, which commonly are present in foods, are known to be neurocarcinogenic in animals. Oxidants in the environment can cause DNA damage, so it has been hypothesized that antioxidants, such as vitamin E, found in certain foods may protect against the development of cancers. Epidemiologic studies, however, have provided mixed support for the idea that the intake of *N*-nitroso compounds, antioxidants, or specific nutrients in foods can influence the risk of developing brain tumors (reviewed by Berleur and Cordier[17]).

Also lacking is conclusive evidence that occupational exposure to industrial chemicals leads to the development of brain tumors,

Table 70-3 Hereditary Syndromes Associated with Brain Tumors

Syndrome	Associated CNS Tumors	Gene	Chromosomal Locus	Defective Protein and Normal Function
Neurofibromatosis type 1	Optic pathway gliomas, meningiomas, neuromas	*NF1*	17q11–12	Neurofibromin; GTPase-activating protein (GAP) that negatively regulates Ras
Neurofibromatosis type 2	Bilateral acoustic neuromas, meningiomas, gliomas	*NF2*	22q12	Merlin; related to membrane cytoskeleton linker protein 4.1 superfamily
Tuberous sclerosis	Cerebral hamartomas	*TSC1*	9q34	Hamartin
	Subependymal giant cell astrocytoma (SEGA)	*TSC2*	16p13	Tuberin; associates with hamartin; both are involved in signaling downstream of Akt
von Hippel-Lindau syndrome	Hemangioblastomas	*VHL*	3p25–29	VHL protein; degrades HIF1a
Li-Fraumeni syndrome	Malignant gliomas	*TP53*	17p13	p53; maintains genomic stability
Cowden's syndrome	Meningiomas	*PTEN*	10q23	PTEN; lipid phosphatase, counters PI_3 kinase activation
Gorlin's syndrome (nevoid basal cell carcinoma syndrome)	Medulloblastomas	*PTCH*	9q22	Cell surface receptor; regulates normal brain development
Turcot's syndrome	Medulloblastomas	*APC*	5q21	APC; part of β-catenin/Wnt signaling pathway
	Malignant gliomas	*hMLH1*	3p21	Involved in mismatch repair
	Malignant gliomas	*PMS2*	7p22	Involved in mismatch repair
Familial retinoblastoma	Pineoblastomas	*RB*	13q14	Rb protein; regulates entry into S phase
Ataxia-telangiectasia	CNS lymphoma	*ATM*	11q22–23	ATM protein; involved in DNA damage sensing
Multiple endocrine neoplasia syndrome 1 (MEN-1)	Pituitary adenomas	*MEN1*	11q13	Menin

APC, adenomatous polyposis coli; ATM, ataxia-telangiectasia mutated; CNS, central nervous system.

although a number of studies have suggested such a link (reviewed by Wrensch and coworkers[18]). Some of the chemicals that can induce brain tumors in laboratory animals, such as polycyclic aromatic hydrocarbons, can do so only when administered by direct contact or transplacentally, but not by inhalation or dermal contact; the latter two modes of exposure are more relevant in the occupational setting. Specific chemicals that have been examined include cosmetics containing *N*-nitroso compounds, organic solvents, chemicals used in the manufacture of synthetic rubber, formaldehyde, phenols, polycyclic aromatic compounds, polyvinyl chloride, and pesticides. Vinyl chloride can induce brain tumors in rats; however, a recent review found that the association in humans is inconclusive.[19] Bohnen and Kurland reviewed studies examining the incidence of brain tumors in agricultural workers exposed to pesticides and found that the results were inconclusive.[20] A large meta-analysis of studies examining workers in the petrochemical industry found no increased risk of brain tumors in this population.[21]

Recently a great deal of interest has emerged in a possible association between use of cellular telephones and the risk of brain tumors. In a case-control study, Inskip and coworkers were unable to show a correlation between the duration of cell phone use and the development of gliomas, meningiomas, and acoustic neuromas.[22] Other large case-control studies also have failed to find any association between cell phone use and the risk of developing brain tumors.[23–25] Nevertheless, some still claim that there is a link between cell phone use and brain tumors.[26]

Other factors that have been analyzed for their possible relationship to the development of brain tumors include a history of head trauma and injury, drugs and medications, allergies, seizures, smoking and alcohol consumption, and exposure to power-frequency electromagnetic fields. None of these factors, however, have been shown to be conclusively important (reviewed by Wrensch and associates[18]).

Most brain tumors represent sporadic cases; however, familial clustering has been noted. It is estimated that hereditary syndromes account for 2% of childhood brain tumors, although this may be an underestimate because hereditary syndromes may go undiagnosed in a number of cases.[27] Some hereditary syndromes known to be associated with brain tumors are listed in Table 70-3 (reviewed by Kimmelman and Liang[28]). Some of the associations are extremely strong. Nearly 70% of all optic pathway gliomas occur in patients with neurofibromatosis type 1 (NF-1), and acoustic neuromas commonly occur in patients with NF-2. In addition, hereditary immunosuppression disorders such as Wiskott-Aldrich syndrome, as well as treatment-associated immunosuppression as in organ-transplant recipients, or exogenous immunosuppression as in human immunodeficiency virus (HIV) infection, are known to be associated with an increased risk of primary CNS lymphoma.

TUMOR BIOLOGY

In the past decade, the field of oncology has seen explosive growth in elucidation of basic biologic processes. Normal cells have constraints in their ability to grow; for example, their growth generally is inhibited when they contact other cells. Tumor cells, by contrast, have sustained genetic mutations that allow them to overcome these constraints. Some of these changes allow them to proliferate in the absence of external cues. Other genetic changes allow them to invade adjacent normal tissues. Still other mutations allow tumor cells to induce angiogenesis and develop their own blood supply.

Cell Proliferation

Normal cells rely on growth factors secreted in their local environment to stimulate their growth. Many CNS tumors, however, have developed the ability to express their own growth factors along with the respective receptors, resulting in an autocrine loop that allows for self-stimulation.[29] Platelet-derived growth factor receptor-α (PDGFR-α), for example, is overexpressed in all grades of astrocytomas, but

only higher-grade tumors overexpress the ligands PDGF-A and PDGF-B.[30] Insulin-like growth factors and their receptors both are expressed in brain tumors including gliomas and meningiomas.[31] The epidermal growth factor receptor (EGFR) is amplified or overexpressed in 50% of glioblastomas,[29] and expression of transforming growth factor-α (TGF-α), a ligand that binds to this receptor, is increased in many gliomas.[32,33] Both scatter factor (also known as hepatocyte growth factor [HGF]) and its receptor c-Met are expressed in gliomas, with the highest level of expression seen in the most malignant tumors.[34]

As a result of increasing expression of receptors and ligands, increased signaling occurs in many brain tumors, resulting in activation of many different pathways that are important in proliferation (reviewed by Rao and James[32]). The best-studied of these pathways is the microtubule-associated protein (MAP) kinase pathway, which involves Ras and Raf. Another pathway that has attracted much attention recently is the phosphoinositide-3 (PI_3) kinase pathway, which leads to activation of Akt. Mutation of *PTEN*, which occurs in 30% to 40% of glioblastomas, also can lead to increased Akt activation in these tumors.[35]

Ras activation commonly is seen in human astrocytomas and neurofibromas despite the fact that these tumors rarely contain Ras mutations. In astrocytomas, Ras activation probably occurs through activation of growth factor receptors such as EGFR and PDGFR.[36] Other mechanisms of activation of aberrant G proteins have been identified in other CNS tumors (reviewed by Woods and coworkers[37]). In NF-1, loss of expression of neurofibromin, an inactivator of Ras, is seen (see Table 70-3). This loss of neurofibromin leads to the increased Ras activation seen in NF1-associated astrocytomas. Pituitary adenomas often show activation of the α subunit of the large heterotrimeric Gs protein, resulting in mitogenic signaling.

Cell proliferation is intimately tied to cell cycle regulation. For many cancers, mutations in two different pathways are important for deregulating the cell cycle. The first of these is the p16/Cdk4 or Cdk6/cyclin D/Rb pathway. The second is the p21/p53/Mdm2/$p19^{ARF}$ pathway. Mutations in both of these pathways are common in many brain tumors, particularly gliomas.

Invasion

Many brain tumors, particularly gliomas, display an invasive phenotype, with infiltration of tumor cells into surrounding tissues, making a cure very difficult to achieve. In fact, tumor recurrence was reported in one case even after the drastic measure of taking out the entire hemisphere in which a glioma was located.[38] Numerous molecules associated with invasion have been found to be upregulated in gliomas, including tenascin-C, secreted protein acidic and rich in cysteine (SPARC), various integrins, and matrix metalloproteinases (reviewed by Demuth and Berens[39]).

Angiogenesis and Hypoxia

For a tumor to grow beyond a certain size, it must develop a blood supply. The process of angiogenesis is described in detail in Chapter 8. A number of growth factors are known to be important in angiogenesis. The most prominent of these is vascular endothelial growth factor (VEGF), which is overexpressed in many brain tumors. In one study, increasing VEGF expression correlated with increasing malignant grade in astrocytomas, oligodendrogliomas, and ependymomas.[40] This study also found that increased expression of the VEGF receptors Flt-1 and KDR in tumor vasculature was found to correlate with increasing VEGF expression and malignant grade. Growth factors other than VEGF that may play a role in angiogenesis in gliomas include members of the TGF-β family, PDGF, placenta growth factor, basic fibroblast growth factor, and scatter factor/hepatocyte scatter factor (HSF).[41] Angiogenesis can also be negatively regulated by factors such as thrombospondins 1 and 2 (TSP1 and TSP2). TSP1 is positively regulated by p53, so loss of p53, which commonly occurs in gliomas, can lead to decreased TSP1 expression and increased angiogenesis.[41]

Angiogenesis is particularly prominent within glioblastomas. One of the characteristic features of these tumors is endothelial proliferation and neovascularization. A variety of growth factors that can increase angiogenesis are expressed by glioblastomas, foremost being VEGF. VEGF, also known as vascular permeability factor (VPF), is a potent inducer of capillary permeability. The high levels of VEGF expression in glioblastoma may be responsible for the edema associated with these tumors. Some evidence indicates that genetic changes common to glioblastomas, such as EGFR activation and *PTEN* mutation, may contribute to high levels of VEGF expression, perhaps through activation of the PI_3 kinase pathway.[42–44]

Despite expressing high levels of VEGF, glioblastomas contain significant regions of hypoxia, which may be a cause of treatment resistance. Hypoxia has been shown to be present in malignant gliomas by both polarographic needle electrode measurement[45,46] and binding of the 2-nitroimidazole EF5.[47] Hypoxia as measured by needle electrodes was not prognostic for survival.[46,47] The latter study, however, found a correlation between more rapid tumor recurrence and hypoxia as measured by EF5 binding.

The presence of hypoxia in glioblastomas is consistent with the histologic features commonly seen in these tumors, including the presence of pseudopalisading necrosis and proliferative blood vessels. It has been proposed that pseudopalisades seen within glioblastomas represent a wave of tumor cells actively migrating away from central hypoxia that arises secondary to vaso-occlusion and intravascular thrombosis.[48] It may seem counterintuitive that hypoxia can persist in the presence of high VEGF levels and robust neovascularization; however, the explanation may be that although hypoxia may stimulate VEGF and the formation of new vessels, many of these vessels are nonfunctional and do not transport oxygen well.

Stem Cells

The stem cell hypothesis proposes that a small fraction of cells with stem cell properties are the source of renewal of the tumor and determine a tumor's behavior. Such stem cells have been identified in human brain tumors and express the neural precursor marker CD133.[49,50] A number of strategies may be used to target these stem cells.[51] It recently has been demonstrated that these stem cells may be relatively radioresistant as a result of overexpression of DNA damage repair proteins including the checkpoint kinases Chk1 and Chk2.[52] The cells may be made more radiosensitive by using specific inhibitors of Chk1/Chk2. Piccirillo and colleagues showed that $CD133^+$ glioblastoma stem cells have a functional bone morphogenic protein (BMP) receptor pathway.[53] By exposing mice implanted with orthotopic glioblastomas to BMP4, they were able to cause the $CD133^+$ cells to differentiate toward glial cells and reduce tumor growth. These two strategies potentially may be used to target stem cells in glioblastomas. Another potential strategy is to target the tumor stroma, which provides a specialized niche for tumor cells. Calabrese and associates showed recently that stem cells in brain tumors occupied a perivascular niche and can be targeted by using antiantiangiogenic therapy.[54]

CLINICAL PRESENTATION

Pathophysiology of Signs and Symptoms

Parenchymal brain tumors produce clinical signs and symptoms by three main mechanisms, each of which has important implications for therapy: (1) Infiltration along nerve fiber tracts is typical of low-grade astrocytomas and oligodendrogliomas. The first clinical manifestation may be a single seizure. Normal brain tissue may be present within areas appearing abnormal on MRI, and functional mapping may be necessary for safe resection of these slowly growing tumors.[55–58]

(2) Displacement of brain tissue with production of vasogenic edema is typical of cerebral metastases. Such tumors sometimes can be resected or irradiated focally with less risk to adjacent normal brain tissue than is the case with infiltrating tumors. (3) Rapidly growing aggressive tumors such as high-grade astrocytomas may enlarge as a mass and also destroy surrounding neuropil to such an extent that surgical resection, although helpful for the reduction of mass effect and ICP, may not alleviate local symptoms and signs.

Intracranial neoplasms tend to produce progressive symptoms. Location and rate of growth determine both general and specific localizing symptoms and signs. Thus, a patient with a low-grade glial tumor may have seizures for many years or may exhibit behavioral alteration for many months before developing focal signs. With a more aggressive glial neoplasm, headache and focal signs may develop over a few weeks. Acute apoplectic onset is associated with hemorrhage or the development of hydrocephalus.

Brain tumor symptoms may be general, localizing, or falsely localizing. *General symptoms* include headache, lethargy, nausea, vomiting, and vague balance difficulties. These symptoms tend to be manifestations of increased ICP from a combination of expanding tumor volume and the production of associated vasogenic cerebral edema. Tumors also may cause raised ICP by obstruction of the ventricular system or blockage of the venous sinuses. Abrupt headache and exacerbation of neurologic signs may accompany the plateau waves of sudden increased ICP.

Sustained ICP in excess of 200 mm H_2O causes brain shifts that can displace brain tissue through fixed intracranial openings, producing life-threatening herniation syndromes[59] (Fig. 70-2; Table 70-4). The *uncal herniation syndrome* is caused by tumors arising in the lateral aspect of the brain, most commonly the temporal lobe. The earliest, most consistent sign of uncal herniation is a unilaterally dilated pupil due to compression of the ipsilateral third cranial nerve. This is followed by extraocular movement abnormalities consistent with an oculomotor palsy. The posterior cerebral artery may be compressed against the tentorium, leading to homonymous hemianopia. Brainstem compression can cause contralateral hemiapresis or, on occasion, ipsilateral hemiparesis. This is a result of compression of the contralateral cerebral peduncle against the edge of the tentorium, causing what is known as Kernohan's notch phenomenon.[60] Patients with uncal herniation initially may be awake, but progression to obtundation, coma, and death may occur rapidly, within hours.

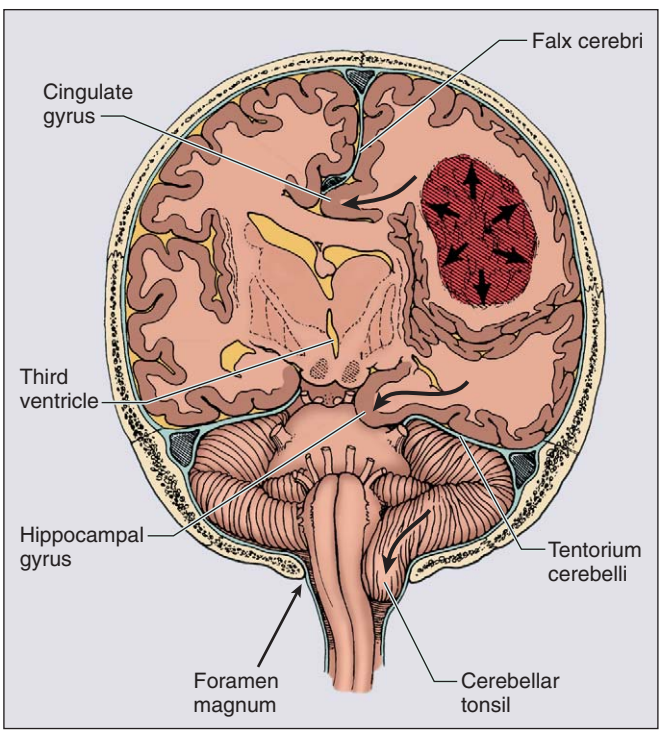

Figure 70-2 • Intracranial herniation syndromes evoked by supratentorial masses. The tumor and its edema *(arrows)* have produced the following *(curved arrows)*: cingulate gyrus herniation under the falx cerebri; diencephalic herniation across the midline compressing the ipsilateral ventricle and producing the hydrocephalus in the contralateral ventricle; hippocampal gyrus herniation through the tentorial notch compressing the posterior cerebral artery and brainstem, and herniation of the cerebellar tonsils through the foramen magnum (Adapted from Plum F, Posner JB: The Diagnosis of Stupor and Coma, 3rd ed, Philadelphia, FA Davis, 1980.)

The *central herniation syndrome* results from tumors that arise along the midline axis of the brain, especially those deep in the basal ganglia and thalamus regions. The initial signs and symptoms are due to diencephalic compression. The first evidence for this syndrome often is an alteration in the level of alertness and behavior. Some patients become agitated; others become very drowsy. Hemisensory or hemiparetic deficits and periodic Cheyne-Stokes respirations may develop in these patients. Initially with diencephalic compression, pupils are small (1 to 3 mm), but as the syndrome progresses and the midbrain and upper pons are compressed, the pupils dilate moderately and fix at midposition (3 to 5 mm). As the syndrome progresses, patients become progressively lethargic and apathetic and may develop Cushing's signs of hypertension and bradycardia due to direct compression of the hemodynamic control nuclei within the brain stem.[61,62]

Tonsillar herniation may be caused by an expanding mass in the posterior fossa, the region of the brain between the tentorium and the foramen magnum. This results in the cerebellar tonsils being pushed through the foramen magnum. The syndrome is characterized by posterior headache, vomiting, stiff neck, and sometimes opisthotonic posturing. Other features may include dysconjugate eye movements and syncope with cough or sudden postural change. Frequently, these patients complain of visual dysfunction due to progressive papilledema affecting visual acuity. As a result of direct compression of the medulla and its respiratory center, irregular breathing and acute apnea may develop in these aptients. Further compression of the brainstem can lead to Cushing's signs of hypertension and bradycardia. Tumors in the posterior fossa may also completely obstruct the fourth ventricle, leading to an obstructive hydrocephalus, which, if left untreated, will manifest as a central herniation syndrome. From a clinical standpoint, tonsillar herniation can be very difficult to diagnose. Patients often are agitated at the onset of the syndrome and frequently are sedated with narcotics, which only further compromises respiratory function, with the potential for a fatal outcome.

These herniation syndromes can rapidly progress from the onset of symptoms to death. They can be precipitated by medical procedures. Lumbar puncture may lead to tonsillar herniation, and ventriculostomy may result in upward herniation in which the brainstem is forced up through the tentorial notch. A high index of suspicion is required in order to successfully diagnose and treat this condition by emergency intubation and administration of appropriate therapy (see later under Treatment of Brain Tumor Symptoms).

General Signs and Symptoms

Headache results from traction on pain-sensitive structures of the intracranial contents including the large cerebral vessels, the dura and meninges, the venous sinuses, and cranial nerves V and IX. Headache is the most common symptom of a brain tumor and occurs in approximately 50% of patients at some time during the course of the illness.[63] Headache more frequently accompanies rapidly growing than slowly growing tumors. Tumors located in neurologically noneloquent brain areas such as the nondominant frontal and temporal lobes may manifest with headache as the sole clinical manifestation. The "classic" brain tumor-associated headache often is worse in the

Table 70-4 Important Clinical Syndromes in Patients with Brain Tumors

Syndrome/Signs and Symptoms	Localization and Pathogenesis	Common Tumor Type(s)
Obstructive hydrocephalus		
Headache, papilledema	Posterior fossa	Medulloblastoma, ependymoma, astrocytomas
Nausea, vomiting	Third ventricle compressed with growth of tumor or cyst	
Ataxia, stiff neck		
Communicating hydrocephalus		
Headache/pressure waves	Arachnoid granulation	Meningeal gliomatosis, any primary or metastatic tumor type
Gait apraxia	Scarring from treatment, hemorrhage, or infection	
Venous sinus thrombosis	Sinus	Meningioma
Uncal herniation		
Pupil dilation, oculomotor palsy	Temporal lobe herniates through tentorial notch, leading to compression of posterior cerebral artery, contralateral peduncle, midbrain	Any tumor type
Heminiaopia		
Ipsilateral hemiparesis		
Coma		
Central herniation		
Lethargy, small pupils	Diencephalic compression	Any tumor type
Cheyne-Stokes respiration		
Tonsillar herniation		
Posterior headache	Cerebellar tonsil herniates into foramen magnum	Posterior fossa tumor (astrocytoma, ependymoma, medulloblastoma)
Stiff neck		
Opisthotonos		
Pituitary apoplexy		
Headache, diplopia	Hemorrhage into pituitary	Pituitary adenoma, meningioma, craniopharyngioma
Third nerve palsy		
Hypotension		

morning and lateralized to the affected side of the brain. Brain tumor-associated headache may be worsened by coughing or straining. A majority of patients with brain tumors, however, do not have these classic symptoms but instead have headaches that are deep, aching, and difficult to distinguish from tension-type headache. As a general rule, headaches from posterior fossa tumors are localized to the back of the head or neck, whereas headaches from tumors of the anterior and middle cranial fossas may be referred to the forehead or eye, at times being misconstrued as "sinus" headache.

Brain tumor-associated cognitive changes initially may be subtle and frequently are misdiagnosed as depression or, in the older patient, age-associated forgetfulness or early Alzheimer disease. The patient may complain of additional nonspecific signs and symptoms such as fatigue, concentration problems, irritability, and loss of interest in usual activities. Frontal lobe tumor location is the most common site for tumors producing these symptoms as the initial manifestation of neoplasm. Hypomania and psychosis are less common cognitive symptoms and when occurring as the presenting symptoms usually are associated with temporal lobe tumors.

Roughly paralleling cognitive decline and of poor localizing value by themselves, several other symptoms may emerge. Dysphagia is a common complaint, and caregivers may note that the cognitively impaired patient seems to take a long time to chew and swallow. Oral candidiasis is a potential complicating issue in patients on long-term corticosteroid therapy and appropriate treatment should be instituted. Similarly, incontinence tends to parallel the degree of cognitive impairment. Urinary retention may occur in patients with bifrontal brain disease or with spinal cord problems. Opiate medications may exacerbate the urologic problems.

Seizures occurring for the first time in adults are more likely to be due to focal brain pathology, particularly neoplasms, than seizures occurring in childhood. Intracranial tumors produce both generalized tonic-clonic seizures, secondarily generalized tonic-clonic seizures, and partial, localization-related seizures. The tumors that are most likely to manifest with seizures are slowly growing astrocytomas and oligodendrogliomas or oligoastrocytomas. Seizures occur at some time in 25% to 50% of patients with brain tumors.[64–66] Tumors in the cortical and subcortical cerebral hemispheres, particularly the insula, are the most likely to produce seizures. Such seizures may be more difficult to control than those of idiopathic epilepsy and many patients require more than one antiepileptic drug (AED; see later under Treatment of Brain Tumor Symptoms). Seizure frequency may increase during radiation treatment and continue at an increased frequency for several months thereafter because of localized swelling.

Papilledema, swelling of the optic nerve head with engorgement of retinal veins, usually indicates raised ICP. In the pre-CT and MRI era, papilledema was a more frequent finding in brain tumors than it is today, because diagnosis now occurs earlier in the disease course. Currently, papilledema is seen in less than 20% of patients at presentation, down from 59% in the report by Huber.[67]

The development of papilledema is dependent on the location of the tumor and the rate of growth. Papilledema is more common in patients with infratentorial tumors than in those with supratentorial tumors. Other papilledema-producing tumor areas include the third ventricle, cerebral aqueduct, and fourth ventricle. Thus, in adults, medulloblastomas, glial tumors of the cerebellum, hemangioblasto-

mas, and tumors of the cerebellopontine angle are most commonly associated with papilledema.

Vomiting, with or without nausea, may occur as a result of direct simulation of emetic centers in the floor of the fourth ventricle. This mechanism explains the nausea and vomiting seen with raised ICP, particularly when the rise in pressure has been rapid and is associated with hemorrhage or herniation. Patients with posterior fossa tumors frequently experience nausea and vomiting. More commonly, however, nausea is a nonlocalizing symptom, so the differential diagnosis must include adverse drug reactions from AEDs, analgesics, or other concurrent medications and gastritis from high-dose corticosteroid treatment.

Localizing Signs of Intracranial Tumor

Focal clinical signs of intracranial tumor reflect the location of the mass and its associated vasogenic edema, which often is of much greater volume. This chapter does not provide a detailed discussion of every possible localizing sign but rather focuses on the general principle of neurologic localization and the specific emergent syndromes that should be recognized because of their localizing and management importance (summarized in Table 70-4).

Disorders associated with *frontal lobe lesions* include early impairment of intellectual function and language function if the dominant frontal lobe is involved. Patients with bilateral frontal tumors appear to lack initiative and spontaneity—a state called *abulia*. Such patients may have an impaired gait with difficulty initiating walking. Personality changes include inattentiveness, apathy, and depression, as well as the less common disinhibition and inappropriate affect leading to socially inappropriate behaviors. As tumors enlarge to involve the motor cortex, contralateral motor problems, such as hemiparesis or monoparesis, may develop in these patients.

Receptive language, auditory discrimination, and memory all are important functions of the dominant temporal lobe. Patients with *nondominant temporal lobe tumors* may have seizures involving visual, olfactory, or gustatory hallucinations. Deep temporal tumors may cause a contralateral visual field cut (superior quadrantanopia).

The parietal lobe is demarcated form the frontal lobe by the central sulcus. Parietal lobe functions include tactile perceptions, integration of sensory, visual, and auditory information and visual discrimination in the inferior contralateral quadrant. When tumor involves the nondominant *parietal lobe*, inattention to the deficit (anosognosia) may be a prominent feature of the presentation.

Tumors in the occipital lobes cause a contralateral quadrantic or hemianopic defect, sometimes with sparing of central macular vision.

Tumors of the brainstem cause a great many focal deficits early in their course. Typically, a combination of cranial nerve palsies and long tract signs such as hemianesthesia or hemiparesis coupled with ataxia reflecting cerebellar involvement give a clue to the localization. Patients with brainstem tumors experience difficulty with swallowing and speech articulation. They are at risk for aspiration.

Cerebellopontine angle tumors such as acoustic neuromas impair function of the eighth cranial nerve and produce unilateral hearing loss, tinnitus, and, later, vertigo. Involvement of adjacent cranial nerves VII and V leads to facial palsy and facial anesthesia. Later cerebellar dysfunction reflects tumor growth in this area.

Tumors of the pituitary and suprasellar region produce endocrinologic abnormalities either by hormonal production by secretory adenomas or by impingement on hypothalamic-pituitary connections. Visual defects reflect chiasmatic involvement. The most common pituitary region field defect is a bitemporal hemianopia.

Pineal region tumors (germ cell tumors, pineocytoma, and pineoblastoma, as well as gliomas of this region) may compress the aqueduct of Sylvius, causing hydrocephalus. Compression of the pretectal area produces a characteristic syndrome (Parinaud's syndrome) with paralysis of upgaze, ptosis, and loss of pupillary light reflexes, along with retraction-convergence nystagmus.

Many primary tumors are capable of *diffuse infiltration of the meninges*. Gliomas, lymphomas, and oligodendrogliomas all may invade the subarachnoid space, producing a meningeal reaction that may mimic chronic infection. They produce variable cranial nerve and spinal root dysfunction and diffuse headache, and sometimes lead to communicating hydrocephalus. Elevated cerebrospinal fluid (CSF) protein, low CSF glucose, and positive results on cytologic studies are the diagnostic hallmarks.

On occasion, the clinician will be faced with symptoms that appear to give a clue to the patient's tumor site but in fact are *false localizing symptoms*. Abducens nerve (cranial nerve VI) palsies may reflect brainstem involvement but commonly are a nonlocalizing sign of raised (or, much less commonly, low) ICP. Ocular pain is of little localizing value because it may reflect any of the structures innervated by the first division of the fifth cranial nerve. Thus, eye pain may reflect any process in the anterior or middle cranial fossa. Diplopia may result from cranial nerve invasion by brainstem or leptomeningeal tumor but also can be caused by excess levels of AEDs.

Posterior head pain may reflect posterior fossa disease but also may come from the upper cervical segments, and spinal cord tumor or caudal extension of a primary brainstem tumor should be considered if the patient presents with pain in the occiput. Another sign of cervical cord disease is bilateral upper limb weakness or numbness.

Gait disorders pose another potential hazard for falsely localizing signs and symptoms. A frontal lobe gait ataxia may mimic basal ganglia or even cerebellar disease. The affected patient walks slowly, with a wide-based gait, and seems to have difficulty initiating movements. Proximal leg weakness may reflect spinal metastases from intracranial or systemic tumor, but probably the most common cause of proximal leg weakness is corticosteroid-induced myopathy.

Treatment of Brain Tumor Symptoms

Acute Raised Intracranial Pressure

The most immediate life-threatening syndromes are the herniation syndromes, but rapid increase in vasogenic edema also mandates aggressive treatment of evolving neurologic signs and symptoms. If the patient is rapidly deteriorating, intubation and hyperventilation aiming for a PCO_2 of 25 to 30 mmHg are required. Mannitol is administered intravenously in a loading dose of 1 to 2 g/kg, followed by 0.5 to 1 g/kg every 6 hours as needed to control ICP. Mannitol may be transiently effective, but a rebound pressure increase sometimes develops after 24 to 48 hours. Intravenous dexamethasone in a loading dose of 20 mg followed by 6 to 10 mg every 4 to 6 hours is appropriate to start as initial treatment as well. Electrolytes and glucose levels must be monitored, and gastritis prophylaxis is required. Acute neurosurgical interventions include ICP monitoring devices and ventricular drainage or tumor decompression in cases of obstruction. Fluid management requires avoidance of hyponatremia.

Chronically Increased Intracranial Pressure

Dexamethasone in doses of 8 to 40 mg per day repairs the "leaky" blood-brain barrier of tumor vasculature. Controlling the edema helps to control headache, nausea, and seizures as well. Chronic raised ICP can cause visual loss, so careful ophthalmologic follow-up evaluation with visual field assessment is essential. Acetazolamide therapy for symptomatic plateau waves has been useful for some patients with raised ICP from intracerebral or leptomeningeal tumor.[68]

In the doses required to treat cerebral edema, corticosteroids produce many adverse effects. These range from the easily managed gastritis symptoms and glucose intolerance to insomnia, steroid psychosis, intractable hiccoughs, and disabling myopathy. The psychosis may readily respond to reduction of steroid dose and addition of neuroleptics. Treatment of the steroid myopathy, however, will require weeks of physical therapy with attempts at steroid reduction.

Anecdotal reports suggest that substitution of a nonfluorinated steroid such as methylprednisolone for fluorinated steroids such as dexamethasone may help reverse the weakness.[69]

Many brain tumor patients remain on corticosteroids for prolonged periods. They are thus susceptible to infection, particularly with *Pneumocystis jiroveci*, which carries a 50% mortality rate. Among solid tumors primary and metastatic brain tumors have the highest rate of *Pneumocystis* infection that occur in 2% of patients and prove fatal to 40% of these.[70] The mean duration of steroid therapy before infection was seven months with a mean dexamethasone equivalent dose of 1 to 2 mg per day.[71] In view of these statistics chemoprophylaxis with one tablet twice daily of trimethoprim-sulfamethoxazole twice weekly should be given to patients with brain tumors who are on corticosteroids longer than 4 weeks.

With long-term use of corticosteroids, an adrenal insufficiency state may develop in these patients, manifested by lethargy, hypotension, electrolyte imbalance, and diffuse weakness on steroid withdrawal. Intercurrent systemic stressors such as surgery or systemic infection may lead to serious hypotension. Chronic glucocorticoid supplementation with hydrocortisone 10 to 20 mg per day is essential for these patients.[72,73]

Seizures

Neuro-oncologists often find themselves working closely with epileptologists as they seek to control seizures with minimal side effects. Because brain tumor patients frequently require corticosteroids, analgesics, anxiolytics, and antiemetics, drug-drug interactions make epilepsy management complex.

The potential interaction of AEDs with other medications required for brain tumor patients has led to reconsideration of prophylactic use of antiseizure drugs. Cytochrome P-450 enzyme-inducing drugs such as phenytoin and carbamazepine may interact with numerous chemotherapeutic agents, as well as newer biologic agents such as tyrosine kinase receptor inhibitors (as discussed later under General Principles of Chemotherapy), reducing levels achieved and diminishing efficacy. AEDs also may increase the corticosteroid dose required for effective vasogenic edema treatment. For those patients with low-grade gliomas who may be on AEDS for many years there is also the risk of teratogenesis and osteoporosis.

A rash develops in approximately 20% of patients with gliomas treated with phenytoin or carbamazepine and cranial irradiation; the most serious and sometimes life-threatening reaction, the Stevens-Johnson syndrome, occurs in a few patients. This reaction is seen in the setting of hypersensitivity to AEDs unmasked during the taper of high-dose corticosteroids. The mechanism may be depletion of suppressor T cells by radiation, allowing emergence of the hypersensitivity syndrome.[74,75] Treatment is controversial, but often the corticosteroid dose is doubled as AEDs are withdrawn abruptly.

In view of all of the potential hazards of AEDs, it is worthwhile to consider whether their prophylactic use is justified in the brain tumor population. A controlled prospective study of patients with brain tumors addressing the question of prophylaxis for epilepsy showed an overall incidence of 26% with no difference in the seizure rate between patients taking AEDS and those without prophlyaxis.[76] A second study involving 100 patients with brain tumors confirmed the lack of efficacy of AEDs in preventing seizures or altering survival outcome in this clinical setting.[77] These findings are consistent with those of Foy and colleagues, who conducted a prospective trial in 276 patients who had undergone craniotomy (not all of whom had tumors) who were randomized postoperatively to receive phenytoin, carbamazepine, or no treatment. No difference in the incidence of seizures (37%) or postoperative complications was found among the groups.[78] For all of these reasons, a practice parameter published by the Quality Standards Subcommittee of the American Academy of Neurology concluded that no benefit could be established for routine prophylactic use of AEDs in patients with brain tumors.[79]

Table 70-5 Adverse Effects of Antiepileptic Drugs: Special Issues in Patients with Brain Tumors

Drug	Potential Adverse Effect(s)
Oxcarbazepine	Hyponatremia (confusion, seizures)
Gabapentin	Sedation, ataxia, weight gain
Depakote	Weight gain, platelet dysfunction
Topiramate	Memory/word-finding problems, weight loss
Zonisamide	Sedation
Levetiracetam	Psychosis, irritability, lethargy

Even after the acute phases of successful tumor treatment, epilepsy management may continue to be a major issue in quality of life for long-term survivors of low-grade brain neoplasms. A particularly dangerous late consequence of chronic antiepileptic therapy with phenytoin, carbamazepine, and phenobarbital is osteoporosis; therefore, long-term survivors should be screened regularly with dual-energy x-ray absorptiometry (DEXA) scans.

In the last 20 years, several AEDs have been introduced that offer new choices for brain tumor patients and the possibility of limiting side effects while achieving excellent seizure control. Of the newer agents, levetiracetam is emerging as an excellent choice in brain tumor patients as its level is not affected by chemotherapy drugs and it does not alter the metabolism of any chemotherapeutic agents. The clinician must be familiar with some side effects specific to these drugs (summarized in Table 70-5) in order to diagnose symptoms accurately, eliminate the offending drug, and avoid unnecessary diagnostic and therapeutic interventions.

Deep Venous Thrombosis

Deep venous thrombosis is extremely common in patients with brain tumors, with a reported incidence of 28% to 45%.[80,81] Among these patients, those with gliomas and meningiomas are at the highest risk for thromboembolism, which is a common cause of fever of unknown origin in this population. Alterations in fibrinolysis, immobility, paresis, tumor necrosis factor, steroids and neurosurgical procedures all combine to make brain tumor patients a high-risk group. Many of these patients receive vena cava filters because of the perceived risk of hemorrhage into their intracranial tumors. Retrospective studies, however, have suggested a very low risk of hemorrhage and in addition have demonstrated an incidence of complications of vena cava filters of greater than 60% in this patient group. Complications included pulmonary embolism, filter thrombosis, and postphlebitic syndrome.[82] Low-molecular-weight heparins have a good safety profile in the neurosurgical population.[83] Prophylaxis with enoxaparin 40 mg subcutaneously daily plus external compression stockings has been found to be superior to compression stockings alone for the prevention of venous thromboembolism after neurosurgery.[84,85] Although no absolute guidelines are available, most neurosurgeons would be reluctant to institute full anticoagulation in these patients within 3 weeks of surgery. A subset of patients with late white matter changes due to radiation therapy, like patients with extensive ischemic leukoaraiosis, may be at special risk for brain hemorrhage while on heparin.

DIAGNOSTIC IMAGING

Lumbar Puncture

Lumbar punctures are not commonly employed for the diagnosis of brain tumors. With primary gliomas the yield from CSF cytology at

initial diagnosis is extremely low. Leptomeningeal metasases occur in 4% to 15% of patients with solid tumors, most commonly from breast, lung, melanoma (reviewed by Taillibert and coworkers[86]). Hematologic malignancies also commonly involve the meninges. Leptomeningeal seeding from supratentorial malignant gliomas is usually an end stage finding. Patients with leptomeningeal tumor frequently present with signs and symptoms such as focal cranial nerve neuropathies, paresis of one or more limbs, headaches, and lethargy, which would be more expeditiously evaluated with a brain MRI study.

Skull X-Ray Studies

Plain films of the skull have been used in the past to determine evidence of mass effect due to shift of the calcified pineal gland. This has been largely replaced with the modern use of computed tomography and magnetic resonance imaging. Plain radiographs of the skull are still useful for evaluating skull lesions such as dermoids and epidermoids as well as eosinophilic granulomas. These are primary lesions of the skull which frequently can be best seen with plain skull x-ray films. Epidermoid and dermoid tumors of the bone are congenital tumors derived from ectopic epithelium. These are benign lesions but can grow to be quite large and are usually painless, causing deformity of the skull. Eosinophilic granulomas may be associated with Hand-Schüller-Christian disease, a triad of diabetes insipidus, exophthalmos, and bone lesions usually found in the skull. Other primary bone lesions that can be found on plain skull films include multiple myeloma and plasmacytoma. Bone foramen abnormalities occurring in the skull include fibrous dysplasia and Paget's disease. Fibrous dysplasia can be cystic or sclerotic and usually occurs in the anterior middle fossa. This can cause proptosis of the eye and compression of the cranial nerves exiting the middle fossa causing pain and entrapment syndromes. Paget's disease is benign but thought to be a premalignant condition causing similar symptoms to fibrous dysplasia due to thickening of the bone at the skull base constricting neural foramen. Occasionally meningiomas can grow selectively into the bone rather than into the intracranial compartment. This causes thickening of the bone with compression syndromes as previously described causing proptosis of the eye, constriction of neural foramen causing cranial nerve deficits and more commonly, complaints of headache syndromes. Due to the thickening and sclerotic changes seen in the latter three disease states, these lesions are frequently evaluated with plain skull radiographs as part of the workup.

Computed Tomography

A CT scan usually is the first study obtained when a patient presents with a neurologic complaint. CT scans can be obtained quickly in most hospitals as a screening tool. Hemorrhagic lesions can be seen as a result of the increased density of blood. Infarcts will manifest acutely as edematous tissue and can be confused with tumors, especially low-grade gliomas, which may not enhance with contrast agents. Iodinated contrast agents are useful to differentiate the tumor from the surrounding edematous brain tissue, because the contrast agent is able to leak out of the vascular space into the tumor owing to breakdown of the blood-brain-barrier. The pattern of ring enhancement of tumors may be difficult to distinguish from the ring enhancement of a cerebral abscess, though brain tumors are far more common than brain abscesses in the United States. CT images have limitations at the skull base due to volume averaging artifact as the x-ray beam slides over uneven bone ridges. This makes it difficult to interpret findings in the skull base and in the posterior fossa (the region between the tentorium and the foramen magnum). CT scans are still the study of choice in patients who cannot undergo magnetic resonance imaging (MRI), such as those with implanted pacemakers, defibrillators, or other metal devices that prevent imaging by MRI.

Magnetic Resonance Imaging

MRI has become the study of choice for evaluating brain tumors. The high degree of definition of the anatomy of the brain as well as the absence of bony artifacts seen in CT scans has enabled magnetic resonance imaging (MRI) to provide exceptional images of the tumor. Localization of the lesion is precise as an MRI is done in three planes. The study of choice for evaluating brain tumors is MRI with and without contrast. Much like CT scan contrast, the MRI contrast agent gadolinium is able to penetrate into the tumor because of breakdown in the blood-brain barrier and subsequent "leak." This enables the tumor site to become white on the T1 weighted images. Gadolinium enhancement can be crucial in identifying leptomeningeal disease as thickened areas of the dura, as well as "sugar coating" the brain itself.

Multiple sequences may be obtained from the MRI scans that highlight different properties of both the brain and the tumor. Of particular interest are the T_2-weighted and fluid-attenuated inversion recovery (FLAIR) images showing the vasogenic edema created by the tumor. Evaluating this edema pattern is very important in assessing the degree of mass effect. The volume of edematous brain may represent the true limits of a glioma tumor, because tumor cells are present in the nonenhancing tissue surrounding the enhancing tumor.[87] This provides the rationale for extending the irradiated zone in standard external beam radiation therapy to include the edematous volume of brain plus a margin of 1 to 2 cm. Presence of an edema pattern extending into the corpus callosum implies direct tumor invasion into the corpus callosum. The extremely compact fiber tracts passing through the corpus callosum will not allow edema fluid to pass through, so any edema seen is created by local tumor infiltration. This point is very important to keep in mind in assessing extent of tumor.

Endothelial proliferation with neovascularity is a hallmark of malignancy in brain neoplasms. MRI perfusion imaging can be performed in combination with conventional MRI examinations to determine the extent of neovascularity. Correlation between regional cerebral blood volume and grade of malignant glioma appears to be very good. In particular, this is especially helpful in distinguishing grade III from grade IV malignant gliomas.[88,89] It has been noted that anaplastic astrocytomas with gadolinium enhancement show a higher vascularity index than that in tumors without gadolinium enhancement. Perfusion imaging may enable monitoring of the antiangiogenic effects of treatment in brain tumors. Perfusion imaging appears to be useful in assessing benign tumors such as meningiomas to determine the vascularity of these tumors, which may be associated with progression.[90]

MRI techniques have been utilized to identify areas of brain activity in real time. This functional MRI technique has become quite useful in identifying regions of eloquent brain adjacent to tumors.[91,92] By identifying language and motor areas adjacent to tumors one can determine the degree of aggressive surgical resection that can be carried out and also the best way to preserve this functional activity.[93] Functional MRI scans are being imported into frameless stereotaxy units that are used for intraoperative surgical planning.[94] By using discrete motor, sensory, language or visual paradigms, the relevant part of the cortical brain can be activated for identification of functional activity. The one limitation to functional MRI scanning is that it does not identify subcortical white matter tracts that are activated by the investigated activity.

A great deal of interest has centered on the capability of routine clinical MRI scanners to perform MR spectroscopy (MRS) as a technique to evaluate molecular components of a defined voxel within the brain tissue. Today's smaller voxel sizes allow a much greater degree of selectivity in evaluating components of a tumor. MRS has been applied quite extensively to malignant gliomas, for which the most important molecular components are *N*-acetylaspartate (NAA), creatine, choline, and a combined peak of lipids and lactate.[95] MRS

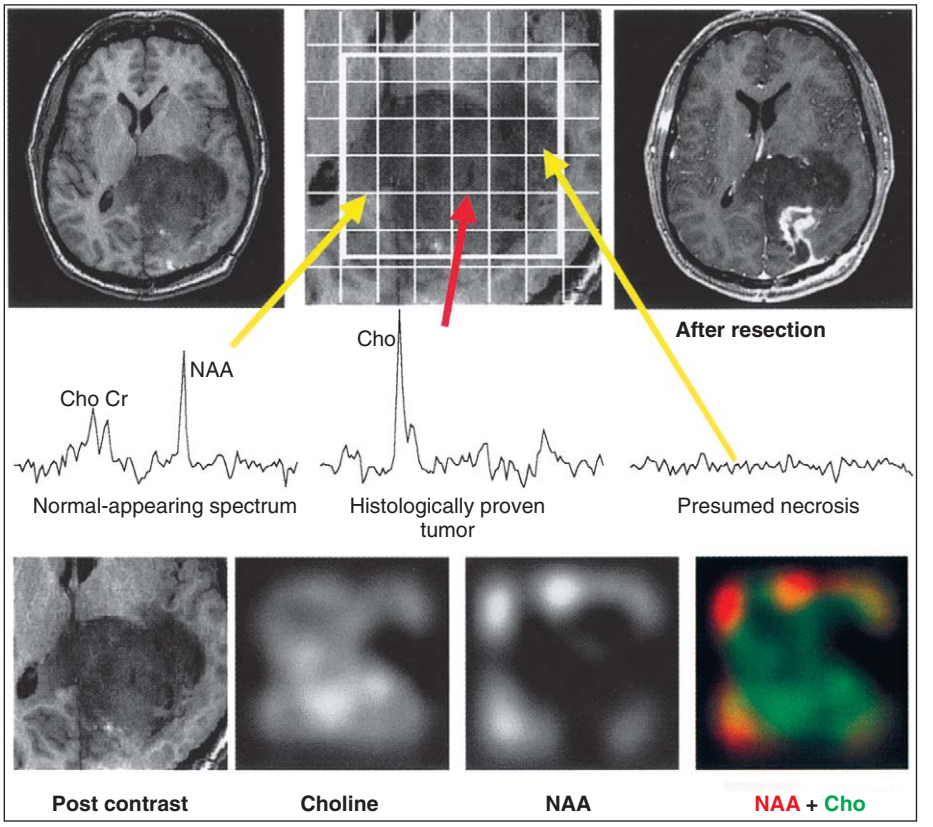

Figure 70-3 • MRI/MRS studies of WHO grade II oligoastrocytoma. Axial T_1-weighted post-gadolinium MRI on day before surgery *(top left panel)* shows area of hypodensity that does not enhance (bottom left panel). MRS *(middle panel)* shows area of high choline (Cho; 1.8 times greater than adjacent brain) and low NAA levels, as well as a smaller region of no significant metabolite levels, which is presumed necrosis. The resection was limited to a region of elevated choline with no significant NAA. Cr, creatine; NAA, *N*-acetyl aspartate; WHO, World Health Organization. (From Vigneron A, Bollen A, McDermott M: Three-dimensional magnetic resonance spectroscopic imaging of histologically confirmed brain tumors. Magn Res Imaging 2001;19:93.)

can be useful in diagnosis in that malignant gliomas exhibit a higher choline peak relative to creatine, and a lower NAA peak, with increasing grade of malignancy (Fig. 70-3). An additional peak beyond the NAA peak identifies lipids and lactate, which also constitute markers of malignancy and can be seen both in primary gliomas and metastatic tumors. MRS can be used to determine whether a region of enhancement in a previously treated tumor represents active tumor or radiation necrosis. MRS has been used to follow treatment effects over an extended period of time. Most useful has been the development of the multivoxel technique, in which large areas of the brain can be mapped with individual small voxels so that it is possible to determine small areas of active tumor within a large region of brain.

MRI has the capability to specifically identify vascular structures such as major arteries and veins. MR angiography (MRA) and MR venography (MRV) can be useful in evaluating major vessels at the base of the skull for skull base tumors. The quality of MRA and MRV has been steadily improving, and both of these techniques provide a noninvasive means for evaluating these vascular structures without the need for angiography.

Positron Emission Tomography

PET imaging uses a radioactive isotope, ^{18}F-fluorodeoxyglucose (FDG), to image metabolism of glucose in the brain. Because glucose is the sole fuel for brain tissue this metabolic imaging allows visualization of brain physiology. PET scans will be positive in glioblastoma, primary CNS lymphoma, oligodendroglioma, and malignant meningioma owing to the high uptake of FDG.[96] Anaplastic astrocytomas and oligodendrogliomas, meningiomas, and metastatic tumors show variable FDG uptake; low-grade gliomas and radiation necrosis show little to no FDG uptake (Figs. 70-4 and 70-5).

Intraoperative Ultrasound Examination

In general, brain tumors are echogenic, so real-time ultrasound studies can be used for localization. Ultrasound examination can be used to identify normal intracranial structures such as the ventricles, the falx, and the tentorium. Exact tumor localization is necessary because of the limited operative exposure to the brain. The ultrasound transducer can be applied to the dura surrounding the brain or placed directly on the brain tissue. Ultrasound examination can be quite useful in finding large brain tumor cysts, which can cause herniation of the brain during surgery. With accurate localization of the cyst by this means, a needle can be inserted to drain the cyst, thereby rapidly decompressing the brain.

SURGERY: GENERAL CONSIDERATIONS

The successful resection of a brain tumor requires removing the tumor only, without injuring surrounding normal brain. The approach to removal of brain tumors follows the mantra of real estate agents: "location, location, location." Deep tumors that are in noneloquent regions of brain can be easily accessed and removed, whereas superficial tumors may not be easily resectable owing to their location within extremely eloquent brain tissue.

The goals of surgery are (1) to establish the histology of the lesion; this is frequently better performed through a craniotomy with a more aggressive debulking of the tumor, rather than a simple stereotactic biopsy, so that there is no question of sampling error; (2) to debulk the mass effect of the tumor to correct a neurologic deficit and to prevent imminent death in patients with large tumors and early herniation syndromes; and (3) to debulk the tumor to increase efficacy of radiation therapy and chemotherapy, which produce the best response rate when they are used with minimal tumor burden.

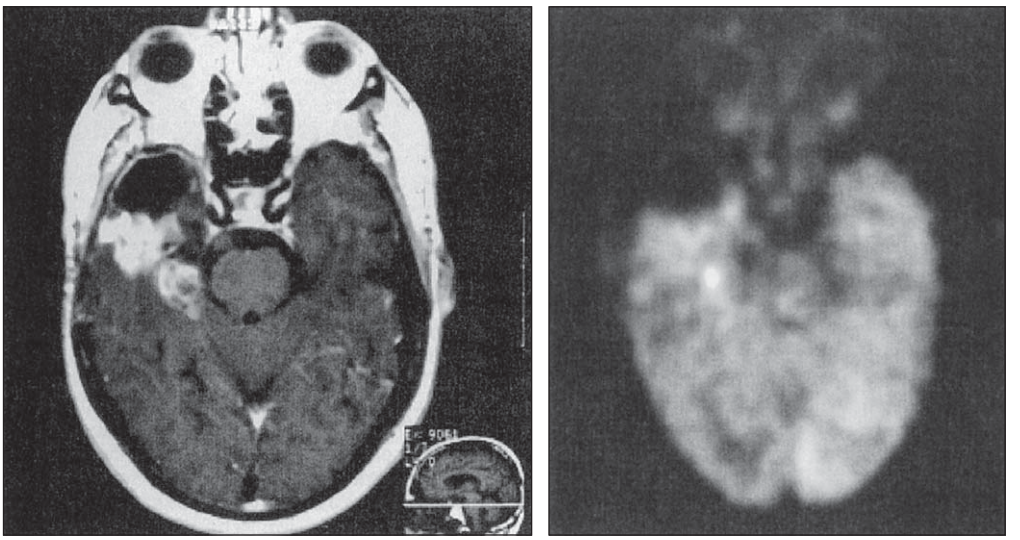

Figure 70-4 • Positron emission tomography (PET) scan of recurrent glioma. The patient had undergone surgical resection of an anaplastic oligodendroglioma 15 months earlier. Areas of contrast enhancement on T_1-weighted magnetic resonance imaging (MRI) scan *(left panel)* have high fluorodeoxyglucose (FDG) accumulation, consistent with recurrent high-grade tumor on the co-registered FDG-PET image *(right panel)*. (From Hagge RJ, Wong TZ, Coleman RE: Positron emission tomography. Brain tumors and lung cancer. Radiol Clin North Am 2001;39: 874.)

Establishing a tissue diagnosis is extremely important for therapeutic and prognostic considerations. Frequently, the histologic diagnosis may be straightforward; however, a category of tumors exists that manifest as mixed gliomas, in which tissue sampling can induce errors in diagnosis.[97] A limited biopsy specimen may show a solitary cell type, but further examination of a more extensive specimen may reveal the presence of other components. This is particularly important when the other components identified may change the histopathologic interpretation from a grade II glioma to an anaplastic grade III glioma. Noninvasive means of establishing tissue diagnosis have been pursued, primarily through the use of MRS.[98,99] Significant progress has been made to determine histologic diagnosis of tumors with MRS; however, MRS is still not specific enough to form the basis for major therapeutic decisions. Histopathologic determination remains the gold standard.

The most common presenting manifestations in patients with glioma are headache and seizures.[100] Debulking large tumors will reduce the dural stretch, decreasing headaches. The incidence of seizures in patients with malignant gliomas can be decreased by at least 75% with attempts at gross total resection.[101] Recovery from other neurologic deficits manifesting as hemiparesis, visual field loss, or aphasia, for example, will depend on whether the impaired brain tissue is simply compressed by the tumor mass or whether the tumor itself has directly destroyed these neural tracts. In the former case, but not the latter, debulking the tumor will help relieve the patient's symptoms.

As a result of liberal use of CT and MRI scans, herniation syndromes with brain tumors, as noted earlier under Pathophysiology of Signs and Symptoms (in the clinical presentation section), are uncommon presentations. Occasionally, however, patients present with central or uncal herniation syndromes from late-stage brain tumors. These patients need to have an emergency CT or MRI scan and undergo rapid evaluation for possible surgery for reduction of mass effect as a life-saving measure.

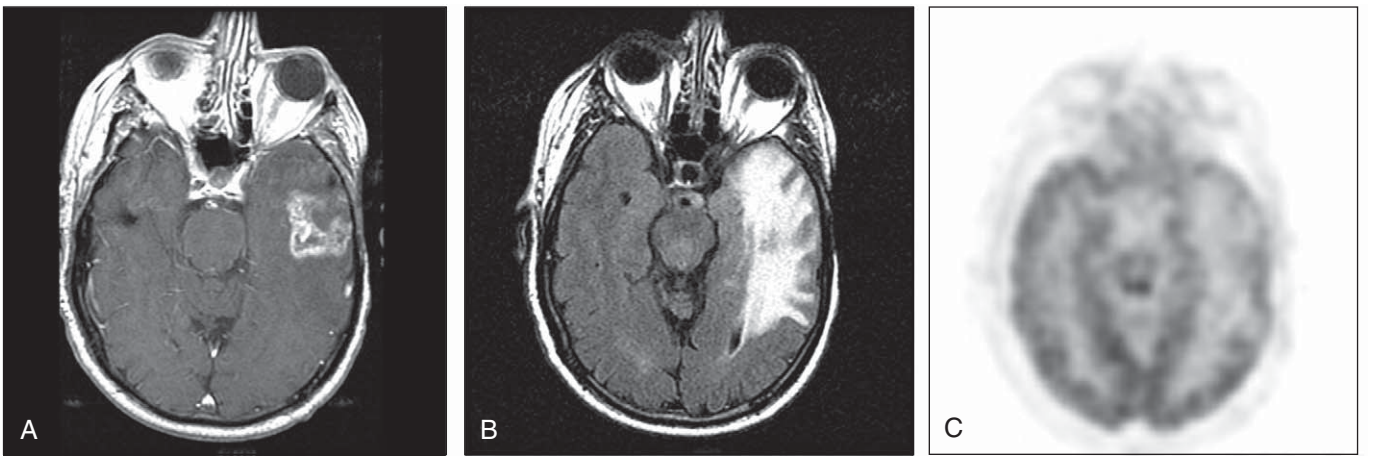

Figure 70-5 • Positron emission tomography/magnetic resonance imaging (PET/MRI) studies showing radiation necrosis of the brain. The patient had had a recurrence of a basal cell carcinoma involving the skin overlying the zygoma and the left periauricular region, with extension into the temporalis muscle. He underwent surgical resection, but because of perineural invasion, he received radiation therapy at a dose of 6400 cGy postoperatively to the tumor bed. Approximately 2 years later, he presented with aphasia and confusion. **A,** T_1-weighted post-gadolinium MRI showed a ring-enhancing mass in left temporal lobe, a finding highly suggestive of malignancy. **B,** FLAIR MRI showed extensive edema. **C,** An ^{18}F- fluorodeoxyglucose (FDG) scan, however, showed patchy areas of hypometabolism within the anterior and lateral aspects of the left temporal lobe—findings consistent with radiation effect, not malignancy. The patient underwent surgery with resection of the lesion, which confirmed it to be radiation necrosis without any evidence of malignancy.

Another rationale for maximal debulking is to reduce the tumor burden by one or two log orders of cells. Such cytoreduction is perfomed in the hope of increasing efficacy of both radiation therapy and chemotherapy for these tumors.

RADIATION THERAPY: GENERAL CONSIDERATIONS

Radiation is commonly used to treat many different types of brain tumors. The radiation oncologist must decide on many factors in the treatment plan for an individual patient, including treatment volume, dose, and fractionation. Treatment techniques including three-dimensional conformal therapy, stereotactic radiotherapy, and intensity-modulated radiation therapy (IMRT) are being used in a majority of patients presenting with brain tumors. Proton therapy, which has increasing availability in the United States, may be used for specific cases, especially for tumors at the skull base.

Radiation Therapy: Technical Details

Treatment planning starts with a review of the MRI scan to identify the target volumes. The appropriate volume to be irradiated varies according to the tumor type. Most brain tumors including gliomas and meningiomas are treated with focal radiation to the lesion plus a margin. The actual abnormality seen on imaging studies is termed the *gross tumor volume* (GTV). Additional tissue surrounding the GTV that is thought to potentially contain tumor cells is included in the *clinical target volume* (CTV). For some tumors such as glioblastomas, which can be highly infiltrative, the CTV includes the area of edema as demonstrated on the FLAIR or T_2 sequences plus a 1.5- to 2.0-cm margin. For other tumors that do not infiltrate, such as meningiomas, pituitary adenomas, acoustic neuromas, and craniopharyngiomas, the CTV typically would be much tighter than that used for glioblastomas. An additional volume is included around the CTV to take into account day-to-day setup error and to allow for buildup of dose, resulting in the *patient treatment volume* (PTV). Treatment planning proceeds by placing the patient on a CT simulator, generally in the supine position. Multiple immobilization devices are available, including thermoplastic masks, bite blocks, and systems that include motion tracking devices. After the CT scan is obtained, a previously obtained MRI scan can be fused onto the treatment planning system to better define the target volumes. In addition to the tumor, normal structures including the optic nerves, chiasm, cochlea, and brainstem often are drawn as areas to limit the radiation dose. Computerized treatment planning is then used to generate radiation beams and dose distributions.

Most brain tumors are treated with focal radiation therapy; however, for some tumors, such as PNETs and metastatic germ cell tumors of the CNS, it may be necessary to include the entire craniospinal axis in the irradiated zone. In such cases, a special technique must be used. For craniospinal irradiation, the optimal patient position is prone. This facilitates daily setup and treatment, with the spinal canal included in one or two fields entering from the patient's back and the entire cranial contents included in opposed lateral fields. Because abutting fields are used to encompass the entire craniospinal axis, the possibility exists for overlap between fields, resulting in a potential overdosage to part of the spinal cord. Therefore, great care must be taken during the setup of these fields. In many institutions, a technique termed *feathering* is used in which the matchlines between fields are changed periodically to ensure that an overdose or underdose does not occur in the same region of the spinal cord throughout the entire treatment.

Stereotactic Radiotherapy

Stereotactic radiotherapy is a technique for delivering high-dose radiation to a target volume with very tight margins, thereby sparing surrounding normal tissues. This technique can be implemented in a number of ways using various devices, including (1) a Gamma Knife machine, which contains 201 fixed cobalt sources that converge to a single point; (2) a conventional linear accelerator ("linac") outfitted with additional hardware so that it can deliver focused radiation, generally using between 3 and 5 arcs; and (3) delivery of charged particles such as protons, which, because of their physical properties, deposit energy in a narrower region than is possible with x-rays.

Stereotactic radiation can be delivered in a single large fraction. When this is done, the technique is termed *stereotactic radiosurgery*. Despite of its name, no surgery is performed. A sterotactic headframe often is screwed to the skull. In adults, this can be done using local anesthesia, but in children, conscious sedation or general anesthesia must be used. The headframe allows for localization of the tumor in a three-dimensional coordinate system and also immobilizes the head during treatment, thereby allowing for delivery of radiation with precision to a very tightly defined volume. For linear accelerator-based radiosurgery, the patient has a CT scan performed with the headframe in place. At our institution, MRI with gadolinium contrast is performed before placement of the headframe. The MRI images are then fused to the CT images, and a treatment plan is devised that targets the lesion while minimizing dose to normal structures. For Gamma Knife radiosurgery, an MRI-compatible headframe is placed before a contrast-enhanced MRI scan is obtained for use in target definition. The doses of radiation that are used in stereotactic radiosurgery range from 10 to 24 Gy and are based on the histologic tumor type and the volume of tissue irradiated. The doses used are based on the likelihood of tumor control and the risk of developing radiation necrosis.[102] The choice between a Gamma Knife and a linear accelerator is based on availability. Generally, Gamma Knife doses are prescribed to the 50% isodose line, and those with linear accelerator-based therapy, to the 80% isodose line.

Stereotactic radiotherapy also can be delivered in a fractionated regimen over several days or weeks. Of course, in this instance a headframe that is screwed into the skull cannot be used. Therefore, relocatable headframes have been developed. These headframes use custom-made moldings conforming to the patient's occiput and a bite block to maintain a precise and reproducible fit day to day.

A large experience has been accumulated with the use of stereotactic radiotherapy, in either a single fraction or a fractionated regimen, for the treatment of intracranial metastases, arteriovenous malformations, and primary brain tumors. The use of this modality to treat arteriovenous malformations is beyond the scope of this chapter, and its use in treating intracranial metastases is covered in Chapter 56. The use of stereotactic radiotherapy techniques for the treatment of meningiomas, pituitary adenomas, and acoustic neuromas is discussed in greater detail in the corresponding sections in this chapter.

Delivery of charged particles including protons has been used to treat brain tumors. Because of their physical properties, protons result in more limited dose to normal tissues than is possible with conventional x-rays. Only six centers in the United States have protons or other charged particles available for medical treatment, although a number of new facilities have recently been opened, and additional sites are in the planning phase.

Intensity-Modulated Radiation Therapy

The technique of IMRT uses multiple segmented fields with inverse treatment planning algorithms. In addition to defining the doses to be delivered to the GTV, CTV, and PTV, dose constraints are placed on normal structures to limit their radiation exposure. Constraints include the maximum dose to the entire structure and limits to a portion of the structure, as well as the maximum point dose within the structure. The most common mechanism of delivering this dose is use of multiple fields, typically 5 to 9, with use of a multileaf collimator to divide each field into multiple beamlets. From 50 to more

than 100 beamlets may be used. Most modern radiation departments have access to this technique.

Adverse Effects after Irradiation of the Brain or Spine

Acute and Early Delayed Effects after Cranial Irradiation

A variety of adverse effects may follow irradiation of the CNS (reviewed by Schultheiss and associates[103]). These effects can be divided into acute, which occur during the treatment; delayed early, which occur within a few months of radiation; and late, which occur months to years later.

Acute effects of cranial irradiation include fatigue, nausea, headaches, anorexia, and alopecia. Patients often complain of fatigue, not just with cranial irradiation, but with irradiation to other regions of the body, and as a result they often need to sleep longer than usual or take naps during the day. Patients may experience nausea within hours after the administration of the radiation and headaches during the course of treatment. Nausea usually is well controlled with antiemetics such as ondansetron or granisetron. Nausea and headaches are thought to be caused by radiation-induced edema and can be ameliorated with corticosteroids. In patients receiving craniospinal radiation, the nausea and anorexia may be compounded by the radiation that the upper gastrointestinal tract receives as an exit dose from the spinal field. Hair loss generally starts after the scalp has received 20 to 30 Gy. It generally is not permanent, but regrowth of hair may take months, and the new hair often is thinner than the original or even of a different color. In areas that receive a high dose of radiation, especially with tangentially directed fields, alopecia may be permanent. Other acute side effects of cranial irradiation may include accumulation of cerumen in the ear canals and serous otitis media.

The most common delayed early effect from radiation is the somnolence syndrome which is characterized by excessive drowsiness, nausea, and irritability.[104] If it occurs, it generally does so one to three months after radiation has been completed. This syndrome is thought to be due to transient, diffuse demyelination. It usually is seen after whole-brain irradiation for ALL but also can develop after limited-field irradiation for brain tumors. The syndrome resolves spontaneously, but steroids can shorten its duration. Delayed early effects occurring after cranial irradiation also can take the form of focal neurologic signs due to intralesional reactions related to tumor response or perilesional reactions related to edema or demyelination.

Brain Necrosis and Neurocognitive Deficits Following Cranial Irradiation

The pathophysiology of late effects from CNS irradiation is poorly understood. Some of the effects may be caused by degenerative changes in the supporting glial cells, whereas others may be caused by vascular changes due to endothelial cell loss and capillary occlusion.

One of the most serious late effects of cranial irradiation is brain necrosis, which may cause significant and persistent neurologic injury.[105,106] Second, it may produce progressive cerebral edema and mass effect requiring prolonged corticosteroid use or surgery. Third, it may be confused with tumor growth, resulting in the inappropriate use of antitumor therapies. The onset of radiation necrosis includes behavioral changes—lethargy and dementia, headache and papill-edema, and seizure. Clinical signs and symptoms are usually identified from 2 to 3 years after irradiation, although confirmed cases been detected as early as 9 months and as late as 16 years after completion of radiation therapy. The signs and symptoms are strongly related to the site of radiation necrosis; however, the most common clinical signs are focal motor deficits. Radionecrosis often is difficult to distinguish from recurrent tumor by CT or MRI, which may show increased signal intensity on T_2-weighted images and contrast enhancement on T_1-weighted images.[107] As discussed earlier (in the "Diagnostic Imaging" section), and as shown in Figure 70-5, however, PET scanning with FDG may help distinguish viable tumor from necrotic tissue.[108–110] Surgical exploration often is necessary not only to establish a diagnosis but also as a therapeutic intervention to remove the region of necrosis. Histopathologically, the changes seen in radiation-induced necrosis generally are limited to the white matter and include focal coagulative necrosis and demyelination.[111] Accurate data regarding the incidence of brain necrosis based on CT and MRI findings come from a randomized trial of irradiation for low-grade gliomas.[112] In this study, the 2-year actuarial incidence of brain necrosis was 2.5% for patients receiving 50.4 Gy and 5% for those receiving 64.8 Gy.

Neurocognitive deficits often are observed after cranial irradiation, especially in young children. Many of the sequelae appear several years after treatment of children with brain tumors, which mandates long-term follow-up. Sequential assessments of neurocognitive function demonstrated progressive deterioration during 6 years after radiotherapy in children with ALL treated with 18 Gy of whole-brain irradiation.[113] Numerous studies of neurocognitive function in children after whole-brain irradiation for ALL have been performed.[114–118] In summary, these findings show that whole-brain irradiation can lead to decline in neurocognitive function, an effect that appears to be greater in younger children and with higher doses of radiation (24 Gy) but can be seen after 18 Gy.[113] It also is possible that an interaction between methotrexate (intrathecal or high-dose systemic) and whole brain irradiation causes these late effects.[118]

Another treatment complication associated with cranial radiotherapy is leukoencephalopathy. This most is often associated with intravenous or intrathecal methotrexate and cranial irradiation.[105,119] Young age also is an important risk factor; however, leukoencephalopathy can affect all age groups. Histologically, multifocal white matter destruction with loss of myelin can be seen, especially in the periventricular regions; MRI scans show these periventricular abnormalities. CT scans also may reveal the presence of intracerebral microcalcifications due to mineralizing microangiopathy. The clinical expression of leukoencephalopathy ranges from mild evidence of white matter injury on neuroimaging studies to severe necrotizing leukoencephalopathy with profound neurologic impairment and, in some cases, death. Mild or subclinical cases are more common than severe necrotizing leukoencephalopathy. The bulk of the experience comes from children who received 24 Gy of whole-brain radiation along with high doses of intravenous and intrathecal methotrexate. The frequency of leukoencephalopathy is low in patients who receive cranial radiotherapy and intrathecal methotrexate or cranial irradiation and intravenous methotrexate but may be as high as 45% in patients who receive all three treatments.[120] In general, methotrexate is most toxic when given during or after radiation.

Although the major portion of the literature on neurocognitive function after cranial irradiation concerns children, some data on adults are available. Taphoorn and colleagues found no significant differences in neurocognitive function between patients with low-grade gliomas who received radiation (45 to 63 Gy) and those who did not.[121] In another retrospective study, young adults with low-grade brain tumors treated with 54 to 56 Gy of radiation to limited fields often showed a transient, early delayed drop in neuropsychological performance at 6 months; however, the risk of long-term cognitive dysfunction was low, at least up to the age of 4 years.[122]

In an NCCTG randomized study of 64.8 versus 50.4 Gy for treatment of low-grade gliomas,[112] data regarding cognitive performance were collected prospectively. Analysis of these data with a median follow-up time of 7.4 years in survivors showed that the vast majority of patients with normal baseline findings on the Mini-Mental Status Examination (MMSE) maintained these after radiotherapy.[123] Patients with abnormal MMSE results before radiotherapy were more likely to have an improvement in cognitive abilities than deterioration after receiving radiotherapy. Armstrong and coworkers

conducted prospective, comprehensive, longitudinal neuropsychological testing on 26 adult patients with low-grade supratentorial brain tumors, mostly gliomas, who had received radiotherapy.[124] Nine patients underwent testing at 6 years after radiotherapy. No declines were noted on most neurocognitive tests. Seven of the 37 neuropsychological tests showed improvement over 6 years. However, declines emerged only after 5 years on selected tests of cognitive function such as visual memory.

On the basis of these and other studies, one recent review on the neurocognitive effects of radiotherapy on patients with low-grade gliomas came to the conclusion that the weight of evidence suggests only sporadic, limited neurocognitive damage from focal radiotherapy at the doses usually prescribed.[125] These patients do not appear to suffer from widespread cognitive impairment or dementia.

Cranial irradiation can result in arterial vascular problems such as vessel obliteration or narrowing, resulting in a stroke-like syndrome.[126] These complications are rare, but when they occur they are more likely to happen after irradiation of the parasellar region.

Endocrine Deficits after Cranial or Spinal Irradiation

Endocrine problems are common after cranial irradiation, particularly in children.[127–129] Such problems include growth hormone deficiency and thyroid and gonadal dysfunction.

The hypothalamus is more radiosensitive than the pituitary gland and is responsible for endocrine dysfunction at lower doses. At higher doses (greater than 40 Gy), however, both the anterior pituitary gland and the hypothalamus contribute to endocrine dysfunction. Of all the hormones, growth hormone is the most likely to show deficiency following irradiation. Growth hormone deficiency is seen in a majority of children who have received whole-brain irradiation. One study found that in children with ALL given 24 Gy to the whole brain, 56% developed growth hormone deficiency, whereas no such problems were seen in children given 18 Gy, at least 4 years later.[130] The latency of onset is dose-dependent, being shorter with higher doses.[131] Growth may be further impaired by spinal irradiation, which directly affects vertebral body growth center.

Precocious puberty may also occur after relatively low doses, on the order of 18 Gy.[132] Deficiencies in the other hormones, such as gonadotropins, TSH, and ACTH, are rare after doses below 40 Gy, however.[128] Thyroid dysfunction is common in patients with brain tumors treated with high-dose radiotherapy.[133] Constine and associates studied endocrine function in 32 patients with brain tumors not involving the hypothalamic-pituitary region who received 39.6 to 70.2 Gy to this region.[134] Hypothalamic or pituitary hypothyroidism developed in 65% of the patients. Fourteen of 23 (61%) postpubertal patients had evidence of hypogonadism as manifested by oligomenorrhea or low estradiol levels or low testosterone levels. Half of the patients had mild hyperprolactinemia. Subtle abnormalities in adrenal function were seen in 35% of patients.

In patients receiving craniospinal radiation, hypothyroidism also may occur secondary to exit dose to the thyroid gland. In a study of radiation therapy for brain tumors not involving the hypothalamic-pituitary axis from the Christie Hospital in Manchester, the incidence of hypothyroidism was 15% or 33% ($P = 0.013$), respectively, for patients receiving cranial or craniospinal irradiation.[135] The mean spinal dose was 29 Gy, and the exit dose to the thyroid gland ranged from 10 to 15 Gy.

Optic Neuropathy after Cranial Irradiation

Irradiation of tumors that are close to the optic nerves or chiasm may result in sufficient dose to these structures that optic neuropathy is a concern. Two major classes of optic neuropathy are recognized: anterior optic neuropathy and retrobulbar optic neuropathy.[136] The former is thought to be due to vascular injury affecting the nerve head inside the globe anterior or adjacent to the lamina cribrosa. This is associated with swelling of the optic head, in contrast with retrobulbar optic neuropathy, which is due to more proximal injury to the optic nerve. Diagnostic criteria for retrobulbar optic neuropathy include (1) visual loss (monocular or binocular) accompanied by corresponding visual field defects, (2) funduscopic examination often showing a pale optic disc but without edema, (3) onset 6 months to several years after radiation therapy that delivered a significant dose to the optic nerve-chiasm, and (4) no radiologic evidence of visual pathway compression.[137] MRI scans may show pathologic contrast enhancement of the region of the optic nerve-chiasm that received a high dose of radiation.[138]

Parsons and colleagues examined radiation-induced optic neuropathy in patients receiving radiation treatment for primary extracranial head and neck tumors at the University of Florida.[136] Of 215 optic nerves at risk, these investigators found anterior optic neuropathy in 5 nerves and retrobulbar optic neuropathy in 12. No injuries were observed in 106 optic nerves that received less than 59 Gy. The 15-year actuarial risk of optic nerve neuropathy after 60 Gy more was 11% when daily fractions less than 1.9 Gy were used, versus 47% when 1.9 Gy or more was used.

The foregoing data suggest that the optic nerve-chiasm tolerance is at least 59 Gy; however, the University of Florida population did not include patients with intracranial tumors compressing the optic nerve-chiasm. It is possible in the latter situation that the tolerance of the optic nerve-chiasm is lower as a result of ischemic injury. In some patients with pituitary adenomas or craniopharyngiomas treated with irradiation, optic neuropathy developed after doses as low as 45 to 50 Gy, although in many of these cases the daily fraction size was greater than 2 Gy.[137,139,140] On the basis of these results, most investigators currently recommend limiting the optic chiasm-nerve dose to 50 Gy in 1.8- to 2-Gy fractions in the treatment of pituitary adenomas or craniopharyngiomas. For other brain tumors requiring higher doses, most radiation oncologists would try to restrict the optic nerve-chiasm dose to 54 Gy or lower. Adherence to these guidelines should keep the risk of radiation-induced optic neuropathy extremely low (1% or less) but unfortunately will not completely eliminate it.

Second Malignant Neoplasms Developing after Cranial Irradiation

Second malignant neoplasms including malignant gliomas and meningiomas remain relatively uncommon consequences of radiation therapy for brain tumors.[6,141] Recent reports raise concerns that the addition of adjuvant chemotherapy may increase the risk of second malignancies in long-term survivors of childhood brain tumors.[15,16] This may be especially true after prolonged use of alkylating agents and etoposide with or without irradiation.

Myelopathy after Spinal Irradiation

A delayed early effect that can be seen after irradiation of the cervical spine is Lhermitte's syndrome, which is characterized by an electric shock-like sensation precipitated by forward neck flexion.[142] The symptoms typically start weeks to a few months after completion of radiation therapy. They are maximal at first but abate with time, without the development of any objective signs. The paresthesias most commonly occur in the lumbosacral region but also can involve the upper and lower extremities and the upper back. This transient form of Lhermitte's syndrome can occur after doses of radiation well within accepted spinal cord tolerance and is not associated with any permanent late sequelae. The pathogenesis is thought to involve an inhibitory effect on oligodendrocytes that results in transient reversible demyelination. A more ominous form of Lhermitte's syndrome can manifest after a longer latency period after completion of radiation therapy (at least a year), which then progresses to chronic radiation myelopathy.

Chronic myelopathy is the most catastrophic late effect that can occur after spinal cord irradiation. Nearly half of the affected patients will die from complications.[143] A biphasic distribution in the latency

period from irradiation to the onset of myelopathy has been observed. The early peak is from 12 to 14 months, and the second peak, from 24 to 28 months. The pathologic insults that lead to myelopathy include damage to oligodendroglial cells, causing demyelination and white matter necrosis, and death of endothelial cells, resulting in vascular injury. In some patients, partial neurologic dysfunction develops; others progress to complete paraplegia or quadriplegia. No clinical or radiologic findings are pathognomonic for radiation-induced myelopathy. Therefore, the diagnosis usually is made by a combination of (1) neurologic abnormalities corresponding to a level just below the irradiated region, (2) a history of spinal cord irradiation with a high total dose (greater than 45 Gy) at least 6 months before the onset of signs and symptoms, (3) MRI findings of increased signal intensity on T_2-weighted images in the irradiated region,[144] and (4) exclusion of other etiologic factors. The MRI findings in spinal cord myelopathy can mimic tumor recurrence with gadolinium enhancement on MRI (Fig. 70-6).

The probability of developing chronic radiation myelopathy is dependent not only on the total dose delivered to the spinal cord but also on the fraction size. It is now well recognized that larger fraction sizes are associated with more severe later effects. This correlation was not always appreciated, however, and many of the cases of chronic myelopathy described in the literature occurred in patients who received 40 to 60 Gy to the cord in large daily fractions (2.45 to 5 Gy) (as described by Schultheiss and associates[103]). Using standard fraction sizes (1.8 to 2 Gy per day), a commonly observed limit for dose to the spinal cord is 45 Gy. In a study of the incidence of myleitis after irradiation of the cervical cord, Marcus and Million found that of 1112 patients, only 2 (0.18%) developed chronic radiation myelopathy.[145] Two out of 471 patients (0.42%) receiving between 45 and 50 Gy developed this complication. Myelitis developed in none of the 442 patients who received between 40 and 45 Gy and none of the 75 who received greater than 50 Gys. The investigators' conclusion was that even with doses of up to 50 to 55 Gy to the cervical cord, the likelihood of developing chronic myelopathy was extremely low. Even if the spinal cord dose is limited to 45 Gy, myelitis may still develop. This report cited published cases in which myelitis developed with doses less than 45 Gy or even less than 40 Gy, given in 1.8- to 2-Gy daily fractions. Such cases, however, are extremely rare, with an estimated risk of 0.2% or less for the development of chronic myelopathy at this dose.[103]

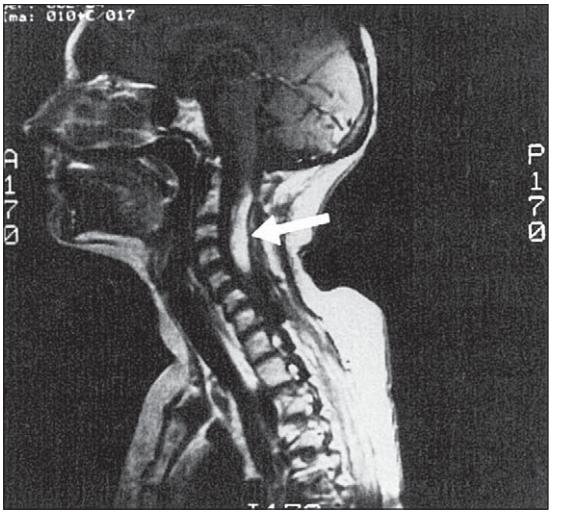

Figure 70-6 • Magnetic resonance imaging (MRI) in a patient with radiation necrosis of the spinal cord. The patient received 45 Gy of radiation to the cervical cord (C1 to C6) for grade II astrocytoma of the cord. Four years later she presented with weakness of the upper extremities. T_1-weighted post-gadolinium MR image showed enlargement of the cervical cord and enhancement *(arrow)*, thought to be consistent with recurrence. The patient received chemotherapy without improvement and eventually died as a result of respiratory failure. Autopsy of the spinal cord showed chronic radiation changes and necrosis of the cervical cord but no evidence of recurrent tumor. (From Phuphanich S, Jacobs M, Murtagh FR, Gonzalvo A: MRI of spinal cord radiation necrosis simulating recurrent cervical cord astrocytoma and syringomyelia. Surg Neurol 1996;45:363.)

GENERAL PRINCIPLES OF CHEMOTHERAPY

Chemotherapy of brain tumors involves many of the same problems as chemotherapy for systemic cancer, including lack of specificity, intrinsic or developing cellular resistance, intolerance of normal tissue to drug toxicity, synergistic toxicity between chemotherapy and radiation therapy, and systemic toxicity. Brain tumor therapy also is associated with specific problems of drug delivery across the blood-brain or blood-tumor barrier. Cerebral edema may impede drug delivery, and corticosteroids that effectively treat the edema may "repair" tumor vessels and impede the delivery of chemotherapy to the tumor. Thus, a recurring disappointment in clinical chemotherapy trials has been the failure to translate promising preclinical chemotherapy findings into meaningful improvement in patient survival.

Further complicating assessment of chemotherapy in brain tumor patients is the observation that corticosteroids also often reduce MRI contrast enhancement and relieve symptoms, making it difficult to distinguish chemotherapy effect from corticosteroid effect.[146] Further confusion may arise when neuroimaging documents enlargement of mass after stereotactic radiosurgery that may progress over many months. Because PET scanning may not reliably distinguish radiation necrosis from tumor progression, the results of concurrent chemotherapy may be ambiguous.[146] Conventional MRI response criterion of 25% to 50% reduction in contrast-enhancing tumor, therefore, may not always be a true measurement of chemotherapeutic efficacy. Radiation therapy also may result in endovascular changes, making access to the brain more difficult for chemotherapeutic agents. Attempts to circumvent this problem by administering chemotherapy before irradiation remain an area of active investigation.

Clinical criteria for chemotherapeutic success are similarly confusing. Performance status, measured in many clinical trials by the Karnofsky Performance Scale (KPS), is affected by tumor site, presence of seizures, and adverse effects of AEDS and steroids. Thus, appropriate measurement of chemotherapeutic efficacy should not be median survival alone. Median progression-free survival or 6-month progression-free survival and reduction in seizure frequency, corticosteroid requirement, and focal deficits all are parameters that must be measured. For long-term survivors, cognitive impairment and other serious acute and chronic neurologic toxicities of cytotoxic chemotherapy and newer molecular strategies factor into the assessment of chemotherapeutic program efficacy.

Finally, chemotherapy of primary brain tumors for the past 20-some years has been designed on the assumption that the problem is one of local control, with few recurrences outside the original tumor site.[147] With longer survivals and better local tumor control, however, however, a higher rate of multicentric cerebral and even leptomeningeal disseminated disease has been noted among patients with high-grade glial tumors, and oncologists may need to design future systemic regimens with these considerations in mind.

An important consideration in the chemotherapy of brain tumors is the ability of the drugs to cross the blood-brain barrier. This physiologic barrier defines the restricted transport between blood and the CNS of water-soluble, ionized molecules larger than about 200 daltons. The blood-brain barrier is formed by the endothelial cells of brain capillaries, with some contribution from astrocytes. Brain capillaries differ from capillaries elsewhere in the body by the presence of tight intercellular junctions. The brain's extracellular or intersititial fluid is an ultrafiltrate essentially identical to CSF. Capillaries of the

choroid plexuses are fenestrated, allowing access of large protein molecules into the plexus stroma. The epithelial cells separating stroma from CSF, however, have apical tight junctions. The brain lacks a lymphatic system.

These features of the blood-brain barrier and the blood-CSF barrier exclude entry of large molecules such as proteins and limit entry of smaller molecules to their ability to cross the lipid bilayer of cells. Lipid-soluble molecules such as nicotine, ethanol, heroin, and the alkylating agent BCNU (carmustine) pass readily across the blood-brain barrier. Another function of the blood-brain barrier may be that of pumping out chemicals potentially harmful to the brain. P glycoprotein, a blood-brain barrier protein, is present in the membrane of some brain tumor cells and serves to reduce the intracellular concentration of several chemotherapeutic agents.[148] The P glycoprotein is encoded by a gene responsible for a form of resistance to chemotherapy: the *MDR1* gene (for *m*ulti*d*rug *r*esistance).[149] Numerous studies have linked the expression of P glycoprotein with resistance to topoisomerase inhibitors including VP-16 (etoposide), VM-26 (teniposide), camptothecin, and other drugs such as paclitaxel and their derivatives. In preclinical studies in nude mice bearing human glioblastoma implanted tumors, coadministration of P glycoprotein inhibitors such as valspodar (SDZ PSC-833) resulted in marked improvement in access of paclitaxel and 90% reduction in tumor volume.[150] Not all malignant gliomas contain tumor cells that express P glycoprotein, and the expression in such cells does not correlate with tumor grade. Little evidence links the expression of *MDR1* gene to patient response to specific chemotherapeutic drugs.[151,152]

Another mechanism involved in glioma cell BCNU resistance is O^6-methylguanine DNA-methyltransferase (MGMT) expression. MGMT repairs nitrosourea-induced DNA damage by catalyzing the transfer of a methyl group from the O^6 position of guanine to its own molecule through a cysteine acceptor site. Not all BCNU-resistant glioma cell lines overexpress this enzyme, but the presence of MGMT recently has been shown to correlate with survival in patients with glioblastomas treated with nitrosoureas. Patients who had high levels of MGMT had a median survival period of 9 months, versus 15 months for those with low levels of MGMT. Administration of MGMT inhibitors resulted in increasing the cytotoxic effects of BCNU.[153]

Quantitative examination of the blood-brain barrier and the brain-tumor barrier has resulted in new avenues of investigation for brain tumor chemotherapy. Methotrexate entry into brain tumors can be enhanced by intra-arterial delivery, but the use of hyperosmolar mannitol for this purpose results in a far greater increase of drug entry into normal brain tissue than into tumor. Human and rat studies of BCNU, cisplatin, and other agents after blood-brain barrier disruption in both primary glial tumors and primary CNS lymphoma have demonstrated significant toxicity.[154,155] Attempts to deliver BCNU and other drugs intra-arterially have been largely abandoned because of unfavorable survival compared with that for patients who received intravenous treatment; the poor outcomes were due in large part to marked cerebral and ocular toxicity.[156–158]

The blood-brain barrier in brain tumors is impaired in many pathologic states, including traumatic injuries, infections, ischemia, and neoplasms. In brain tumors, the degree to which the tight endothelial cell junctions of the blood-brain barrier are disrupted and vascular permeability is thereby increased varies within even a single tumor. The persistence of a relatively intact barrier impedes entry of some water-soluble chemotherapeutic agents into areas of tumor, leading investigators to look for methods of opening the blood-brain barrier that are less toxic than intra-arterial mannitol. Another method of opening the barrier has been with the agent RMP-7, a bradykinin analog. On the basis of earlier promising studies in rat tumors in which intravenous RMP-7 selectively increased uptake of carboplatin into tumors, a randomized controlled trial of intravenous carboplatin and RMP-7 versus carboplatin and placebo was conducted in patients with recurrent malignant glioma. No significant differences were found in median survival times, median time to progression, or findings on neuropsychological, functional independence, or quality of life assessments. The use of RMP-7 had no effect on the pharmacokinetics or toxicity of carboplatin.[159]

SUPRATENTORIAL GLIOMAS

Clinical Considerations

Patients with supratentorial gliomas may present with general signs and symptoms such as changes in mental status, seizures, headaches, papilledema, and nausea and vomiting, as listed earlier under Clinical Presentation. They also may have focal signs and symptoms, dependent on tumor location, as discussed previously.

The past few decades have seen a change in clinical presentation with supratentorial low-grade astrocytomas. In the pre-CT era, patients often presented with headaches, papilledema, and motor weakness (as described by Vertosick and coworkers[160] and in the references cited in their report). In more recent series, however, in which CT or MRI scans were performed routinely, at least two thirds of patients presented with seizures, and very few had other signs or symptoms.[160–162] A possible explanation is that in the pre-CT era, many of these patients would have been placed on antiseizure medication and would not have been diagnosed with a brain tumor until their tumor grew large enough to cause signs and symptoms of increased ICP.

A history of seizures also is extremely common in patients with oligodendrogliomas, occurring in 70% to 90% of cases. The duration of symptoms can be prolonged. In a study by Ludwig and coworkers, 55% of patients had symptoms for longer than 1 year before diagnosis, and 37% had symptoms for longer than 3 years.[163] A few patients had symptoms for 10 to 15 years before diagnosis.

Low-grade astrocytomas decrease in frequency with increasing age. Their incidence is highest between the ages of 20 and 40 years and decreases in patients older than 50. Oligodendrogliomas display a similar age-related frequency. Conversely, high-grade astrocytomas, including glioblastomas, increase in frequency with increasing age (after the age of 60 years; see Fig. 70-1).

Pathologic Classification of Supratentorial Gliomas

Astrocytomas arise from astrocytes, the supporting cells of the central nervous system. Glial fibrillary acidic protein (GFAP) is expressed in the cytoplasmic processes that extend from the astrocytes; therefore, antibodies against this protein can be used in immunohistochemical studies. Over the years, many different histopathologic staging systems have been used. Kernohan devised a four-tiered system that classified tumors into grade 1, the slowest-growing tumors, through grade 4, the most malignant tumors.[164] A three-tiered system including astrocytoma, anaplastic astrocytoma, and glioblastoma, developed by Ringertz, was used in many cooperative trials.[165]

More recently, Daumas-Duport and Scheithauer, reviewing cases from the Mayo Clinic and Sainte-Anne's Hospital in Paris, devised a system using the presence of nuclear atypia, mitoses, endothelial proliferation, and necrosis to grade tumors from 1 through 4.[166] This system led to a better discrimination of outcome for patients who underwent treatment at the Mayo Clinic than did the Kernohan system.

The most widely used system today for classification of astrocytomas is the WHO system.[167] Grade I is reserved for pilocytic tumors, which are the most benign in terms of histology, generally curable with surgery alone. Because they are more common in children than in adults, they are discussed in greater detail later under Childhood Brain Tumors. The remaining categories are grade II (diffuse astrocytomas), grade III (anaplastic astrocytomas), and grade IV (glioblastomas).

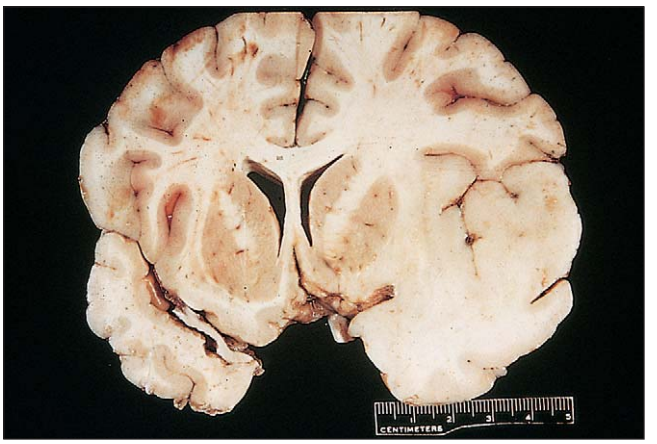

Figure 70-7 • Diffuse low-grade astrocytoma, gross specimen. WHO grade II astrocytoma arises diffusely and infiltrates the right frontal lobe. Gross determination of the tumor's boundaries is almost impossible, but the tumor is evident as an ill-defined area of enlargement, with loss of distinction between the gray and white matter. (Maher EA, McKee AC: Neoplasms of the central nervous system. In Skarin AT [ed]: Dana-Farber Cancer Institute Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 405)

Diffuse astrocytomas (grade II) are poorly defined, gray tumors that expand the parenchyma and obliterate normal gray matter–white matter boundaries[168] (Fig. 70-7). Microscopically there are increased numbers of irregularly distributed astrocytes with mildly atypical nuclei (Fig. 70-8A). Tumor cells can be seen infiltrating into normal brain tissue at some distance from normal tissue. Diffuse astrocytomas often are classifed into one of three subtypes: fibrillary, which is the most common subtype, protoplasmic, or gemistocytic.[169] Fibrillary astrocytomas are composed of tightly interlacing bundles of small, spindle-shaped cells amid a predominantly fibrillar matrix. Gemistocytic astrocytomas contain plump cells with distinct, round pink cytoplasm arranged on a more delicately interlacing fibrillar matrix, whereas protoplasmic astrocytomas are composed of small, round, regular cells with indistinct cytoplasmic boundaries arranged on a loosely fibrillar stroma.

Microscopically, anaplastic astrocytomas (WHO grade III) are distinguished from grade II tumors by their greater cellularity, increased nuclear pleomorphism, and of most importance, mitotic activity (see Fig. 70-8B). In both these and grade IV glioblastomas, tumor cells can be seen infiltrating into surrounding normal brain tissue, often at a great distance from the primary tumor mass. Histologically, glioblastomas are distinguished from anaplastic astrocytomas by the presence of endothelial proliferation or necrosis (Fig. 70-9). The necrosis can form a serpentine pattern referred to as "pseudopalisading," in which tumor cells crowd around the edges of the necrotic region. The presence of necrosis is of particular importance in grading gliomas and has been associated with shorter

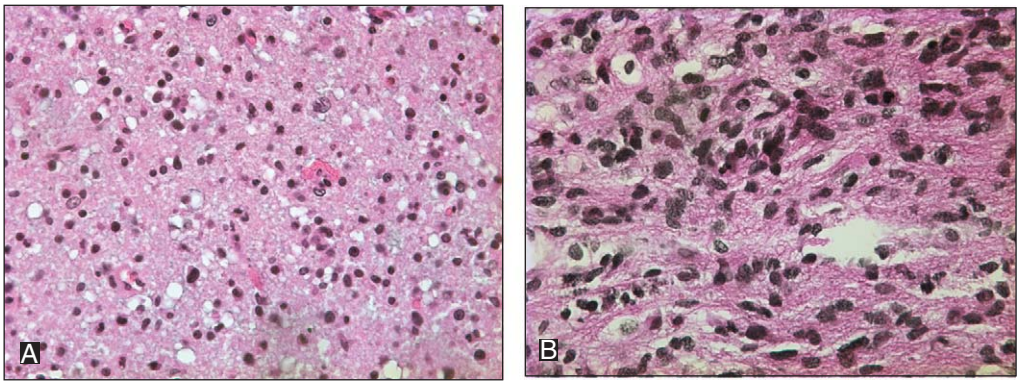

Figure 70-8 • Histologic appearance of low-grade astrocytoma versus anaplastic astrocytoma. **A,** Low-grade astrocytoma (WHO grade II) shows low cellularity, slight nuclear pleomorphism, no endothelial proliferation, and no necrosis. **B,** Anaplastic astrocytoma (WHO grade III) shows increased cellularity, pleomorphism, and mitotic activity compared with the grade II tumor in **A.** Anaplastic astrocytoma also lacks endothelial proliferation and necrosis. (Courtesy of Dr. Daniel Skovronsky, Department of Pathology, University of Pennsylvania School of Medicine.)

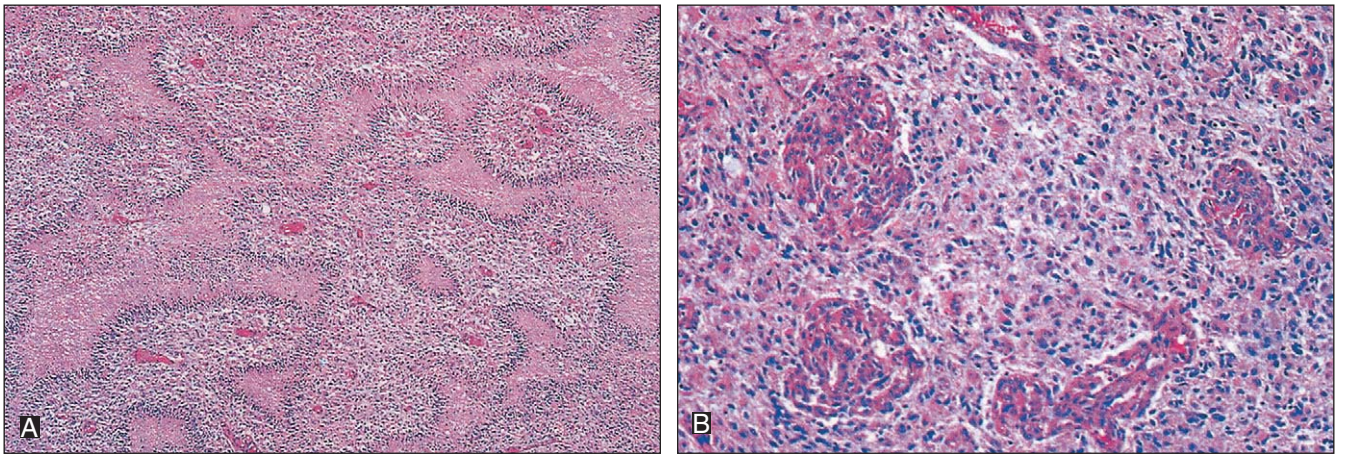

Figure 70-9 • Glioblastoma (grade IV astrocytoma): histologic appearance. **A,** Pseudopalisading cells surrounding regions of necrosis. **B,** Endothelial proliferation, which in this case has reached dramatic proportions, with the formation of tangled clusters of neovascular channels, often referred to as "glomeruloid" blood vessels because of their resemblence to renal glomeruli. (From Maher EA, McKee AC: Neoplasms of the central nervous system. In Skarin AT [ed]: Dana-Farber Cancer Institute Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 406.)

Figure 70-10 • Glioblastoma: gross specimen. The tumor appears as a necrotic, hemorrhagic infiltrating mass. (From De Girolami U, Anthony DC, Frosch, MP: The central nervous system. In Cotran RS, Kumar V, Collins T [eds]: Robbins' Pathologic Basis of Disease, 6th ed. Philadelphia, Saunders, 2003, p 1344.)

survival.[170] Grade IV glioblastomas show areas of hemorrhage, necrosis, and cystic change on gross examination[172] (Fig. 70-10). Glioblastomas can manifest with multicentric disease, but this occurs in less than 5% of cases as determined at autopsy of patients with untreated tumors.[147]

In addition to pathologic grading by morphology, techniques have been developed to measure cell kinetics based on the idea that faster-growing tumors are more malignant. These include immunohistochemical staining using antibodies directed against Ki-67 (MIB-1) or proliferating cell nuclear antigen (PCNA). Another technique involves calculation of an S phase fraction by measuring the incorporation of bromodeoxyuridine (BUdR) or iododeoxyuridine (IUdR) into tumor cells after intravenous injection of the agent. The predictive power of all three of these techniques has been compared with that for clinical parameters.[171] Problems with application of these methods remain, so they are not routinely used, but they offer some promise as a means of providing prognostic information independent of histology. Likewise, it is very possible that immunohistochemical stains for genetic changes found in glial tumors also will be used in the future to assess prognosis.

The different grades of astrocytoma carry very different prognoses. With WHO grade I (pilocytic) astrocytomas, a cure rate greater than 90% after surgical resection alone can be expected. By contrast, with WHO grade IV tumors, the median survival period is 1 to 2 years, even after aggressive combined-modality therapy. With WHO grade III tumors, long-term survival rates on the order of 20% are usual, but the median survival period is approximately 2 years. WHO grade II tumors carry a better prognosis than grade III tumors; nevertheless, recurrence with a higher-grade tumor is common with grade II tumors, although this may take 6 to 8 years to occur.

Most oligodendrogliomas occur in the cerebral hemispheres (80%), but they can occur in the lateral and third ventricles. Oligodendrogliomas arise from oligodendrocytes, which produce myelin. They often involve the subcortical white matter, with extension into the cerebral cortex. On gross examination, oligodendrogliomas often are soft and gelatinous and better circumscribed than astrocytomas.[168] They frequently contain calcifications. Despite their gross appearance suggesting that they are contained, they can infiltrate surrounding tissues, including the subarachnoid space and leptomeninges,

Owing to fixation artifact, oligodendrogliomas appear microscopically as sheets of cells with nuclei surrounded by a clear halo of cytoplasm, giving the cells the appearance of a "fried egg" (Fig. 70-11A). Unlike astrocytomas, oligodendrogliomas lack fibrillary cytoplasmic processes. Calcifications are present in 90% of these tumors. A common finding is a network of capillaries, lending a "chicken wire" pattern. The current WHO classification for oligodendrogliomas is a two-tiered system of grade II (oligodendroglioma) and grade III (anaplastic oligodendroglioma).[167] Features suggestive of anaplasia include cytologic atypia and increased mitotic activity (see Fig. 70-11B). Two other features, microvascular proliferation and pseudopalisading necrosis, when present in an oligodendroglial tumor would classify it as a grade III tumor, in contrast with an astrocytic tumor, in which these features would make it a glioblastoma (grade IV). The prognosis with anaplastic oligodendrogliomas is less favorable than with low-grade tumors, but they are much more sensitive to chemotherapy than their astrocytoma counterparts, as discussed in detail later on. In the Mayo Clinic series, the 5- and 10-year survival rates and median survival period for low-grade oligodendrogliomas were 75%, 46%, and 9.8 years, respectively, versus 41%, 20%, and 3.9 years for high-grade tumors.[172]

Distinct from oligodendrogliomas are mixed gliomas or oligoastrocytomas. According to the WHO classification, this latter category includes tumors that show "a conspicuous mixture of two distinct neoplastic cell types resembling the tumor cells in oligodendroglioma and diffuse astrocytoma."[167] The two components may be in different regions or diffusely mixed together. This definition is vague in that an oligodendroglioma with a very small astrocytic component may be classified by some pathologists as a pure oligodendroglioma but by others as a mixed oligoastrocytoma. In the WHO classification, these tumors are subdivided into oligoastrocytomas (grade II) and anaplastic oligoastrocytomas (grade III). Grading of these tumors is very difficult because the two components often differ in grade. In particular, it is problematic how to classify a tumor that has oligodendroglioma-like regions in a background that otherwise appears to be a glioblastoma. Some experts have referred to these as glioblasto-

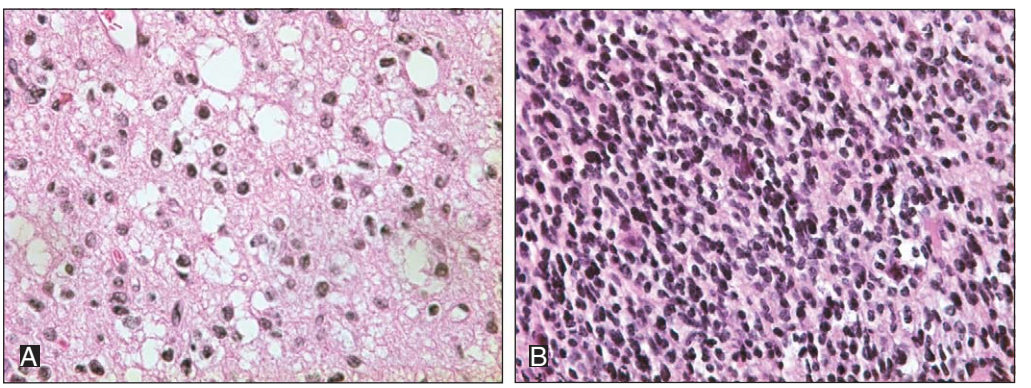

Figure 70-11 • Histologic appearance of oligodendroglioma versus anaplastic oligodendroglioma. **A,** In WHO grade II oligodendroglioma, oliogodendrocytes are uniform cells with small, round nuclei and a characteristic perinuclear halo ("fried egg" cells). **B,** Grade III oligodendroglioma shows cytologic atypia and increased mitotic activity compared with the tumor in **A.** (Courtesy of Dr. Daniel Skovronsky, Department of Pathology, University of Pennsylvania School of Medicine).

mas with oligodendroglioma component, which may carry a better prognosis than that for ordinary glioblastomas.[173]

Overall, patients with oligodendrogliomas have a better prognosis than patients with astrocytomas.[112] Oligoastrocytomas might be expected to have an intermediate prognosis, and in some series this is the case. For example, in the Mayo Clinic experience, the 5- and 10-year survival rates and the median survival period were 46%, 17%, and 4.7 years for low-grade diffuse astrocytomas, compared with 73%, 49%, and 9.8 years for low-grade oligodendrogliomas.[174] The respective figures for patients with oligoastrocytomas were in between, at 63%, 33%, and 7.1 years. In the University of California at San Francisco series, however, 5- and 10-year survival rates for patients with pure oligodendrogliomas and with oligoastrocytomas were identical.[175] The discrepancy between these series may be due to the difficulty in categorizing these tumors, and to interinstitutional differences in pathologic interpretation.

Imaging of Supratentorial Gliomas

WHO grade I (pilocytic) astrocytomas show enhancement on CT and MRI scans. By contrast, WHO grade II astrocytomas typically are poorly defined, hypodense or isodense lesions on CT scans that do not enhance. Either localized or homogeneous enhancement, however, can be seen in up to 30% to 40% of cases, with calcification in 5% to 10% of cases.[162,176] MRI shows low signal intensity on T_1-weighted images and high signal on T_2-weighted images (Fig. 70-12A and B). Grade III anaplastic astrocytomas and grade IV glioblastomas generally enhance with contrast although in one study, enhancement was not seen in 40% of the former and in 4% of the latter (see Fig. 70-12C and D).[177] The region of enhancement typically has a ring-like appearance surrounding an area of necrosis. The perimeter of the enhancing region does not define the border of the tumor, and malignant cells may be present beyond this. T_2-weighted MRI images show abnormalities that are more extensive than those seen on a contrast-enhanced CT scan or T_1-weighted MRI scan. In one study in which stereotactic biopsy findings were correlated with radiologic findings in patients with gliomas, isolated tumor cells often were found as far away as the region showing increased signal intensity on T_2-weighted images.[87]

At least 50% of oligodendrogliomas show calcifications, which can be appreciated on plain films of the skull as well as on CT scans.[178] Enhancement of oligodendrogliomas can be seen on CT and MRI scans, but this often is mild and poorly defined.

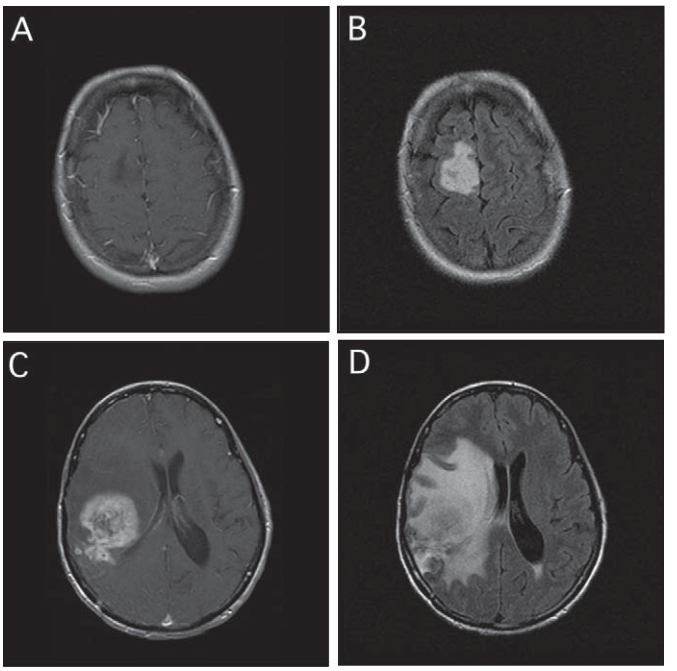

Figure 70-12 • Magnetic resonance imaging: low-grade astrocytoma versus glioblastoma. **A,** WHO grade II astrocytoma: T_1-weighted post-gadolinium axial image shows no enhancing mass; however, a region of hypodensity is seen. **B,** Corresponding FLAIR image of the tumor in **A** shows abnormality consistent with edema. **C,** WHO grade IV glioblastoma: T_1-weighted post-gadolinium axial image shows the presence of a large mass compressing the right lateral ventricle. A rim of enhancement with central necrosis is typical of these tumors. **D,** Corresponding FLAIR image of the tumor in **C** shows extensive peritumoral edema. FLAIR, fluid-attenuated inversion recovery; WHO, World Health Organization.

Genetics of Supratentorial Gliomas

Genetic Changes in Astrocytomas

The p53 pathway frequently is disrupted in all grades of astrocytomas. This can occur by mutation of p53 itself, by overexpression of MDM2, which degrades p53, or by mutation or deletion of $p14^{ARF}$, which positively regulates p53 by inhibiting MDM2 expression. In one study, the p53 pathway was disrupted by one of these mechanisms in 67% of diffuse astrocytomas, 72% of anaplastic astrocytomas, and 76% of glioblastomas.[179] Therefore, disruption of the p53 pathway appears to be an early event in the genesis of astrocytomas. It is possible that mutation of p53 in low-grade astrocytomas leads to genomic instability that sets the stage for additional mutations that lead to the formation of higher-grade tumors. The p53 gene (*TP53*) is located on the long arm of chromosome 17 (17p), which frequently is lost in both low-grade and high-grade astrocytomas, suggesting that p53 is the target for this genetic change (reviewed by Ichimura and coworkers[180]).

The Rb pathway, which regulates the G_1/S transition, commonly is disrupted in high-grade astrocytomas. This can occur through deletion or mutation of *RB* itself; deletion or mutation of *CDKN2A*, which encodes the cyclin-dependent kinase inhibitor p16; deletion or mutation of *CDKN2B*, which encodes the cyclin dependent kinase inhibitor p15; or amplification of the *CDK4* gene. Ichimura and coworkers noted that one of these changes had occurred in 67% of glioblastomas and 21% of anaplastic astrocytomas, but in none of 15 low-grade astrocytomas.[181] These findings suggest that progression to a higher grade glioma is facilitated by deregulation of the G_1/S transition.

Loss of heterogosity (LOH) of 13q and 9p has been identified in high-grade astrocytomas, and these deletions may lead to alterations in the Rb pathway. LOH of chromosome 13 occurs in 30% to 40% of higher-grade astrocytomas.[180] The Rb gene (*RB*), which maps to 13q14, is the likely target of this deletion. *CDKN2A* is located on 9p21, and this chromosomal region is homozygously deleted in at least 30% to 40% of glioblastomas and in approximately 10% of anaplastic astrocytomas, but never in diffuse astrocytomas.[180] Because two different gene products, CdkN2A and $p14^{ARF}$, both are transcribed from a single locus on 9p21, deletion of this region leads to simultaneous disruption of both the Rb and p53 pathways.

Astrocytic tumors also frequently display high-level expression of PDGF ligands and receptors.[30] Most studies have found that the PDFG-α receptor is overexpressed in 60% to 90% of low- and high-grade astrocytomas. By contrast, overexpression of the ligand PDGF-A or -B is not very common in low-grade gliomas but is seen in higher-grade tumors, suggesting that this growth factor participates in an autocrine loop in these tumors.[30]

Genetic Changes in Glioblastomas

Approximately 80% of all glioblastomas develop without any prior history of a glioma and are termed primary glioblastomas. The clinical history usually is short, on the order of months, and the patients tend to be older, with a median age of 55 when diagnosed. These

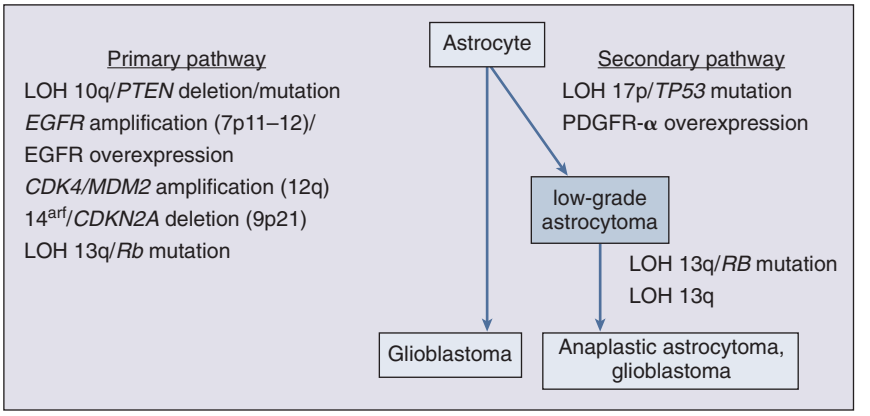

Figure 70-13 • Molecular alterations during "gliomagenesis." Two pathways for the development of glioblastomas have been described. In the secondary pathway shown, the patient has a history of a prior lower-grade astrocytoma, whereas in the primary pathway, no such history exists. The Rb/p16/Cdk4 pathway is disrupted in primary and secondary glioblastomas to a similar extent with LOH 13q/*RB* mutation and *CDK4* amplification. However, 9p/*CDKN2* deletion, another means of disrupting the Rb pathway, is seen more commonly in primary glioblastomas. These three changes targeting the Rb pathway appear to be mutually exclusive. *EGFR,* epidermal growth factor receptor; LOH, loss of heterozygosity; PDGFR-α, platelet-derived growth factor receptor-α.

tumors tend to be large with lots of edema, central necrosis, and ring enhancement. In 20% of the cases, the patient has an antecedent history of a lower-grade glioma (grade II or III), generally 5 to 10 years previously. These secondary glioblastomas tends to arise in younger patients, with a median age of 40 years.

The genetic changes seen in primary and secondary glioblastomas are very different[182–188] (Fig. 70-13). Primary glioblastomas often show homozygous deletions of the *CDKN2A*/*p14*^{ARF} locus on 9p21 (in 30% to 40% of cases) or amplification of *CDK4* and *MDM2* on 12q13–15 (in 8% to 13% of cases).[180] Either of these sets of genetic changes will cause disruption of both the p53 and Rb pathways.

EGFR amplification, leading to overexpression, is seen in approximately 35% of primary glioblastomas, rarely in anaplastic astrocytomas, and never in diffuse astrocytomas.[29] Another 15% of primary glioblastomas overexpress EGFR without amplification. Approximately half of glioblastomas with *EGFR* amplification express a mutant form of the receptor.[183] The most common mutant is known as ΔEGFR or EGFRvIII, which is missing exons 2 to 7, resulting in an in-frame deletion of 801 base pairs of the coding sequence of the extracellular domain.[183,184] This particular mutant form of EGFR is constitutively activated and cannot be downregulated. Its expression in glioblastoma cells has been associated with increased proliferation, decreased apoptosis, and increased tumorigenicity and invasion in vivo.[184] Even in glioblastomas that overexpress wild-type EGFR, which is not constitutively active, the ligands EGF and TGF-α often are coexpressed, which may activate an autocrine loop that allows for self-stimulation.[29]

Up to 90% of primary glioblastomas exhibit deletion of 10q, on which is located the tumor suppressor gene *PTEN*.[186] The retained *PTEN* allele is mutated in approximately 50% of tumors with 10q loss, leading to complete loss of functional PTEN protein. Therefore, the incidence of *PTEN* mutation in glioblastoma is at least 45%.[180] One study suggested a potential association between lower PTEN levels and shorter survival in patients with glioblastomas, although this did not reach statistical significance.[187] *PTEN* mutations have been found in anaplastic astrocytomas, although at a much lower frequency than in glioblastomas.[188] This study found the presence of *PTEN* mutations in anaplastic astrocytoma to be a powerful prognostic factor portending a poorer outcome.[188]

In contrast with primary tumors, secondary glioblastomas rarely display EGFR amplification.[189–191] Secondary glioblastomas have loss of 10q, but they do not have mutations of the retained *PTEN* gene.[190] Both the p53 and Rb pathways generally are disrupted in secondary glioblastomas, as is the case with primary glioblastomas; however, the mechanisms tend to be different. Both wild-type p53 alleles are lost in more than half of all secondary glioblastomas, generally one allele by deletion and the second by mutation. By contrast, p53 mutations rarely are seen in primary glioblastomas (occurring in less than 10% of cases).[189,191] The Rb pathway is disrupted in secondary glioblastomas, often through loss of both wild-type alleles.[180] Secondary glioblastomas may also show disruption of the p53 and Rb pathways through promoter methylation of CdkN2A and p14^{ARF}.

Genetic Changes in Oligodendrogliomas and Oligoastrocytomas

Two chromosomal abnormalities frequently are seen in oligodendrogliomas: deletion of 1p and deletion of 19q. Oligodendrogliomas exhibit LOH at 19q in up to 88% of cases and LOH at 1p in up to 100% of cases.[192] LOH of 1p and 19q is common in both grade II and III oligodendrogliomas, so these changes probably occur early during tumorigenesis.[193,194] By comparative genome hybridization, loss of 1p and 19q is found in 79% and 74%, respectively, of oligodendrogliomas but in only 25% and 30% of oligoastrocytomas.[192] Finer mapping indicates that the regions of interest lie in 1p36 and 19q13, although the specific genes have not yet been identified. Some evidence suggests that AOs with 1p or 19q deletions respond much more favorably to chemotherapy than tumors without these losses.[195] This is discussed in greater detail later on (under Chemotherapy for Newly Diagnosed Anaplastic Oligodendrogliomas). A correlation also has been found between oligodendroglioma location and the presence of these genetic alterations. Anaplastic oligodendrogliomas arising from frontal, parietal, or occipital lobe were more likely to contain 1p or 19q deletions than those arising in temporal lobe, insula, or diencephalon.[196]

Although 1p and 19q losses are the most common genetic abnormalities in oligodendrogliomas, other mutations have been reported. In one genetic analysis of 446 CNS tumors, *TP53* mutations and homozygous deletions of *CDKN2* were identified in 5% and 11%, respectively, of oligodendrogliomas. The same mutations were seen in 37% and 15%, respectively, of oligoastrocytomas.[197]

Surgery for Supratentorial Gliomas: Extent of Surgical Resection

The role of extent of surgical resection in the treatment of gliomas has been controversial for many years.[198–200] Virtually all of the reviews in this subject area have been retrospective; therefore, they are subject to significant selection bias. It is likely that patients with the most favorable, easily resectable lesions within noneloquent brain regions have tended to undergo aggressive resections, whereas those with deeper lesions in more eloquent brain regions have been selected for stereotactic biopsy to minimize surgical morbidity. Some experts have advocated maximal resection for gliomas, reasoning that this approach is associated with improved survival.[201] A possible explanation for this outcome may be that fewer cells are left behind that need to be eradicated with irradiation and chemotherapy.

Other investigators have advocated stereotactic biopsy alone as the preferred mode of histological diagnosis in the treatment of patients

with gliomas.[199,202] Stereotactic biopsy affords a histological diagnosis with a low complication rate (2% to 5%). However, stereotactic biopsy may lead to an inaccurate pathologic diagnosis. In a review of data for 81 consecutive patients initially diagnosed with stereotactic biopsy who subsequently underwent a craniotomy, Jackson and colleagues showed that the histopathologic classification based on stereotactic biopsy findings was incorrect in 38% of the patients.[198] This represented sampling error in these patients, 96% of whom underwent biopsy at outside institutions. Despite the fact that these were tumors located in eloquent brain and previously treated by neurosurgeons, gross total resection could be achieved in 57% of these patients once they reached a major tertiary care hospital (M.D. Anderson Cancer Center, Houston, Texas). Major complications were seen in only 12.3% of the patients undergoing aggressive craniotomy for resection of the malignant glioma located in eloquent brain.

To specifically address the role of aggressive resection of gliomas in prolonging survival, Lacroix and coworkers performed a retrospective multivariate analysis of outcomes for 416 patients using prospectively collected data.[200] Postoperative volumetric MRI scans were obtained on all patients so that a blinded neuroradiologist was able to determine extent of resection given as a percentage of the original tumor. Patients with a resection of 98% or more of the tumor volume had a median survival period of 13 months, versus 8.8 months for patients with a less than 98% resection. Also found to be significant were age, KPS score, and extent of tumor necrosis. Even when statistical analysis controlled for these other three factors, extent of resection remained a significant variable.

Navigation during Surgery

Intraoperative MRI scanners have allowed for real-time evaluation of the extent of tumor resection. Imaging of relevant anatomy can be performed during surgery with MRI in order to provide real-time feedback regarding the surgical resection. Schulder and colleagues reviewed the cases of 93 patients who underwent neurosurgery aided by a low-field intraoperative MRI scanner.[203] These investigators found that surgery was directly affected by imaging in 51% of the operations. Second lesions not otherwise evident on the initial preoperative scan were seen in 21 patients, and in another 14 patients unnecessary dissection was avoided as a result of real-time imaging. Intraoperative MRI scanners with field strengths of 1.5 T are being used not only for anatomic imaging but also for perfusion imaging and MR angiographic imaging. Frameless stereotactic units have been available for many years, allowing for downloading preoperative MRI scans to an intraoperative computer workstation to create a three-dimensional reconstruction of the images. The patient's head can be directly referenced to the images for precise intraoperative localization to less than 2 mm. Investigators have been able to import both PET and functional MRI data into the frameless stereotaxy units to map out functional brain during surgery.[94,204]

Intraoperative cortical and subcortical mapping has been used to define eloquent brain during resection of gliomas.[205,206] Intraoperative cortical mapping has enabled neurosurgeons to become more aggressive with tumors located within eloquent brain regions. This application is especially useful with low-grade gliomas that occur immediately adjacent to motor and speech areas. Cortical mapping may be done with the patient lightly anesthetized but awake enough to respond to questions so that speech areas can be mapped.

Complications of Surgery

A recent analysis by the Glioma Outcome Project reviewed perioperative complications and neurologic outcomes for patients who underwent craniotomy for the diagnosis and treatment of gliomas.[207] The Glioma Outcome Project was a prospectively compiled database capturing information on 788 patients. Of these, 499 underwent either a first or second craniotomy for treatment of their malignant glioma, and the remaining 289 patients underwent stereotactic biopsy only. No difference was found in the characteristics of the patients who underwent first or second craniotomy. Analysis of the perioperative symptoms, however, revealed that patients undergoing a second craniotomy had a higher incidence of altered level of consciousness and papilledema, whereas those undergoing a first craniotomy had a higher incidence of headache. The incidence of depression was higher in patients undergoing a second craniotomy: 11% in the group undergoing the first craniotomy versus 20% in the patients undergoing a second craniotomy. This difference may reflect the presence of a chronic disease state. The rate of systemic infections also was higher in patients undergoing a second craniotomy at 4.4%, versus zero in patients undergoing a first craniotomy. This is not unexpected, because these patients frequently have been heavily pretreated with radiation therapy and chemotherapy, as well as long-term steroid use, causing significant immunosuppression. Evaluation of postoperative neurologic status showed that neurologic status was the same or better in 92% of the patients undergoing their first craniotomy, whereas this rate dropped to 82% in patients undergoing their second craniotomy. Nevertheless, the overwhelming majority of patients are benefited by a debulking procedure to reduce neurologic deficits. As has been shown in multiple other studies, the most important preoperative factor associated with good neurologic outcome has been KPS score. Those patients with higher KPS scores fared better with surgery than did patients with lower scores. This finding is a reflection of degree of neurologic injury. The Glioma Outcome Project is perhaps the only prospectively collected database for evaluating outcomes of surgery in the treatment of malignant gliomas. The analysis of these data reveals that the incidence of further neurologic deficit with craniotomy is only 8% in patients undergoing their first operation, versus 18% in patients undergoing a second craniotomy for resection of a malignant glioma. In view of the severity of the disease, this is certainly an acceptable risk. Of greater importance, they are objective prospectively obtained data showing improvement in neurologic outcome with aggressive debulking surgery. An important point is that these data were compiled from participating institutions, and the decision for surgery was left to the discretion of the surgeon; therefore, certainly selection bias obtained in terms of who underwent radical surgery versus stereotactic biopsy. The investigators do not discuss the frequency of tumors in eloquent versus noneloquent brain. Nevertheless, findings of this study are representative of the general practice of surgical neuro-oncology throughout the nation.

Convection-Enhanced Delivery

Local therapy for gliomas has been an intriguing concept because of the anatomically limited nature of the disease. Gliomas do not metastasize outside of the CNS and frequently recur within a 2-cm margin of the previous resection.[147] Simple diffusion will work for small molecules and some forms of chemotherapy. With the advent of biologic modifying agents with large molecular weights, however, another development has been convection-enhanced delivery—that is, pressure-driven delivery of drugs directly into the brain tissue, causing a gradient to induce bulk flow into the interstitial space of the brain, thereby distributing macromolecules across a distance measured in centimeters, rather than millimeters. Use of this technique to deliver two such agents has been described. The first agent is a conjugate of transferrin and a mutant *Diphtheria* toxin infused into patients with malignant gliomas.[208] The investigators reported at least a 50% reduction in tumor volume in 9 of 15 patients. The second clinical trial administered a conjugate of IL4 with *Pseudomonas* exotoxin for patients with recurrent malignant gliomas.[209] This study was a safety and toxicity trial and has been carried forward using IL-13 into the recently concluded Phase III Randomized Evaluation of CED (Convection Enhanced Delivery) of IL13-PE Compared to Gliadel Wafer with Survival Endpoint Trial (also known as the PRECISE Trial). The survival data for this study are not available at this time. The preclinical and some of the clinical studies using convection-enhanced delivery show excellent distribution through-

Box 70-1. MANAGEMENT OF SUPRATENTORIAL ASTROCYTOMAS

- **Grade I (pilocytic) astrocytomas:** Surgery is curative. If residual tumor is seen on postoperative imaging, the patient should undergo a second craniotomy to resect the entire tumor. Radiation therapy and chemotherapy have limited usefulness for treatment of these tumors.
- **Grade II (low-grade) astrocytoma:** Surgery is the mainstay of therapy for tumors in noneloquent regions of brain. In patients younger than 40 years of age who undergo gross total resection, no additional therapy is given. In patients younger than 40 with incomplete resection and patients older than 40 with or without complete resection, adjunctive treatment with radiation therapy (54 to 60 Gy) is indicated.
- **Grade III astrocytoma (anaplastic astrocytoma) and grade IV gliomas (glioblastoma):** Surgery is required to establish tissue diagnosis, preferably with debulking as well. Chemotherapy is begun with temozolomide during radiation therapy and continued for six cycles after completion of the radiation regimen. The radiation dose generally is 60 Gy. Tumor tissue is sent for analysis of *O^6-methylguanine DNA-methyltransferase (MGMT)* promoter activity. Temozolomide is offered to all patients, however, regardless of promoter methylation status.

out the brain, and the agent has been reported to pass through normal brain to reach a second site of tumor, with excellent drug delivery to the second tumor site.[208] Box 70-1 summarizes the recommended approach to management of supratentorial gliomas.

Radiation Therapy for Supratentorial Gliomas

Radiation Therapy for Low-Grade Gliomas

Numerous retrospective reports have been published on the use of radiation therapy for low-grade gliomas (summarized by Leighton and associates[210]). These studies are plagued with a myriad of problems, making them inconclusive. In order to contain sufficient patient numbers, most of these reports span decades, sometimes going back as far as the 1940s. Obviously, before the advent of CT scans, accurate treatment planning would have been difficult, as would good radiologic follow-up to document relapses. Before the 1960s, radiation was given using orthovoltage machines, which do not have the capability to deliver treatment to deep tissues. The doses given to some of the patients would be considered inadequate by today's standards. In these studies, immediate postoperative radiation often was given to patients with poor prognostic features, thereby potentially skewing the results in favor of observation.

The results of these retrospective studies have largely been superseded by the results of three randomized trials, two from the European Organization for Research and Treatment of Cancer (EORTC) and one from the North Central Cancer Treatment Group (NCCG; Table 70-6). The EORTC 22844 trial randomized adults with supratentorial low-grade astrocytomas, oligodendrogliomas, or mixed oligoastrocytomas to receive either 45 Gy or 59.4 Gy of radiation after surgery.[211] The NCCG study was similar except that patients were randomized to receive either 50.4 or 68.4 Gy after surgery.[112] Patients underwent a range of surgical procedures, including biopsy and subtotal or gross total resection. Neither study showed any benefit to the higher dose in terms of overall survival or progression-free survival. If anything, the NCCG study showed a worse survival in patients receiving the higher dose of radiation (64.8 Gy). The 5-year survival rate in both studies ranged from 58% to 72%.

The EORTC also performed study 22845, in which patients who underwent surgical treatment for astrocytomas, oligodendrogliomas, or mixed oligoastrocytomas were randomized to receive either adjunctive irradiation in a dose of 54 Gy or no upfront radiation therapy.[212] Patients in the latter group had the option of receiving radiation if progression of disease was observed. No difference was seen in overall survival between the early radiotherapy and observation groups (see Table 70-6: 5-year survival rate, 68% versus 66%; median survival period, 7.4 versus 7.2 years). A statistically significant advantage, however, was observed in the patients who received radiation in terms of progression-free survival (55% versus 35% at 5 years; median time to progression, 5.3 versus 3.4 years; $P < 0.0001$). The absence of any difference in survival has supported the position of experts who advocate delaying radiation. Conversely, those favoring upfront radiation in the treatment of low-grade gliomas have cited the improved progression-free survival in the irradiated group, and the fact that at 1 year, seizures were better controlled in the radiation treatment arm.

These randomized trials confirmed the importance of certain prognostic factors in low-grade gliomas. In the NCCG trial, three prognostic factors—histologic subtype, patient age, and tumor size—were consistently associated with overall survival in multivariate analysis.[112] The 5-year survival rates for patients with oligodendroglioma-predominant tumors and those with astrocytomas were 74% and 56%, respectively ($P = 0.0001$); for patients younger than 40 years of age and those ≥40 or older, 77% and 60%, respectively ($P = 0.025$); and for preoperative tumor size less than 5 cm and 5 cm

Table 70-6 Results of Treatment for Low-Grade Gliomas: Selected Randomized Trials

Study	Years	Histologic Type	Treatment Protocol	No. of Patients	5-Year Survival	5-Year PFS
Karim et al[211]	1985–1991	9% A, grade 1	45 Gy	171	58%, $P = 0.94$	47%, $P = 0.73$
EORTC 22844		60% A, grade 2	59.4 Gy	172	59%	50%
		22% O				
		9% mixed				
van den Bent et al[212]	1986–1997	2% A, grade 1	Observation	157	66%, $P = 0.87$	35%, $P < 0.0001$
EORTC 22845		60% A, grade 2	54 Gy	154	68%	55%
		25% O				
		10% mixed				
Shaw et al[112] NCCTG	1986–1994	32% A or mixed (A > O)	50.4 Gy	101	72%, $P = 0.48$	55%, $P = 0.65$
		68% O or mixed (O > A)	64.8 Gy	102	65%	52%

A, astrocytoma; EORTC, European Organization for Research and Treatment of Cancer; NCCTG, North Central Cancer Treatment Group; O, oligodendroglioma; PFS, progression-free survival.

or greater, 81% and 61%, respectively ($P = 0.008$). In the EORTC 22844 study, the extent of resection had a great impact on overall survival: Patients who had greater than 90% of their tumor removed did much better than those who underwent a biopsy. Multivariate analysis of data from the two EORTC trials confirmed that astrocytoma histology, age older than 40 years, and preoperative size greater than 6 cm all were unfavorable prognostic factors but also uncovered a few others, such as tumor crossing midline and the presence of neurologic deficits before surgery.[213]

On the basis of these randomized trials, it is evident that in adults with low-grade gliomas, no difference in survival is achieved whether radiation therapy is given postoperatively or delayed until recurrence. Therefore, a reasonable management strategy would be observation in a patient with a completely resected low-grade glioma. Many investigators, however, still advocate radiation after complete resection in older patients (older than 40 years) or after incomplete resection. The standard dose is 54 Gy given in 1.8-Gy fractions over 6 weeks. It is common to treat the MRI-defined gross tumor volume (GTV) with a 1.5- to 2-cm margin.

Radiation Therapy for High-Grade Gliomas

The earliest randomized trial to demonstrate that radiation therapy was beneficial in the treatment of high-grade gliomas was conducted by the Brain Tumor Study Group (BTSG 69-01)[214] (Table 70-7). Patients were randomly assigned to one of four groups: supportive care, whole-brain radiation therapy (WBRT), BCNU, or WBRT plus BCNU. The role of BCNU is discussed further under Chemotherapy for Gliomas later on. This BTGS trial clearly showed a benefit for radiation alone versus supportive care with a median survival for 9 months versus 3.5 months and a 1-year survival rate of 24% versus 3% ($P = 0.001$). On the basis of this trial, radiation therapy has remained an essential component in the treatment of high-grade gliomas. A second randomized trial from the Scandinavian Glioblastoma Study Group confirmed the efficacy of radiation using a lower dose of WBRT (45 Gy) compared with supportive care (see Table 70-7).[215]

The results from BTSG 69-01 and two successive BTSG studies were pooled together to examine dose response.[216] The original studies were all randomized, but patients were not randomly assigned to different radiation doses; therefore, the analysis of dose was a retrospective one. With this caveat kept in mind, the study showed a benefit to using 60 Gy versus 50 Gy (median survival, 10.5 versus 7 months; $P = 0.004$). The Medical Research Council in Great Britain performed a randomized study examining dose in radiation treatment for high-grade astrocytomas.[217] After surgery patients were randomly assigned to receive either 45 or 60 Gy of radiation. The treatment volumes used in this study were very generous but less than for whole-brain levels. Among patients receiving 45 Gy, irradiation was mostly to the entire supratentorial region. Among those who received the higher dose, a dose of 40 Gy was delivered to volumes similar to those in the first group, followed by an additional 20 Gy to the tumor volume with a 1-cm margin.

The current standard of care in RTOG studies is to define the initial volume as the preoperative lesion with edema as seen on T_2-weighted MR images with a 2-cm margin. This volume is treated to 46 Gy, followed by a boost to the gadolinium-enhancing lesion seen on T_1-weighted images with a 2.5-cm margin to 60 Gy.

By pooling the results of three RTOG studies and using a nonparametric recursive partitioning technique, Curran and associates identified several significant prognostic factors for survival in patients with high-grade gliomas: histologic type, KPS score, age, neurologic function, and duration of symptoms.[218] Patients could be placed into groups I through IV with different outcomes on the basis of these factors.

Data have been accumulated regarding the radiologic response of high-grade astrocytomas to radiation therapy. In one multicenter trial, patients had CT scans done at several points in management: (1) preoperatively, (2) at the end of radiation therapy, (3) 6 to 8 weeks after the end of radiation therapy coinciding with the start of chemotherapy, (4) 8 weeks after the first course of chemotherapy, and then (5) every 3 to 4 months.[219] The radiation dose consisted of 44 Gy to the whole brain, followed by 14 Gy to the tumor volume. Twenty-two of 63 evaluable tumors (35%) responded to irradiation, defined as showing a decrease in the enhancing tumor volume by 25% or more. The vast majority of responding tumors, 20, showed a response by the end of radiation therapy. In two tumors, the response occurred between the end of radiation and the start of chemotherapy (8 weeks later). Three tumors (5%) progressed by the end of radiation therapy. Complete disappearance of the enhancing mass was extremely rare, occurring in only three tumors (5%). Response was more common in patients with anaplastic astrocytomas (11 of 21, or 52%) than in those with glioblastomas (11 of 42, or 26%), although this difference did not reach statistical significance.

Because of the poor survival of patients with high-grade astrocytomas, numerous strategies have been tried to improve the results with irradiation. These efforts fall into two main classes: first, increasing radiation dose, and second, modulating the radiation response. Doses higher than 60 Gy have been used, but to no avail. The RTOG 74-01–ECOG 1374 trial randomized between 60 Gy WBRT and a total dose of 70 Gy (60 Gy WBRT followed by a 10-Gy boost) but showed no improved survival with the additional dose (see Table 70-7).[220] Hyperfractionation also has been used to try to increase the total dose. In the Brain Tumor Cooperative Group (BTCG) study 77-02, patients who were randomly assigned hyperfractionated WBRT (66 Gy in 1.1-Gy twice-daily fractions) with BCNU showed no difference in survival compared with those who received conventional WBRT (60 Gy).[221] In RTOG trial 90-06, patients were randomized to receive either 60 Gy in conventional fractionation or 72 Gy in a hyperfractionated regimen (1.2 Gy twice daily). No differences were found in survival between the two groups.[222]

Radioactive implants also have been used to increase dose locally to the tumor bed. Single-institution data suggested improved outcome with this approach over conventional radiotherapy.[223] In the BTCG 87-01 trial, patients were randomized to receive either an ^{125}I seed implant (60 Gy) or no implant at surgery (see Table 70-7). Thereafter, patients received 60 Gy via external beam radiation. Remarkably, no survival benefit was found for use of 120 Gy delivered with brachytherapy and external beam irradiation.[224] In a trial conducted at the Princess Margaret Hospital, patients underwent surgery followed by 50 Gy of external beam radiation and then were randomized to either receive an ^{125}I implant (60 Gy) or not.[225] This study too showed no improvement with an implant.

An implantable balloon has been developed for the delivery of brachytherapy. This implantable balloon (Gliasite) comes in several sizes to fit the diameter of the resection cavity. After resection of the tumor, the balloon is placed in the cavity and filled with x-ray contrast medium. The catheter is attached to the balloon and then is brought out through the skull, and an infusion port at the end of the catheter is attached to the skull. A liquid form of ^{125}I (Iotrex), specifically developed for use in the Gliasite, can then be used to fill the balloon 2 to 3 weeks after insertion. Dwell times range from 2 to 5 days, based on the calculated dose of radiation, following which the Iotrex is withdrawn from the balloon via the infusion port. Loading and unloading of the Iotrex are done percutaneously. Patients can be sent home with appropriate radiation safeguards (personal communication, Allen Sills, MD, Memphis, Tennessee); alternatively, the patient is kept in the hospital with the appropriate radiation isolation precautions. This device provides brachytherapy directly to the resection cavity, with minimal exposure of unaffected brain to the radiation source. The device is used for treatment of primary gliomas as well as metastatic tumors. The dose for recurrent gliomas is 60 Gy at 1 cm and for metastatic lesions 60 Gy at 0.5 cm. Use of the Iotrex has yielded significant improvements in quality of life and tumor control.[226,227]

Table 70-7 Results of Treatment for High-Grade Astrocytomas: Selected Randomized Trials Focusing on Radiation and Radiation Modifiers

Study	Years	Gliomas (%)	Treatment Protocol	No. of Patients	Median Survival (mo)	18-Month Survival (%)	Comment(s)
Walker et al[232]	1969–1972	90	Supportive care	31	3.5	0	RT superior to supportive care (P = 0.001)

*During the early part of the study, external beam radiation was given to whole brain to a dose of 43 Gy, followed by a boost to the tumor volume for an additional 17.2 Gy. From May 1989, WBRT was dropped, and the entire dose was restricted to tumor volume.

†All patients in this trial had AAs.

Another means of increasing dose to the tumor region after conventional radiation therapy has been stereotactic radiotherapy. Single-institution studies have shown improved results with this approach—for example, from the Joint Center for Radiation Therapy at Harvard.[228] This approach was tested in the RTOG study 93-05, in which patients in the control group received standard fractionated radiotherapy (60 Gy in 30 fractions) with BCNU chemotherapy, whereas patients in the experimental group received a radiosurgery boost (15 to 24 Gy) before external beam radiation therapy. Preliminary results in abstract form from this trial indicate no benefit for the radiosurgery boost (see Table 70-7).[229]

Numerous agents have been tried in combination with radiation in attempts to improve survival. Conventional chemotherapy is discussed later under Chemotherapy for Gliomas. Halogenated

pyrimidine analogs are incorporated preferentially into dividing cells, with substitution of pyrimidine for the thymidine in DNA, sensitizing cells to double-strand breaks. In vitro, this can lead to radiosensitization by preventing the repair of double-strand breaks. The halogenated pyrimidine BUdR has been studied in a randomized trial. Prados and associates randomized patients with anaplastic astrocytomas to receive radiation therapy and chemotherapy with procarbazine, CCNU (lomustine), and vincristine (the PCV regimen), with or without the radiosensitizer BUdR, which was given as a 96-hour infusion concurrently with the radiation.[230] No difference in survival was found, however.

Glioblastomas are thought to have regions of hypoxia that can lead to radioresistance. Therefore, agents that are hypoxic cell sensitizers have been used in conjunction with radiation (see Table 70-7). The hypoxic cell sensitizer misonidazole was tested in RTOG trial 79-18 but was not found to lead to an improvement in survival.[231] Misonidazole also showed no benefit in another randomized trial, BTSG 77-02.[221]

The one agent that has clearly been shown to be of benefit when combined with radiation is the alkylating agent temozolomide. The results with this drug for treatment of glioblastomas are discussed next.

Chemotherapy for Gliomas

Chemotherapy for Newly Diagnosed High-Grade Astrocytomas

The role of chemotherapy in the treatment of high-grade astrocytomas has been investigated for more than 30 years. The earliest prospective brain tumor chemotherapy clinical trials were performed by the BTCG/Brain Tumor Study Group (BTSG) investigators. In BTSG 69-01, Walker and colleagues found that median survival was not significantly prolonged in patients receiving carmustine (BCNU), but at 18 months, 19% of patients reciving chemotherapy, radiation therapy, and surgery were alive, compared with 4% of those treated with radiation therapy and surgery alone.[232] In BTSG 75-01, Green showed that the addition of chemotherapy to surgery and radiation therapy significantly increased mean survival from 40 weeks to 50 weeks and increased the percentage of patients surviving 18 months to 24%.[233] In these and most studies of chemotherapy as adjuvant therapy for high-grade astrocytoma, the benefit was greater in patients with anaplastic astrocytoma than in those with glioblastoma.

Another well-studied and frequently used chemotherapy regimen is combination therapy with procarbazine, CCNU, and vincristine (i.e., PCV). Although initial reports suggested a survival advantage for patients with anaplastic astrocytoma receiving PCV over those receiving BCNU, subsequent meta-analysis of four studies failed to confirm this finding.[234] The PCV regimen clearly is more toxic as a result of myelosuppression and peripheral neuropathy and has been replaced by temozolomide.

The introduction of temozolomide has dramatically altered the treatment of high-grade gliomas. Temozolomide is an oral alkylating agent whose levels are not affected by AEDs or other hepatic enzyme-inducing drugs. Toxicity with this drug is relatively mild, with good CNS penetration. The pivotal study conducted jointly by the European Organization for Research and Treatment of Cancer (EORTC) trial 22981–26981, and the National Cancer Institute of Canada (NCIC) trial CE.3 confirmed the usefulness of temozolomide and radiation in newly diagnosed glioblastomas.[235] This study randomized 573 patients to receive 60 Gy of standard fractionated radiation or the same radiation regimen with daily temozolomide at 75 mg/m^2 followed by six cycles of adjuvant temozolomide (150 to 200 mg/m^2 for 5 days during each 28-day cycle). The patients in the radiation plus temozolomide arm had a statistically significant improvement in survival over those in the radiation only arm ($P < 0.001$; Fig. 70-14A). At follow-up evaluation at a median of 28 months, the median survival periods in the two arms were 12.1 and 14.6 months, respectively. The 2-year overall survival rates were 10.4% and 26.5%, respectively.

Hegi and coworkers subsequently evaluated the status of the epigenetic silencing of the MGMT DNA repair gene (*MGMT*) by promoter methylation in patients enrolled in this trial.[236] Two hundred six of the patients enrolled in EORTC 22981–26981–NCIC CE.3 had samples in which MGMT promoter methylation could be assessed. The MGMT promoter methylation occurred in 45% of these cases, and this was found to be an independent favorable prognostic factor regardless of treatment ($P < 0.001$). Patients with a methylated MGMT promoter had better survival than those without (see Fig. 70-14B). The median and 2-year survival rates for patients receiving radiation versus radiation and temozolomide based on MGMT promoter methylation status are shown in Table 70-8. Even among patients with unmethylated MGMT, a trend toward increased survival is recognized for those receiving temozolomide. These data have made irradiation plus adjuvant temozolomide the standard of care for all patients with glioblastoma regardless of *MGMT* status. The relative contributions of oral daily temozolomide during radiation versus after radiation are not clear, and the optimal dose of temozolomide to inhibit MGMT activity has not been established and is the subject of ongoing trials. In the current RTOG trial, patients with newly diagnosed glioblastoma are randomized to receive standard chemoradiation therapy followed by 12 rather than 6 monthly cycles of adjuvant temozolomide at standard dosing, or, alternatively, dose-intensive temozolomide (21 days on and 7 days off).

Table 70-8 Results of Treatment for Glioblastomas Stratified by MGMT Promoter Status: EORTC Trial 22981-26981 and NCIC Trial CE.3

	MGMT Promoter Status/Treatment*			
Study Result	**Unmethylated ($N = 114$)**		**Methylated ($N = 92$)**	
Median overall survival (mo)	12.2	($P < 0.001$)	18.2	
	Radiation only ($N = 54$)	**Chemoradiation ($N = 60$)**	**Radiation only ($N = 46$)**	**Chemoradiation ($N = 46$)**
	11.8	12.7	15.3	21.7
2-year survival	1.9%	13.8%	22.7%	46%
	($P = 0.06$)		($P = 0.007$)	

EORTC, European Organization for Research and Treatment of Cancer; MGMT, O^6-methylguanine DNA methyltransferase; NCIC, National Cancer Institute of Canada.
*Either radiation therapy only or chemotherapy plus radiation therapy.
Adapted from Hegi ME, Diserens AC, Gorlia T, et al: *MGMT* gene silencing and benefit from temozolomide in glioblastoma. N Engl J Med 2005;352:997.

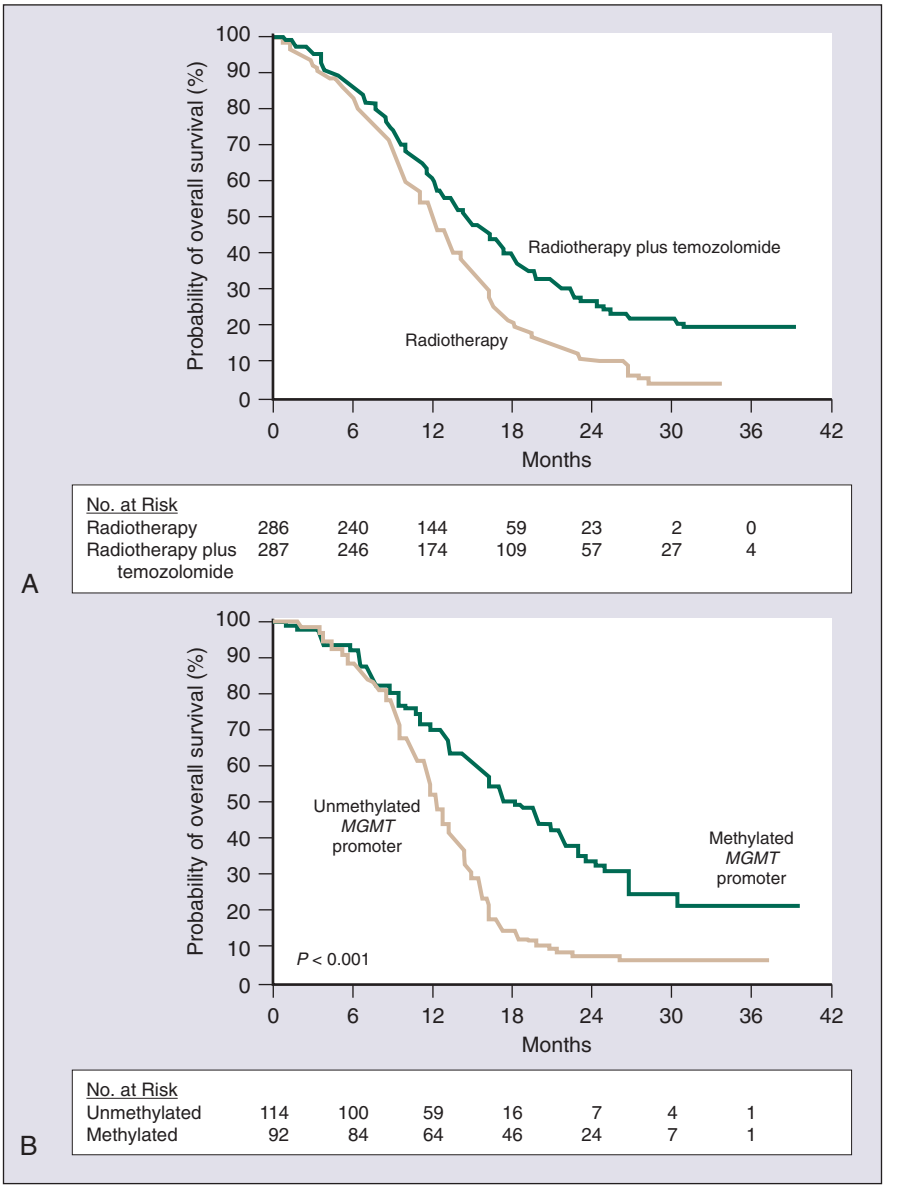

Figure 70-14 • Survival of patients with glioblastoma based on temozolomide administration or *MGMT* status. Patients enrolled in the EORTC trial 22981–26981 and NCIC trial CE.3 were randomized to receive radiotherapy alone or radiotherapy plus temozolomide. **A,** Kaplan-Meier estimates of overall survival according to treatment group. The hazard ratio for death among patients who received temozolomide, compared with those who received radiotherapy alone, was 0.63 (95% confidence interval, 0.52 to 0.75l; $P < 0.001$). **B,** In a subset of the patients enrolled on the trial in **A,** the methylation status of the MGMT (O^6-methylguanine DNA methyltransferase) gene promoter was assessed. The curves in **B** represent Kaplan-Meier estimates of overall survival according to MGMT promoter methylation status. The difference in survival between patients with a methylated MGMT promoter (92 patients, 65 of whom died) and those with an unmethylated MGMT promoter (114 patients, 105 of whom died) was highly significant ($P < 0.001$ by the log-rank test), indicating that the MGMT promoter methylation status has prognostic value. In the group of patients with a methylated MGMT promoter, a risk reduction of 55% (hazard ratio for death, 0.45; 95% confidence interval, 0.32 to 0.61) was determined, as compared with the patients with an unmethylated MGMT promoter. (**A,** From Stupp R, Mason WP, van den Bent MJ, et al: Radiotherapy plus concomitant and adjuvant temozolomide for glioblastoma. N Engl J Med 2005;352:987. **B,** From Hegi ME, Diserens AC, Gorlia T, et al: *MGMT* gene silencing and benefit from temozolomide in glioblastoma. N Engl J Med 2005;352:997.)

Even though the cited data on temozolomide were generated in patients with glioblastomas, many oncologists have extrapolated these findings to anaplastic astrocytomas and have used this agent concurrently with radiation in this setting. Of note, however, some experts have questioned whether concomitant temozolomide should be considered standard therapy in patients with anaplastic gliomas in the absence of randomized data.[237]

Chemotherapy for Recurrent High-Grade Astrocytomas

Patients with high-grade astrocytomas in whom initial therapy with radiation and temozolomide fails to provide benefit are candidates for participation in phase I/II trials. Such trials include drugs as well as a radiolabeled antibody that is infused directly into the tumor. In patients for whom some interval has elapsed between initial temozolomide therapy and failure, retreatment with low-dose daily temozolomide may be tried. Any benefit from chemotherapy for recurrent disease must be measured against the roughly 4- to 5-month median survival after repeat surgical removal of recurrent high-grade astrocytic tumors.

Some patients with recurrent high-grade astrocytomas are offered re-resection with use of either Gliasite (covered earlier under Radiation Therapy for High-Grade Gliomas) or Gliadel (intracavitary biodegradable BCNU wafers). A placebo-controlled multicenter study in 22 patients reported a median survival period of 31 weeks in patients receiving BCNU polymers, compared with 23 weeks in the patients receiving placebo polymers.[238] The use of Gliadel is limited to those patients who can have meaningful re-resection of tumors that are relatively well circumscribed, unilateral, and in noneloquent brain locations—a situation not typical for a majority of anaplastic astrocytic tumors.

Gliadel wafers also have been used in patients with newly diagnosed high-grade gliomas. In one large study, 240 patients received either BNCU or placebo wafers at the time of primary surgical resection and then underwent external beam irradiation of their tumor. Median survival in the BCNU wafer group was 13.9 months, versus 11.6 months in the placebo group. This modest survival advantage may have been partly outweighed by a higher incidence of adverse effects in the BCNU group, including CSF leak and significant

vasogenic edema.[239] Several institutions have reported a high rate of perioperative craniotomy infection after wafer placement.

Irinotecan, a topoisomerase I inhibitor, has been the subject of several studies in patients with recurrent malignant astrocytoma. A respectable 10% to 15% objective imaging response rate has been achieved after thrice-weekly infusions.[240] In two other studies seeking maximal tolerated dose, a marked effect of concomitant enzyme-inducing AEDs was found. Patients taking cytochrome P-450-inducing AEDs achieved lower levels of the active metabolite SN-38 (7-ethyl-10-hydroxycamptothecin) than those measured in patients not receiving AEDs.[241] Subsequent and ongoing irinotecan studies have stratified patients according to AED use.

Chemotherapy for Low-Grade Astrocytomas

Chemotherapy for low-grade astrocytomas usually is reserved for those patients whose unresectable tumors are progressively symptomatic. Radiation therapy traditionally has been used as a first-line treatment for progression. Potential toxicity of any proposed therapy for low-grade gliomas must be balanced against the long natural history. Particularly in younger patients and in those whose tumors have an oligodendroglial component, median survival periods may approach 10 years, with 5-year survival rates of 75% or higher.[178] Indeed, some investigators have argued that quality of life considerations, with particular attention to cognitive status, dictate a prolonged "wait and see" policy in patients with suspected low-grade glioma.[242] Some variants of low-grade glial tumors cary a more ominous prognosis and for the rare situation of multicentric gliomatosis cerebri, chemotherapy may be a reasonable first-line approach. A recent case report documents both MRI and MRS improvement in this usually untreatable condition.[243] Potential considerations in the use of alkylating agents for patients with low-grade astrocytomas should include the risks of hematologic malignancies (5% at 5 years) and sterility. When the astrocytoma contains a portion of oligodendroglial cells, an increasingly common practice is to recommend chemotherapy, but the percentage of oligodendroglial cells required to convey chemosensitivity to the entire mass is unknown. Molecular genetic analysis of oligoastrocytomas has suggested an inverse correlation between 1p or 19q deletions and p53 mutations, rarely occurring in the same tumor (see earlier under Genetics of Supratentorial Gliomas).[194] Tumors with 1p or 19q deletions tend to have a predominant oligodendroglial component. It remains to be seen if patients with low-grade tumors can be reliably selected for chemotherapy on the basis of these criteria.

Examination of quality of life outcomes must factor into recommendations for chemotherapy and radiation therapy. The trend over the last 30 years has been for increasing survival times, with a majority of patients receiving only surgery as a first course of treatment.[244] Patients who have a low risk of progression—those who are younger than 40 years of age with tumors less than 4 cm in diameter and who have undergone gross total resection—have an overall 5-year survival rate of 94%, with a progression-free 5-year survival rate of 50%. For these patients, close observation seems indicated.

The Radiation Therapy Oncology Group (RTOG) recently completed trial 9802 for histologically confirmed low-grade gliomas (Fig. 70-15). Patients who had undergone total resection and were younger than 40 years of age (low-risk group) were managed by observation. The remaining patients were randomized to receive either radiation therapy alone (54 Gy) or radiation therapy followed by six cycles of PCV chemotherapy. The results have been reported in abstract form.[245] For the low-risk patients who were observed, overall survival (OS) at 2- and 5-years was 99% and 94%, respectively, with a median follow-up time of 4 years. Progression-free survival (PFS) at 2- and 5-years was 82% and 50%, respectively. For the high-risk patients who were randomized to RT versus RT + PCV, there was no difference in OS or PFS between the two groups. OS at 2- and 5-years was 87% and 61% (RT alone) versus 86% and 70% with RT + PCV ($P = 0.72$)."

The RTOG currently has a trial (3302) open that is a phase II study for patients with high-risk low-grade gliomas that uses daily temozolomide for 12 cycles.

Chemotherapy for Newly Diagnosed Anaplastic Oligodendrogliomas

Over the past decade, increasing evidence has accumulated to confirm that anaplastic oligodendrogliomas and possibly anaplastic oligoastrocytomas are special types of malignant gliomas that are sensitive to chemotherapy. Although the molecular markers of chemosensitivity, allelic loss of 1p and 19q, have been shown to have prognostic significance in multiple studies, the reason for oligodendroglial chemosensitivity remains unknown. Zlatescu and colleagues have made the clinically interesting observation that allelic loss of 1p and 19q is related to tumor location and extent of tumor spread in the brain.[196] Anaplastic oligodendrogliomas located in the frontal, parietal, and occipital lobes were significantly more likely to harbor 1p or 19q loss than are histologically identical tumors arising in the temporal lobe, insula, or diencephalon. Frontal tumors tend to have greater bilateral diffuse spread, and investigation of the biologic significance of these growth and invasion differences eventually may have implications for management strategies.

In the first large study of chemotherapy for anaplastic oligodendrogliomas, Cairncross and the National Cancer Institute of Canada conducted a multicenter phase II trial of intensive PCV chemotherapy (i.e., procarbazine, CCNU, and vincristine) using higher doses of the first two drugs than are found in the standard PCV regimen.[246] This study included new or recurrent anaplastic oligodendrogliomas and reported a 75% overall response rate, with 38% complete responses. Time to tumor progression was at least 16.3

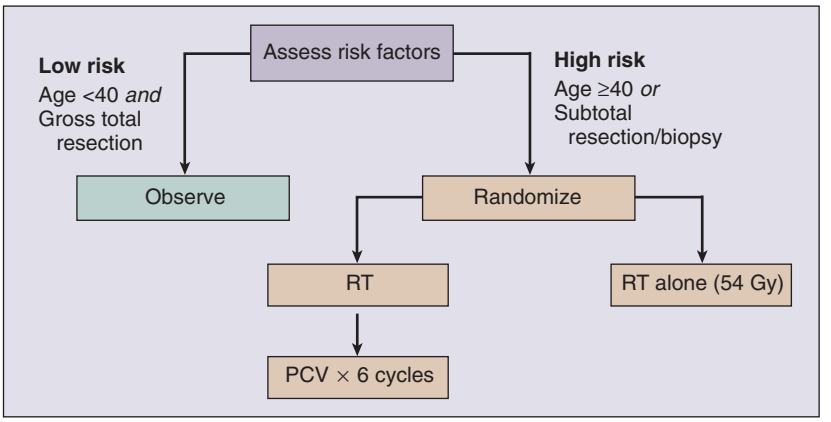

Figure 70-15 • Schema for RTOG/Intergroup 9802 protocol for treatment of low-grade gliomas. Protocol was open to patients with histologically verified WHO grade II astrocytoma, oligodendroglioma, or oligoastrocytoma. The study was closed to accrual in June 2002. Results have been reported only in abstract form. CCNU, vincristine; PCV, procarbazine; RT, radiation therapy.

months for the entire eligible group and at least 25.2 months for complete responders.

Two randomized trials have been conducted comparing radiation only with radiation plus PCV chemotherapy in patients with newly diagnosed anaplastic oligodendrogliomas or anaplastic oligoastrocytomas.[247,248] In RTOG 9402, patients were randomized to receive radiation only or up to four cycles of intensive PCV chemotherapy followed by radiation.[248] In EORTC 226951, patients were randomized to receive radiation only or radiation followed by six cycles of standard PCV chemotherapy.[247] The two studies showed remarkably similar results. In both studies, the addition of PCV chemotherapy improved progression-free survival but not overall survival. Patients with combined 1p and 19q loss showed a much better survival than that observed for patients with intact 1p and 19q; however, even in this chemotherapy-sensitive subgroup, the addition of PCV did not improve overall survival.

The PCV regimen has significant hematologic toxicity, and given its lack of survival benefit in anaplastic oligodendrogliomas in these randomized phase III trials, there has been a movement toward temozolomide, which is much better tolerated. In spite of a lack of randomized data with temozolomide in anaplastic oligodendrogliomas, many oncologists are currently using this drug concomitantly with radiation, extrapolating from the experience with glioblastoma.[235]

Chemotherapy for Recurrent Anaplastic Oligodendroglioma and Oligoastrocytoma

Most patients with recurrent AOs who received PCV at initial presentation are currently being treated with temozolomide at relapse. Several small trials have shown the safety and efficacy of temozolomide following prior PCV therapy (Table 70-9).[249–251] An open label phase II trial of temozolomide in 47 patients with anaplastic oligodendroglioma or anaplastic oligoastrocytoma who relapsed after radiation and PCV chemotherapy demonstrated an objective response rate of 43%, median PFS of 7.5 months and 34% rate of disease-free survival at 12 months.[251] In another phase II multicenter trial that included patients with anaplastic oligodendroglioma or anaplastic oligoastrocytoma, a response rate was seen in 26% of patients who had previously received PCV therapy and in two out of three chemotherapy-naive patients.[249] A short time to tumor progression appears to be a bad prognostic factor for response to both first-line PCV chemotherapy and temozolomide.

Brandes and associates recently reported on 67 patients with recurrent anaplastic oligodendroglioma or anaplastic oligoastrocytoma treated with temozolomide at the time of disease progression.[252] All patients had received surgery and radiotherapy, and none had received prior chemotherapy. The overall response rate was 46% and was higher in those with anaplastic oligodendroglioma than in those with anaplastic oligoastrocytoma (62% versus 25%; $P = 0.003$). Combined 1p and 19q loss (present in 48% of patients) significantly correlated with response rate ($P = 0.04$), time to progression ($P = 0.003$), and overall survival ($P = 0.0001$). By contrast, only a borderline correlation was found between MGMT promoter methylation (present in 69% of assessable patients) and overall survival ($P = 0.09$).

Chemotherapy for Low-Grade Oligodendrogliomas and Oligoastrocytomas

Temozolomide has been used in patients with low-grade oligodendrogliomas or oligoastrocytomas that have recurred. The EORTC conducted one study using temozolomide for patients who had received PCV chemotherapy and irradiation for their initial disease,[253] and another study for patients who had received surgery and irradiation without chemotherapy initially.[254] These studies showed 25% to 53% response rates, respectively, to temozolomide (see Table 70-9). Loss of 1p has been correlated with response to temozolomide for first-line chemotherapy in patients with recurrent oligodendrogliomas.[255,256]

Therapy for Elderly Patients with Malignant Gliomas

Elderly patients with malignant gliomas have a poorer outcome than that for younger patients. Brandes and coworkers evaluated the role of surgery, radiation therapy, and chemotherapy for the treatment of newly diagnosed glioblastoma in patients older than 65 years of age.[257] These investigators found that the main predictive factor in evaluating this treatment was perioperative KPS score. The higher the KPS score, the better the patient fared, regardless of the treatment. Patients were stratified into group A (surgery with radiation therapy to a dose of 59.4 Gy), group B (surgery, radiation therapy, and PCV chemotherapy), and group C (surgery, radiation therapy, and temozolomide). The median time to disease progression was significantly better in group C patients. Overall survival was better in group C, but this did not reach statistical significance. Hematologic toxicity was higher in patients on a PCV regimen than in those receiving temozolomide.

Another study evaluated the role of debulking craniotomy versus stereotactic biopsy in the treatment of malignant gliomas in patients older than 65 years of age.[258] Patients in this study were randomized to undergo either stereotactic biopsy or craniotomy for debulking of the tumor. Patients were evaluated with an intention to treat analysis. The median survival period was 171 days after craniotomy versus 85 days after biopsy. The difference was not statistically significant; however, this finding did suggest that patients undergoing a more aggressive craniotomy survived longer. Time to deterioration was 105 days in the craniotomy group and 72 days in the biopsy group. This increased time to deterioration corresponds with maintenance of

Table 70-9 Results of Treatment for Recurrent Low-Grade and Anaplastic Oligodendroglioma and Oligoastrocytoma: Temozolomide-Based Chemotherapy Regimens

Study	Tumors Treated	No. of Patients	CR/PR/SD	MTP (mo)	6/12-Month PFS	MST(mo)
Yung et al[250]*	AA, AOA, AO	111	8%/27%/26%	5.4	46%/24%	13.6
Chinot[251]	AO, AOA	47	15%/28%/40%	7.5	NR/34%	8.8
van den Bent et al[249]	AO, AOA	30	10%/21%/28%	NR	44%/27%	7

AA, anaplastic astrocytoma; AO, anaplastic oligodendroglioma; AOA, anaplastic oligoastrocytoma; CR, complete response; MTP, median time to progression; MST, median survival time; NR, no response; O, oligodendroglioma; OA, oligoastrocytoma; PFS, progression-free survival; PR, partial response; SD, stable disease.

*This study also included AA and is included here for comparison. Patients with AOA and AO had better survival than those with AA.

†In these reports, none of the patients had received any prior chemotherapy before being placed on temozolomide at relapse.

quality of life during this time period. Both groups of patients tolerated the radiation therapy well.

On the basis of these results, it appears that patients with malignant gliomas older than 65 may still benefit from aggressive therapy if they have a reasonable performance status. Therefore, old age alone should not be a criterion for minimizing therapy. An abbreviated radiotherapy regimen may be considered in older patients with a poor performance status. Roa and associates randomized patients with glioblastoma older than the age of 60 to receive a standard course of radiation (60 Gy in 30 fractions over 6 weeks) or a shorter course (40 Gy in 15 fractions over 3 weeks).[259] Overall survival times measured from randomization were similar at 5.1 months for standard RT versus 5.6 months for the shorter course ($P = 0.57$). The survival probabilities at 6 months were also similar, at 44.7% for standard RT versus 41.7% for the shorter course.

Quality of Life after Therapy for Gliomas

Quality of life issues are paramount in treatment for patients with gliomas. Taphoorn and coworkers found that drowsiness, fatigue, memory deficits, and concentration problems were more common complaints in patients with low-grade gliomas than in control patients with hematologic malignancies. An analysis of quality of life was performed in patients participating in an EORTC trial of randomization to either 59.4 or 45 Gy for low-grade gliomas.[211] This analysis found that patients receiving the higher dose complained of more fatigue and insomnia immediately after radiotherapy and poorer emotional functioning 7 to 15 months after institution of therapy.[260]

The EORTC/NCIC performed a quality of life study as part of a randomized trial of radiation versus radiation plus temozolomide for patients with glioblastoma.[261] The study investigators found that health-related quality of life measures (fatigue, overall health, social function, emotional function, future uncertainty, insomnia, and communication deficit) did not deteriorate by a clinically meaningful amount in either treatment group over time after treatment, and even improved for some parameters. Furthermore, the addition of the temozolomide regimen to radiotherapy did not negatively affect health-related quality of life. Notwithstanding these results, patients with malignant gliomas face enormous stresses. They face the same burdens of dealing with a terminal disease as patients with breast cancer, lung cancer, and other malignancies, but they have unique perspectives in that they are uniformly concerned about the potential for damage to the brain and the effect of cognitive function. These patients not only have to deal with concepts of dying and leaving behind their families and friends but also have a constant worry about being in a persistent vegetative state and being a burden to their families. Measurement of quality of life is important to elucidate the impact of available treatments on the disease: The goal is to improve survival, but not at the sacrifice of quality of life.[262]

New Approaches to Therapy of Gliomas

The disappointing results with conventional cytotoxic chemotherapy have led to efforts to find more effective and better-tolerated therapies. The challenge of neuro-oncology is to develop new compounds or procedures of gene transfer that specifically target the molecular alterations of glioma tumor cells and restore normal gene expression, cell cycle regulation, and apoptosis.[263] Significant progress is likely to come from some combination of cytotoxic chemotherapy with biologic agents directed at genetic alterations specific to brain tumors, such as growth factor receptors. Receptors are tempting targets because they are extracellular and easily accessible to drugs or antibodies. A number of agents targeted to the EGFR receptor and the vIII variant are being tested. These EGFR inhibitors have shown limited utility in the clinic with brain tumors. These inhibitors may be effective only in patients with tumors that have a susceptible target. In one study, patients who had received treatment with gefitinib or erlotinib were analyzed for expression of EGFR, the deletion mutant EGFRvIII, and the tumor suppressor gene *PTEN*. Tumors that coexpressed EGFRvIII and PTEN were most likely to respond to EGFR kinase inhibitors.[264]

Receptor tyrosine kinases (RTKs), such as PDGF and insulin-like growth factor (IGFR) receptors, regulate cell proliferation and differentiation. Deregulated RTK signaling frequently is found in human astrocytic tumors. In addition, gefitinib and erlotinib, mentioned earlier, and other inhibitors of RTKs have been evaluated in malignant glioma including imatinib mesylate. Other agents target farnesyl transferase, histone deacetylase, rapamycin (mTOR), protein kinase C, and the ubiquitin-proteosome pathway. In general, small early trials have been disappointing, although the agents were well tolerated. Most are metabolized through the cytochrome P-450–CYP3A4 system, and significant dose modifications are necessary in patients with brain tumors who are taking enzyme-inducing AEDs.

Because gliomas produce specific angiogenic peptides such as VEGF (see the molecular genetics section earlier in this chapter) to stimulate new blood vessel formation, angiogenesis inhibitors are a logical drug development target. Hypoxic areas within gliomas may stimulate angiogenesis and promote invasiveness of glial cells.[265] Many of these changes in gene expression are mediated by hypoxia-inducible factor-1 (HIF-1). Many antiangiogenic agents directed against VEGF, VEGFR, and other targets are in clinical trials. Bevacizumab, a humanized monoclonal antibody against VEGF, showed a 63% radiologic response rate in patients with recurrent high-grade gliomas.[266]

The transfer of genetic material to tumor cells to make them more susceptible to chemotherapy, or to reverse the alterations that sustain the neoplastic phenotype, has been studied in several centers. Gene therapy strategies include transfecting antioncogenes or drug-activating enzymes to glioma cells. The most extensively studied system is the "suicide gene therapy" with herpes simplex thymidine-kinase (HSV-tk) gene inserted into a replication defective murine retrovirus. Murine fibroblasts are engineered to produce these recombinant retroviruses, which are injected into gliomas, infecting the proliferating tumor cells and making them produce thymidine kinase. The tumor cells then are susceptible to the antiherpes drug ganciclovir, while nondividing brain cells are not infected. Clinical studies using this promising approach have been disappointing because of poor tumor cell transfection efficiency, although some long times to tumor progression have been reported.[267–269] A prospective controlled trial in patients with newly diagnosed glioblastoma showed no improvement in survival or time to tumor progression when intraoperative HSV-tk therapy and standard radiation therapy were compared with surgery and irradiation alone.[270] Adenoviral and adeno-associated viral vector genes are being studied as well. A phase I study of stereotactic injection of an adenovirus vector to transfer wild-type p53 gene is among the early clinical trials now under way that involve viral vectors to replace tumor suppressor genes.[271]

Other translational strategies that have moved to small preliminary human trials include glutamine depletion with phenylacetate and 13-*cis*-retinoic acid (CRA), a metabolite of beta-carotene that acts to promote differentiation.[272] Yung and colleagues administered CRA orally, but although toxicity was acceptable, the results were not better than with temozolomide as a single agent.[273]

Another strategy involves drugs that inhibit autophagy, such as hydroxychloroquine, which in a single-institution phase II trial resulted in more than doubling of overall median survival.[274] A phase II trial in patients with newly diagnosed glioblastoma will incorporate chemoradiation therapy with temozolomide and adjuvant temozolomide in addition to chronic daily hydroxychloroquine.

Biologic response modifiers that stimulate or restore the immune system include monoclonal antibodies, interferons, and interleukins. Inhibitors of TGF-β2, a cytokine that promotes invasion and angiogenesis, have been shown to inhibit glioma growth in vitro.[275]

Despite effective neuroimaging and earlier diagnosis, advances in the understanding of cellular events that underlie progression of brain tumors, a steady stream of novel agents, and suggestive preclinical

animal studies, clinical trials have proved disappointing. Because of the heterogeneity of malignant glial tumors, treatment strategies probably will require synergistic combinations of cytotoxic agents and noncytotoxic specific molecular methods, with the hope that genetic profiling eventually will help pinpoint appropriate choices for individual patients.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Histopathologic Features

Primary CNS lymphoma (PCNSL) has been known previously by many other names, including "reticulum cell sarcoma," "diffuse histiocytic lymphoma," and "microglioma." The cell of origin is the B lymphocyte, and PCNSL is therefore a high-grade non-Hodgkin's B-cell neoplasm, usually diffuse large cell or large cell immunoblastic type. A frequent finding is perivascular clusters of lymphocytes, and T-lymphocyte infiltrates are common in immunocompetent patients.[276] Although the Epstein-Barr virus genome has been found in HIV-infected patients with PCNSL, no consistent confirmation of viral etiology of PCNSL has been possible among immunocompetent patients. Human herpesvirus 8 (Kaposi's sarcoma-associated herpesvirus) was reported in over 50% of both normal and immunocompromised patients with PCNSL.[277] Human T-cell lymphotropic virus type 1 (HTLV-1) and hepatitis C virus have not been associated with PCNSL.

Only 1% to 3% of PCNSLs are of T-cell origin. The incidence of T-cell PCNSL appears to be higher in Japan than in the United States.[278] Primary T-cell lymphoma has been diagnosed in both immunocompromised and immunocompetent patients. A younger age at diagnosis for T-cell lymphomas has been suggested, and presentation as an infratentorial lesion appers to be more frequent, with one third to one half of reported cases in the cerebellum or brainstem.[279] T-cell lymphoma may appear as a large cystic mass on MRI. The prognosis for T-cell PCNSL may be worse than that for comparably staged B-cell tumors. Authors of published case reports suggest that this tumor should be treated aggressively with regimens used for the more common B-cell lymphomas.[280]

Tumor Biology

PCNSL arises in the brain leptomeninges, spinal cord, or eyes and rarely spreads outside the central nervous system. Its predilection for the periventricular white matter gives rise to the characteristic neuroimaging appearance of a hyperdense mass on unenhanced CT or a hypointense appearance on long TR-weighted MRI. Three fourths of immunocompetent patients have a solitary enhancing mass lesion at presentation. After contrast administration, most bulky masses of PCNSL enhance, most often homogeneously but occasionally in a ring-like pattern (Fig. 70-16). PCNSLs, however, appear to be diffusely infiltrative at the time of presentation. These areas of disease are not visible on neuroimaging studies because they are behind a relatively intact blood-brain barrier. Postmortem correlates with findings on MRI performed shortly before death show widespread microscopic infiltration in areas that appear normal on the MRI scan.[281] Therefore, PCNSL can be classified as stage 1E disease and should be considered for treatment purposes to be a *whole-brain disease*.

Until the 1980s, PCNSL was considered a rare tumor, accounting for approximately 2% of CNS malignancies in immunocompetent patients and 1% to 2% of all lymphomas.[282] The demographics of the disease have changed, however, both among immunocompetent patients and among those with HIV infection and organ transplant recipients. The incidence of PCNSL among immunocompetent persons has increased 25-fold to 51 cases per 10 million by 2000. Among immunocompetent patients with PCNSL, median age at diagnosis is 55 years, and males outnumber females by 2 : 1. Among patients with AIDS, the median age is 35 years, and 95% of HIV-infected patients with PCNSL are male.[283] Among organ transplant recipients, the peak incidence of PCNSL is at 6 months after transplantation, a period much shorter than in the pre-cyclosporine transplantation era.

Recent data from the Surveillance, Epidemiology, and End Results (SEER) program show an overall decline in total PCNSL incidence rates, from a peak of 102 per million in 1995 to 51 in 1998, a decrease largely attributable to decline in the disease in males younger than 59 years of age. The annual rate among patients older than 60 has remained unchanged since 1994.[284] The decline in the younger male population with PCNSL reflects the advent of effective antiretroviral therapy and a declining incidence of PCNSL in the HIV-infected population.[285] This chapter discusses PCNSL and its treatment in the immunocompetent population.

Clinical Diagnosis and Staging

The most common clinical presentation is one of progressive focal symptoms. Seizures also may occur. Less commonly, progressive cognitive decline without focal symptoms leads to the diagnosis. Several variant clinical presentations are possible in the immunocompetent population: primary ocular, meningeal, or relapsing-remitting disease; intravascular malignant lymphomatosis with stroke-like onset; or

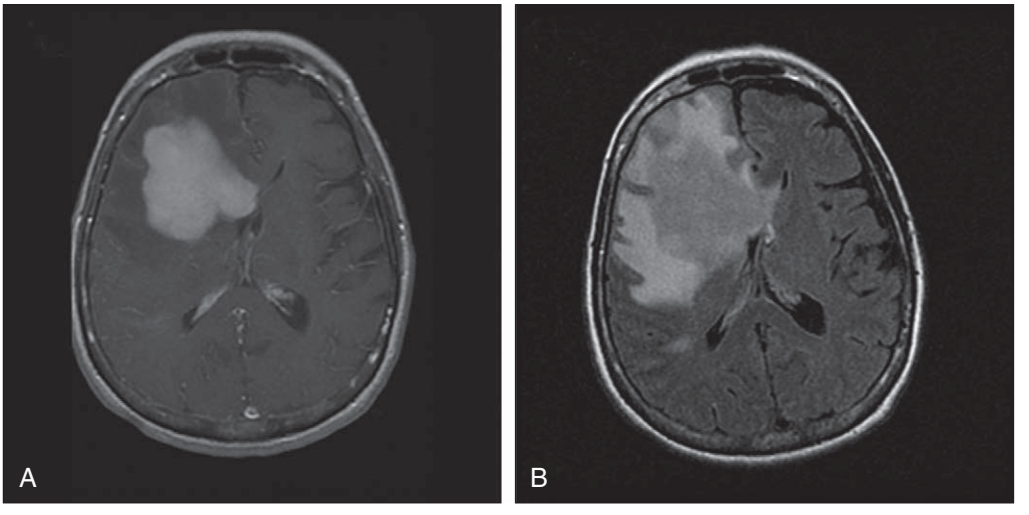

Figure 70-16 • Central nervous system lymphoma seen on magnetic resonance imaging. **A,** T_1-weighted post-gadolinium axial image shows a homogeneously enhancing frontal mass compressing the ventricles. **B,** Corresponding fluid-attenuated inversion recovery (FLAIR) image shows extensive peritumoral edema.

neurolymphomatosis with both peripheral and CNS involvement. Considerations in the differential diagnosis for PCNSL include high-grade glial tumor, CNS metastases, neurosarcoidosis, and tumefactive multiple sclerosis. Spinal cord PCNSL is very rare. Ocular lymphoma may be the first manifestation of the disease or its relapse. Patients with ocular lymphoma have a 50% to 80% chance of developing cerebral lymphoma.

Initial evaluation of patients with suspected PCNSL should include a thorough physical examination to exclude possible extraneural sources of lymphoma. Neurologic evaluation is directed at clarification of the extent of CNS disease. Extraneural sites are uncommon in patients without prior known lymphoma, and extensive abdominal and pelvic studies usually are not warranted. Chest x-ray studies should be performed, and blood tests should include a complete blood count (CBC) and liver function tests, as well as HIV testing. Gadolinium-enhanced spinal MRI should be performed, because bulky nodular disease sometimes can be seen in the leptomeninges.

Ophthalmologic consultation for slit-lamp examination is a critical part of the workup, because up to 10% to 15% of patients with PCNSL will have vitreous involvement at the time of diagnosis, and half of these will have no visual symptoms. Lumbar puncture should be performed if not contraindicated because of the intracranial mass location(s). Glucose and protein determinations, cell count, and flow cytometry should be performed. Recent reports of molecular diagnosis of PCNSL by the demonstration of monoclonality by amplification of the rearranged IgH genes by polymerase chain reaction (PCR) to the CDR-III region raises the possibility of definitive diagnosis even with few cells present in the CSF.[286] In several cases, however, the PCR analysis was negative even when conventional cytologic findings were suggestive of malignancy. In another study, monoclonal patterns in the CSF were found in 77% of biopsy-proven cases, with no false positives among control subjects.[287] At present, however, it is premature to base clinical therapeutic decisions on these promising early findings.

When the foregoing procedures fail to confirm the diagnosis, the surgical procedure of choice is a stereotactic brain biopsy. Aggressive surgical resection does not improve survival and may cause deterioration owing to the deep location of many PCNSLs. It is most important to try to *withhold corticosteroids* from patients during initial evaluation and surgical confirmation. Corticosteroids repair the blood-brain barrier and also have a direct cytolytic effect on B-cell lymphomas. Although the patient's clinical symptoms may abate with early institution of corticosteroids, with frequent nearly complete resolution of MRI-enhancing abnormalities, diagnosis will be compromised, and corticosteroids will have to be withdrawn in order to proceed with definitive biopsy confirmation. Recent interest has focused on immunohistochemical definition of morphologic markers of prognostic significance on the biopsy material (Fig. 70-17). Braaten and colleagues studied the expression of BCL-6 antigen in PCNSL and found that the presence of this antigen predicted a median survival of 101 months, compared with 14.7 months in patients without this marker.[288] Other groups of investigators, however, have found that the marker correlates with a negative prognosis, so clinical decisions cannot be made on the basis of early immunohistochemistry studies.[289]

Treatment

PCNSL is an aggressive disease for which median survival in immunocompetent patients is only 3 months without treatment. Increasing age and poor performance status are important negative prognostic variables. The goal of treatment is to eradicate both contrast-enhancing mass lesions and microscopic infiltration of brain, spine, leptomeninges, and vitreous. Treatment must be designed to maximize efficacy but also to minimize toxicity to the brain. Optimal treatment has not been established. The reason for the lack of standardized treatment protocols is the relatively small number of patients and the absence of a phase III randomized trial.[290] In the past 15 years, however, steady increases in median survival have been achieved in patients with PCNSL. Five-year survival rates on the order of 40% are now being reported by many groups of investigators, with median survival periods of 3 to 4 years.[291–293]

Radiation treatment alone led to median survival periods of 18 months in early clinical trials, with only 3% to 4% 5-year survival rates.[294,295] Chemotherapy was first used as an adjunct to radiation therapy more than 20 years ago after methotrexate was found to be effective in the treatment of systemic lymphoma. Twelve studies totaling more than 450 patients have established the efficacy of multiple chemotherapeutic regimens. Initially, most were used along with or after a course of whole-brain radiation therapy. The most commonly used drugs have been methotrexate, cytarabine, and cyclophosphamide. The first two agents have been administered intravenously and intrathecally. Extension of median survival periods for up to 4 years with combined regimens was achieved in the mid-1990s. The most frequently used combined regimen involved administration of intravenous methotrexate at doses ranging from 3.5 to 8 g/m^2 every 10 to 14 days for three cycles, followed by whole-brain radiation therapy to a dose of 40 to 50 Gy, with subsequent administration of cytarabine 3 g/m^2 for three cycles. DeAngelis and colleagues reported a 58% complete response rate, with additional 36% rate of partial responses and progression-free median survival for 24 months.[296] A worse prognosis was associated with age older than 60 years (survival for 50.4 months versus 21.8 months). With improved survival, however, severe delayed neural toxicity has developed in increasing numbers of patients. At 18 months, 15% to 50% of patients who had received combined radiation therapy and chemotherapy were found to have extensive white matter abnormalities, with consequent severe cognitive decline.[297–299] Age and pre-existing white matter disease due to hypertension may be relative risk factors.[295,300] This complication typically begins from 4 months to several years after treatment.[297] Recognition of the serious sequelae of

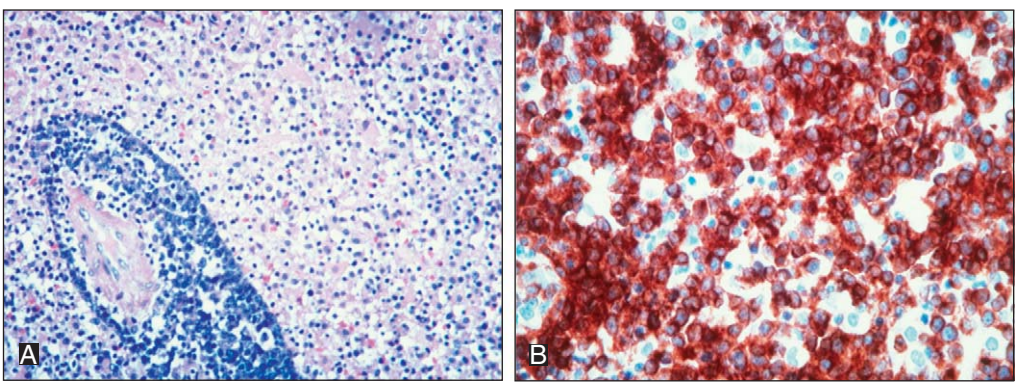

Figure 70-17 • Central nervous system lymphoma: histologic features. **A,** High-grade B-cell lymphoma with dense perivascular lymphocytic cuffing. (Hematoxylin and eosin staining.) **B,** Dense staining with CD20 (a B-cell marker) in the same specimen as in **A.**

combined radiation therapy and chemotherapy led to attempts to provide chemotherapy as the sole modality for treatment of newly diagnosed PCNSL. Initial response rates to chemotherapy vary from 50% to 100%, with duration of response between 12 and 44 months. Typical of the successes of many clinical trials are the results of Cher and colleagues, who reported complete responses in 17 of 19 patients receiving methotrexate alone, with an event-free median survival period of 32 months and overall survival period of 53 months.[301] Therapeutic levels of methotrexate can be achieved in the CSF after intravenous drug administration, making it possible to achieve clearance of malignant cells from the CSF without intrathecal administration.[302]

Attempts to improve on the results of methotrexate have included a variety of other multidrug chemotherapy regimens. Standard regimens effective in the treatment of comparable systemic non-Hodgkin's lymphomas (CHOP, CHOD, or MACOP-B) are not effective for PCNSL.[303–306] Attempts to disrupt the blood-brain barrier with hyperosmolar intra-arterial mannitol do not provide additional survival benefit beyond that achieved with intravenous methotrexate-based regimens.[307]

Many neuro-oncologists, therefore, have concluded that high-dose methotrexate should be offered to all patients as the first-line agent for treatment of PCNSL.[308] However, there are dissenting opinions. Herrlinger and colleagues recently reported only a 29.7% complete response rate with intravenous methotrexate while 37.8% of their patients progressed, and they revisit the question of whole brain radiation therapy as a first-line treatment for PCNSL.[309] Most centers, however, have based their therapy on methotrexate regimens. Long-term follow-up of patients who achieved durable remissions for more than 1 year suggests that chemotherapy alone is associated with a low risk of neurotoxicty even in the elderly, although MRI may show significant areas of clinically asymptomatic leukoencephalopathy.[310–312] The neuropsychological outcome after chemotherapy alone for primary CNS lymphoma is quite good, whereas increasing numbers of studies document progressive dementia, sometimes with gadolinium-enhancing lesions on MRI, as early as several months after combined-modality treatment.[313–315] Autopsy studies have confirmed not only widespread "pan-brain" infiltrative lymphoma but extensive vascular changes and leukoencephalopathy in patients who received radiation with or without chemotherapy.[316]

The following recommendations apply to immunocompetent patients only. The goal of treatment is to achieve a complete response while avoiding irradiation of normal brain. Patients with AIDS-related PCNSL require individualized treatment based on their immune status and presence of concurrent infections.[317] Transplant recipients similarly require an initial attempt at reduction of immunosuppression, and their treatment also must be tailored to the extent of organ dysfunction due to the primary disease process and concurrent therapy.

No firmly established dose for methotrexate has been confirmed; doses in excess of 3.5 g/m^2 have been shown to achieve satisfactory CSF drug levels. Figure 70-18 presents an algorithm for the diagnosis and management of PCNSL at the Hospital of the University of Pennsylvania; the recommended approach to management of these

Box 70-2. MANAGEMENT OF PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA AT THE UNIVERSITY OF PENNSYLVANIA

- Primary central nervous system lymphoma (PCNSL) is a non-Hodgkin's B cell lymphoma arising in the brain, leptomeninges, spinal cord, or eyes. It should be regarded as a whole-brain disease; it rarely spreads outside the nervous system.
- Optimal treatment of PCNSL is not yet fully established, but experience acquired during the past decade with various combinations of radiation therapy and chemotherapy suggests that initial induction treatment should be attempted with a methotrexate-based intravenous chemotherapy regimen and that concurrent intrathecal chemotherapy is not necessary. Median survival times longer than 40 months have been reported with methotrexate monotherapy, with significantly less cerebral white matter toxicity and its clinical correlate of cognitive decline, than seen in earlier protocols that included cranial irradiation.
- Intravenous methotrexate 8 g/m^2 every 14 days for up to 8 cycles is used for induction therapy, followed by 11 monthly cycles of methotrexate at the same dose in patients in whom a complete response is attained. Leucovorin rescue also is given, and concurrent corticosteroids and antiepileptic drugs as indicated are prescribed.
- Adequate delivery of chemotherapy to microscopically infiltrated areas of brain protected by the blood-brain barrier remains a significant challenge, and recurrence at multiple cerebral sites remains a problem for which effective therapy remains to be developed.
- Retreatment of a prior complete responder at relapse with the foregoing intensive methotrexate regimen is feasible. Alternatives include whole-brain radiation therapy, cytarabine, and investigational regimens using temozolomide or rituximab.

tumors is summarized in Box 70-2; and Figure 70-19 presents an algorithm for treatment of these tumors. Patients with PCNSL receive methotrexate 8 g/m^2 every 14 days for up to 8 cycles. The calculated dose is diluted in 500 mL of 5% dextrose in water (D_5W) and given intravenously over a 4-hour period. Patients achieving a complete response will receive 2 additional doses of methotrexate at 14-day intervals, followed by 11 monthly doses of methotrexate 8 g/m^2 so long as a complete response is maintained. MRI scans are obtained monthly during induction therapy and at 3-month intervals during maintenance therapy. The methotrexate protocol involves close clinical monitoring, adjustment of intravenous fluid, and calcium leucovorin rescue, in addition to frequent monitoring of urine pH, renal function, and methotrexate levels.

Contraindications to methotrexate therapy include allergy to methotrexate; inability to achieve adequate hydration because of cerebral edema, or cardiac or pulmonary problems; and concurrent immunosuppressive treatment. Patients should not have received prior cranial irradiation. Patients with renal dysfunction resulting in a creatinine clearance of less than 50 mL/min or serum creatinine level greater than 2 mg/dL should not receive methotrexate. Patients with significant ascites or pleural effusions may experience delayed methotrexate clearance because of third space accumulation.

Calcium leucovorin rescue therapy should begin 24 hours after the *start* of methotrexate infusion. The dose is adjusted according to methotrexate levels. Any dose of leucovorin greater than 50 mg should be given intravenously. If the plasma concentration of methotrexate at 24 hours is greater than 10^{-5} M, 100 mg/m^2 of leucovorin is given intravenously every 6 hours until rescue is achieved and continued at 25 mg intravenously or orally every 6 hours until the methotrexate plasma concentration is less than 10^{-7} M. In most patients, the methotrexate concentration clears to this level by 72 hours after the infusion.

Patients with an established PCNSL diagnosis may receive concurrent corticosteroid therapy to alleviate symptoms. Concurrent use of salicylates or other nonsteroidal anti-inflammatory drugs or sulfonamide medications is prohibited for at least 1 week before the initiation of methotrexate therapy. Many patients with PCNSLs will remain on corticosteroids for extended periods. The combination of corticosteroids and methotrexate may lead to a low CD4$^+$ count, and

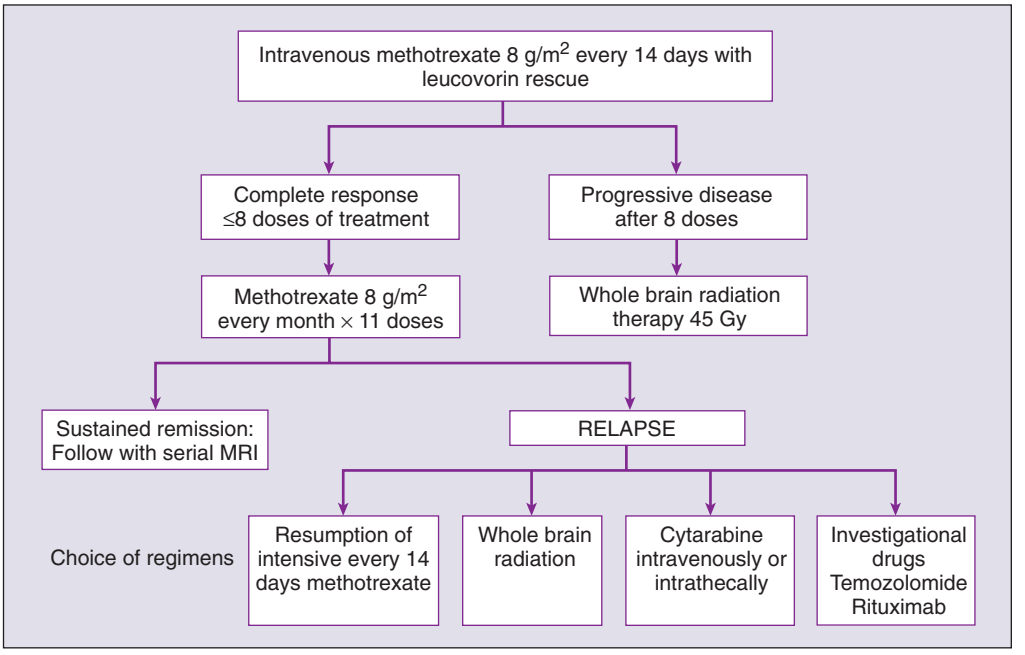

Figure 70-19 • Algorithm for definitive treatment of primary central nervous system lymphoma. MRI, magnetic resonance imaging.

these patients will be at risk for *Pneumocystis jiroveci* pneumonia. Like patients with other brain tumors, patients with PCNSL should receive prophylaxis with trimethoprim-sulfamethoxazole two or three times per week, with discontinuation of this drug 1 week before institution of methotrexate therapy.[318] Concurrent AED therapy is acceptable, and management of nausea associated with chemotherapy does not differ in this population from that for other patients receiving comparable regimens.

The management of progressive or recurrent PCNSL is not yet well established. Age and performance status of the patient must be taken into account. In general, greater than 25% enlargement of previous areas of gadolinium contrast enhancement, the appearance of new lesions, or the appearance of malignant cells in the CSF, vitreous, or, rarely, elsewhere in the body constitutes treatment failure. Cher and colleagues have reported that for patients who have completed their maintenance therapy, return to a more intensive methotrexate dosage regimen may lead to a second complete response.[301] For patients who have progressed through therapy, other chemotherapeutic agents such as cytarabine given intravenously or intrathecally may be considered. At relapse or in the case of failure to achieve complete response after 8 cycles of methotrexate, many treating physicians would consider palliative radiation therapy. The immediate palliation of progressive signs and symptoms is a realistic goal but must be weighed against the possibility that survival will be extended enough to allow emergence of late cognitive neurotoxicity. At most centers, whole-brain irradiation to 40 to 45 Gy in 20 doses is given over 4 to 5 weeks.

After initial diagnosis, surgical intervention usually has little place in treatment. The need for intrathecal chemotherapy, however, may mandate placement of an Ommaya reservoir. Development of communicating hydrocephalus with or after treatment of meningeal lymphoma may require shunting.

Parenchymal treatment failure is the most common pattern of relapse. Ocular, meningeal, and late rare extra-CNS relapses (breast, abdominal wall, bone, lymph nodes) have been described and may be seen with increasing frequency as patients survive longer. Temozolomide is under investigation as an agent for treatment of progressive PCNSL. Rituximab, a monoclonal antibody against the B cell-specific CD20 antigen, has been demonstrated to be effective against various non-Hodgkin's lymphomas, but CSF drug levels attained with intravenous therapy are not high.[319] Attempts to circumvent this problem have involved intraventricular administration through an Ommaya reservoir, with some early reports indicating total clearing of tumor cells with leptomeningeal lymphoma.[320] Whether rituximab will clear parenchymal masses is not clear. Intensive chemotherapy followed by hematopoietic stem cell rescue using a regimen of cytarabine and etoposide has been reported to give a complete response rate of 70%, with a median progression-free survival period of 3 years.[321] Several of the patients in the reported study, however, had intraocular lymphoma only.

MENINGIOMA

Clinical and Pathologic Considerations

Meningiomas account for approximately 30% of all intracranial tumors (see Table 70-1). The male-to-female ratio is 1 : 2, with the incidence increasing with age and reaching a peak in the seventh decade.[322] These tumors arise from arachnoidal cells in the meninges, not the brain parenchyma; therefore, they are extra-axial. They produce signs and symptoms by compressing normal tissues. The locations of meningiomas in two large series are shown in Table 70-10.[322,323] The specific signs and symptoms depend on the anatomic location of the meningioma. For example, meningiomas arising from the cerebral convexity can cause altered mentation and seizures, whereas those arising from the suprasellar region are likely to cause loss of vision, bitemporal hemianopia, and optic atrophy.

Table 70-10 Meningiomas: Distribution by Anatomic Location

	FREQUENCY (%*)	
Tumor Location	**Series 1***	**Series 2†**
Convexity	34	21
Parasagittal	22	17
Sphenoid ridge	17	16
Lateral ventricle	5	—
Tentorium	4	—
Cerebellar convexity/posterior fossa	5	14
Parasellar	3	12
Intraorbital	2	2
Cerebellopontine angle	2	—
Olfactory groove	3	10
Foramen magnum	1	—
Clivus	1	—
Spine	—	8
Other	1	—

*Of 179 cases reported by Rohringer and associates[322]; this series included only cases of intracranial meningiomas, none of the spine.

†Of 225 cases reported by Mirimanoff and coworkers.[323]

Numerous potential etiologic agents for meningiomas have been investigated, including radiation, trauma, viruses, occupational exposure, diet, and exposure to sex hormones (reviewed by Longstreth and colleagues[324]). Only ionizing radiation, however, has been strongly implicated in the pathogenesis of these tumors—for example, after scalp irradiation for tinea capitis (as discussed previously under Epidemiology).[9] Some relationship with breast cancer may exist, because the likelihood of developing a meningioma after developing breast cancer, or breast cancer after meningioma, is higher than in the general population.[325]

Deletions of chromosome 22 are frequent in meningiomas. The likely target of this chromosomal deletion is the *NF2* gene, which is mutated in patients with neurofibromatosis type 2 (NF-2). One of the tumor types commonly seen in these patients is meningioma.[326] The *NF2* gene also appears to have an important role in the pathogenesis of sporadic meningiomas. One study found *NF2* mutations in 60% of sporadic meningiomas, all of which had lost one copy of chromosome 22.[327] However, 40% of meningiomas have neither allelic loss of chromosome 22 nor *NF2* gene mutation; therefore, a second tumor suppressor gene probably is linked to the development of meningiomas.

Grossly, meningiomas appear as rounded masses, well circumscribed in contour, with a well-defined dural base that can be easily separated from the underlying brain tissue (Fig. 70-20). Often these tumors extend into the adjacent bone. Histologically, several different subtypes of benign meningiomas are recognized, including syncytial, fibroblastic (fibrous), transitional (mixed), psammomatous, microcystic, and papillary; however, these distinctions carry little prognostic significance.[169] Of more importance prognostically is whether the meningioma is benign, which it is in 90% of the cases.[322] Features of atypical meningiomas are focal isolated necrosis, prominence of nucleoli, and mitotic figures with high cell density.[169] Malignant meningiomas are characterized by invasion into adjacent normal brain tissue. In one large study based on data from the U.S. National Cancer Data Base (NCDB), the overall 5-year survival rates in patients with benign, atypical, and malignant meningiomas were 70%, 75%, and 55% respectively.[328]

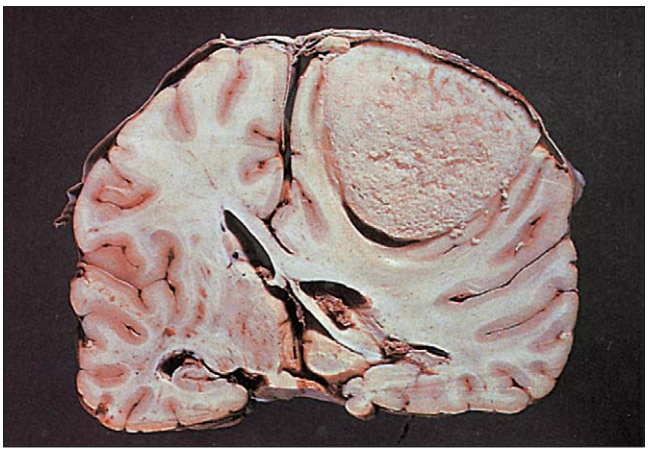

Figure 70-20 • Meningioma: gross specimen. A large-convexity meningioma severely displaces the underlying tissue downward and laterally, creating a midline shift and resulting in marked ventricular compression. (From Maher EA, McKee AC: Neoplasms of the central nervous system. In Skarin AT [ed]: Dana-Farber Cancer Institute Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 420.)

Meningiomas have a distinctive appearance on radiologic studies. On MRI, most meningiomas are isointense with gray matter on T_1-weighted scans and enhance intensely with gadolinium[329] (Fig. 70-21). Peritumoral edema is evident in 60% of meningiomas, and associated bony changes, either destruction or hyperostosis, are seen in 20%. The bony changes are better visualized on CT scans than with MRI.[329] Within the tumor may be seen calcifications, central necrosis, or pseudocysts.

Surgery and Conventional Radiation Therapy for Meningiomas

In a classic paper describing the outcome in 225 patients with meningiomas treated with surgery as the sole modality at Massachusetts General Hospital, Mirimanoff and associates found progression-free survival rates of 93%, 80%, and 68% at 5, 10, and 15 years, respectively, for those who underwent a total resection versus 63%, 45%, and 9% for those who underwent a subtotal resection ($P < 0.0001$).[323] In general, lower rates of progression were seen with sites associated with higher resectability rates. For example, meningiomas in the convexity, 96% of which underwent total resection, had a 5-year recurrence or progression rate of 3%, versus 34% for lesions in the sphenoid ridge, which had only a 28% rate of total resection. These results suggested that surgery alone was inadequate therapy for meningiomas if total resection could not be achieved. In a subsequent study from Massachusetts General Hospital, Miralbell and coworkers reported on 17 patients who underwent subtotal resection of a meningioma followed by radiation therapy.[330] Their 8-year progression-free survival rate was 88%, which was much better than the 48% rate calculated for the cohort of patients with subtotal resections who did not receive postoperative radiation.

Another retrospective study from the University of California at San Francisco reached similar conclusions regarding the improvement in local control with postoperative radiation therapy in patients who have undergone a subtotal resection.[331] This series included mostly patients with benign meningiomas. A much poorer outcome was observed for patients with malignant meningiomas than for those with benign meningiomas (5-year progression-free survival rate of 89%, versus 48%; $P = 0.001$).[331]

The foregoing studies all have used conventional fractionated radiation therapy, usually to doses ranging from 50 to 60 Gy of radiation via conventional fractionation and delivery techniques. Most investigators today would recommend approximately 54 Gy for benign meningiomas after incomplete resection and up to 60 Gy for meningiomas that have atypical or malignant features.

Figure 70-21 • Meningioma. Axial T_1-weighted post-gadolinium magnetic resonance image shows an extra-axial enhancing mass that compresses the underlying brain tissue.

Stereotactic Radiation Techniques for Meningiomas

Substantial experience with use of stereotactic techniques in the treatment of meningiomas has been accumulated. One of the centers with extensive experience with this technique is the University of Pittsburgh: In a long-term follow-up study of 99 patients with meningiomas treated with Gamma Knife stereotactic radiosurgery from 1987 to 1992 with 9 to 25 Gy (median marginal dose of 16 Gy), the total rate of failure was 11% at 63 to 120 months after stereotactic radiosurgery.[332] A majority of meningiomas showed a decrease in size by MRI with time. At years 4 to 6, 69% of cases showed a decrease in size by MRI scan; by years 8 to 10, this number had increased to 88%.

The Mayo Clinic and the Brigham and Women's Hospital also have reported rates of local control on the order of 89% in benign meningiomas with use of Gamma Knife- and linear accelerator-based stereotactic radiosurgery.[333,334] Follow-up remains short, however, with a median duration of 31 to 40 months. Furthermore, in both of these series, patients with atypical or malignant features did poorly. In the Mayo Clinic series, the 5-year local control rates were 93%, 68%, and zero for benign, atypical, and malignant meningiomas, respectively ($P < 0.0001$). Despite the goal to deliver an extremely conformal dose, stereotactic radiosurgery can cause significant complications. Rates of complications, often involving cranial nerves, have been reported in the 5% to 13% range.[332–334] With the reduction in radiation dose used to treat meningiomas, however, this complication rate has decreased.

A large experience has been reported for use of stereotactic radiosurgery for treatment of cavernous sinus meningiomas. Because of their location, surgical resection can cause significant complications, particularly cranial nerve morbidity and resulting extraocular muscle paralysis.[335] A number of institutions have reported high local control rates, in the 91% to 98% range, using marginal doses that typically range from 12 to 18 Gy, but with very short follow-up (median, 2 to 3 years).[336–338] The current standard dose delivered with stereotac-

tic radiosurgery or Gamma Knife for treatment of these tumors is a marginal dose of 14 Gy. Furthermore, cranial nerve V appears to be sensitive to single high-dose fractions, because the incidence of trigeminal nerve dysfunction has ranged from 4% to 11% in these series when higher doses are used.

In an effort to decrease late effects, fractionated stereotactic radiotherapy (FSRT) also has been used to treat meningiomas. At the University of Heidelberg, a dose of 56.8 Gy was given in 1.8-Gy daily fractions, delivered using a relocatable headframe, for treatment of large base-of-skull meningiomas.[339] At a median follow-up time of 35 months, the 5-year progression-free survival rate was 94% for 180 patients with benign meningiomas but 78% for those with atypical features. Another instance in which the fractionated technique has been used instead of conventional stereotactic radiosurgery is for treatment of optic nerve sheath meningiomas, because of the potential risk of optic nerve injury with a single large dose of radiation. One group of investigators reported using FSRT with 50 to 54 Gy in 1.8-Gy fractions to treat these tumors.[340] Of 22 optic nerves with vision before FSRT, 20 nerves (92%) demonstrated preserved vision, and 42% manifested improvement in visual acuity and/or visual field at follow-up.

A nonrandomized comparison of conventional (nonstereotactic) fractionated radiotherapy versus Gamma Knife radiosurgery for selected patients with cavernous sinus meningiomas was reported by Metellus and coworkers.[341] Thirty-eight patients received fractionated radiotherapy, and 38 had Gamma Knife radiosurgery. Both groups fared well, with progression-free survival rates of 94.7% and 94.4%, respectively. Permanent morbidity was seen in 2.6% of patients in the first group and in none in the second group. These results suggest that in selected patients, Gamma Knife radiosurgery can be performed with little late morbidity.

In summary, numerous reports have described the use of stereotactic techniques for delivering radiation to meningiomas as an alternative to surgery or after subtotal resection. In view of the long natural history of these tumors, however, much longer follow-up will be needed to adequately evaluate these modalities.

Medical Therapy for Meningiomas

A number of agents, including hydroxyurea, interferon-α, tamoxifen, and mifepristone (RU-486), have been reported to be provide modest benefit in patients with recurrent meningiomas.[342] Isolated reports have indicated reduction in the size of meningiomas with hydroxyurea[343] and RU-486.[344,345] Other studies have not always reported regression, although in some cases, treatment with either of these agents appears to halt the growth of the tumor or to ameliorate the patient's symptoms, or both.[346–348] Box 70-3 summarizes the recommended approach to management of meningiomas.

Box 70-3. MANAGEMENT OF MENINGIOMAS

- Meningiomas are extra-axial tumors that arise from dura; common locations are cerebral convexity, parasagittal falx, and sphenoid ridge.
- A very long natural history is characteristic, mandating prolonged follow-up.
- Greater than 90% of these tumors are benign; the remainder exhibit atypical histologic features or frank invasion of brain parenchyma.
- Primary treatment is surgical, if feasible.
- Radiation therapy is reserved for tumors that are incompletely resected, recur after surgery, are inaccessible to surgical resection, or have atypical or invasive features.
- The standard radiation dose has been approximately 54 Gy for benign meningiomas and up to 60 Gy for those with atypical or invasive features.
- Stereotactic radiation therapy techniques have been used; however, follow-up is still short in these studies.
- Anecdotal reports exist of responses to medical therapy (hydroxyurea and antiestrogen and antiprogesterone agents).

PITUITARY ADENOMA

Clinical and Pathologic Considerations

Pituitary adenomas make up 10% to 15% of all intracranial tumors. They arise from the anterior lobe of the pituitary gland. The pituitary gland and stalk normally are isointense with brain on T_1-weighted MRI scans. The gland and stalk, however, intensely enhance after contrast administration because of the absence of a blood-brain barrier. Pituitary adenomas generally are seen as hypointense foci on T_1-weighted MRI scans and do not enhance with gadolinium.[349] Other abnormalities that can appear as a hypointense, nonenhancing lesion in the pituitary include pars intermedia cysts, metastases, infarctions, and epidermoid cysts and abscesses.

Asymptomatic pituitary adenomas were found in 1.5% to 27% of autopsy cases and in 10% of normal adult volunteers by MRI scanning. Symptomatic pituitary adenomas are much less common. These tumors can give rise to signs and symptoms through secretion of hormones or by compression of nearby structures, causing neurologic disturbances such as headaches, bilateral bitemporal hemianopia from compression of the optic chiasm, and cranial nerve palsies from invasion into the cavernous sinus. Adenomas also can cause hypopituitarism from compression of the pituitary stalk.

Many investigators have studied the genetics of pituitary adenomas. Patients with multiple endocrine neoplasia type 1 (MEN-1) are predisposed to developing pituitary adenomas as well as parathyroid and pancreatic islet tumors (reviewed by Thakker[350]). Anterior pituitary tumors occur in 30% of patients with MEN-1, most commonly prolactinomas but also nonfunctional and growth hormone (GH)- and adrenocorticotropic hormone (ACTH)-secreting tumors. *MEN1* mutations are not commonly found in sporadic pituitary adenomas; however, one gene that is mutated in a substantial proportion of pituitary adenomas is that encoding the α subunit of the guanosine triphosphate (GTP)-binding protein Gs.[351] Mutation of this gene leads to constitutive activation of the cyclic adenosine monophosphate (cAMP) pathway. The mutated form of this gene is called *gsp* and is present in 10% to 40% of GH-secreting adenomas.[351]

At one time, pituitary adenomas were classified according to their staining characteristics (basophilic, eosinophilic, chromophobe). Today, however, they are classified according to secretion of hormones. In one series of 684 patients with pituitary adenomas who underwent surgery, prolactinomas were the most common (43%), followed by nonsecreting tumors (30%)[352] (Table 70-11). Thyroid-stimulating hormone (TSH)-secreting tumors were rare in this series (2 of 684), as they are in others.

Adenomas also are classified on the basis of size as either macroadenomas (greater than 1 cm in diameter) or microadenomas. Nonsecreting adenomas generally are macroadenomas at the time of diagnosis because they usually come to medical attention fairly late, when they are causing neurologic symptoms due to mass effect. The same is true for gonadotropin-secreting adenomas, which are inefficient producers and secretors of hormones. GH-secreting adenomas and prolactinomas in men often are macroadenomas at the time of diagnosis, probably because their clinical effects evolve over time and often are ignored early on. Because the same pituitary stem cell can produce both GH and prolactin, many patients have adenomas that secrete both hormones. Prolactinomas in women and ACTH-secreting adenomas usually are microadenomas at diagnosis. Prolactinomas in women commonly cause amenorrhea and galactorrhea. ACTH-secreting adenomas often cause dramatic clinical signs and symptoms associated with hypercortisolism that rapidly bring patients to medical attention. ACTH-secreting pituitary adenomas also can

Table 70-11 Pituitary Adenomas: Clinical Presentation by Endocrine Secretion

Type	Frequency* (%)	Signs and Symptoms	Typical Size at Diagnosis
Prolactinoma	43	*Women*: Amenorrhea, galactorrhea	*Women*: Microadenoma
		Men: Impotence, hypopituitarism	*Males*: Macroadenoma
Nonsecreting gonadotropin	30	Hypopituitarism	Macroadenoma
GH-secreting	17	Gigantism in children	Macroadenoma
		Acromegaly in adults	
ACTH-secreting	7	Cushing's syndrome	Microadenoma
		Nelson's disease	
TSH-secreting	<1	Hyperthyroidism	Can be microadenoma; often macroadenoma owing to delayed diagnosis

ACTH, adrenocorticotropic hormone; GH, growth hormone; TSH, thyroid-stimulating hormone.
*Among 684 cases reported by Oruckaptan and colleagues.[352]

be seen in approximately 25% of patients who have undergone bilateral adrenalectomies for Cushing's syndrome secondary to loss of negative feedback control by cortisol on the hypothalamus. In a majority of these patients, hyperpigmentation develops as a result of ACTH hypersecretion. This is termed *Nelson's syndrome*, and in this setting the pituitary tumors usually are very large and often are difficult to completely resect.[353]

Surgery for Pituitary Adenomas

The current therapy for most pituitary adenomas, excluding prolactinomas, involves surgery. For nonsecreting tumors, which tend to be large and manifest with neurologic signs and symptoms, surgery offers rapid decompression of the visual pathways. For hormonally active tumors, surgery leads to a rapid drop in hormone secretion. The current preferred technique is the transsphenoidal approach, which was popularized by Harvey Cushing in the early 1900s. It then fell out of favor but regained popularity in the 1960s.[354] Transsphenoidal resection is fairly safe, with a mortality rate less than 1%.[355] The most common complications arising from this surgery are nasal septum perforation, anterior pituitary insufficiency, postoperative diabetes insipidus (which usually is transient), and CSF leak sometimes leading to meningitis.[355] Much rarer complications include carotid artery injury and loss of vision. A recent variation of this approach has been to use an endoscope through the nostril to gain access to the pituitary transsphenoidally, thereby eliminating the need for conventional skin incisions and further improving postoperative recovery.[356] The transsphenoidal approach is used in more than 90% of pituitary operations. It is appropriate for resection of microadenomas, enclosed macroadenomas with symmetrical suprasellar extension, and even some invasive adenomas. If the pituitary adenoma is very fibrous or exhibits significant extension into the middle cranial fossa, however, a transsphenoidal resection may be impossible, and it may be necessary to perform an intracranial operation.

The success of surgery alone in curing adenomas depends on the size of the tumor. In a review of transsphenoidal resection for GH-secreting adenomas, in most series hormonal normalization was seen in 67% to 91% of microadenomas but in only 48% to 65% of macroadenomas.[357] ACTH-secreting adenomas, which generally are less than 1 cm at diagnosis, show a normalization of hormones following resection in 75% to 96% of cases in most surgical series (reviewed by Ludecke and coworkers[358]). TSH-secreting adenomas are rare compared with other pituitary adenomas, and when diagnosed they are often large. Normalization of TSH after resection of these tumors has varied widely in different series, ranging from 33% to 86%.[359]

The results of surgery for hormone-inactive adenomas are harder to document because the criteria for surgical success are less well defined. Clinical improvement can be seen even without total removal of the tumor. Series in which CT or MRI scans were performed a few months after surgery show a wide range of gross complete resection rates for these tumors, from 28% to 84%.[360–362] A review of several surgical series showed that the likelihood of normalization of visual fields after surgery ranged from 16% to 53% and that visual field improvement occurred in 26% to 70% of cases.[363]

Medical Therapy for Pituitary Adenomas

Although surgical resection and radiation therapy are effective therapies for prolactinomas, the primary treatment for these tumors currently is medical.[364] This is due to the availability of drugs that can suppress prolactin secretion and shrink these tumors. Surgical resection and radiotherapy are still used for the treatment of prolactinomas in the minority of patients who fail to respond to drugs or who cannot tolerate them.

Clinical manifestations of prolactinomas differ between the sexes. In premenopausal women, oligomenorrhea or amenorrhea and galactorrhea are extremely common. Infertility also may be the presenting sign, and women often have decreased libido. Estrogens have a marked stimulatory effect on prolactin synthesis and secretion; therefore, pregnancy can stimulate the growth of these tumors. In men and postmenopausal women, these tumors generally are asymptomatic until they are large enough to compress nearby structures, causing signs and symptoms such as visual deficits, headaches, and panhypopituitarism. Chronic hyperprolactinemia leads to decreased libido and impotence in 90% of men. Galactorrhea is uncommon in men but can occur in 10% to 20% of cases. The problems with reproductive and sexual function are due to inhibition of pulsatile gonadotropin secretion.

Secretion of prolactin by the lactotroph cells in the anterior pituitary gland is negatively regulated by dopamine produced by the hypothalamus. Therefore, dopamine agonists such as bromcriptine stimulate dopamine secretion by the hypothalamus and inhibit prolactin secretion by the lactotrophs. Administration of bromocriptine has been the standard therapy for prolactinomas for decades. This agent has been shown to decrease tumor size and normalize prolactin levels in 70% to 90% of patients. Bromocriptine also restores ovulation and menses and improves visual fields in a similar percentage of cases. Tumor shrinkage and decrease in prolactin levels can take anywhere from days to weeks to months to occur. Unfortunately, the action of bromocriptine is reversible; therefore, when the drug is discontinued, regrowth of the tumor with increase in the prolactin

level usually is seen. Therefore, lifelong administration is the rule, and many patients can tolerate prolonged treatment for years. Bromocriptine has been used prophylactically during pregnancy to reduce symptomatic tumor enlargement. Of note, however, 10% to 20% of patients experience side effects such as nausea, vomiting, dizziness, postural hypotension, and headaches. In patients who have limiting toxicity with bromocriptine or whose tumor fails to respond to this drug, newer dopamine agonists such as lisuride, pergolide mesylate, cabergoline, and tergulide have been used with some success (reviewed by Nomikos and coworkers[365]).

A few drugs are now available for the treatment of endocrine hypersecretion in pituitary tumors other than prolactinomas. For GH-secreting adenomas, somatostatin analogs such as octreotide and lanreotide have been shown to reduce GH levels in more than 90% of patients, with almost complete suppression in half.[366] Synthetic agents that block GH binding to its receptor or growth hormone-releasing hormone to its receptors in the pituitary are being used experimentally. In general, these drugs are not being used for first-line therapy in patients with GH-secreting adenomas but rather are indicated in patients in whom surgery has been unsuccessful.

TSH-secreting adenomas often are very large at diagnosis, making complete surgical resection difficult. Because these tumors express somatostatin receptors, octreotide and lanreotide can decrease tumor size and decrease TSH secretion.[366]

Radiation Therapy for Pituitary Adenomas

Radiation therapy also is highly effective in controlling pituitary adenomas. Nowadays, however, it is rarely given as sole treatment for newly diagnosed pituitary adenomas. In contrast with surgery, radiation therapy will not result in a rapid reversal of neurologic signs and symptoms or a rapid drop in hormonal secretion. Radiation therapy usually is reserved for patients who either have residual disease after surgery or have a recurrence after surgery. Radiation therapy occasionally is used as the sole primary therapy in patients who have a medical condition that makes their tumor inoperable.

The overall 10-year control rate using radiation therapy is on the order of 85% to 95% based on a number of large retrospective series.[367–371] In a study from the University of Heidelberg, in 138 patients with pituitary adenomas who received radiation as initial therapy or after recurrence, the overall local control was 95% with a mean follow-up time of 6 years.[369] Likewise, in a study from the University of Florida with a median follow-up time of 9.2 years, the overall local control rate at 10 years was 93%.[367] Ninety-eight patients in this series had surgery and radiotherapy as initial therapy, and their 10-year local control was 95%. This was comparable to the 10-year local control rate of 90% for the 23 patients who had radiotherapy alone for newly diagnosed adenomas, but better than the 80% control rate seen in 20 patients who received radiation for a recurrence after their initial surgery ($P = 0.03$). Similar findings regarding improved local control in patients receiving surgery and radiation "up front" compared with those receiving radiation at recurrence were obtained from the Princess Margaret Hospital study that examined 160 patients with hormonally inactive pituitary adenomas.[368] Pituitary adenomas can occur in the pediatric population, although they are much less common than in adults. In one study in 11 patients aged 19 or younger with pituitary adenomas, treatment consisted of surgery plus radiation or radiation only.[372] At a median follow-up time of 15.6 years, only two had failed to respond to treatment.

In the foregoing studies, local control refers to lack of disease progression, clinically and radiologically. In many patients who have hormone elevations at the outset, however, complete normalization may not be achieved after radiation therapy. In the University of Heidelberg series, of 68 patients with hormonally active pituitary adenomas, 52% of patients showed some reduction in their hormonal overproduction, but only 38% demonstrated complete normalization.[369] Furthermore, in patients who had a response, it often took years, in some cases up to 9 years. A study from the Princess Margaret Hospital specifically analyzed data for 145 patients who received radiation for hormonally active pituitary adenomas.[370] The progression-free survival rate was 96% at 10 years; however, the actuarial long-term biochemical remission rate was only 40%. Radiation is thus highly effective in preventing pituitary adenomas from growing; however, it is far less effective in normalizing hormone levels in patients with hormonally active tumors.

Late Effects after Pituitary Irradiation

In the foregoing series, the median doses ranged from 45 to 50 Gy.[367–370] In the University of Heidelberg study, a statistically significant dose-response relationship was found in favor of a dose of 45 Gy or less.[369] One of the worrisome potential late effects of using higher total doses is the possibility of radiation-induced optic neuropathy. In some series, visual problems develop in a few patients after radiation, presumably as a result of optic nerve damage, but such complications are uncommon, ranging in frequency from 0.7 to 2%.[367,369,370] As discussed earlier (under "Adverse Effects after Irradiation of the Brain or Spine"), the risk of optic nerve-chiasm injury is dependent on both total dose and dose per fraction. At the doses commonly used to treat pituitary adenomas (45 to 50 Gy), the risk of radiation-induced optic neuropathy with standard fractionation (1.8 to 2 Gy per day) is very low but not zero.

Doses of 45 to 50 Gy to the pituitary gland carry a substantial risk of causing hypopituitarism. In patients who did not have hormonal deficiencies at the start, the risk of developing insufficiency of a given hormone ranged from 10% to 30% in the series discussed earlier.[367–370] It is likely that in half of all patients who received radiation doses of 45 to 50 Gy, deficiency of at least one pituitary hormone will develop 5 years after radiotherapy. This is an ongoing risk after radiation therapy, however, and can occur many years later; therefore, patients must be monitored indefinitely for this complication.

Second malignant neoplasms are always a concern in patients who receive radiation and who are expected to be long-term survivors. In an analysis of 334 patients with pituitary adenomas treated at the Royal Marsden Hospital with surgery and radiation therapy (median dose of 45 Gy), a secondary brain tumor (two astrocytomas, two meningiomas, one meningeal sarcoma) developed in 5 patients, for an actuarial risk of 1.3% at 10 years and 1.9% at 20 years.[373] The relative risk for developing a second tumor compared with the incidence in the normal population was 9.3. A report from the Princess Margaret Hospital presented similar conclusions. In a series of 306 patients with pituitary adenomas treated with irradiation, gliomas of the brain developed in 4 patients, with a latency of 8 to 15 years. The relative risk compared with risk in the normal population was 16, with an actuarial risk of 1.7% at 10 years and 2.7% at 15 years.[374]

Stereotactic Radiation Techniques for Pituitary Adenomas

A number of institutions have reported using stereotactic means of delivering radiation to pituitary adenomas, both in fractionated and single-dose regimens. Investigators have used FSRT with 45 to 50 Gy in 1.8-Gy daily fractions delivered using relocatable stereotactic headframes.[375,376] Stereotactic radiosurgery also has been used, with single fractions ranging from 10 to 27 Gy.[375–377] The local control rates using these techniques has been reported to be greater than 90%; however, the length of follow-up in these studies is too short to allow definite conclusions to be drawn.

The rationale for using single large doses is the contention that the interval to normalization of hormonal levels is shorter with this approach than with conventionally fractionated radiation therapy. Yoon and colleagues reported that 11 of 13 patients with prolactino-

Box 70-4. MANAGEMENT OF PITUITARY ADENOMAS

- Pituitary adenomas are extremely common as an incidental finding (in up to 10% of normal volunteers by magnetic resonance imaging screening).
- These tumors may become symptomatic, when the patient comes to medical attention, because of hormone secretion, compression of nearby structures causing neurologic symptoms, or compression of the pituitary stalk, leading to hypopituitarism.
- These tumors are classified by size as microadenomas (1 cm or less in diameter) or macroadenomas.
- Initial therapy for most prolactinomas is with a dopamine agonist (e.g., bromocriptine, lisuride, pergolide), which usually decreases prolactin levels and shrinks the tumor.
- Initial therapy for most other pituitary adenomas is transsphenoidal surgical resection, which is safe and leads to rapid reversal of neurologic signs and symptoms. Surgery normalizes hormone levels in most patients with microadenomas.
- Radiation therapy currently is reserved for treatment of residual disease or recurrence after surgery, or for patients who are not eligible for surgery because of medical reasons. In patients with elevated hormones, normalization of levels after radiation therapy may take years. A dose on the order of 45 Gy in 180-cGy daily fractions should offer good control with extremely low risk of optic neuropathy.

mas had normalization of their hormone level within 1 year.[377] Mitsumori and associates found that the average time to normalization with stereotactic radiosurgery was 8.5 months, versus 18 months with FSRT (45 Gy in 1.8-Gy daily fractions).[376] Pouratian and associates reported on 23 patients with prolactinomas that had failed to respond to medical and surgical treatment and then were treated with Gamma Knife radiosurgery.[378] Subsequently, a normal prolactin level was attained in 26%, by an average time of 24.5 months. Remission was significantly associated with the patient's being off a dopamine agonist at the time of irradiation. Box 70-4 summarizes the recommended approach to management of pituitary adenomas.

ACOUSTIC NEUROMA

Clinical and Pathologic Considerations

Acoustic neuroma has many other names; in addition to neuromas, these tumors also are referred to as neurilemmomas, neurinomas, neurofibromas, schwannomas, and nerve sheath tumors. They are benign tumors that most commonly originate from cranial nerve VIII, usually in the vestibular region of the internal auditory foramen, where the nerve acquires a Schwann sheath. For this reason, these tumors also are sometimes called *vestibular schwannomas*. Neuromas can affect other cranial nerves, such as the trigeminal nerve and nerves in the jugular foramen region; however, these are much less common than acoustic neuromas.[379,380]

Acoustic neuromas account for 8% to 10% of all primary intracranial tumors, generally affecting people in the fifth decade of life. These tumors characteristically grow very slowly. Early on, they are asymptomatic, but with enlargement, they lead to progressive hearing loss and tinnitus.[381] The hearing loss typically is in the conversational range. As the tumor expands and compresses cranial nerve VIII, it may cause vertigo and unsteadiness of gait. With growth into the cerebellopontine angle, cranial nerves V and VII may be compressed, resulting in otalgia, facial numbness, facial palsy, and change in taste. With continued growth, brainstem compression and obstruction of the fourth ventricle may develop, causing hydocephalus. Because signs and symptoms can arise insidiously, a progressive hearing loss and gait unsteadiness may evolve over years in some patients before the tumor is diagnosed.

Patients with NF-2 often have bilateral acoustic neuromas; in fact, this finding is diagnostic for NF-2.[326] Acoustic neuromas in patients with NF-2 contain mutations in the *NF2* gene and chromosome 22 deletions. Sporadic unilateral acoustic neuromas arising in patients without NF-2 also are associated with chromosome 22 deletion and *NF2* mutation.[382,383]

Surgery for Acoustic Neuromas

Traditionally, acoustic neuromas have been treated by surgical resection. A number of different approaches can be taken, including the suboccipital approach, the translabyrinthine approach, and the middle fossa approach.[384] Some centers strongly favor one approach over the others, but many surgeons make a decision on a case-by-case basis. The translabyrinthine approach is the only procedure that inherently sacrifices hearing in the course of the procedure; therefore, it generally is not used in patients who have some residual useful hearing.[385] Hearing preservation is possible but not guaranteed with either the suboccipital or middle fossa approach. In one series of patients who underwent a resection using the suboccipital approach with an attempt to preserve hearing, 18 of 46 (39%) patients who had good preoperative hearing maintained good hearing after surgery.[386] The middle fossa approach is indicated in patients who have useful hearing and have tumors entirely contained within the internal auditory canal. In one series using this approach, total tumor removal was achieved in 98% of the cases, with hearing preservation in 59%.[387] Approximately 89% of patients maintained normal or near-normal facial nerve function.

Catastrophic complications such as brainstem stroke, postoperative cerebellar hemorrhage, or death are rare after surgery for acoustic neuromas.[388] Two other serious complications that are more common are CSF leak, which can lead to meningitis, and cranial nerve VII palsy. Some surgical teams feel that CSF leak and damage to the facial nerve are more likely with the suboccipital approach than the translabyrinthine approach; however, both complications have been described with both approaches.[385,389] In an effort to decrease damage to the facial nerve, many surgeons routinely perform intraoperative electromyographic monitoring.[388] Persistent headaches that last for months to a year are more common after surgery using the suboccipital approach, presumably as a result of aseptic meningitis from contamination of the subarachnoid space with bone dust when the internal acoustic canal is drilled intradurally.[384]

Radiotherapy for Acoustic Neuromas

Radiation therapy often is effective in cases in which total resection cannot be performed. In a series from the University of California at San Francisco, postoperative radiation therapy (at a dose greater than 45 Gy) decreased the recurrence rate after subtotal resection from 46% (6 of 13 patients) to 6% (1 of 11 patients) ($P = 0.01$).[390] Radiation therapy also is effective in controlling acoustic neuromas that are not surgically resected. Proton beam therapy has been used to deliver single large radiation fractions to acoustic neuromas. In the Massachusetts General Hospital series, 68 patients received a dose of 12 Gy to the tumor margin. With a median follow-up time of 44 months, the 5-year actuarial control rate was 84%.[391]

Single large doses of radiation delivered using stereotactic radiosurgery also have been used. The University of Pittsburgh has accumulated one of the largest experiences with this approach. An analysis of their first 5 years of using Gamma Knife radiosurgery with a 12- to 20-Gy marginal dose showed a 98% local control.[392] Of patients with normal function of cranial nerves VII and V before radiosurgery, however, 15% and 16%, respectively, developed some dysfunction afterward. Furthermore, of patients with useful hearing before radiosurgery, only 47% maintained the same level of hearing. Other institutions also found high local control rates, along with

high rates of cranial nerve V and VII dysfunction, after single large stereotactic doses using either a Gamma Knife machine[393] or a linear accelerator.[394] On the basis of their initial results, the investigators at the University of Pittsburgh changed their policy by decreasing the marginal dose and using MRI scans for treatment planning purposes.[395] From 1992 to 1997, 190 patients underwent Gamma Knife radiosurgery delivering 11 to 18 Gy to the margin of the tumor (median dose, 13 Gy). With a median follow-up time of 30 months, the 5-year actuarial tumor control rate was 97%, and 71% of patients retained useful hearing. The 5-year rates for developing facial weakness and facial numbness were 1% and 2.7%, respectively.[395]

In order to potentially reduce late effects, a number of institutions have started using FSRT. Both hypofractionation (25 Gy in 5-Gy fractions, 30 Gy in 3-Gy fractions, 21 Gy in 7-Gy fractions)[396,397] and conventional fractionation with 54 to 58 Gy in 1.8- to 2-Gy fractions[398,399] or 36 to 44 Gy in 1.8-Gy fractions[400] have been used. Although the follow-up is very short in some of these series, the control rates have ranged from 97% to 100%, with a useful hearing rate ranging from 72% to 85% and low rates of cranial nerve V and VII dysfunction. Although the jury is still out on use of single-dose stereotactic radiosurgery versus FSRT for acoustic neuromas, the experience at Jefferson University Hospital strongly favors the latter. Patients have received treatment with either Gamma Knife stereotactic radiosurgery (12-Gy marginal dose) or FSRT (50 Gy in 2-Gy fractions) in a nonrandomized fashion. The rates of cranial nerve V and VII preservation were equally high in both groups (93% to 98%), as were the local control rates (97% or better). A significant difference, however, was found in the rates of serviceable hearing (33% for Gamma Knife stereotactic radiosurgery versus 81% for FSRT).

As indicated by the foregoing findings, radiation therapy can be a useful alternative to surgery to control the growth of acoustic neuromas. Undoubtedly, however, debate will continue regarding the merits of one treatment over the other, as well as the optimal radiotherapy technique. Although the previous discussion centered on the treatment of acoustic neuromas, some evidence indicates that SRS is effective in controlling the growth of trigeminal neuromas and alleviating trigeminal neuralgia, as either an alternative or adjunct to surgery.[401]

CEREBELLAR HEMANGIOBLASTOMAS

Clinical and Pathologic Considerations

Hemangioblastomas are low-grade vascular tumors that constitute 1% to 2% of intracranial tumors. They usually occur in the cerebellar hemispheres and vermis, although they can involve the pons, medulla, and spinal cord. Most cases occur sporadically, but 20% occur as part of the familial von Hippel-Lindau syndrome.[402] Patients with this syndrome have a germline mutation in the *VHL* gene. Tumors that these patients develop have sustained a mutation in the second *VHL* allele, leading to loss of VHL protein function and resulting in stabilization of the HIF-1α protein under normoxic conditions. Stabilization of HIF-1α leads to constitutive high levels of expression of target genes including VEGF (vascular endothelial growth factor) (reviewed by Kaelin[403]). For this reason, the tumors seen in patients with von Hippel-Lindau syndrome are highly vascular. Other abnormalities seen in these patients include retinal angiomas, renal cell carcinomas, and cysts involving many organs such as the pancreas, kidney, lungs, and liver. Pheochromocytomas also may develop in these patients, who often display erythrocytosis as a result of increased erythropoietin production. Sporadic hemangioblastomas, which occur in patients not suffering from von Hippel-Lindau syndrome, also contain mutations in the *VHL* gene in at least 20% of cases.[404]

Patients with cerebellar hemangioblastomas often present in the third decade of life. Presenting manifestations stem from cerebellar dysfunction, increased ICP, and involvement of nearby cranial nerves. These signs and symptoms include headaches, nausea, vertigo, diplopia, tinnitus, ataxia, and poor coordination.[405] The lesion is well visualized by CT scanning or MRI. Angiography, which generally is performed before surgery, shows the highly vascular nature of these tumors.

Histologically, hemangioblastomas show numerous capillary and sinusoidal channels lined with endothelial cells. A cystic component often is present; the cyst is filled with xanthochromic, proteinaceous fluid, with a vascular nodule in the cyst wall. In one series, 6 of 19 patients (32%) had a solid lesion without a cystic component.[406] Lesions of this type are more likely to originate in the brainstem.

Therapy for Cerebellar Hemangioblastomas

The primary therapy for most patients with these tumors is surgical resection, if this can be done safely. If a cyst is present, it is drained; then the solid component is dissected and removed. If the tumor involves the brainstem, however, surgery may be extremely risky, with the potential for massive hemorrhage or extensive postoperative edema leading to death.[406] Surgical resection historically has been associated with high local control rates. In one series, recurrence was noted in only 13 of 112 patients (12%) after surgery.[405] In 6 patients, disease recurred in the original tumor bed, after incomplete removal, and in 10 patients, recurrence was in a different site or in the same site after gross total resection.

For patients with unresectable or incompletely resected hemangioblastomas or for those whose tumors are medically inoperable, radiation therapy usually is given. In a series from the Mayo Clinic, 27 patients received radiation treatment, 6 because of microscopic positive margins after surgery and 20 for gross residual disease.[407] In patients with gross residual disease, the rate of local control was 57% for those who received 50 Gy or more but only 33% for those receiving less than this dose. In four of the six patients with microscopic residual disease, this protocol achieved local control. For all 27 patients, the overall 15-year survival rate was 58%, and the relapse-free survival rate was 42%. Sung and associates also found that patients who received a higher dose (40 to 55 Gy) had a superior survival compared with those who received 20 to 36 Gy.[408] On the basis of these results, therefore, it would be reasonable to use approximately 50 Gy in patients requiring radiation therapy.

Radiosurgery has been used for cerebellar hemangioblastomas. In a study from three institutions, 38 hemangioblastoma lesions in 22 patients were treated stereotactically, with single fractions ranging from 12 to 20 Gy (median, 15.5 Gy).[409] The vast majority of these tumors had not undergone gross total resection. With a median follow-up time of 24.5 months, the 2-year actuarial overall survival rate was 88% and the 2-year progression-free survival rate was 86%.

CHORDOMAS AND CHONDROSARCOMAS INVOLVING THE BASE OF THE SKULL

Clinical and Pathologic Considerations

Chordomas constitute less than 0.1% to 0.2% of all intracranial tumors. They arise along the path of the primitive notochord, which stretches from the tip of the dorsum sellum to the coccyx. Fifty percent of chordomas arise from the sacrococcygeal region, but a third arise from the base of skull, most commonly the clivus but occasionally the petrous bone. Chordomas rarely metastasize. Grossly, they are extradural, often multilobulated and pseudoencapsulated. They may have a consistency that can range from extremely soft to woody or cartilaginous. Histologically, nests and cords of large vacuolated epithelioid cells can be seen within a myxoid stroma. There is a chondroid subtype that contains areas with a hyaline-appearing stroma. Previously, it was thought that the chondroid subtype might have a more favorable outcome than the typical chordoma; however, this has not been substantiated in recent studies.

In a report from the Mayo Clinic, diplopia was the most common symptom followed by headaches, ptosis, retro-orbital pain, and neck pain. Cranial deficits were very common, especially cranial nerve VI, although deficits of cranial nerves III, IV, V, IX, X and XII also were seen.[410] In the same study, MRI was demonstrated to be the best modality for demonstrating the entire extent of cranial chordomas and the involvement of adjacent structures. These tumors typically appear hypointense (black) on T_1-weighted images and hyperintense (white) on T_2-weighted images. Other possibilities to be considered in the differential diagnosis for a clival lesion are metastasis, myeloma, osteochondroma, meningioma, and chondrosarcoma.

Low-grade chondrosarcomas often are lumped together with chordomas. The former arise from primary mesenchymal cells or embryonal rests of cartilaginous matrix. Chondrosarcomas are composed of either hyaline cartilage or myxoid cartilage, or a mixture of the two. The myxoid variant may be confused with chordoma.

In one large series of chondrosarcomas of the base of the skull, 6% arose from the sphenoethmoid complex, 28% from the clivus, and 66% from the temporo-occipital region.[411] Chordomas and low-grade chondrosarcomas have a similar radiologic appearance. Together they account for almost all primary malignant bone tumors arising from the base of the skull. Both rarely metastasize; however, they can result in significant morbidity from local invasion or can be fatal. Even though they are treated similarly, low-grade chondrosarcomas appear to have a better prognosis than chordomas, as discussed next.

Therapy for Chordomas and Chondrosarcomas Involving the Base of the Skull

Surgery is almost always performed when a chordoma or chondrosarcoma in the base of skull is suspected, both to establish a diagnosis and to alleviate symptoms. The surgery often is performed jointly by a neurosurgeon and a head and neck surgeon. Complete resection can be curative, but this is often not possible because of the extent of disease. In a series of 60 patients (46 with chordomas, 14 with chondrosarcomas) from the University of Pittsburgh, the tumors were treated primarily with surgery.[412] Approximately 67% underwent total or near-total resection, and 20% received postoperative radiation because of radiologic evidence of residual tumor. The 5-year recurrence-free survival rates were 65% for patients with chordomas and 90% for those with chondrosarcomas ($P = 0.09$). Two common problems following surgery were the development of CSF leakage and new cranial nerve deficits, which occurred in 30% and 80% of cases, respectively.

In a series from the Mayo Clinic, 51 patients with intracranial chordomas were treated with subtotal resection (78%) or biopsy (22%); 76% received postoperative radiation (median dose 50 Gy).[413] However, in spite of this extra treatment, the 5-year actuarial disease-free survival was only 33%. The most important factor for survival on multivariate analysis was young age. Those less than 40 years of age had a 10-year actuarial survival of 63% versus 11% for those greater than 40. The use of postoperative radiation did not improve overall survival but did show a trend toward improved disease-free survival, especially in patients younger than 40 years old.

Because tumors in the base of skull are near critical structures within the brain, there has been a growing use of radiation techniques that can deliver doses to a tightly conformal treatment volume, such as stereotactic radiation and proton beam therapy. Some reports have described using both stereotactic radiosurgery (SRS) to deliver single large fractions[414] and fractionated sterotactic radiotherapy (FSRT).[415] In one series, 45 patients (37 with chordoma and 8 with chondrosarcoma) received fractionated radiation using a stereotactic headframe but with conventional fractionation (1.8 Gy per day) to a total median dose of approximately 65 Gy.[415] Among the patients with chondrosarcomas, the local control was 100% at 5 years. In patients with chordomas, however, local control rates were only 50% at 5 years and 40% at 8 years.

Some experts consider fractionated proton beam therapy to be the treatment of choice for incompletely resected skull base chondrosarcomas and chordomas, although the availability of facilities that can deliver such treatment is very limited. The advantage of proton beam therapy is that, unlike conventional x-rays, protons have a very sharp fall-off in dose. Proton beam therapy has been used since the 1970s at Massachusetts General Hospital. In a report from that institution, 200 patients with chondrosarcomas of the skull base were treated with surgery followed by radiation.[411] A gross total resection was achieved in only 5% of patients. Radiation was delivered using a combination of x-rays and proton beam therapy to a dose of 64.2 to 79.6 cobalt-gray-equivalents (median dose, 72.1 C-G-E in 38 fractions). The 10-year local control and progression-free survival rates were 98% and 99%, respectively. By contrast, the experience with almost 300 patients with skull base chordomas treated in a similar manner was not nearly as good, with 5- and 10-year progression-free survival rates of 70% and 45%, respectively.

GLOMUS TUMORS OF THE BASE OF THE SKULL

Clinical and Pathologic Considerations

Glomus tumors are low-grade tumors of neural crest origin arising from the paraganglionic (glomus body) cells; therefore, they are also referred to as nonchromaffin paragangliomas. Becase they are thought to be associated with chemoreceptor tissue, they are also known as chemodectomas. Glomus tissue is found along the vagus nerve, the glossopharyngeal nerve, and the jugular ganglion. Glomus tumors are often divided into those arising in the soft tissue of the neck (glomus vagale and carotid body) and those involving the temporal bone or base of skull (glomus jugulare and glomus tympanicum). Only the latter group will be discussed in this chapter as they often have intracranial extension and are managed by neurosurgeons.

Glomus jugulare tumors originate from the jugular bulb in the skull base, whereas glomus tympanicum tumors arise from the middle ear cavity along the nerve of Jacobsen (cranial nerve X) or Arnold (cranial nerve IX). In one series, 57 of 75 (76%) patients with glomus tumors of the head and neck region had glomus jugulare tumors, whereas 11 of 75 (15%) had glomus tympanicum tumors.[416] In this series, otologic signs and symptoms were common in patients with both of these tumors. Conductive hearing loss and/or tinnitus occurred in the majority of these patients. Over a third had bleeding from the ear, ear pain, a polyp visible in the ear canal and/or a mass behind the tympanic membrane. Cranial nerve impairments were also very common, specifically cranial nerve VII in patients with glomus tympanicum tumors and cranial nerves V, VI, VII, VIII, IX, X, XI, and XII in patients with glomus jugulare tumors.

CT and MRI often are diagnostic with these tumors. Cerebral angiography will demonstrate the extremely vascular nature of these tumors and generally is performed immediately before surgery.

Therapy for Glomus Tumors of the Base of the Skull

The therapy for glomus tumors is very controversial, with some experts strongly advocating surgery and others strongly advocating irradiation. When surgery is performed, it generally preceded by embolization to reduce the subsequent operative time and blood loss. Surgery for glomus tumors involving the base of the skull usually is performed jointly by a neurosurgeon and a head and neck surgeon, often using a combined suboccipital and transtemporal approach. The results with surgery in the modern era have been excellent, with local control rates ranging from 83% to 95% (reviewed by Hinerman and coworkers[417]). The main complications after surgery have been cranial nerve palsies, especially the facial nerve, and CSF leak.

An extensive literature regarding radiation treatment for glomus tumors has been accumulated. In a series of 46 patients with glomus

tumors treated with radiation at doses ranging from 35 to 66 Gy at the Royal Marsden Hospital, the 10-year local control rate was 90%, with a median follow-up time of 9 years.[418] Some late relapses occurred, so the 25-year local control rate dropped to 73%. In two patients, both of whom had received 64 Gy or more, a facial nerve palsy developed as a late complication. In a series from the University of Florida, 53 patients with temporal bone glomus tumors (46 with jugulare and nine with tympanicum tumors), most of whom had no prior therapy, received radiation therapy at doses ranging from 37.7 to 60 Gy (median dose, 45 Gy).[417] The 10-year local control rate was 92%, with a median follow-up time of 15 years. On the basis of their experience, the investigators recommended 45 Gy in 1.8-Gy fractions when radiation was used. Their review of the literature showed local control rates ranging from 83% to 100% in series using radiation therapy for temporal bone glomus tumors. A few reports have described stereotactic radiosurgery using single large fractions (20 to 25 Gy)[419,420]; the follow-up is short, however, and this modality cannot be considered to be a standard treatment for this disease.

Therefore, both surgery and irradiation can offer excellent local control for glomus tumors. The decision between the two often is based on consideration of treatment complications. It may be reasonable to use primary resection for early-stage base of skull glomus tumors in which the risk of surgical complication should be low and to reserve radiation therapy for patients with large tumors or with incomplete surgical resections.

PINEAL REGION TUMORS

The pineal gland is located adjacent to the cerebral aqueduct and brainstem. Therefore, tumors in this location frequently obstruct the posterior aspect of the third ventricle and aqueduct of Sylvius, causing acute hydrocephalus with headaches, papilledema, nausea, vomiting, diplopia, and lethargy. As tumors grow anteriorly, the midbrain tegmentum and quadrigeminal plate are compressed resulting in Parinaud's syndrome: paralysis of upward gaze, diminished pupillary response to light and retractory or convergence nystagmus.

In the United States and Europe, tumors of the pineal region account for less than 0.5% to 1% of all intracranial tumors.[421] In Japan, however, they account for 3% of all intracranial tumors. Tumors in this location are much more common in childhood and account for 3% to 11% of intracranial tumors in this age group.[422]

In series from the United States and Europe, roughly a third of all pineal region tumors are germ cell tumors, a majority of which are germinomas.[421,423] In Japan, germ cell tumors comprise a larger percentage of all pineal region tumors because germinomas are much more common than in the West. Because germ cell tumors occur most commonly in the second decade of life, they are discussed in the section on childhood brain tumors. Approximately a third of pineal region tumors are of glial origin, mostly astrocytomas, but also glioblastomas, oligodendrogliomas, and ependymomas. These tumors are managed in a similar manner as for their counterparts in other parts of the brain, as discussed elsewhere in this chapter.

Pineal parenchymal tumors (PPTs) account for slightly less than a third of all pineal region tumors. A little less than half of PPTs are pineocytomas; the other half are pineoblastomas. Pineocytomas are histologically benign neoplasms composed of well-differentiated pineal parenchymal cells. These tumors generally affect young adults and rarely disseminate. In one study, the 5-year actuarial survival rate for nine patients with pineocytomas was 86%.[424] After resection, all of these patients received local field radiotherapy to a dose greater than 50 Gy without craniospinal irradiation.

By contrast, pineoblastomas consist of embryonal cells indistinguishable from those characteristic of PNETs in other CNS sites, tend to disseminate through the CSF, and have a much poorer prognosis than pineocytomas. Pineoblastomas are rare in adults,[425] generally occurring in the first 2 decades of life. Management of these pineoblastomas is similar to that of other supratentorial PNETs, as discussed later under Childhood Brain Tumors. A small percentage of PPTs (less than 10%)—mixed pineocytoma-pineoblastoma tumors or PPTs of intermediate differentiation—do not fit either of the two categories.[426] These tumors, like pineoblastomas, have the capacity to seed the CSF; therefore, some experts have recommended craniospinal irradiation for management in such cases.[426] In one study, the 5-year survival rate for patients with PPTs excluding pineocytomas (15 pineoblastomas, 2 mixed PPTs, 4 PPTs with intermediate differentiation) was 49%.[424] A multicenter retrospective study examining adults with PPTs found that those with tumors of intermediate differentiation had a better outcome than those with pineoblastomas: 10-year survival rates of 72% versus 23%, respectively ($P = 0.001$), and rates for control of spinal disease at 10 years of 81% and 50% ($P = 0.04$).[425]

TUMORS OF THE SPINAL AXIS

Clinical and Pathologic Considerations

Tumors of the spinal cord are far less common than intracranial tumors, accounting for only 15% of all CNS tumors. The distribution of histologic types of tumors involving the spinal axis is different from that of tumors affecting the brain (Table 70-12).[427] For example, neuromas (schwannomas) account for almost one fourth of all spinal axis lesions but are very uncommon in the brain. Most spinal axis tumors are intradural, although chordomas are extradural (see Table 70-12). Clinically these tumors manifest in one of three ways: (1) radicular pain secondary to compression or infiltration of spinal cord roots, causing a knife-like sensation along the nerve distribution; (2) sensorimotor deficits dependent on the level of the tumor, characterized by muscle weakness, paresthesias (pain and temperature abnormalities contralateral to the side of muscle weakness; and (3) central syringomelia with destruction of the central gray matter causing motor neuron destruction and muscle wasting, loss of pain and temperature sensation with preservation of touch.

The imaging modality of choice for spinal tumors is MRI.[428] Both meningiomas and schwannomas are intradural but extramedullary. The signal intensity of meningiomas on T_1- and T_2-weighted images is similar to that of the normal cord whereas for neuromas the signal is increased on T_2-weighted images. Meningiomas typically enhance with gadolinium. Spinal cord ependymomas and astrocytomas generally are intramedullary tumors. The exception is ependymoma involving the conus medullaris, which is not actually an intrinsic tumor of the spinal cord. Ependymomas and astrocytomas of the spinal cord have a similar appearance on MRI. T_1-weighted images show an enlarged spinal cord extending for several vertebral body segments. Both astrocytomas and ependymomas may have cysts that are visible on MRI. T_2-weighted images show increased signal intensity in the region of the tumor, with accompanying adjacent edema. Both tumor types typically enhance with gadolinium although there are rare

Table 70-12 Primary Spinal Axis Tumors: Distribution by Histologic Type

Tumor	Location	Frequency (%)
Meningioma	Intradural; extramedullary	42
Schwannoma	Intradural; extramedullary	22
Ependymoma*	Intradural; intramedullary	15
Astrocytoma	Intradural; intramedullary	11
Other		6

*Ependymomas of the spinal cord are intramedullary, but myxopapillary ependymomas of the cauda and filum terminale are intradural but extramedullary.

Data from Los Angeles County, 1972–1985 (reported by Preston-Martin[427]).

exceptions. The gadolinium enhancement in ependymomas tends to be very homogenous with clear demarcation of the upper and lower extent, unlike astrocytomas, in which the true extent often is underestimated by MRI. Because they arise from cells in the central canal, ependymomas are centrally located and expand circumferentially. In contrast, astrocytomas can originate from anywhere in the spinal cord. The differential diagnosis of these tumors includes various nonmalignant conditions such as multiple sclerosis, transverse myelitis, and infarction of the cord. Hemangioblastomas are much less common than astrocytomas or ependymomas. They show enlargement of the spinal cord with multiple cysts. One or more intensely enhancing nodules may be present in the cyst wall.

Chordomas Involving the Spinal Axis

Chordomas involving the base of the skull have been discussed earlier; however, these tumors also can involve the sacrum or the mobile spine. Unlike the other histologic tumor types listed in Table 70-12, chordomas are extradural tumors. Radiation therapy has been used but with poor results. In a series from the Princess Margaret Hospital, 48 patients with chordoma (23 of the sacrum, 5 of the mobile spine, and 20 of the base of the skull) received radiation therapy, most immediately after initial diagnosis but some after local failure after surgery.[429] Survival rates were 54% at 5 years and 20% at 10 years, and patients with nonclival disease did just as poorly as patients with clival disease.

In patients with chordomas of the sacrum or spine who are able to undergo a radical resection, there is a reasonable chance for long-term local control and cure. In a series from the Sahlgrenska University Hospital in Sweden, 39 patients (30 involving the sacrum, 9 involving the mobile spine) underwent surgery as the primary treatment.[430] Most patients presented with pain, but many also had neurologic symptoms. En bloc surgical resection was performed in 35 cases. The final surgical margins were negative for tumor in 23 patients but only marginal or positive in 16. With a mean follow-up time of 8.1 years, 23 patients (59%) were found to be disease-free at the time of last follow-up evaluation. Local recurrence was seen in 17 patients (44%), and distant metastases in 11 (28%). The estimated 10- and 15-year survival rates were 64% and 52%, respectively.

Spinal Meningiomas

Meningiomas are the most common spinal axis tumor (see Table 70-12). They are associated with neurofibromatosis 2, as are their intracranial counterparts.[326] The prognosis with surgery is excellent. In a large series of meningiomas from MGH treated with surgery alone, 18 (8%) involved the spine (see Table 70-12).[323] No failures were observed at 5 years, and a 13% recurrence rate at 10 years. In a report from the Milan Neurologic Institute, the crude recurrence rate was 6% in 150 patients with spinal meningiomas who had a complete tumor resection versus 17% in the 6 patients who underwent subtotal resection.[431] Of 80 patients who had undergone a total resection at the Cleveland Clinic, only one relapsed, at 8 years.[432] Even the seven patients who had a subtotal resection did well, with only two relapsing, one at 13 and one at 16 years. These findings indicate that patients with these tumors do very well after total resection. In the event of subtotal resection, radiation therapy should be considered, as in the case of intracranial meningioma.

Spinal Schwannomas

Schwannomas (neuromas) arise from the Schwann sheath, which covers the extramedullary axons of the nerve roots. They are evenly distributed throughout the cervical, thoracic, and lumbar regions but are uncommon in the sacral region. The lesions are benign and well encapsulated; therefore, total surgical resection usually is possible and is curative.

Spinal Cord Ependymomas

Although spinal cord ependymomas are less common than meningiomas and schwannomas involving the spinal axis (see Table 70-12), they account for 60% of all intramedullary tumors. They occur more frequently in the middle adult years and are rare in children. Because of their central location within the spinal cord, ependymomas often manifest with dysesthesias followed by progressive motor dysfunction but without objective evidence of sensory dysfunction.[433] A variety of histologic subtypes have been described, including cellular (the most common), epithelial, fibrillar, malignant, and myxopapillary. The last subtype is seen only in the filum terminale or the conus medullaris and is, therefore, technically not an intramedullary tumor.

Spinal cord ependymomas have a more favorable outcome than that noted for intracranial ependymomas. The primary treatment for these tumors is surgery. Although not usually encapsulated, benign spinal cord ependymomas generally do not infiltrate adjacent normal tissue. Therefore, the surgeon usually can find a plane between tumor and normal tissue, allowing for gross total resection, which is associated with a very low rate of recurrence. In one series of 38 patients with spinal cord ependymomas who underwent a gross total resection, none had recurred after a mean follow-up time of 24 months.[433] In another series, of 11 patients with spinal ependymomas who underwent gross total resection, only one patient required a second operation for recurrent tumor.[434] By contrast, of 13 patients who underwent a subtotal resection, continued tumor growth led to a second operation in 5 patients and death in 1 patient.

It is hard to assess the role of postoperative radiation for this tumor because of the limited number of retrospective studies with small numbers of patients. Generally postoperative radiation has been given to patients who had a subtotal resection. In a review of 11 series using surgery followed by postoperative radiation for spinal ependymomas, both the 5- and 10-year survival rates ranged from 60% to 100% with most of the series showing 5-year survival rates in the 80% to 90% range and local relapse rates from 13% to 33%.[435] In two of the largest series from the Princess Margaret Hospital[436] and the Royal Marsden Hospital/Atkinson Morley's Hospital,[437] patients with high-grade tumors had a much higher relapse rate than those with low-grade tumors. In both of these series, when failures occurred, they were usually local.

Based on the limited data available, it is difficult to make strong recommendations. However, for benign ependymomas that are totally resected, there does not appear to be a need for postoperative radiation. For incompletely resected benign ependymomas, it would be reasonable to give 45 to 50 Gy to the tumor bed. For high-grade ependymomas, some would advocate giving all patients postoperative radiation, regardless of the extent of surgical resection. The actual volume that should be irradiated is unclear. High-grade spinal ependymomas have been reported to fail intracranially. This has led some to advocate craniospinal radiation,[436] although there is little evidence that the addition of cranial irradiation adds any benefit.[437] If one considered craniospinal irradiation for a high-grade spinal ependymoma, a reasonable dose would be 36 Gy followed by a boost to the primary tumor bed to a dose of 50 to 54 Gy.

Spinal Cord Astrocytomas

Astrocytomas are slightly less common than ependymomas in the spinal cord, accounting for approximately 40% of all intramedullary spinal tumors. Most spinal astrocytomas are low-grade; in adults only 10% to 15% are high-grade. In children, high-grade astrocytomas are even less common, but pilocytic astrocytomas are seen. As with ependymomas, the initial therapy for astrocytomas of the cord is surgical resection. Astrocytomas tend to be more infiltrative than ependymomas, however, making it difficult to find a plane of resection between tumor and normal cord in order to perform a total resection.

Spinal astrocytomas have a poorer prognosis than spinal ependymomas. In a study from Hokkaido University, of 13 patients with astrocytomas and 22 ependymomas, the five-year actuarial survival rate for the two groups were 50% and 96%, respectively ($P = 0.007$). The histologic grade of the astrocytoma has as significant influence on prognosis. In a series from the Mayo Clinic, of 43 pilocytic astrocytomas and 25 diffuse fibrillary astrocytomas, the 10-year survival rates were 81% and 15%, respectively.[438] In a series from the University of California at San Francisco, 12 patients with low-grade spinal astrocytomas had a relapse-free survival of 53% whereas the 3 patients with high-grade tumors all died within 8 months.[439] The 5-year survival for patients with low-grade astrocytomas has been in the 55% to 79% range in other series[440,441]; however, for high-grade astrocytomas, it is rare to have survivors at 5 years, with a median survival period of 1 year or less.[441,442]

As with spinal astrocytomas, it is hard to conclusively demonstrate that postsurgical radiation improves outcome; however, generally it has been given to patients who have had a subtotal resection. Most investigators have used 45 to 50 Gy to local fields for low-grade astrocytomas. High-grade astrocytomas have been known to recur with CNS dissemination, leading some to recommend craniospinal irradiation. However, in spite of such aggressive therapy, these tumors still recur.

There are no strong data supporting the use of chemotherapy for spinal cord astrocytomas. However, nitrosureas and other agents used in intracranial astrocytomas have been used with anecdotal reports of efficacy (reviewed by Balmaceda[443]).

Miscellaneous Intramedullary Tumors

Of the 10% of intramedullary spinal cord tumors that are not ependymomas or astrcocytomas, there is a mixture of uncommon tumors including hemangioblastomas, ependymomas, and gangliogliomas (reviewed by Miller and McCutcheon[444]). Although exceedingly rare, there are reports of primary intramedullary germ cell tumors and PNETs.[443,445]

Hemangioblastomas are benign vascular lesions associated with von Hippel-Lindau disease in 10% to 30% of cases, as is the case for their cerebellar counterpart (discussed in the Cerebellar Hemangioblastomas section). They typically occur in men in their fourth decade of life. Most of these tumors appear as an enhancing tumor nodule within a cyst or syrinx. Because they have well-defined margins, surgical resection usually provides a cure, although care must be taken to avoid excessive bleeding of these vascular tumors.[446]

Subependymomas are benign well-circumscribed lesions that affect men between 30 and 60 years of age. Subependymomas typically are avascular and well demarcated from the normal cord, enhancing the feasibility of complete surgical resection. Gangliogliomas generally are benign tumors that have neuronal differentiation. They usually are seen intracranially, but tumors in the spinal cord have been reported. The primary treatment for these tumors is complete surgical resection; however, this approach is associated with a significant risk of recurrence. In one series of 30 spinal gangliogliomas, the 5-year actuarial survival rate was 84%, but the 5-year event-free survival rate was only 36%.[447]

CHILDHOOD BRAIN TUMORS

Primary CNS tumors are the most common solid tumors and the leading cause of cancer-related morbidity and mortality in children.[448] CNS neoplasms constitute 24% of all malignancies in children younger than 14 years of age in the United States. An estimated 3410 new cases of childhood (age 0 to 19 years) primary benign and malignant brain tumors were diagnosed in 2005.[1] Of these, 2330 were estimated to be in children younger than 15 years. The annual age-adjusted incidence rate is currently approximately 3.9 per 100,000 children.[449,450] During the period 1973 through 1994, the reported incidence of primary malignant brain tumors among children in the United States increased by 35%.[450] This increase may be due to improved detection and reporting facilitated by the availability of high-resolution neuroimaging.[451]

These observations also raise serious concerns that environmental factors may play a substantial causative or contributory role. Despite these concerns, epidemiologic studies investigating maternal nutritional intake, childhood diet, childhood exposure to electromagnetic fields, and parental occupational exposure have not established direct links between these factors and the development of childhood brain tumors.[452–455] As noted earlier in the section on epidemiology, however, strong data support a connection between cranial irradiation in childhood and the subsequent development of brain tumors.

Hereditary factors are estimated to be primarily responsible for approximately 2% of childhood brain tumors.[27] Nearly 70% of all optic pathway gliomas occur in patients with neurofibromatosis type 1 (NF-1),[456] and almost all childhood vestibular schwannomas occur in patients with NF-2. Hereditary immunosuppression disorders, as seen in Wiskott-Aldrich syndrome and ataxia-telangiectasia, as well as treatment-associated immunosuppression, as in organ transplant recipients, or exogenous immunosuppression, as in HIV infection, are known to be associated with an increased risk of primary CNS lymphomas.[457–459]

Primitive Neuroectodermal Tumors

PNETs constitute 23% of pediatric CNS tumors and are the most common malignant brain tumor in childhood.[453] When located in the cerebellar vermis, the site of approximately 85% of all CNS PNETs, these tumors usually are called *medulloblastomas*. Other common locations include the pineal region (pineoblastoma, 10%) and supratentorial regions (5%).[460–462] The nosology of these tumors is the subject of long-standing controversy among neuropathologists. Rorke has suggested that they be grouped together as primitive neuroectodermal CNS tumors (i.e., PNET) on the assumption that they each arise from neoplastic transformation of pluripotent uncommitted neuroectodermal precursors.[463,464] For cerebellar medulloblastoma (i.e., PNET/MB), recent evidence supports the hypothesis that that these tumors arise from disordered cerebellar granular cell development.[465] The cells of origin for pineal and supratentorial PNETs have not been identified; however, microarray studies demonstrate different patterns of gene expression for medulloblastoma, pineal, and supratentorial PNETs.[466]

A variety of cytogenetic and molecular genetic abnormalities have been observed in childhood PNETs. The most common, observed in 40% to 50% of cases, is a deletion of the short arm of chromosome 17, typically resulting in the formation of an isochromosome i(17q).[463] Putative tumor suppressor locations have been identified on 17p and 9q. Multivariate analysis has not clearly identified a clinical prognostic significance for 17p deletion either altering clinical outcome or associated with higher metastatic stage.[467] A putative tumor suppressor locus located on the long arm of chromosome 9 has been identified in 10% to 18% of PNETs.[468,469] The locus for nevoid basal cell carcinoma syndrome (Gorlin's syndrome) has been mapped to this region of chromosome 9. The gene responsible for nevoid basal cell carcinoma syndrome is the human homologue of the *Drosophila* Patched-encoding gene (*PTCH*).[470] It encodes a cell surface receptor that, among other functions, regulates normal brain development by repressing transcription of genes encoding members of the transforming growth factor-β (TGF-β) and Wnt families of signaling proteins.[471] Sonic hedgehog is a PTCH ligand that has many functions as an oncoprotein in mammalian tumors.[472] The incidence of PNET/MB among patients with nevoid basal cell carcinoma syndrome is reported to be approximately 4%.[473] Mutations in *PTCH* have been identified in nearly 12% of sporadic PNET/MBs,[474] and one PNET/MB was shown to contain a mutation in the Sonic hedgehog gene.

These observations indicate that multiple genes in the Sonic hedgehog PTCH signaling pathway contribute to PNET tumorigenesis.

The clinical presentation with PNET/MB is dominated by signs and symptoms of obstructive hydrocephalus and increased ICP: headache, nausea, and vomiting; drowsiness and other behavior changes; and ataxia. These clinical characteristics often are indistinguishable from those of other posterior fossa tumors, including ependymoma and cerebellar astrocytoma. To differentiate posterior fossa tumors, computer-based neural networks combining data from neuroimaging studies (Fig. 70-22A–C) and patient characteristics have been successfully used. In a series of 33 children with posterior fossa tumors, an experienced neuroradiologist was able to correctly predict the tumor type in 73% of cases, whereas the neural networks using different datasets had 95% accuracy.[475]

Preoperative management includes the assessment and treatment of increased ICP. Patients with papilledema and significant visual impairment require emergency placement of an external third ventricle drain, followed immediately by tumor resection. Prolonged delay between ventricular drainage and tumor resection significantly increases the risk of transtentorial upward herniation. For patients with less severe signs and symptoms of increased ICP, corticosteroids and acetazolamide (Diamox) may be used to relieve symptoms, reduce tumor swelling, and permit further surgical planning.

Surgical treatment of PNET/MB has three objectives. First, sufficient tissue must be obtained to permit accurate histopathologic diagnosis. Second, tumor removal should be complete or near-complete, because complete tumor removal favorably influences prognosis.[476] Third, every effort should be made to reestablish normal CSF flow. A majority of children with PNET/MB will not need a permanent ventriculoperitoneal shunt. The incidence of tumor dissemination to the abdomen by ventriculoperitoneal shunt is extremely low.[477]

Two postoperative syndromes may complicate the clinical course of patients with PNET/MB and other posterior fossa tumors. Aseptic meningitis may occur in up to 5% of patients undergoing posterior fossa surgery and is not limited to those with PNET/MB. Fever and meningismus, ranging in intensity from mild to severe, develop 5 to 10 days after surgery. Although this complication may occur more frequently in patients with large postoperative pseudomeningoceles under tension, no clinical features have been found to reliably distinguish this presumed chemical meningitis from bacterial meningitis. Therefore, CSF analysis and culture are essential. If no infectious etiology is identified, this complication may be effectively treated with corticosteroids. A second syndrome, that of cerebellar mutism after resection of posterior fossa tumors, was noted in the early 1980s.[478,479] This condition is far more common than was originally reported and occurs in up to 15% of children with large midline cerebellar tumors.[480] Complete or near-complete loss of speech often is accompanied by severe lower cranial nerve, cerebellar, and motor abnormalities as well as visual disturbances.[481] Cerebellar mutism typically manifests 1 to 4 days after surgery and may be more frequent in cases of aggressive surgical pursuit of PNET/MB adherent to or invading the brainstem. Most patients with this syndrome recover functional speech during a period of several weeks to months from onset, although it is common to have significant residual dysfunction in speech, lower cranial nerve conduction, and motor coordination.

The need for adjuvant therapy in PNET/MB is determined by postoperative staging for prognostic risk factor assessment. The most important clinical prognostic factor is metastatic stage, followed by postoperative residual tumor volume, tumor location, and patient's age at diagnosis.[476,482,483] PNET/MB commonly is associated with seeding of the spinal cord (Fig. 70-23). Accordingly, three tumor staging studies are important for PNET/MB: (1) neuraxis staging evaluation by spinal MRI (performed preoperatively or 10 to 14 days after surgery) to identify metastatic tumor aggregates; (2) CSF cytologic examination (performed intraoperatively or 10 to 14 days after surgery) to identify leptomeningeal tumor spread; and (3) postoperative neuroimaging to assess residual tumor. On the basis of these studies, patients with PNET/MB can be classified into two risk-for-recurrence groups—standard risk and high risk. Standard-risk patients must have no evidence of metastatic disease, 1.5 cm or less of residual tumor, be older than 3 years at diagnosis, and have primary tumor located in the posterior fossa only.[484] High-risk patients have one or more of the following conditions: evidence of leptomeningeal tumor spread; greater than 1.5 cm of residual tumor; age younger than 3 years at diagnosis; or primary tumor location outside the posterior fossa.

Clinical prognostic factors alone are not sufficient to distinguish a low-risk from a standard-risk group. Furthermore, a potentially very-high-risk group of patients may benefit from therapy regimens significantly different from those for standard- or high-risk PNET/MB. It is unlikely that additional clinical prognostic factors will be identified, and the identification of biologic prognostic factors will facilitate a more sensitive and specific stratification of patients to risk-adopted therapies. Accordingly, biologic studies of large, representative and relatively homogeneously treated PNET/MBs are of great interest. Independent retrospective studies of patients with childhood PNET demonstrate that tumor expression of the neurotrophin receptor TrkC is a potent biologic prognostic factor.[485,486] Other candidates include HER2/HER4 coexpression,[487] GFAP expression,[488] *MYC* amplification,[469] and PDGFR expression.[489] Larger prospective studies are planned to determine if these new biologic factors will supplement, or supplant, the significance of clinical factors.

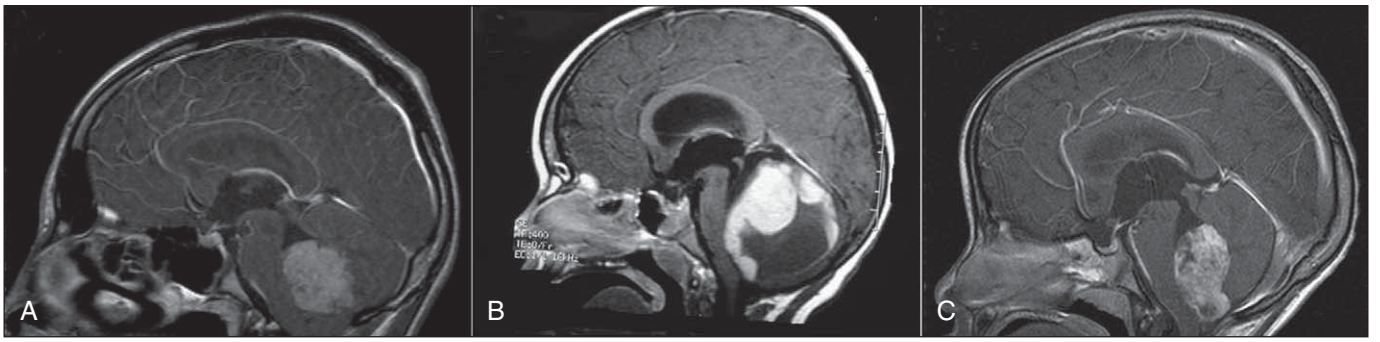

Figure 70-22 • Posterior fossa tumors. Sagittal T_1-weighted post-gadolinium magnetic resonance imaging of three different posterior fossa tumors: **A,** Medulloblastoma shows homogeneous contrast enhancement without evidence of cyst formation. **B,** Cerebellar pilocytic astrocytoma shows prominent cyst or multicyst formation, with one or more contrast-enhancing mural nodules. **C,** Ependymoma arising from the floor of the fourth ventricle shows a heterogeneous contrast enhancement pattern and extends inferiorly to the upper cervical spinal cord. Note that the pilocytic astrocytoma shows intense enhancement despite being a low-grade glioma (WHO grade I).

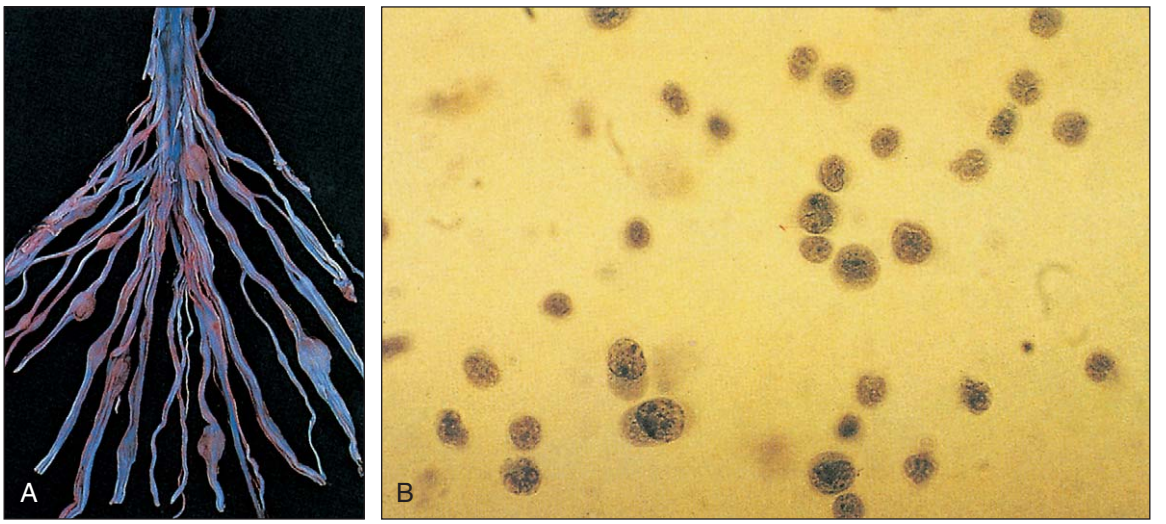

Figure 70-23 • Disseminated medulloblastoma. **A,** "Studding" of caudal nerve roots from spinal arachnoid spread of tumor. **B,** Malignant cells identified on cytologic examination of cerebrospinl fluid. (From Maher EA, McKee AC: Neoplasms of the central nervous system. In Skarin AT [ed]: Dana-Farber Cancer Institute Atlas of Diagnostic Oncology, 3rd ed. St. Louis, Mosby, 2003, p 415.)

Treatment approaches for PNET/MB are determined by assignment of the patient to either a standard- or a high-risk category. Four general trends have emerged. Patients in the high-risk category receive 36 Gy of radiation to the craniospinal axis and chemotherapy. Patients in the standard-risk category are eligible for treatment with less intensive approaches, including reduced craniospinal irradiation (e.g., 2400 cGy) to decrease the risk of significant treatment-associated toxicities. Infants and children younger than 3 or 4 years of age may be given intensive chemotherapy alone to postpone or avoid the neurotoxic effects of radiation on developing brain. Newer protocols combine systemic and intrathecal chemotherapy with conformal radiation therapy to the tumor bed. For recurrent tumors, the introduction of high-dose chemotherapy followed by peripheral blood stem cell (PBSC) rescue may offer some hope for retreival, especially for patients with minimal residual disease before high-dose chemotherapy. Nevertheless, the prognosis for recurrent PNET/MB remains very poor.

Radiation therapy is the mainstay of PNET/MB treatment. Cumulative local tumor doses should be approximately 56 Gy. Doses less than 50 Gy have been shown to be less effective.[490] Radiation should be delivered to the entire craniospinal axis, regardless of the tumor metastatic stage.[491] Treatment with craniospinal irradiation (to a dose of 36 Gy) and local boost radiotherapy (for a total dose of 54 Gy) without adjuvant chemotherapy results in long-term disease control in approximately 60% of children with PNET/MB.[492] After whole-brain radiotherapy, however, many children will have significant long-term neurocognitive sequelae, including a demonstrable drop in overall intelligence. This decline in intelligence is influenced by age at irradiation and dose used. Silber and colleagues reported that patients who received a dose of 36 Gy to the whole brain scored 8.2 points less on intelligence quotient (IQ) testing than those with 24 Gy, and 12.3 points less than those who received 18 Gy.[493] Older age at the time of irradiation was associated with less decline in subsequent IQ score.

Serious long-term side effects of radiotherapy on the developing nervous system prompted efforts to reduce the dose of craniospinal radiation therapy in nonmetastatic PNET/MB. The lowest craniospinal radiotherapy doses reported, 18 Gy in 10 fractions, with 50.4 to 55.8 Gy to the posterior fossa tumor bed, has been used in combination with vincristine during irradiation and subsequent vincristine, CCNU, and cisplatin.[494] Ten patients between 18 and 60 months of age, and without evidence of tumor dissemination, received treatment according to this approach. With a median follow-up time for living patients of 6.3 years, the survival rate at 6 years was 70% ± 20%. The three patients who relapsed all were found to have spinal metastases, in association with brain or posterior fossa recurrence. These data suggest that a subset of patients with these tumors can be cured with chemotherapy and reduced doses of craniospinal irradiation.

The optimal dose of craniospinal radiation therapy remains uncertain. A prospective single-arm study reported the use of 23.4 Gy for craniospinal radiation therapy, standard local radiotherapy (55.8 Gy), and adjuvant vincristine, CCNU, and cisplatin chemotherapy given during and after radiotherapy.[495] After 3 years, the progression-free survival rate for 68 children aged 3 to 10 years with nondisseminated PNET/MB treated with this approach was 86% ± 4%.

Prospective studies demonstrate that chemotherapy has an important role in the treatment of high-risk PNET/MB. PNET/MB are responsive to a variety of chemotherapeutic agents, including cisplatin, cyclophosphamide, vincristine, CCNU, and busulfan.[496] Incorporation of cisplatin, CCNU and vincristine into a postirradiation chemotherapy regimen for high-risk patients resulted in 5-year survival rates in excess of 80%.[497] Of note, this survival rate was significantly higher than survival rates for standard-risk patients treated with radiation therapy alone (i.e. historical controls). This and other single-institution studies have provided strong support for the use of effective adjuvant chemotherapy for all PNET/MB patients.

High-dose chemotherapy (HDCT) with peripheral blood stem cell (PBSC) rescue is a therapeutic strategy that has shown encouraging results in the treatment of relapsed PNET/MB.[498] In children with recurrent PNET/MB, Kalifa and associates used a high dose busulfan-thiotepa regimen.[499] Of 28 patients evaluable for tumor response, complete tumor resolution was obtained in 36%, a partial response in 39%, and no response in 25%. Finlay and colleagues reported a series of 23 patients with recurrent PNET/MB.[500] The chemotherapy consisted of carboplatin, thiotepa, and etoposide followed by PBSC rescue. Three patients died of treatment-related toxicities. Overall, 7 of the 23 patients (30%) remained free from tumor recurrence at a median follow-up of 54 months after HDCT. These results are better than previously reported phase II trial results. Prospective collaborative national and international studies will determine different HDCT regimens that not only aim at maximiz-

Box 70-5. MANAGEMENT OF MEDULLOBLASTOMAS AND PRIMITIVE NEUROECTODERMAL TUMORS

- Medulloblastoma and related primitive neuroectodermal tumor (MB/PNET) constitute the most common malignant childhood brain tumor.
- Surgical objectives include gross total resection to establish diagnosis, restore cerebrospinal fluid (CSF) flow, and improve survival.
- Postoperative staging should be undertaken in all patients and should include magnetic resonance imaging (MRI) of the brain within 24 hours of surgery, an MRI study of the entire spine 10 to 14 days after surgery, and CSF cytologic studies 10 to 14 days after surgery. These studies determine subsequent risk-based treatments.
- Standard-risk patients must meet *all* of the following criteria: age older than 3 years, cerebellar location, little or no residual tumor (less than1.5 cc), and *no* evidence of metastatic tumor spread. All other patients are considered to be in the high-risk category.
- Treatment in standard-risk patients consists of lower-dose craniospinal RT to doses of approximately 24 Gy in 1.8-Gy daily fractions, tumor doses of approximately 55.8 Gy, and less intensive chemotherapy.
- MB/PNET in high-risk patients is treated with craniospinal irradiation to doses of approximately 36 Gy in 1.8-Gy daily fractions, tumor irradiation to doses of approximately 55.8 Gy, and intensive chemotherapy.

ing survival but also address toxicity and quality of life. Box 70-5 summarizes the recommended approach to management of medulloblastomas and primitive neuroectodermal tumors.

Low-Grade Astrocytomas of Childhood

Low-grade gliomas-astrocytomas occur throughout the brain and spinal cord. The predominant histologic subtype for cerebellar astrocytomas is pilocytic, whereas optic pathway or hypothalamic low-grade gliomas are more commonly fibrillary in appearance. Optic pathway or hypothalamic gliomas may be classified by location as follows: (1) those anterior to but not involving the chiasm, (2) chiasmal tumors with extension posteriorly along the optic radiations, and (3) chiasmal-hypothalamic tumors for which the initial site of tumor growth cannot be determined.

Optic Nerve Gliomas Anterior to the Chiasm

Optic nerve gliomas anterior to the chiasm manifest with symptomatic and progressive visual loss or proptosis, or both. Their appearance on CT and MRI studies usually is sufficiently diagnostic that routine biopsy is not necessary. Meningiomas of the optic nerve sheath often can be distinguished from optic nerve gliomas on the basis of neuroimaging characteristics. Optic nerve gliomas should be treated conservatively. Progressive tumor growth together with severe visual dysfunction justifies surgical resection of the nerve. Surgical resection is curative, and no further therapy is required. As a rule, optic nerve gliomas anterior to the chiasm do not invade the chiasm itself. For patients with progressive tumor growth and functional vision, radiation therapy is rarely indicated, and current chemotherapy is similar to that for chiasmal gliomas, discussed next.

Chiasmal and Chiasmal-Hypothalamic Gliomas

Chiasmal and chiasmal-hypothalamic gliomas constitute 60% to 85% of all optic pathway-hypothalamic tumors. These tumors, especially very large chiasmal-hypothalamic glioma, often come to medical attention before the age of 5 years with signs and symptoms of visual loss and hydrocephalus. Older children are more likely to present with symptoms, which include those of endocrinopathies and behavioral changes. Children younger than 2 years of age may present with a diencephalic syndrome characterized by frequent vomiting, anorexia, and failure to thrive.[501] In children with chiasmal tumors involving the optic nerve, the diagnosis frequently is made on the basis of radiographic criteria alone. Especially in children with NF-1, diffuse enlargement of the optic chiasm, with extension posteriorly along the optic radiations to the geniculate bodies and beyond, may be sufficiently characteristic to permit reliable diagnosis. Surgical biopsy with histologic confirmation is advisable for large globular tumors with hypothalamic involvement. Although diagnostic confusion is not common, these tumors may have a clinical and neuroimaging appearance similar to that of solid craniopharyngiomas or germ cell tumors.

Most chiasmal and chiasmal-hypothalamic gliomas are not "cured" by currently available surgical approaches, radiation therapy, or chemotherapy. The slow and often erratic growth of these tumors has led some experts to conclude that most of these "benign" tumors will eventually be fatal.[502] In the past decade, the development of more effective chemotherapy strategies makes this conclusion far less certain, and a majority of patients remain alive without progressive tumor growth in excess of 10 years. In most cases, the decision to initiate treatment is based on clinical or radiographic evidence of tumor growth from serial observations, rather than automatically initiating treatment at the time of tumor diagnosis. Patients with severe visual loss or clear historical evidence of rapid clinical worsening represent exceptions to this approach. Whereas some patients show significant changes in visual acuity or neuroimaging scans within weeks or months of initial diagnosis, many others remain clinically stable for months or years without interval treatment.

For patients who retain a degree of useful vision, chiasmal and chiasmal-hypothalamic gliomas cannot be completely resected. Surgical debulking of large chiasmal-hypothalamic gliomas, however, is increasingly recognized to provide rapid relief of symptoms caused by mass effect and hydrocephalus, delay the need for radiation therapy in young children, result in years of clinical stability without tumor growth, and improve the effectiveness of subsequent radiation therapy.[503,504]

Local involved-field radiation therapy has been shown to be effective in arresting tumor growth and causing tumor shrinkage.[505,506] Complete tumor regression is rare after irradiation, however. Because more than 90% of patients with optic pathway-hypothalamic gliomas survive longer than 10 years,[505,507] the late effects of radiation therapy, including neurocognitive problems, endocrinopathy, optic nerve injury, and radiation-induced second neoplasms, are important considerations. These issues have stimulated the investigation of alternative treatment approaches, including chemotherapy.

Chemotherapy has a defined role in the treatment of optic pathway-hypothalamic gliomas. In a large multi-institutional trial of carboplatinin and vincristine, 60% of the patients with progressive low-grade glioma had a significant reduction in tumor volume, and another 30% of patients had tumor stabilization.[508] A different regimen developed at University of California at San Francisco included procarbazine, 6-thioguanine, dibromodulcitol, CCNU, and vincristine. This treatment protocol resulted in prolonged periods of disease stabilization with a median time to tumor progression of 132 weeks in children with low-grade gliomas.[509] For younger children, particularly those younger than 5 years of age, the use of chemotherapy delays or obviates the need for radiation therapy, thereby reducing or eliminating the neurologic morbidity associated with radiation therapy in young children. Currently used chemotherapy regimens for optic pathway tumors generally are well tolerated, can be administered in the outpatient setting, and are not associated with a high incidence of serious late effects. Because of the successful outcomes with chemotherapy in younger children, the use of chemotherapy to treat these tumors in older patients has been attempted. It remains to be proved, however, whether the duration of

progression-free survival for patients treated with chemotherapy is comparable to that for radiotherapy.

The incidence of optic pathway tumors in patients with NF-1 is markedly higher than in the general population. Up to 15% of children in whom the diagnosis of NF-1 is confirmed will be found to have optic pathway tumors when they undergo screening neuroimaging.[510] Most optic nerve gliomas in patients with NF-1 are anterior to the optic chiasm. In slightly more than half of all children with radiographically identifiable optic pathway tumors, however, signs or symptoms directly related to their tumors ultimately developed. When studied systematically, these tumors appear to behave in a more indolent fashion than their counterparts in children who do not have NF-1. However, low-grade gliomas in children with NF-1 are notoriously erratic in their natural history. At times, these tumors appear to undergo rapid growth and then spontaneously arrest. Treatment of anterior optic nerve glioma is necessary only with significant symptomatic tumor progression. Consequently, routine screening neuroimaging of asymptomatic patients is unwarranted.[456] Because optic pathway tumors nearly always arise in children younger than 10 years of age, all younger children with NF-1 should undergo yearly ophthalmologic evaluation and annual assessment of growth to monitor for signs of precocious puberty.

As with their non-NF-1 counterparts, management of children with NF-1 and optic pathway glioma is dependent on the location of the tumor. Anterior optic pathway gliomas do not invade the chiasm in NF-1 patients and are managed according to the clinical symptoms. Chiasmatic optic pathway gliomas are watched closely for neuroimaging or clinical evidence of tumor progression. Progressive chiasmal tumors are treated with chemotherapy strategies associated with a relatively low incidence of second malignancies (e.g., carboplatin and vincristine). Use of nitrosoureas in children with NF-1 is associated with an increased risk of myeloid leukemia. In addition, a pervasive concern remains that use of radiation therapy in this patient population with an increased incidence of glial brain tumors will result in an unacceptably high incidence of treatment-induced secondary brain tumors. The challenge for the future is to determine the most appropriate treatment for each patient, based on rate of tumor progression, age, prior therapy, and visual and endocrine status.

Cerebellar Astrocytomas

Cerebellar astrocytomas of childhood typically are pilocytic or low-grade fibrillary on histopathologic examination. Malignant gliomas of the cerebellum in childhood are extremely rare. The survival rate is determined by the extent of resection, not by histological features. Use of radiation therapy is limited to those cases of recurrent astrocytoma that cannot be resected because of extensive invasion into the cerebellar peduncles or brainstem. Cerebellar astrocytomas have, arguably, the best prognosis of any brain tumor, with 10-year survival rates approaching 100%.[511] If postoperative MRI shows resectable tumor (see Fig. 70-20B), reexploration may be indicated to achieve complete resection.

Ependymoma

Childhood intracranial ependymomas represent approximately 5% to 10% of all childhood brain tumors (see Table 70-2) and behave primarily as localized, relatively noninvasive neoplasms that originate from the ventricular ependymal linings. Nearly 70% of childhood ependymomas are located in the posterior fossa arising from the floor of the fourth ventricle (see Fig. 70-22C). The remaining 30% are located in supratentorial periventricular regions. The classic histologic feature of ependymomas is the perivascular pseudorosette. Two general histologic classifications have been described. *Well-differentiated* ependymomas are moderately to highly vascular, with low mitotic indices and little cellular pleomorphism or evidence of necrosis. *Malignant* ependymomas exhibit higher mitotic rates, substantial cellular atypia, and prominent necrosis. The rare "ependymoblastoma" is best classified as a PNET with histologic evidence of ependymal differentiation and treated in a fashion identical to that for the PNETs. The role of standard histologic classification in prognosis is controversial; however, growing evidence suggests that biologic factors identified in tumor specimens, such as Erb receptor expression, may provide greater prognostic accuracy.[512]

The primary challenge in ependymoma treatment is local control, because metastatic disease at initial diagnosis or first relapse is uncommon.[513,514] Surgical resection of these tumors often is difficult, and complete removal is achieved in less than 50% of the patients. Ependymomas often are located close to brainstem structures, which increases the risk of morbidity when complete resection is attempted. Several studies confirmed the critical role of a radical surgical resection in patients with newly diagnosed ependymomas.[515,516] Five-year progression-free survival rates range from 50% to 70% after complete surgical resection and from zero to 30% after incomplete resection.[517–519] Better survival is noted in children who have undergone complete resection. The frequency of gross total resections has been increased by sophisticated technologies including ultrasonic tissue dissociators, argon lasers, and robotic localizing devices; by experience of the surgeon with childhood tumors; and by the intent and preoperative plan to perform a radical surgical resection.[520] The availability of intraoperative neuroimaging may provide immediate confirmation of the degree of resection and allow the surgeon to reoperate, immediately, if necessary.[521] For patients with residual tumor after initial surgery, re-resection immediately after the postoperative MRI study reveals residual tumor remains an option. Alternatively, deferral of second surgery until the child recovers and receives chemotherapy or radiotherapy may be considered.

Involved-field radiotherapy represents standard therapy for children older than 3 years who have intracranial ependymomas. Conventional radiation therapy doses range from 54 to 56 Gy. Controversial aspects of radiation therapy for ependymomas include treatment volume and the necessity for craniospinal irradiation. On the basis of published reports that indicated a significant risk of CSF seeding, craniospinal irradiation initially was recommended.[522] In subsequent studies, neuraxis relapse in ependymoma occurred in less than 5% of cases.[513] Routine staging for relaps includes postoperative MRI of the brain to characterize the extent of resection. MRI of the spine, as well as lumbar puncture to evaluate CSF cytology, is critically important to therapeutic planning. In the absence of disseminated disease at diagnosis, the pattern of relapse is local in the vast majority of cases and is not influenced by the delivery of craniospinal irradiation. Therefore, prophylactic craniospinal irradiation is no longer recommended. Currently evaluated strategies to enhance local tumor control in patients with residual or progressive disease include radiosurgery-based techniques.[523]

The role of chemotherapy in the treatment of ependymoma is controversial, because these tumors are considered to be relatively chemotherapy-resistant. In a study of 19 children with newly diagnosed ependymoma, a 74% 5-year progression-free survival rate was reported in children with postoperative residual tumor treated with radiation therapy and platinum-based chemotherapy.[524] This rate was higher than published results for radiotherapy alone for this group. On the basis of this finding, current clinical trials use chemotherapy for patients whose postoperative imaging studies are positive for residual tumor. For patients with recurrent ependymoma, options for further therapy other than re-resection are few; usually, maximal irradiation has already been administered, and high-dose chemotherapy is of modest benefit in only a minority of patients.[525,526] Therefore, management consists largely of symptom control and palliation.

Brainstem Glioma

Gliomas of the brainstem, distinctly uncommon in adults, represent a major tumor group in childhood. In past years, brainstem tumors

were considered to represent a single entity, uniformly fatal despite the most intensive therapies. Nevertheless, some children had continuous progression-free survival in excess of 5 years[527]; a larger number of children, however, died from progressive tumor within 18 months. To distinguish good- from poor-risk groups, investigators evaluated neuroimaging characteristics and biopsied these tumors.[527] Results from these studies identified two major classes of brainstem gliomas: (1) diffuse intrinsic brainstem gliomas, typically centered in the pons and upper medulla, which carry a uniformly poor prognosis, and (2) focal brainstem gliomas, typically located in the upper midbrain or lower medulla, which are associated with a substantially better prognosis.

Factors responsible for the initiation and progression of brainstem and supratentorial gliomas in children are poorly understood. Although a model of tumor progression has been proposed for gliomas in adults, it is unlikely that this model is applicable to gliomas in younger children. Malignant transformation from low-grade astrocytoma to malignant glioma is distinctly uncommon in children. The genetic pathways leading to primary (de novo) glioblastoma of pediatric patients appear to be different than those of adult patients, as reflected by the comparatively low frequency of *EGFR* amplification (6%) and *CDKN2A* deletion (19%) and the absence of *MDM2* amplification in childhood glial tumors.[528]

Diffuse Intrinsic Brainstem Gliomas

Diffuse intrinsic brainstem gliomas constitute more than 70% of all brainstem neoplasms. Their MRI characteristics include diffuse infiltrative enlargement of the pons and rostral medulla[529] (Fig. 70-24). T_1-weighted MRI sequences usually show mass effect and reduced signal intensity compared with normal brain. T_2-weighted MRI sequences often reveal regions of high signal intensity representing tumor infiltration with rostral extension into the midbrain and brachium pontis and lateral extension into the cerebellar peduncles. Brainstem enlargement may be unilateral and often is asymmetrical on diagnosis. The fourth ventricle usually is distorted; however, obstructive hydrocephalus is distinctly uncommon at initial presentation. The clinical presentation of diffuse pontomedullary brainstem gliomas classically involves one or more of the following abnormalities: (1) cranial nerve palsies, typically VI and VII; (2) ataxia; and (3) long tract signs, including hyperreflexia and extensor plantar responses. The prediagnostic symptomatic interval often is less than 3 months.

Figure 70-24 • Diffuse pontine glioma. Sagittal fluid-attenuated inversion recovery (FLAIR) magnetic resonance image shows diffuse infiltration of the pons by tumor.

The impetus for biopsy and autopsy studies of these tumors arose from efforts to correlate histopathologic features with clinical outcome. The brainstem is among the most eloquent brain structures, thereby reducing surgical accessibility. These studies showed that a limited surgical procedure, either stereotactic or open biopsy, can be accomplished safely with acceptable risk of morbidity.[530] Information obtained at biopsy, however, was not found to be a uniformly accurate predictor of clinical outcome, possibly because of the difficulty of obtaining a sufficiently large, representative sample.[531] In many centers, current management for these tumors avoids routine diagnostic biopsy when the clinical and neuroimaging features typical of diffuse pontomedullary brainstem gliomas are identified. Diagnostic biopsy is clearly indicated for brainstem mass lesions with an unusual MRI appearance or associated with a highly atypical clinical course. Examples of these circumstances include that of the young child with a several-year history of slowly progressive clumsiness and facial asymmetry who may have a ganglioglioma of the brainstem and the case of the child with the acute onset of facial weakness, ataxia, fever, and CSF pleiocytosis who may have a focal brainstem encephalitis.

In general, no established role is recognized for the routine resection of diffuse intrinsic brainstem gliomas. Early in the clinical course, tumor cells infiltrate widely throughout brainstem structures but still permit neurologic function to remain at normal or near-normal levels. Consequently, removal of tumor is likely to result in severe neurologic deficits. Some diffuse pontomedullary brainstem gliomas may have a cystic projection in a dorsal or lateral direction. These surface projections may provide a limited opportunity for tumor resection. It is uncommon, however, that more than 50% of the tumor can be removed, and limited debulking is unlikely to improve progression-free or total survival.

Diffuse pontomedullary brainstem gliomas are among the least responsive and most treatment-resistant childhood solid tumors. Conventional radiation therapy consists of 54 to 60 Gy, delivered using an involved-field irradiation protocol, administered in single daily fractions of approximately 1.8 to 2 Gy. This approach results in a median survival time of 9 to 13 months from diagnosis.[531] Despite encouraging single-institution reports suggesting prolonged progression-free survival for children with gliomas treated with hyperfractionated radiation therapy in which total radiation doses reached 78 Gy, larger cooperative trials failed to demonstrate a therapeutic advantage for this approach.[532–534] Radiation implants (i.e., brachytherapy) are not appropriate for these tumors, and the role of stereotactic radiosurgery has not been evaluated.

Chemotherapy trials for diffuse pontomedullary brainstem gliomas have yielded similarly disappointing results. Pre-irradiation single-agent or combination chemotherapy infrequently produces objective (i.e., radiographic) response rates that exceed 25%.[531] Furthermore, it is unlikely that even these limited response rates translate into significantly longer total survival. A phase III trial using CCNU, vincristine, and prednisone after radiation therapy failed to show a survival advantage over use of radiation therapy alone.[535] The use of more aggressive chemotherapy strategies including high-dose chemotherapy followed by PBSC reinfusion results in relatively brief-duration responses and few instances of significant tumor reduction lasting 12 months or longer.[536] Accordingly, it is difficult to support the routine use of chemotherapy in brainstem gliomas outside the setting of well-structured clinical trials.

Dorsally Exophytic Tumors

Dorsally exophytic tumors arise from the floor of the fourth ventricle. Although eventually the tumor often completely fills the ventricle, patients may have few if any neurologic signs for years before the development of signs and symptoms of obstructive hydrocephalus. MRI demonstrates a well-demarcated lesion, hyperintense on T_2-weighted images and hypointense on T_1-weighted images but enhancing with gadolinium (Fig. 70-25). Usually these tumors are low-grade fibrillary or pilocytic astrocytomas that are amenable to surgical resec-

Figure 70-25 • Dorsally exophytic brainstem glioma. Sagittal T_1-weighted post-gadolinium magnetic resonance image shows an intensely enhancing lesion filling the floor of the fourth ventricle, attached only at the floor at the level of the pontomedullary junction. Enhancement is characteristic of juvenile pilocytic astrocytomas. (From Halperin EG, Constine LS, Tarbell NJ, Kun LE: Pediatric Radiation Oncology, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 1999, p 99.)

tion. If substantial surgical tumor removal is achieved, often no adjuvant treatment is necessary and the patient can be managed with close observation using serial MRI scans. Use of local radiation therapy or chemotherapy is limited to the uncommon cases of malignant dorsally exophytic gliomas or the occurrence of significant tumor growth after surgery.[537]

Cervicomedullary Tumors

Cervicomedullary tumors occupy the inferior two thirds of the medulla and the upper portion of the cervical spinal cord. These histologically low-grade gliomas tend to extend from their cervicomedullary center in conformance with anatomic boundaries.[538] In contrast with midbrain tumors, intratumoral cysts are uncommon. The prediagnostic symptomatic interval may extend for several years. Surgical resection of these tumors is indicated with clinical or radiographic evidence of tumor growth. Although near-total resection is possible, the poorly defined interface between tumor and normal brainstem often precludes complete surgical removal of these tumors. Long-term follow-up studies indicate that many patients will not have evidence of growth for more than 5 years. When tumor growth is observed, its rate often is extremely slow, and malignant transformation has not been documented. As with the dorsally exophytic tumors, use of radiation therapy or chemotherapy is limited to those few cases in which progressive symptomatic tumor growth is observed and cannot be controlled by surgical approaches alone.

Cystic Nodular Brainstem Tumors

Cystic nodular brainstem tumors may be located in any region of the brainstem but most often are noted in the midbrain.[527] These tumors have a radiographic appearance identical to that of their cerebellar counterparts, and their histologic features typically are those of a juvenile pilocytic astrocytoma. Surgery is appropriate treatment for those symptomatic patients with unequivocal evidence of tumor growth on neuroimaging studies. When possible, resection of the mural nodule usually is curative. In cases in which the major portion of the tumor is in the ventral midbrain, surgical options are limited to a diagnostic biopsy, and treatment consists of radiation therapy or chemotherapy. Long-term survival for patients with these tumors often is in excess of 5 to 10 years, and a conservative management approach often is advisable.

Adult Brainstem Gliomas

As discussed previously, brainstem gliomas are much rarer in adults than in children. They account for less than 2% of all adult brain tumors.[539] In one study of 48 adults with brainstem gliomas, the overall median survival period was 5.4 years and the 3-year survival rate 66%.[540] The study investigators categorized them into three different groups. The most frequent type (in 48% of cases) occurred in young adults and resembled the diffuse pontine glioma of childhood in terms of clinical and radiologic presentation. The overall outcome (median survival of 7.3 years) was much better than that for pediatric diffuse pontine gliomas, however. This may be because in adults, many of these tumors were low-grade gliomas (in 9 of 11 patients who underwent biopsy, the tumor was found to have benign histologic features). The other common tumor type (in 31%), which occurred in elderly patients, showed ring-like contrast enhancement and was associated with a median survival period of only 11 months. Tumors in this category that were biopsied were found to be high-grade gliomas. The third group (8%) consisted of focal tectal gliomas, which affected young adults and had a favorable outcome.

The conclusion that adults with this disease have a better prognosis than children also was reached in a study from the Memorial Sloan-Kettering Cancer Center of 19 adult patients with brainstem gliomas. The investigators found the median survival period to be 54 months and the 5-year survival rate to be 45%.[541]

Intracranial Germ Cell Tumors

Germ cell tumors constitute 12.5% to 16% of all childhood tumors in Japan but only 3% to 11% in United States and Western European countries.[542] A majority are located in the pineal region and approximately a third in the suprasellar region. The clinical presentation of tumors involving the pineal region and the differential diagnosis for these tumors are discussed earlier under Tumors of the Spinal Axis. The clinical presentation with suprasellar germ cell tumor includes panhypopituitarismus, diabetes insipidus, and visual disturbances with usually long prediagnostic symptomatic intervals, often exceeding 1 year.

The neuroimaging characteristics of germ cell tumors, suprasellar or pineal, do not provide sufficient differentiation between germ cell tumor histologic types to render biopsy unnecessary.[542,543] The diversity of tumor types in the suprasellar or pineal region underscores the importance of adequate biopsy samples for accurate diagnosis. Small samples obtained from stereotactic biopsy may not identify mixed tumor types. Therefore, an open surgical biopsy approach, when possible, is preferred. Knowledge of histologic type influences surgical management. Complete resection is curative for well-differentiated teratomas. By contrast, chemotherapy and radiation therapies are ineffective with this tumor. The extent of surgical resection may be less important for germinomas, which are exquisitely sensitive to chemotherapy and radiation therapy, or for the malignant nongerminomatous germ cell tumors, which frequently spread throughout the CSF and are less responsive to irradiation and chemotherapy.

Histologic type also influences radiation treatment planning. Germinomas are very radiation sensitive. Of purely historical interest, 10- to 30-Gy "diagnostic" doses of radiation have been administered to unbiopsied suprasellar or pineal region tumors. If significant tumor reduction was observed, it was assumed to be a germinoma, and radiation therapy was continued to doses ranging from 40 to 56 Gy. This strategy is unacceptable in modern clinical practice for several reasons. Patients with mature teratoma and other radioresistant tumors are likely to receive unnecessary treatment. Furthermore, nongerminomatous or mixed germ cell tumors may respond briskly to radiotherapy but treatment tumor volume may then be insufficient

Table 70-13 Cerebrospinal Fluid and Serum Tumor Markers for Germ Cell Tumors

Tumor	AFP	β-HCG
Germinoma	–	±

for subsequent craniospinal radiotherapy if required. Finally, growing evidence indicates that patients with nongerminomatous or mixed germ cell tumors benefit from a combination of chemotherapy and radiotherapy.

Identification of nongermanomatous or mixed germ cell tumors may be facilitated by evaluation of specific markers in blood or CSF. Alpha-fetoprotein (AFP) is produced initially by the fetal yolk sac and later by hepatocytes. Detection of elevated levels of AFP in a patient with a CNS tumor implies the presence of primitive yolk sac elements[542] (Table 70-13). β-Human chorionic gonadotropin (β-HCG) is a marker for germ cell tumors with syncytiotrophoblast activity. Although pure germinomas may express relatively low levels of β-HCG, choriocarcinomas produce the highest levels of this hormone (see Table 70-13). β-HCG expression is not a marker of metastasis or tumor size. Placental alkaline phosphatase (PLAP) is another marker that has been found to be elevated in patients with germ cell tumors.[544] Its diagnostic use lies more in immunohistochemistry. PLAP immunostaining is positive and diagnostically definitive for germinomas.[542]

Craniospinal irradiation is clearly indicated in cases of documented leptomeningeal metastasis from germinoma; however, its use in patients with normal findings on CSF examination and spinal MRI is controversial. In a series from the University of Pennsylvania in which 39 patients with biopsy-proven germinomas all received craniospinal irradiation, regardless of extent of disease, no relapses occurred over a median follow-up time of 7.1 years, and the 10-year survival rate was 97%.[545] Of note, however, other institutions using more limited radiation fields with or without chemotherapy for biopsy-proven germinomas also have reported 5-year survival rates exceeding 90%.[546,547]

In contrast with germinomas, nongerminomatous germ cell tumors (choriocarcinoma, embryonal carcinoma, yolk sac tumors, and malignant teratomas) have a high incidence of leptomeningeal metastasis,[548] and craniospinal radiation therapy is an important component of the overall treatment plan with these tumors. Well-differentiated teratomas generally are unresponsive to radiation, and use of radiation therapy is limited to unresectable recurrent or progressive teratomas in many centers. For these cases, stereotactic radiosurgery may prove to be of greater therapeutic benefit.

Chemotherapy has an important role in the treatment of many germ cell tumors. Germinomas appear to be as sensitive to chemotherapy as they are to radiation.[549,550] Chemotherapy has been used effectively for germinomas in three settings: (1) chemotherapy without radiation therapy; (2) chemotherapy followed by reduced-dose radiation therapy for tumors with incomplete tumor response; and (3) chemotherapy after radiation therapy for tumors with incomplete tumor response. Malignant nongerminomatous germ cell tumors carry a considerably worse prognosis than that for pure germinomas.[547] Accordingly, in patients with nongerminomatous germ cell tumors,intensified chemotherapy and multimodality therapeutic strategies have been used in an attempt to improve survival.[551] A study of postoperative pre- and postradiation chemotherapy for patients with nongerminomatous germ cell tumor, but no metastases, reported a 4-year progression-free survival rate of 74%.[552]

Craniopharyngioma

Craniopharyngiomas constitute 6% to 10% of all childhood brain tumors and represent one of the three major tumor groups frequently found in the suprasellar region. These tumors probably arise from embryonic epithelial cell rests in the region of Rathke's cleft. Radiographically, their appearance typically includes a cystic or multicystic component, as well as a solid component (Fig. 70-26). Calcifications are present in a majority of cases. Craniopharyngioma cyst fluid, similar to that of a Rathke's cleft cyst, is viscous, with a high cholesterol content. Rupture of the cyst contents during surgical removal is well known to produce an intense chemical meningitis.

The clinical presentation with craniopharyngiomas is similar to that with other suprasellar tumors. The primary age at onset is in the first decade of life; however, presentation before the age of 2 years is uncommon. Approximately 25% of craniopharyngiomas are detected in the third decade or later. The primary signs and symptoms include visual dysfunction; headache; optic pallor; endocrinopathies, including growth failure and diabetes insipidus; and behavioral or learning dysfunction. On the basis of these findings, preoperative assessment of patients with suspected craniopharyngioma should include a thorough visual examination and endocrine evaluation.

Surgical removal of craniopharyngiomas is the primary therapeutic modality.[553] Complete surgical resection obviates the need for further therapy in a majority of cases. When postoperative MRI and intraoperative visual assessment show no evidence of tumor, the rate of recurrence is less than 20%; a majority of recurrences occur within the first 2 years after surgery.[554] The overall surgical approach to craniopharyngiomas, however, remains the subject of considerable disagreement. Gross total resection often is achieved at the expense of panhypopituitarism and behavioral and neuropsychological dysfunction that often severely affects the patient's quality of life.[555–557]

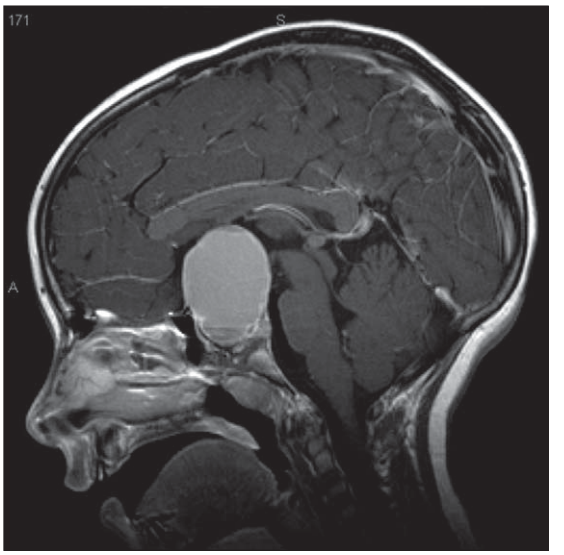

Figure 70-26 • Craniopharyngioma. Midline sagittal T_1-weighted post-gadolinium magnetic resonance image shows an enhancing cystic suprasellar mass.

An alternative surgical strategy involves planned incomplete resection followed by radiation therapy. Radiation therapy represents standard treatment for patients with residual craniopharyngioma.[558–560] Less than 50% of patients with known postoperative residual tumor who do not receive radiation therapy will survive for 10 years. By contrast, those who receive local field radiation, typically at doses of 50 to 56 Gy, have disease-free survival rates of approximately 80% at 10 years. More recent studies suggest that quality of life may be better for these patients than for children managed with aggressive surgical resection alone.[559]

No established role for chemotherapy in the treatment of craniopharyngioma is recognized. In patients whose tumor recurs after external beam irradiation with primarily a cystic component, a technique that may be useful is the instillation of colloidal β-emitting radionuclides, such as ^{32}P or ^{90}Yt.[561] This technique also has been used in some patients as first-line therapy.

Brain Tumors in Infants

Approximately 20% of childhood brain tumors occur in infants and young children before the age of 3 years. Unfortunately, the survival outcomes in this age group have been significantly less favorable than in older children, both overall and for specific tumor types.[562] These children also are at increased risk for substantial radiation-related neurotoxicity, including mental retardation, growth failure, and leukoencephalopathy.[563,564] Therefore, primary postoperative chemotherapy approaches have been adopted with the aim of postponing or even avoiding radiation therapy. Between 1976 and 1988, 17 children younger than 3 years of age with PNET/MB or ependymoma underwent treatment with a multiagent chemotherapy regimen consisting of mechlorethamine, vincristine, procarbazine, and prednisone (MOPP).[565] Radiotherapy was reserved for treatment of recurrent disease. Eight of 12 children with PNET/MB and 2 of 5 children with ependymoma survived, and those children who did not require radiation therapy showed normal height and intellectual ability. Although a subset of infant PNET/MB can be cured by chemotherapy alone,[563,566] expectations that the use of intensive multiagent chemotherapy will improve outcomes for these children have not been realized. Ongoing cooperative group studies are testing chemotherapy dose intensification, addition of intrathecal chemotherapy, and earlier introduction of more limited radiation therapy, with restriction of treatment volumes and use of conformal techniques to minimize exposure of normal tissue.

71 Eye, Orbit, and Adnexal Structures

Zeynel A. Karcioglu and Barrett G. Haik

SUMMARY OF KEY POINTS

Incidence
- Primary ocular (eye) and ophthalmic (eye and adnexae) tumors are relatively uncommon.
- The most common primary ocular tumors are choroidal melanoma and retinoblastoma. The most common adnexal tumors are lymphoma, rhabdomyosarcoma, optic nerve glioma, and epithelial and melanocytic malignancies of the eyelid and conjunctiva, respectively.
- Many systemic diseases can involve the eye and adnexae, especially breast and lung cancers, as well as lymphoma and leukemia.

Etiology
- The etiology of most ophthalmic tumors is unknown.
- Retinoblastoma is the prototypical model of a genetically transmissible tumor via loss of a tumor suppressor gene.
- Squamous tumors of the lids and conjunctiva are associated with sun exposure, immunosuppressed states, and viral infections.
- Ocular and orbital metastases are unexpectedly frequent; approximately 25% of ocular metastases are discovered at an occult stage.

Diagnosis
- Intraocular tumors can be directly visualized, greatly facilitating diagnosis, but the biopsy is not easy and is limited to special circumstances.
- For intraocular tumors, a combination of funduscopic examination, intravenous angiogram, ultrasonography, and CT/MRI imaging can yield diagnostic accuracies over 90%–95%.
- Orbital and adnexal tumors are diagnosed by CT/MRI imaging and biopsy.

Treatment
- Intraocular tumors are treated with local modalities such as external beam irradiation, brachytherapy, and photocoagulation, with or without chemotherapy. If useful vision cannot be preserved in the tumor-containing eye, the eye is enucleated.
- Orbital malignancies are frequently treated by radiation/chemotherapy, but exenteration may be necessary in far-advanced sarcomas.
- Eyelid and conjunctival malignancies are managed by local excision, with or without topical chemotherapy; cryotherapy; or irradiation.
- Metastatic malignancies may be palliated by external beam irradiation.
- Because radiation is widely utilized in treatment of ophthalmic malignancies, radiation toxicity is an exceedingly important issue in management protocols. Ophthalmic tissue components range from extremely radiosensitive tissues, such as the lens, to radioresistant tissues, such as the retina and the optic nerve.

INTRODUCTION

In today's practice of oncology, the role of radiation therapy is vast. As with other oncologic subspecialties, the practice of ophthalmic oncology would be impossible without the use of radiation for imaging and therapeutic purposes.[1] A practical approach to a discussion of ophthalmic tumors—as with tumors of other anatomic regions—is to consider neoplastic conditions of the major structures with primary involvement: the globe, the conjunctiva and eyelids, and the orbit. Because the tumors and tumor-like conditions of these structures are exceedingly diverse, only the common entities that are encountered in daily practice are addressed in this chapter (Tables 71-1 to 71-4).

Retinoblastoma is a much more radiosensitive tumor than uveal melanoma; however, for both of these intraocular neoplasms, radiation treatment, in one form or another, is an indispensable management tool for today's ocular oncologist. Radiation also is used for the treatment of rarer types of intraocular tumors such as juvenile xanthogranuloma, ocular or central nervous system (CNS) lymphoma, multiple myeloma, leukemias, and some metastatic tumors.[2]

One large group of conjunctival, eyelid, and orbital tumors that respond to radiation therapy, alone or in combination with chemotherapy, are the lymphoproliferative neoplasms. In contrast with lymphoid lesions, epithelial tumors of the conjunctiva and the eyelids—including basal cell carcinoma, squamous cell carcinoma, and melanoma—are not very responsive to radiation, and severe ophthalmic complications may develop after radiation treatment. In this group of tumors, certain types of malignancies, such as sebaceous gland carcinoma, pose considerable therapeutic challenges in that although the tumor is radiation sensitive, the therapy results in substantial adverse effects in the eye. In most instances, ocular oncologists avoid this treatment modality. Accordingly, use of irradiation usually is limited to treatment for the advanced stages of these tumors, primarily for palliation.

In orbital tumors other than lymphoproliferative lesions, radiotherapy has been successfully used for rhabdomyosarcoma and, with less rewarding results, for other mesenchymal malignancies. Epithelial tumors of the lacrimal gland, sebaceous gland tumors, and histocytic tumors occasionally respond well to radiation treatment. Primary tumors of the optic nerve, including optic nerve glioma and meningioma, also benefit from radiation treatment. In the advanced stages of aggressive sarcomas, radiation treatment also may be used as an adjunct to surgery and chemotherapy.[3]

Finally, some of the idiopathic inflammatory conditions of the orbit, including Graves disease and pseudotumor of the orbit, also may be treated with radiation.[4,5]

This chapter summarizes the specifics of radiation therapy and other recommended modalities for the management of the ophthalmic neoplasms commonly encountered in clinical practice (for discussion of other, rare ocular and periocular tumors, the reader is referred to ocular oncology textbooks and review references[6–10]). First, however, the effects of radiation on each of the major tissues and structures of the eye are reviewed.

RADIATION TOXICITY IN THE EYE

The eye is a complex organ composed of structures with widely variable radiation sensitivity. Its different components range from extremely radiosensitive tissues, such as the lens, to radioresistant tissues, such as the retina and the optic nerve.[11] The variations in radiation effect on the eye are dependent not only on tissue sensitivities but also on the methods of radiation delivery. Today, a majority of ophthalmic radiotherapy protocols involve the use of external beam radiation therapy (EBRT); indications for brachytherapy are fewer. With EBRT, radiation is delivered as photons (gamma rays or x-rays) or particles (e.g., protons and neutrons), primarily with linear accelerators.[12,13] Newer techniques of radiation delivery improve the rates of ocular toxicity. For example, proton-photon accelerated fractionated radiation (AFR) allows the delivery of treatment doses to advanced tumors of the nasal cavity and paranasal sinus, with tolerable eye complication rates.[14] Modern EBRT techniques such as stereotactic fractionated radiation therapy (SFRT), photon EBRT, and carbon ion boost appear to allow safe delivery of high target doses to patients with locally advanced orbital malignancies. Although the ocular toxicity rates are reported to be reduced compared with the historical neutron therapy data, the follow-up periods are limited because of limited survival of these patients.[15,16]

From the standpoint of radiation toxicity, the eye and periocular tissues can be divided into several zones: external eye (conjunctiva, cornea and the tear layer); anterior intraocular components (iris, anterior chamber angle, and lens), posterior intraocular components (retina, choroid, and optic disc), eyelid, orbital soft tissues, hypothalamus, and pituitary gland.

External Eye

Most of the tissues of the external eye, including the epithelium of the conjunctiva, cornea, glandular excretory ductules, and lacrimal drainage apparatus, have the same sensitivity as that of skin, because these structures are lined with epithelial cells, which are characterized as vegetative intermitotic cells (VICs). During the acute phase of radiation (within 6 months), fractional doses of 20 Gy cause erythema and edema of the eyelid skin and conjunctiva; if the dose is high enough, keratinization of the epithelium also takes place. The tear layer becomes thinner and irregular secondary to edema of the parenchyma of the lacrimal and meiobomian glands and goblet cells. Also, the damage to the epithelial cells of glandular ductules reduces the inflow of tears. Disruption of the tear layer is a serious matter, causing problems ranging from a scratchy sensation and mild visual distortion to severe external eye infections and cornea-sclera melt, which may even lead to perforation. Among its other functions, the tear layer possesses bactericidal properties because it contains immunoglobulins and lysozomes; it also flushes away foreign materials and bacterial debris from the external eye into the lacrimal drainage system. When the composition and the quantity of the tear layer are distorted by radiation-induced changes, both of these antibacterial properties are lost. As the orthovoltage dose approaches 40 to 50 Gy, a confluent mucositis appears. At this stage, lacrimal gland secretions are reduced and thickened, and the external eye may become infected. During this period, photophobia also may be noted.

In the subacute period, ranging from 6 to 24 months, telangiectasias may develop in the skin and the conjunctiva, and the dryness worsens. The cornea demonstrates few structural changes until fractionated doses are in the range of 50 Gy; at this point, superficial punctate keratitis may develop. The cause of corneal damage also is twofold: (1) the direct toxicity of ionizing radiation on its epithelial cells and stromal collagen and (2) drying of the ocular surface. Punctate keratitis, which develops during the acute stages owing to focal epithelial erosion and edema, becomes worse. Along with epithelial changes, the corneal sensation diminishes for weeks to months. During the subacute phase, scarring of the cornea may advance if deep keratitis was present during the acute period. Further scarring may lead to vascularization and thinning of the stroma, which in turn may lead to total opacification or perforation.[17] Medical and surgical management of radiation keratopathy may be difficult owing to poor wound healing.

It would be an error to underestimate the consequences of the dry eye syndrome and to send the patient home with artificial tears and antibiotic or steroid eyedrops or ointments. The management of dry eye should be directed by an ophthalmologist who is familiar with current treatments for radiation toxicity, which range from simple supplementation with artificial tears to complex surgical interventions. The scope of this chapter does not allow a detailed discussion of dry eye management; the reader is referred to recent reviews.[18,19]

The sclera maintains the structural integrity of the anterior eye as well as that of the posterior eye. The sclera consists of thick, irregular collagen bundles, and it is less affected by ionizing radiation than the cornea.[20] No scleral radiation damage has been reported after EBRT at doses up to 60 Gy. High scleral brachytherapeutic doses (e.g., in excess of 600 Gy), however, can cause melting of the sclera.[21] In practice, strontium 90 (^{90}Sr) and ruthenium 106 (^{106}Ru) are more likely to deliver much higher scleral doses than is either iodine 125 (^{125}I) or palladium 103 (^{103}Pd) during plaque radiation therapy of intraocular tumors.[22]

Anterior Intraocular Components

The iris is located behind the cornea and in front of the lens and extends into the ciliary body. The iris and ciliary body are composed of fibroblasts, smooth muscle, vessels, and columnar pigmented and nonpigmented epithelial cells. Many of these cells are reverting postmitotic cells and therefore are quite resistant to radiation. Iritis has been reported with a single dose of 10 to 20 Gy, but severe anterior uveitis is not observed until higher doses of 30 to 40 Gy (in 10-Gy fractions) are given, and then appears only after 6 to 8 weeks. Radiation iritis may be followed by secondary glaucoma. Dry eye-related corneal ulceration also may exacerbate iritis and secondary iris neovascularization.[23] Localized iris atrophy has been noted after brachytherapy for iridociliary melanomas but not after EBRT for orbital tumors.[24,25]

Among the anteriorly located intraocular tissues, the crystalline lens is uniquely susceptible to radiation injury. The lens is an avascular protein structure covered by an elastic tissue capsule. The anterior surface of the lens has a layer of epithelial cells that do not show much mitotic activity; these cells behave as reverting postmitotic cells. Near the equator of the lens, however, the epithelial cells divide regularly and thus behave as VICs. Formation of cataracts is the most frequently encountered delayed radiation effect in the mammalian

eye. It is known that DNA damage and abnormal protein cross-linking lead to development of opacities within the lens protein; however, the exact mechanism of the DNA damage by radiation is not known.[26] Some practitioners postulate that cell membrane permeability changes are caused by radiation, whereas others hypothesize that radiation changes the activity of certain enzymes of the lens cortex.[27] The thermal damage also should be taken into account as a cataractogenic influence because heat cannot be dissipated effectively in the avascular lens tissue.

The best clinical description of radiogenic cataracts has been reported by Cogan and associates[28] (Fig. 71-1). The development of radiation opacity begins in the posterior subcapsular zone when small granules turn into small vacuoles as they enlarge to 3 to 4 mm within months; a central clear area may be identified during development. If this opacity progresses, a hard, central, circular plaque of highly reflective material develops at the posterior pole. As the posterior opacity becomes denser, a faint anterior subcapsular cataract containing interspersed vacuoles and occasional fine striations may be seen. When the changes progress slowly over several years and the entire lens becomes opacified, it can no longer be distinguished from other types of mature cataract.

The development of radiation opacity is dose, time, and age dependent (Fig. 71-2). Significant variation, however, is observed among persons who receive the same dose. The lenticular opacities do not always interfere with vision; clinically significant cataract development usually requires higher doses and longer postradiation times. The latent period for production of cataracts from the time of exposure is on average 2 to 3 years but may range from 6 months to 3 decades.

In Merriam and Focht's classic study, a large series of patients undergoing EBRT for ocular and orbital malignancies was studied from the standpoint of cataract formation.[29] The higher the absorbed dose, the shorter the latent period to cataract fomation. Single doses of 2 Gy or fractionated doses of 4 Gy result in the formation of posterior lens opacities but rarely in significant visual impairment. A dose of 7.5 Gy, however, invariably causes clinically significant cataract formation. A similar incidence has been noted with 14 to 21.5 Gy given over a period of 1 to 3 months. Merriam and Focht concluded that a given dose of radiation becomes less likely to produce a cataract when it is fractionated over a longer period. Fractionation of the radiation dose delays the onset and decreases the incidence of cataract development and slows its progression, as does the use of partial and total shielding of the equatorial areas of the lens.[30]

Because of treatment-related toxicity, studies increasingly focus on long-term complications secondary to hematopoietic stem cell transplantation in survivor populations. Gurney and coworkers recently reported an incidence of cataracts of 36% at 15 years after transplantation; cataracts developed only in those patients who received total-body irradiation as a conditioning regimen or head irradiation before transplantation.[31] Of 4000 cancer survivors, 4% had cataracts. Cataracts were a frequent occurrence in survivors of hematologic diseases (chronic leukemia, 17%; myeloma, 13%; acute leukemia, 9%; and lymphoma, 7%).[32] Cataracts that develop as a late effect following hematopoietic stem cell transplantation are related to either the transplantation process or the transplantation-preparative regimen. Problems related to the transplantation process include delayed recovery of the immune system and chronic graft-versus-host disease (GVHD). Chronic GVHD manifests between 3 and 14 months after transplantation in approximately 20% of matched sibling transplant recipients and in 40% of matched unrelated donor transplant recipients. Cataracts develop secondary to total-body irradiation or prolonged corticosteroid use. Cataracts developing after fractionated radiation do not impair the vision significantly enough to be removed.[33]

Another concern with radiation toxicity is the ocular exposure during modern imaging procedures. Although the great majority of CT scanners deliver lower than the threshold dose for development of cataracts, nevertheless the potential exists for delivery of higher doses.[34]

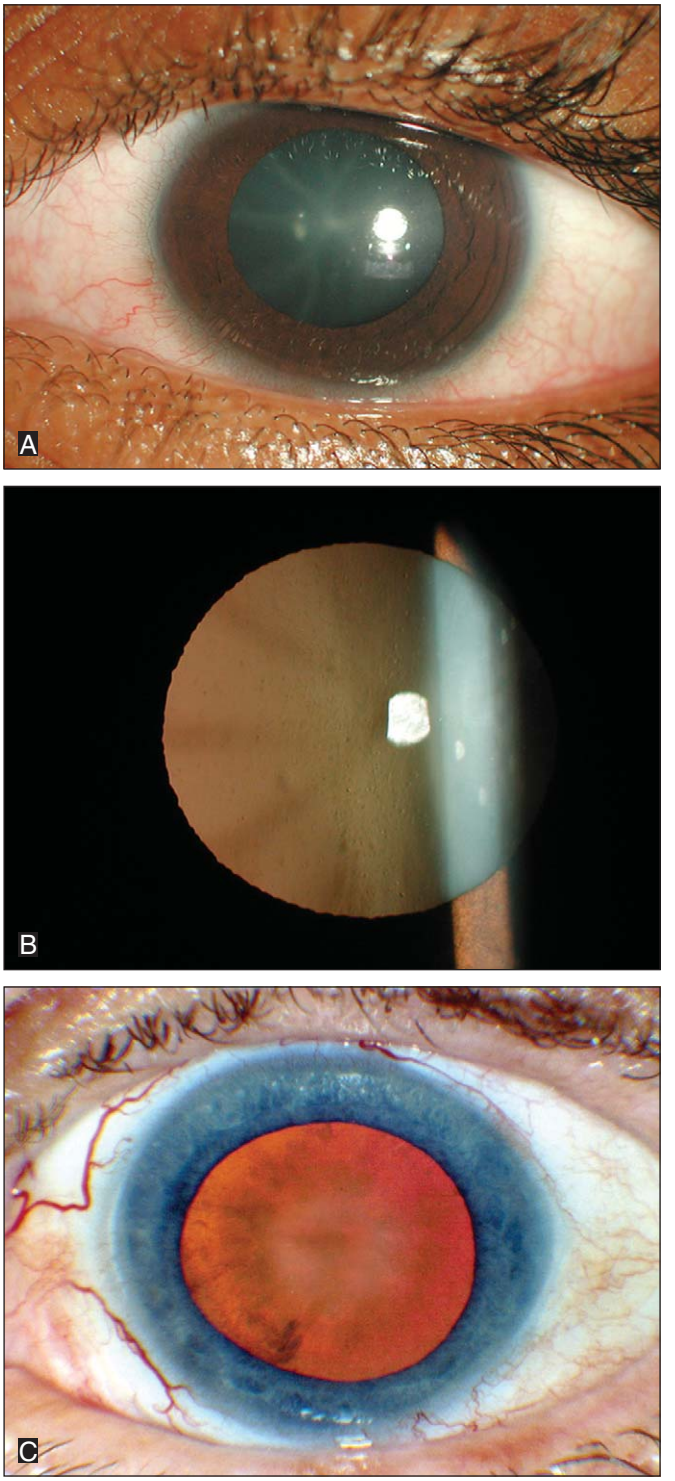

Figure 71-1 • **A–C,** Slit-lamp appearance of radiation cataracts.

It has been reported that comprehensive imaging in patients with stroke may result in radiation exposure up to local doses of 490 mGy. Although critical doses for organ damage (e.g., cataract formation or hair loss) are not reached, physicians need to be aware of possible radiation-induced complications, particularly with repetitive examinations.[35] For decades, it has been known that in utero exposure to radiation, particularly during the first trimester, can result in cataract formation, as well as pigmentary degeneration of

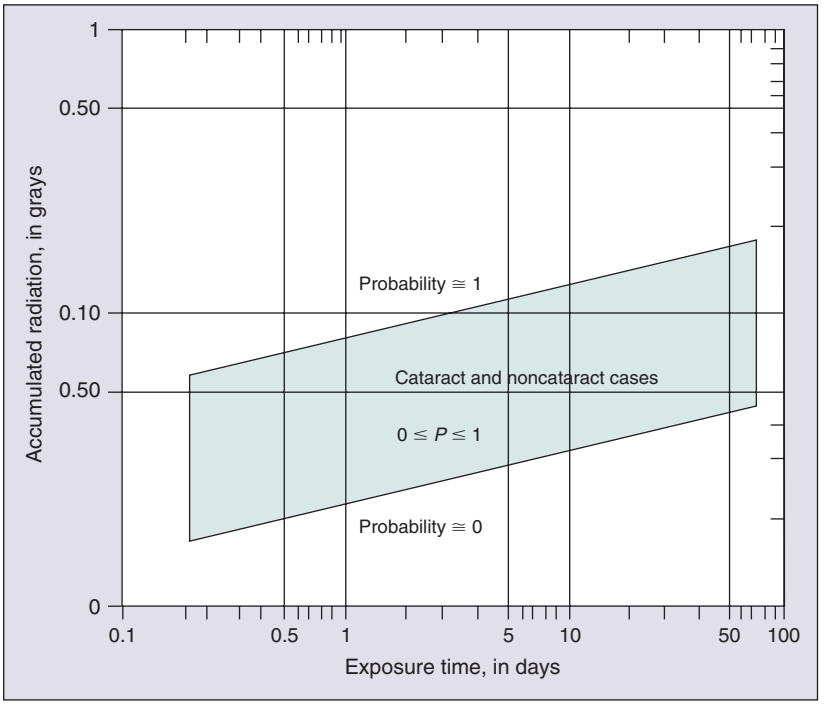

Figure 71-2 • Influence of radiation dose and exposure time on cataract formation in humans. (Data from Mettler FA, Moseley RD: Medical Effects of Ionizing Radiation. Orlando, FL, Grune & Stratton, 1985, p 138.)

the retina or microphthalmia.[36] Bateman indicated that doses in the range of 3 to 5 Gy delivered during the first half of the pregnancy are quite damaging to the neurons of the developing retina, although as the neurons mature, they become much more radioresistant.[37] Long-term topical and systemic administration of corticosteroids is well known to induce formation of posterior subcapsular cataracts. In humans and experimental animals, even a low dose of radiation given with steroid treatment accelerates the development of lenticular opacities.[38]

Posterior Intraocular Components

The retina, choroid, and optic nerve are composed of relatively radioresistant tissues. At common therapeutic dose levels, acute effects of irradiation are rare; however, at doses higher than 50 Gy, acute retinal edema may occur, although this effect usually is transient (Fig. 71-3).

Chronic radiation damage to posterior ocular tissues usually is the result of disruptions in the vascular supply and is primarily a form of microangiopathy. Because of the radiation damage to vascular endothelial cells, abnormal vascular permeability occurs, and vascular lumina are narrowed or obliterated. Owing to vascular disruption, the nerve fiber layer becomes ischemic, with the potential for the development of infarcts, exudates, and hemorrhages. The retinal vascular changes include totally occluded "ghost" vessels, vascular sheathing, microaneurysm formation, increased tortuousity, retinal telangiectasis, and eventually neovascularization (see Fig. 71-3). The associated abnormal vascular permeability may impair vision secondary to macular exudates, often in a circinate pattern. Vascular occlusions of both the arterial and venous circulation may occur. Radiation retinopathy in the macula causes vision loss and blindness. Serious hemorrhagic complications may result from fragile vasculature and the neovascular tufts, leading to a hemorrhagic retinitis or a vitreous hemorrhage. Organized vitreous hemorrhage and associated fibrovascular proliferations may produce a traction retinal detachment followed by phthisis bulbi. Characteristic alterations also occur in the retinal pigment epithelium (RPE), leading to pigmentary mottling over large areas and extensive RPE cell atrophy. Occasionally, large areas of chorioretinal thinning are so pronounced that the sclera can be clearly visualized beneath this layer on ophthalmoscopic examination. Typically, onset of radiation retinochoroidal disease is between 6 months and 3 years after treatment; in some patients, however, the disease develops after much longer periods.[39] It has been reported that retinal damage may be produced by EBRT at doses as low as 15 Gy but is more common after EBRT at fractionated doses of 30 to 35 Gy. (At total fractionated doses of 70 to 80 Gy, retinopathy would occur in 85% of eyes.) Diabetes and chemotherapy, when combined with irradiation, seem to have an additive effect on progression of retinopathy. An associated papillitis often is seen with radiation retinopathy.

Both anterior ischemic optic neuropathy and posterior vascular occlusions can occur in the optic nerve, leading to visual loss (see Fig. 71-3). Radiation optic neuropathy can temporarily cause decreased vision, with later improvement over several months. This entity involves the anterior optic nerve and is characterized acutely by hyperemia and disc edema. Peripapillary hemorrhages and subretinal fluid also may be present. With EBRT, the mean total fractionated dose causing this effect is 55 Gy, with a range of 36 to 72 Gy. The mean latent period after radiotherapy is 19 months (5 to 36 months). Optic atrophy may be found secondary to ganglion cell degeneration or after a direct vascular insult.[40,41]

In a long-term study of optic nerves that received a radiation dose greater than 60 Gy, the 15-year actuarial risk of optic neuropathy was 11% when fraction size was less than 1.9 Gy per day, compared with 47% for larger fractions.[42]

Eyelid and Orbital Tissues

Main eyelid changes associated with EBRT include acute erythema, depigmentation, atrophy, telangiectasias of the eyelid skin, and loss of eyelashes; ectropion and entropion also are seen.[43,44] Radiation typically travels through the skin and other structures of the eyelids on its way to treat orbital tumors. Eyelid skin behaves like skin of other sites, but it is thinner. The first reaction is erythema (typically seen at 2 to 4 weeks after initiation of treatment), followed by dry and moist desquamation. Erythema, or reddening, usually is transient and subsides rapidly. Eyelid and periorbital skin erythema occurs if a single dose of 6 to 8 Gy is given and may not be identified until 1 to 2 days after irradiation. The higher the radiation dose, the more quickly the erythema develops. Erythema increases during the first week and usually fades during the second week. It then may return

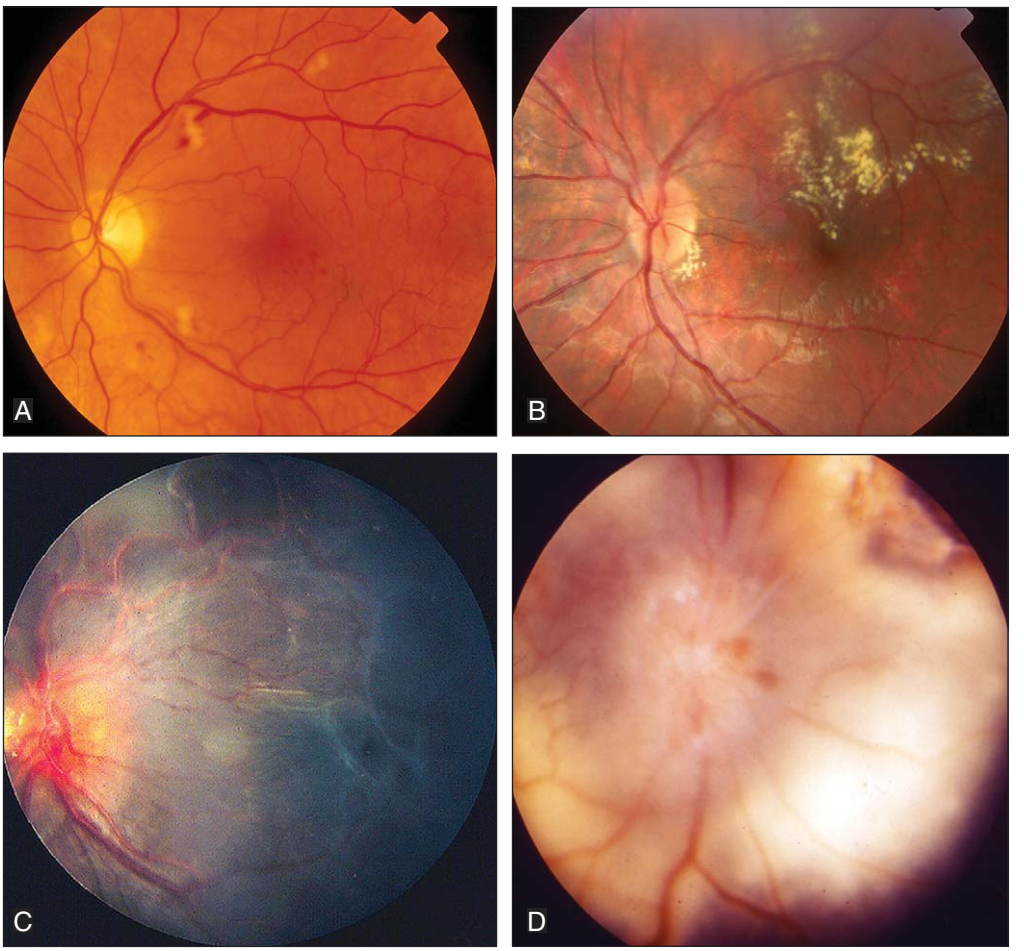

Figure 71-3 • **A,** Acute radiation toxicity with focal intraretinal hemorrhages and cotton-wool spots. **B** and **C,** Chronic radiation toxicity of the fundus with hard exudates, edematous and necrotic retina, infarcted choroid, and vascular changes ranging from tortuosity and engorgement (**B**) to diffuse atrophy ("silver-wire vessels") (**C**). **D,** Acute papillitis secondary to external beam irradiation for treatment of retinoblastoma. (**A** and **B,** Courtesy of Dr. Edward Chaum, Memphis, TN.)

2 to 3 weeks after the initial insult and last for 20 to 30 days. The early reddening presumably is due to release of vasoactive amines. The second phase of erythema is due to vessel damage; thermographic studies demonstrate increased blood flow during the first 2 to 3 months. Desquamation usually is healed by the time treatment has ended because compensatory regeneration occurs in the basal layer of the skin. Moist desquamation is more common after doses of 50 to 60 Gy (in 1.8- to 2.2-Gy daily fractions) given over 5 to 6 weeks, and also more common where superficial lesions break the skin. Healing typically is slow and may take up to 4 weeks. No radiation-related scar usually results unless an unusually high dosage is used or a complication such as secondary infection occurs.

Scarring can result in entropion or ectropion of the eyelids. Slowly progressive skin alterations may lead to depigmentation and telangiectasias.[1] The accessory glands around the eye (including Moll, meibomian, and lacrimal glands) contain reverting or fixed postmitotic cells; the ductal epithelium for some of these glands contains VICs as well. Thus, the excretory ducts, particularly in the meibomian glands, are relatively sensitive to direct effects of radiation, as are the equatorial regions of the optic lens and the basal cell layer of the cornea. Meibomian glands are of about the same radiosensitivity as that of hair follicles, but sweat glands are somewhat more resistant.

With EBRT, temporary loss of hair occurs in about 3 weeks with 3 to 5 Gy. Hair begins to return during the second month, and regrowth continues for up to 1 year. Single doses of 7 Gy may cause permanent epilation, with a latent period of less than 3 weeks. Not all body areas have the same radiation epilation sensitivity. The scalp and beard are most sensitive, with less sensitivity in the eyebrow and then the eyelashes. Eyelash loss may be incomplete or complete, depending on the dose and dose rate. It may occur with as little as 10 Gy but can be permanent with as little as 30 Gy. A radiation dose of 50 Gy has been used to achieve permanent epilation in patients with trichiasis and secondary corneal disease.

Doses in the range of 30 to 40 Gy can be delivered to the entire orbit without functional effect on the main lacrimal gland. On the other hand, evidence of histopathologic atrophy of the lacrimal gland has been reported with single doses of 20 Gy and after 50 to 60 Gy given over a 6-week period.[45] Although the mesenchymal tissues of the orbit including the extraocular muscles, fibroconnective tissue, and fat are rather resistant to radiation, orbital deformity leading to fascial asymmetry remains a major problem, particularly in children younger than 6 to 8 years of age who receive a tumor dose of approximately 50 Gy[46] (Fig. 71-4).

Another very serious side effect of orbital EBRT is that it increases the incidence of multiple primary malignancies in patients with retinoblastoma and other childhood malignancies such as rhabdomyosarcoma, Ewing's sarcoma, Hodgkin's lymphoma, and Wilms' tumor.[47–49] Acute leukemias also have been reported among the patients who survive retinoblastoma.[50] When the relative risk of death was calculated, it was found to exceed the expected rates for malignant tumors of bone and soft tissues by 300-fold, for melanoma by100-fold, and for brain tumors by about 25-fold.[51] At 40 years of follow-up, the cumulative mortality rate for all second primary malignancies was approximately 25% (expected 1.3%) for bilateral tumors and 1.5% (expected 1.1%) for unilateral disease. In the patients with bilateral retinoblastoma, radiotherapy further increases the risk of death. Early detection and management of these tumors are very difficult.

Figure 71-4 • A patient who underwent orbital exenteration and external beam irradiation for unilateral retinoblastoma. Note the deformity of the left socket and ulceration of the skin posteriorly.

Hypothalamus and Pituitary Gland

Hypothalamic and pituitary dysfunction with growth hormone deficiency with height loss is commonly seen in children irradiated for optic nerve glioma.[52,53]

INTRAOCULAR TUMORS

The most commonly encountered malignancies in adults and children—uveal melanoma, metastatic tumors to the eye including leukemia, intraocular lymphoma, and retinoblastoma—are reviewed in this section.

Uveal Melanoma

Uveal melanoma is the most common primary malignancy of the eye, but it comprises only 5% of all melanomas in the body.[54] Up to 85% of ocular melanomas are uveal (primarily choroidal) in origin. The annual incidence of this tumor is approximately 4 per million population in the United States; this incidence is similar to that reported from European countries. The most recently reported male-to-female ratio is 4.9:3.7.[55]

Pathogenesis

Approximately 98% of cases of uveal melanoma occur in the white population. This racial predisposition to uveal melanoma has been explained on the basis of susceptibility of the white persons to the oncogenic effects of sunlight. Although this hypothesis is convincing for skin melanoma, the evidence with regard to uveal melanoma is conflicting.[56] It is well known that intraocular melanoma develops as a result of the proliferation of uveal melanocytes, but the knowledge regarding this tumor's molecular pathogenesis is rather limited. It seems conceivable that these cells are intrinsically resistant to apoptosis because of constitutive Bcl2 expression. Hypothetically, the main event in the neoplastic conversion of the uveal melanocyte appears to be the inhibition of the Rb pathway. Genetic alterations that subvert the Rb and p53 pathways probably occur early, allowing the altered melanocytes to reenter the cell cycle and proliferate. The proliferation of the melanocytes may then become arrested by other tumor suppressor mechanisms, resulting in a dormant nevus; most of the nevi are permanently arrested at this stage. For further growth to occur, activation of a "malignant switch," such as a reinhibition of the p53 pathway, may be necessary subsequent to another genetic shift.[57] Recently, a gene expression-based classification of uveal melanomas that predicts metastatic death has been reported, which may represent a breakthrough in current understanding of the molecular pathobiology of this neoplasm and may lead to major changes in management protocols for uveal melanoma. According to this scheme, class 1 tumors carry a low risk and class 2 tumors a high risk for metastatic death.[57,58]

Table 71-5 Classification of Uveal Melanomas by Size

	Tumor Size		
Dimension	**Small**	**Medium**	**Large**
Diameter (mm)	<10	10–15	>15
Height (mm)	<2	2–5	>5

Clinical Features

Most patients remain asymptomatic unless the tumor involves the macula by means of direct extension, secondary retinal detachment, or macular edema. Large, anteriorly located tumors may induce lenticular astigmatism, cataract, or glaucoma. The typical posterior lesion is an elevated, brown, oval, dome-shaped choroidal mass (Table 71-5). These tumors occasionally may be amelanotic. The presence of orange lipofuscin pigment at the level of the RPE is characteristic of choroidal melanoma (Fig. 71-5). Mushroom-shaped eruption of the tumor through Bruch's membrane also is highly characteristic of melanoma.

Many conventional and newer imaging techniques, including fundus photography, Optomap (Optos, Marlborough, MS), intravenous angiography with or without indocyanine green, A- and B-scan ultrasonography, three-dimensional scan ultrasonography scanning, color Doppler imaging, ultrasound biomicroscopy (using higher-frequency ultrasound), optical coherence tomography (OCT), computed tomography (CT), and positron emission tomography (PET), may be used for diagnosis and treatment of choroidal melanoma. The most useful techniques are fundus photography, A- andB-scan ultrasonography, and intravenous fluorescein angiography (IVFA). Ultrasonography is the most important diagnostic modality in evaluation for suspected choroidal melanoma. Standardized A-scan ultrasonography can reliably differentiate the low-to-medium internal tumor reflectivity with a high initial scleral spike (positive angle kappa sign) of melanomas from medium-to-high internal tumor reflectivity of metastatic tumors and the high internal reflectivity of choroidal hemangiomas and osteomas (Fig. 71-6).

Fine-needle aspiration and incisional biopsy occasionally may be valuable procedures for diagnosis of choroidal tumors of unknown origin. The relatively high frequency of postoperative complications and the potential risk of dissemination of tumor cells underline the importance of careful case selection. In the great majority of cases, the diagnosis of melanoma is based on clinical and imaging information.[59]

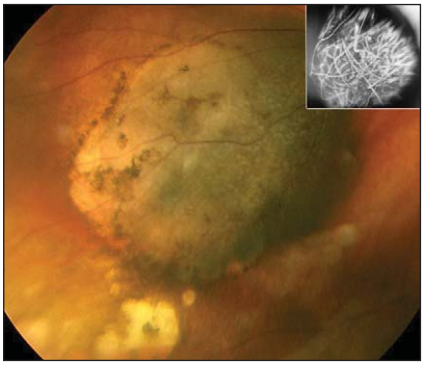

Figure 71-5 • Funduscopic appearance of pigmented choroidal melanoma as a dome-shaped elevation; orange pigment partly covers its surface. *Inset*: Intravenous fluorescein angiography of the tumor depicts diffuse vascularity.

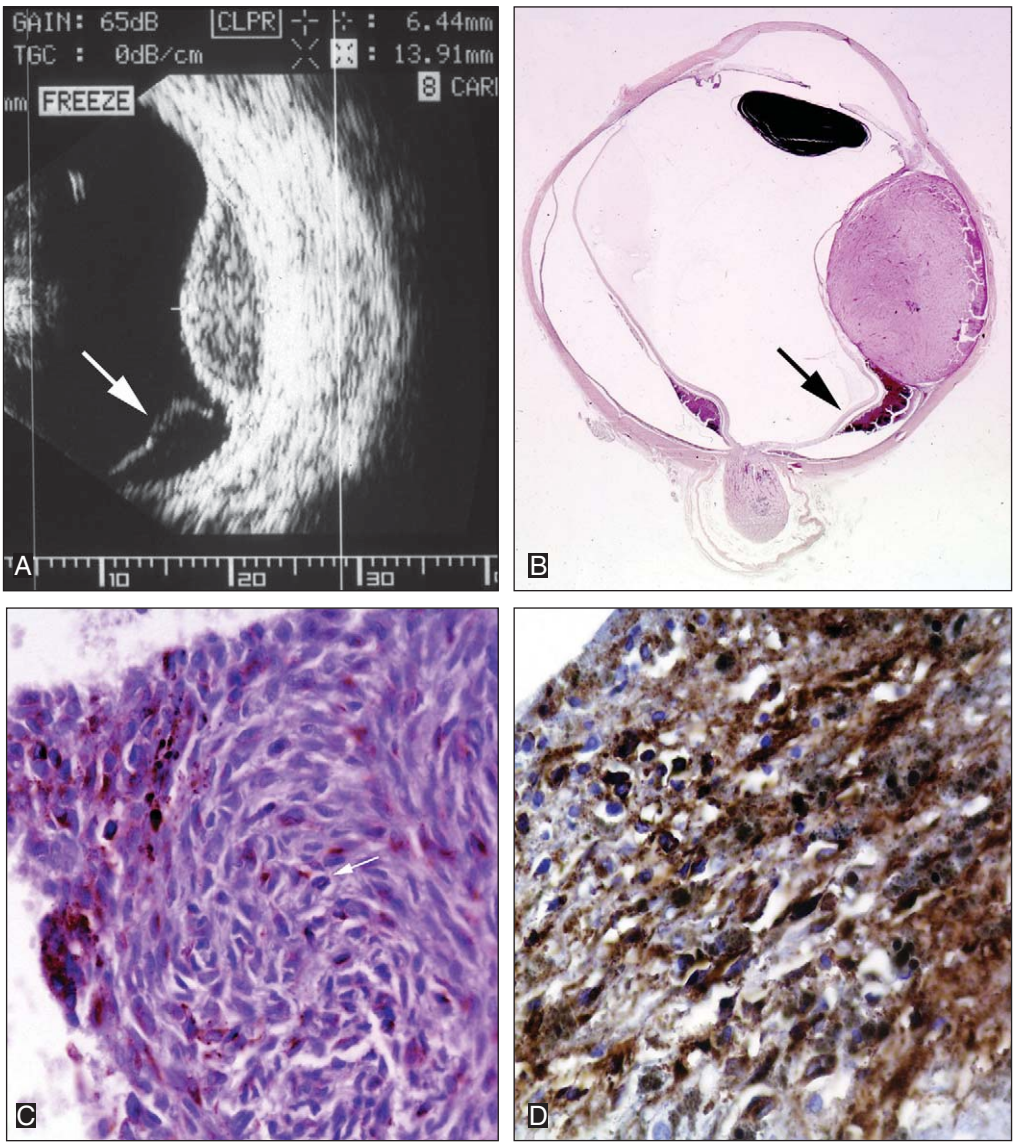

Figure 71-6 • **A,** B-scan ultrasonographic appearance of choroidal melanoma with inferior retinal detachment (*white arrow*). **B,** The low-power histopathologic appearance of a choroidal melanoma with corresponding inferior retinal detachment (*black arrow*) is similar to that of the tumor in **A**. **C** and **D,** Histopathologic detail of a mixed, spindle and epithelioid cell choroidal melanoma in hematoxylin-eosin and Melan A stains, respectively. Numerous pleomorphic epithelioid tumor cells and mitotic figures are present (*white arrow*).

These tumors metastasize primarily to the liver. Usually within 15 years after the initial diagnosis of posterior uveal melanoma, metastasis develops in approximately 50% of the patients. Clinically evident metastatic disease at the time of initial presentation, however, is very rare, so if early metastasis is present, it is subclinical in most cases. The traditional means of metastasis detection has been screening with liver function tests and chest radiographs. Currently, however, the value of whole-body PET/CT in screening for metastatic choroidal melanoma has been emphasized. Liver enzyme levels can be normal in the presence of PET/CT abnormalities, but false-positive results on up to 5% of these assays also are possible.[60] The main disadvantages of PET/CT imaging are the high cost and the sometimes limited availability, but from the standpoint of sensitivity, this approach is superior to the conventional methods of screening for detection of metastatic disease.

Orbital extension of uveal melanoma is another major potential problem with these tumors.[61] Transscleral extension and invasion of the adjacent soft tissues usually occur with large choroidal melanomas composed of epithelioid cells, but occasionally medium-sized tumors of mixed cell type also may invade extraocular structures to a limited degree. Intraocular melanoma is known to leave the eye through emissarial channels, extend onto the scleral surface, and disseminate into the orbital soft tissues (Fig. 71-7). It has been reported that approximately 10% of patients with ciliochoroidal melanomas have extrascleral extension at the time of enucleation.[62] In the early stages of the extrascleral extension, the tumor manifests as a nodular formation, but as it grows, it may be widespread and extend into the meninges, into the optic nerve, and to the lumina of the orbital vasculature (see Fig. 71-7).

With continued growth, the mass effect of the retrobulbar melanoma will result in proptosis, extraocular motility disturbance, congestion, and chemosis. The eye and the periorbita may be painful and tender to palpation, masquerading as an inflammatory condition such as endophthalmitis.[63] Once extraocular extension is clinically suspected, the patient should be investigated with ultrasonography, CT scan, or MRI. Although the diagnosis of intraocular melanoma usually is made by indirect ophthalmoscopy, intravenous fluorescein angiography, and ultrasonography, in cases of suspected orbital extension, imaging with CT scan or MRI is more helpful. A particularly helpful feature of melanoma in MRI is based on the signal characteristics of the melanin. Melanin produces stable free radicals, which create a paramagnetic proton relaxation enhancement, which leads in turn to shortening of T_1 and T_2 relaxation times. The melanoma thus manifests with moderately high signal intensity on T_1-

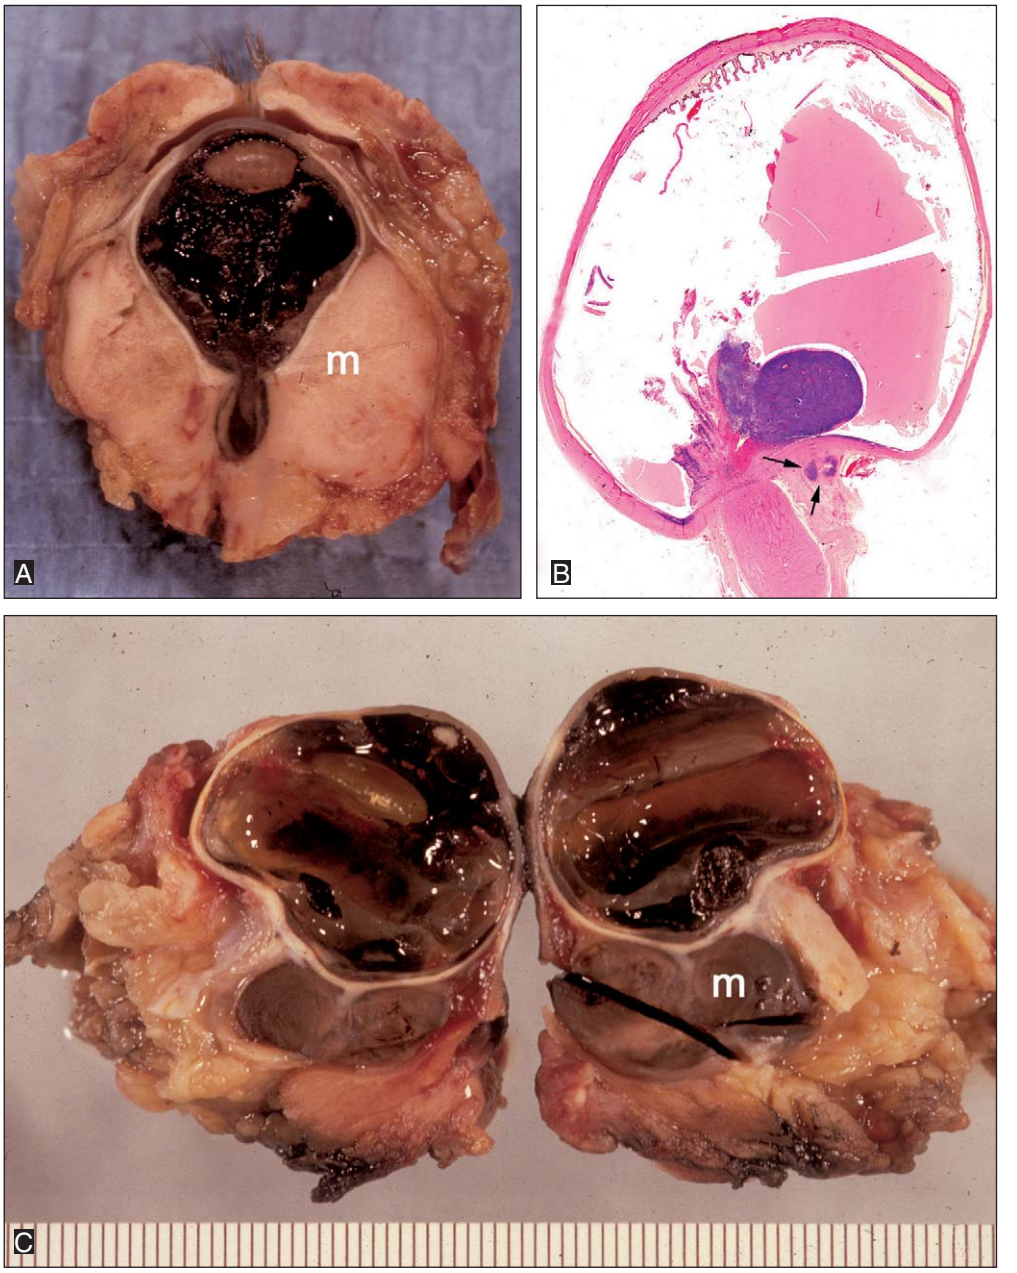

Figure 71-7 • Orbital extension of choroidal melanoma. **A,** The tumor (m) extends into the optic nerve as well as into the orbital soft tissues. Note that it is amelanotic in the orbit but densely pigmented in the optic nerve. **B,** The low-power histopathologic appearance of a juxtapapillary melanoma extending into orbital soft tissues (*arrows*). **C,** The orbital component of this melanoma (m) is as densely pigmented as the intraocular primary tumor.

weighted images and a moderately low signal intensity on T_2-weighted images.[64]

It has been reported that secondary orbital melanoma originating from the choroid can be treated with brachytherapy with some success when the extraocular extension consists of a single nodule that is less than 3 mm in diameter.[63] In cases in which the melanoma nodule is greater than 3 mm in diameter, enucleation is performed to remove the melanoma nodule encased by normal-appearing orbital fat, and secondary EBRT is given. With larger and more invasive tumors, total or partial exenteration is done.[65] In general, extraocular extension, particularly orbital extension, is an indicator of poor prognosis, with a 5-year mortality rate of approximately 55%.

Differential Diagnosis

Other pigmented and nonpigmented mass lesions of the choroid may be clinically confused with choroidal melanoma. Such lesions include nevus, metastatic tumors, choroidal hemangioma, and other benign and malignant tumors; inflammatory lesions; and hemorrhages.[66,67]

Management

The primary objective of any treatment for uveal melanoma is to prevent extraocular direct spread or metastases (Box 71-1). Maintenance or recovery of good vision is rather secondary, for the reason that almost all forms of current therapy lead to vision-impairing complications. The choice among the wide range of therapeutic modalities is based on the patient's age and general health, tumor location and size, the extent of the tumor, the patient's preferences regarding vision and globe preservation, and the risk of metastases. The current belief is that patients in whom metastatic uveal melanoma develops already have micrometastases at the time their intraocular tumors are first detected. Detection of micrometastases is very important, because the outlook with existing therapies for detectable

Box 71-1. MANAGEMENT OF CHOROIDAL MELANOMA

Observation
- Monitoring should include tumor photography, intravenous fluorescein angiography, ultrasonography, and optical coherence tomography.
- Observation with careful follow-up is appropriate management when the tumor is asymptomatic, without signs of growth, and is less than 10 mm in diameter and less than 2 mm in height.

Surgical Excision (External Eyewall Resection)
- Excision is appropriate management when the tumor does not involve the posterior pole and is less than 15 mm in diameter.
- Good initial vision may be retained.
- Surgical excision has limited application today because of high rates of early and late complications.

Radiation Therapy
- Brachytherapy or external beam irradiation with charged particles can be used.
- Irradiation is appropriate management for tumors less than 15 mm in diameter and less than 10 mm in height.
- Radiation therapy can be used when preservation of vision is possible or if the patient has only one seeing eye.
- Ocular retention is possible in up to 90% of the cases, with preservation of vision in more than 50% of eyes.
- Survival rates in patients with medium-sized melanomas treated with brachytherapy are not different from those with enucleation.

Enucleation/Exenteration
Indications for this modality include the following:
- Eyes with no vision potential
- Eyes in which irradiation will unequivocally lead to vision loss
- Eyes with recurrence after irradiation or surgical treatment
- Eyes containing melanoma with significant extraocular extension (secondary external beam irradiation may be required)
- Eyes with complications (e.g., neovascularization, pain)

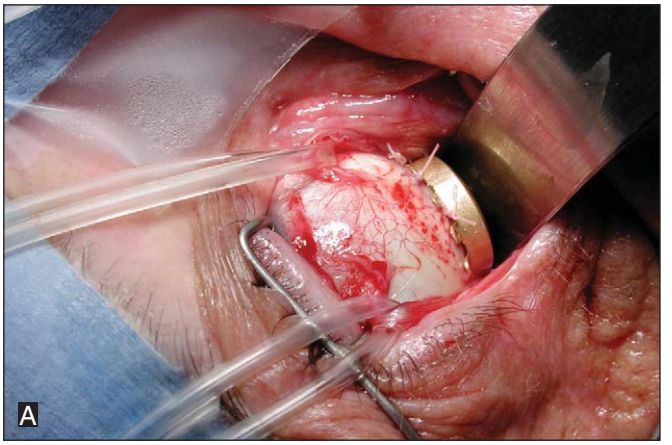
metastatic lesions is dismal; however, treatment of micrometastases promises to be more effective.[57]

At the initial presentation, approximately 30% the tumors are too large for treatment with current eye salvage techniques. Patients with these tumors are managed with primary enucleation. The remaining 70% of tumors are treated with radiation therapy delivered in different forms.[68] The proportion of cases treated by radiotherapy in the United States increased gradually from 2% to 28% over the last 25 years.[69] Brachytherapy frequently is used for tumors 3 to 8 mm in thickness or less than 16 mm in basal diameter[70] (Table 71-6; Fig. 71-8). Irradiation of tumors greater than 10 mm in height or 16 mm in diameter usually leads to serious radiation-related toxicity of the retina and the optic disc. Tumors adjacent to or surrounding the optic nerve also can be treated with brachytherapy, but this strategy increases the chance of nerve and macular radiation toxicity.[71] ^{125}I is the most frequently used radioactive source used in the United States because of its accessibility, relatively long half-life, good tissue penetration, and ease of shielding. The current treatment delivery design includes use of a lead or gold shield with radioactive seeds set within a silicone holder inside the plaque template.

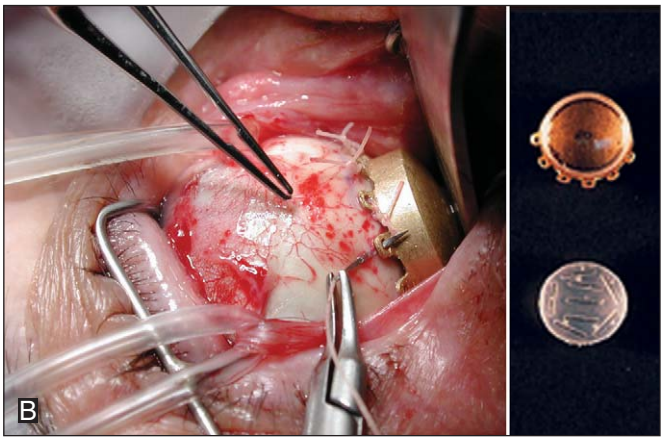
The Collaborative Ocular Melanoma Study (COMS) trial has demonstrated that survival rates in patients with medium-sized melanomas treated with brachytherapy are not statistically different from those for patients whose eyes were enucleated. A mean local control rate of approximately 90% has been reported after approximately 4 years of follow-up. Complication rates and visual outcomes are associated with tumor dose, dose rate, and tumor location and size (patients with larger tumors have worse outcomes). Specifically, maculopathy and papillopathy are more likely to occur in patients with tumors that are near or adjacent to the optic disc or macula. The data from the COMS trial indicate that outcomes for eyes with medium-sized tumors treated with brachytherapy and with enucleation, as determined by Kaplan-Meier analysis, included 5-year rates of all-cause mortality of 18% and 19%, respectively. The 5-year rates of metastasis were 9% after brachytherapy and 11% after enucleation.[72] Studies of juxtapapillary tumors have demonstrated similar rates of metastatic disease.[73] In small choroidal melanomas, on the other hand, the 5-year melanoma-specific mortality rate after ^{125}I plaque radiotherapy has been reported to be approximately 4%.[74]

The COMS trial also reported a 17% incidence of visual acuity of 20/200 or worse by 1 year, and 43% by 3 years after plaque therapy of medium-sized choroidal melanomas.[75] By the fifth year of follow-up, a 10% risk of treatment failure, defined as extrascleral extension, continued growth of the tumor, or recurrence of a tumor that initially responded to radiation, was noted. Although excellent tumor control was achieved in 90% of patients, the visual acuity in 63% of eyes had deteriorated to 20/200 or worse.[76]

Within 12 years after enrollment in the COMS, 45% of the patients were alive and clinically cancer free. Five-, 10-, and 12-year rates of death with histopathologically confirmed melanoma metastasis were 10%, 18%, and 21%, respectively, in the ^{125}I brachytherapy group and 11%, 17%, and 17% in the enucleation group. Older age and larger maximum basal tumor diameter were the primary determinants correlating with melanoma metastasis and death.[77]



It has been reported that final visual acuity after brachytherapy is dependent on the patient's age, systemic medical problems, and initial visual acuity; tumor location and size; presence or absence of subretinal fluid; and the type of isotope used. Visual acuity was best preserved in eyes with small tumors and those with tumors located away from the optic disc and fovea.[78]



The other major radiation delivery system for the treatment of choroidal melanoma is proton beam radiation therapy (PBRT).[79] Although a theoretical advantage of PBRT is the capability focusing the radiation onto the lesion, the efficacy in terms of tumor control and complications is similar to that for brachytherapy.[80] With current PBRT techniques, an approximately 95% local control rate has been achieved. Long-term preservation of eyes is dependent on tumor size and thickness, as is the case with plaque therapy. In one report, approximately 84% of eyes were retained at 15 years.[80,81]

A number of new radiation delivery systems for the treatment of choroidal melanoma are in the process of evolution.[82] The ideal new scheme should be noninvasive and should be less radiotoxic to the eye than PBRT and plaque radiotherapy, while ensuring therapeutic dose delivery as accurate as proton or plaque techniques. It also should allow fractionation of the dose as is used in proton treatment. New techniques, which include gamma knife radiosurgery, linear accelerator-based radiosurgery, and robot-controlled linear accelerator radiosurgery (CyberKnife, Accuray Inc., Sunnyvale, CA), thus far

Table 71-6 Radionuclides Commonly Used in Plaque Brachytherapy for Ocular Tumors

Radionuclide	Half-life
Cobalt 60	5 years
Iodine 125	60 days
Ruthenium 106	366 days
Palladium 103	17 days

have been found to be less effective than conventional delivery systems for the treatment of choroidal melanoma.[83]

Data from the COMS also have revealed that preoperative EBRT before the enucleation of the eyes containing large choroidal melanomas offers no protection against metastatic disease.[84] Other forms of treatment for uveal melanoma—surgical excision of the tumor and laser therapy—have limited applications.

Eye wall resection surgery is done to conserve the eye with as much useful vision as possible when radiotherapy is unlikely to give a satisfactory result, or if extensive retinal detachment develops after radiotherapy. Even in the best hands, however, this kind of surgery is associated with many vision-threatening complications.[85,86] Laser therapy has always been considered to be an attractive potential treatment method for management of choroidal melanoma; however, its applications, even with modern technology, have been limited. At present, the most effective form of laser treatment for uveal melanoma is transpupillary thermal therapy (TTT). TTT is performed with an 810-nm-wavelength laser delivered through a slit-lamp biomicroscope or with an indirect ophthalmoscope. Usually, the eye is anesthetized with a retrobulbar block, and the beam is delivered with use of a lens. The depth of tumor necrosis created by the laser beam is directly correlated with elevations in temperature ranging from 45° to 60° C and exposure time varying from 1 to 10 minutes; but even in the best of circumstances, tumors thicker than 3 mm cannot be effectively treated with TTT. Despite the availability of the aforementioned different treatment modalities, the overall 5-year survival rate for this tumor is still high, ranging from approximately 75% to 85%.[87]

Metastatic Tumors to the Eye

Today, metastatic tumors to the uvea are considered to be the most common type of intraocular neoplasia (Fig. 71-9). The vascular tissue of the posterior choroid is the most likely site for ocular metastasis. Presenting signs and symptoms include metamorphopsia, diminished central vision, and visual field defects. Serous retinal detachment represents the most frequent clinical presentation; pain typically is absent. The diagnostic workup for metastatic lesions is similar to that for choroidal melanoma, with particular use of ophthalmoscopy, IVFA, and ultrasonography. OCT also is useful in the evaluation of secondary RPE changes and in follow-up assessment of lesions after treatment.[88]

Metastatic tumors may originate from a variety of different primary sites, with breast and lung carcinomas being the most common primary malignancies. Treatment options include systemic therapy, EBRT, plaque brachytherapy, PBRT, photodynamic therapy, TTT, and other types of laser photocoagulation[89] (Box 71-2). The selection of the treatment modality depends on the size and location of the tumor, as well as on the life expectancy and preference of the patient. Overall prognosis for patients with metastatic tumors of the choroid is poor. Median survival is approximately 12 months. Palliative treatment for patients with metastatic tumors of the choroid has proved to be effective both in improving visual acuity and in maximizing quality of life.

Another pathologic condition of the eye secondary to neoplasia elsewhere in the body is cancer-associated retinopathy (CAR), an uncommon paraneoplastic retinopathy, most commonly associated with small cell lung cancer, in which antibodies are directed against retinal antigens.[90] Clinical findings typically include bilateral visual loss and electroretinographic abnormalities in the absence of actual metastatic disease in the eye. Visual symptoms may precede diagnosis of the systemic malignancy or ocular metastases.

Ocular Leukemia

Ophthalmic infiltration by acute leukemia is rare.[91] With developing curative advances, the survival of patients with acute leukemia has been considerably prolonged. This has led to an increase in the variability of ocular presentations in the form of side effects of the treatment and the ways leukemic relapses are being first identified as an ocular presentation. Leukemia may involve many ocular and adnexal tissues, including the conjunctiva, cornea, sclera, anterior chamber, iris, lens, vitreous, retina, choroid, and optic nerve, either by direct infiltration or as a result of secondary toxicity due to chemotherapy and radiation therapy (Fig. 71-10). Ocular involvement also may develop in the GVHD reaction seen in patients undergoing stem cell transplantation or occurring as the result of increased susceptibility

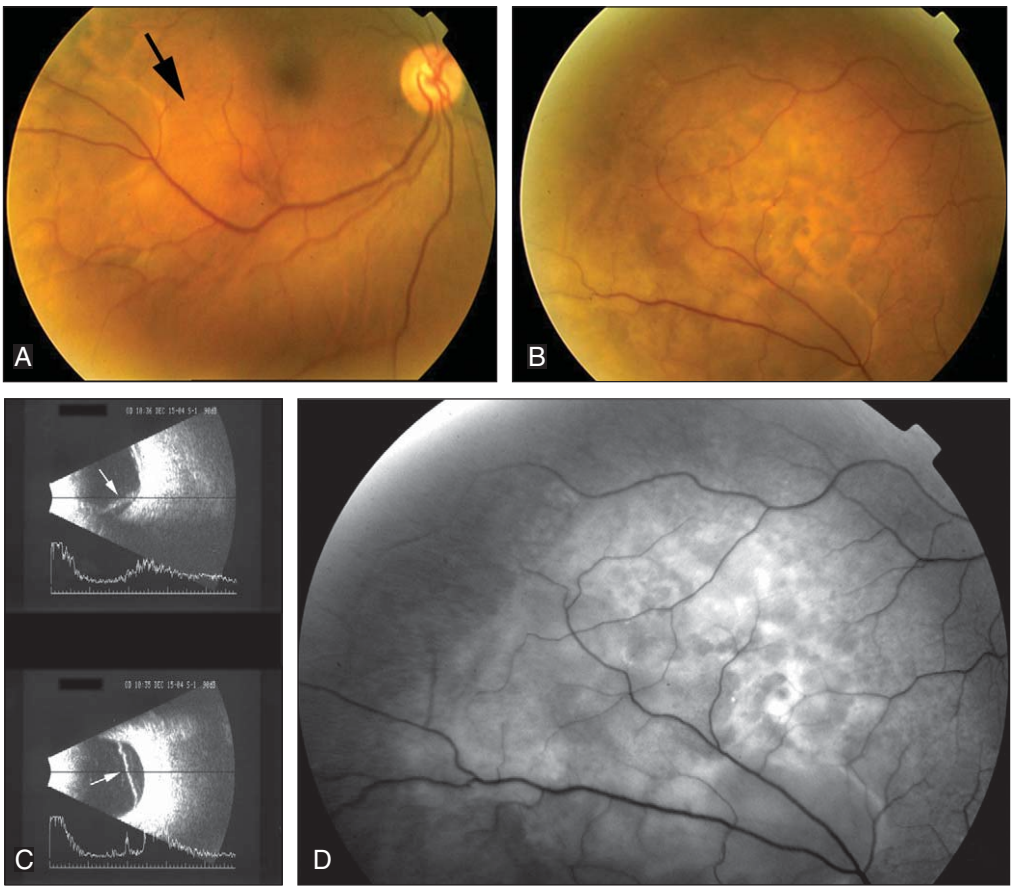

Figure 71-9 • Funduscopic and B-scan ultrasonographic appearance of metastatic breast carcinoma to choroid. **A,** Elevated, nonpigmented mass (*black arrow*). **B** and **D,** Funduscopic and intravenous fluorescein angiography appearance of irregular, flat infiltrates of choroidal metastasis. **C,** The B-scans reveal flat metatastatic lesions and overlying retinal detachments (*white arrows*).

to infections due to immunosuppression in patients with leukemia.[92,93] Early diagnosis and treatment are essential to prevent visual deterioration. Chemotherapy and EBRT are the main modalities of treatment in ocular and orbital leukemia; irradiation may provide more prompt resolution of vision-threatening symptoms.[94]

Box 71-2. MANAGEMENT OF INTRAOCULAR METASTASES

Diagnosis

- Choroidal metastasis should be considered in any patient with cancer who presents with new visual complaints, especially those with breast or lung primaries.
- Indirect ophthalmoscopy shows characteristic multiple, yellowish, low-lying lesions with poorly delineated margins.
- In 10% to 20% of patients, the eye finding is the presenting complaint and precedes the diagnosis of the known primary neoplasm.

Treatment

- Radiation should be given to the eye with metastatic lesions through a lateral field (30 to 40 Gy over 2 to 4 weeks).
- The contralateral eye should be carefully followed to assess for metastatic disease. If no evidence of metastasis is found, treatment fields should avoid this eye as much as possible; if metastases develop later, the fellow eye can then be treated.
- Simultaneous brain metastases should be ruled out.

Intraocular Lymphoma

Primary intraocular lymphoma (PIOL) is a rare subset of intraocular primary CNS lymphoma (PCNSL), in which lymphoma cells invade the eye. PCNSL is an aggressive form of non-Hodgkin's lymphoma typically associated with a worse prognosis than for other extranodal lymphomas with similar histologic characteristics. At least 95% of PCNSLs are of large B-cell histology, the most common subtype of non-Hodgkin's lymphoma. At the time of ocular diagnosis, CNS involvement may or may not be present. The incidence of this tumor has increased over the past several years in immunosuppressed as well as in immunocompetent patients.[95]

Pathogenesis

Some evidence indicates that chronic antigenic stimulation may result in the development of PIOL.[96] The immunophenotype of PIOL is $CD79a^+$, $CD20a^+$, $PAX\text{-}5^+$, $BCL\text{-}2^+$, and $OCT2^+$; the only documented chromosomal translocation is t(14;18), with rearrangements being reported in 56% of the patients.[97]

Clinical Features

In most cases of PIOL, the patient presents with uveitis-like symptoms including pain, blurred vision, and vitritis (Fig. 71-11). It is a common neoplastic masquerade syndrome involving the eye. Its protean ocular manifestations, plus in many cases the initial positive response to steroid therapy for presumed uveitis, may delay proper diagnosis and treatment. A high index of suspicion is essential; prompt tissue biopsy with cytologic and laboratory workup is indicated in any patient in whom PIOL is likely.

Differential Diagnosis

Recent advances in the diagnosis of PIOL are due primarily to improved laboratory methods of processing vitreous specimens for cytologic studies and availability of immunocytologic investigation for lymphoid cells, flow cytometry, cytokine evaluation, and molecular analysis. Because PIOL has a nonspecific presentation, considerations in the differential diagnosis should include infectious and noninfectious causes manifesting with vitreitis or subepithelial infiltration, as well as paraneoplastic syndromes including CRMP-5 optic neuropathies. Because the treatment is prolonged and is associated with significant systemic and ocular complications, tissue diagnosis is important.[96]

Management

Treatment of PIOL may include EBRT and systemic chemotherapy with high-dose methotrexate-based regimens, as well as intraocular injections of methotrexate and rituximab (anti-CD20 antibody). In cases in which the vitreous cells persist after systemic chemotherapy, methotrexate may be given intravitreally thereafter; this is an effective, repeatable, and safe treatment.[98] Ocular remissions typically are sustained for years, but recurrence is possible. EBRT, which usually is delivered with high-energy photons, causes the production of free radicals, which target the DNA of the tumor cell. Today, EBRT to the eye and CNS is being used less often to treat this disease. Prognosis is poor owing to CNS involvement.

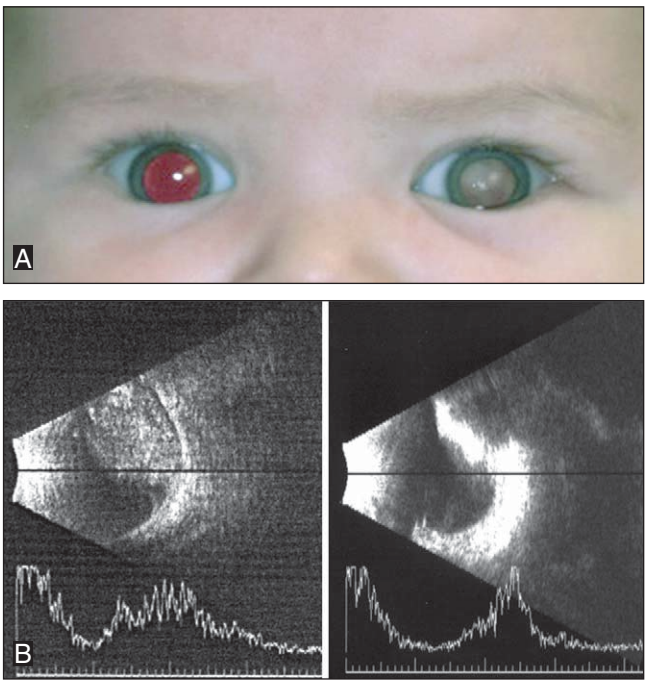
Retinoblastoma

Retinoblastoma, the most common intraocular neoplasm of childhood, is reported to have an incidence of approximately 6 in 100,000 live births, accounting for approximately 10% of cancers during the first year of life. Approximately 300 new cases are diagnosed annually in the United States.[99,100] Approximately one third of cases of retinoblastoma are bilateral tumors.[101] This neoplasm, primarily a disease of early childhood, has been detected even in fetal life.[102,103] It also may rarely occur in children older than 5 years of age and more rarely in young adults.[104]

Pathogenesis

Retinoblastoma is the prototypical model of hereditary neoplasms; it develops as a result of mutational inactivation of both alleles of the retinoblastoma gene (*RB1*).[105] This gene is mapped to chromosomal band 13q14. The *RB*-encoded protein (pRb) is a tumor suppressor that plays a pivotal role in negative control of the cell cycle and in tumor development. It has been shown that pRb is responsible for a major G_1 checkpoint, blocking S-phase entry and cell growth. Loss of pRb functions may induce cell cycle deregulation and so lead to a malignant phenotype. Gene inactivation of pRB through chromosomal mutations is one of the principal reasons for retinoblastoma development.[106] Functional inactivation of pRb by viruses also is documented in many malignancies, including cervical cancer, mesothelioma, and Burkitt lymphoma.[107]

The two-mutation model of Knudson (the "two-hit" hypothesis) dictates that the development of retinoblastoma is caused by two corresponding chromosomal mutations. In hereditary retinoblastoma, the initial occurrence, or "hit," is a germinal mutation that is inherited to be present in all the child's cells. The second hit occurs sometime during development and, if it occurs in a somatic cell such as the primitive photoreceptors, then the tumor develops. Therefore, in hereditary cases of retinoblastoma, all cells in the body are predisposed to neoplastic development, because germline mutation (the first hit) takes place in all cells of the body. This predisposition also may help to explain the high incidence of multiple nonocular tumors, such as sarcomas, lymphomas, and brain, seen in patients with hereditary retinoblastoma.



On the other hand, in most cases of unilateral sporadic retinoblastoma, the two hits occur during development of the retina, and both are somatic mutations. Theoretically, the rest of the body carries no higher risk for the development of other tumors, because affected persons have a normal chromosomal pattern in cells elsewhere in the body. It is well known that survivors of hereditary retinoblastoma have an increased risk for multiple malignant and benign neoplasms, especially soft-tissue sarcomas.[108] Some reports indicate a greater than 10-fold increase in overall mortality in patients with retinoblastoma compared with the general population, because of second malignancies.[109] For practical purposes, a child with retinoblastoma has approximately a 5% chance of developing another malignancy during the first 10 years of follow-up, 20% during the first 20 years, and 25% within 30 years. Survivors of hereditary retinoblastoma revealed a statistically significant increase of leiomyosarcoma and other soft-tissue sarcomas that persists decades after their initial diagnosis. These patients should undergo lifelong medical monitoring for sarcomas.[110] The 30-year cumulative incidence of nonocular tumor development is approximately 30% for those patients with retinoblastoma treated with EBRT, compared with approximately 10% for those patients who did not receive radiation. It has been reported that among patients with retinoblastoma treated with radiotherapy, an increased incidence of soft-tissue sarcomas, especially leiomyosarcomas, are found in the radiation field, as well as outside the field of radiation.[110]

Morphologically and clinically, hereditary and nonhereditary tumors generally are indistinguishable. The most important differences are that hereditary retinoblastoma usually occurs at a younger age and is more likely to be bilateral and multicentric. Although approximately one third of cases of retinoblastoma are inherited, only about 5% of patients in newly diagnosed cases present with a family history. Patients with bilateral tumors and those with a positive family history can be safely assumed to have a germinal mutation for the *RB* gene; for practical purposes, these patients are at a 50% risk of transmitting the *RB* gene to their offspring by autosomal dominant transmission. The gene is approximately 80% penetrant, so clinical expression will be seen in approximately 40% of these patients' children; some offspring may be merely carriers of the gene, without development of clinical manifestations of the tumor. Approximately 15% of unilateral tumors develop by germinal mutations that, by chance, affect only one eye. The remaining 80% to 85% of unilateral tumors are due to somatic mutations that involve only the retina; in such cases, the disease is not passed on to future generations.

Clinical Features

Leukocoria, or cat's eye reflex (seen in 55% of cases), and strabismus (seen in 20%) are the most common presenting signs of retinoblastoma in children in Western countries[111,112] (Fig. 71-12). Retinoblastoma also may manifest with atypical features such as uveitis, vitreous hemorrhage, and orbital cellulitis, particularly in older children.[104] An important point is that invasive treatment and vitrectomy should be avoided in these children until the possibility of underlying retinoblastoma is excluded.[113]

The most dependable way of diagnosing retinoblastoma is by means of dilated indirect ophthalmoscopic examination performed with the patient under general anesthesia (EUA); tumor, if present, is recognized as a characteristic whitish gray mass within the eye[114] (Fig. 71-13). Dilated fundus examination also permits identification of multifocal tumor or vitreous seeding. Currently this examination is made even more rewarding with the digital image capture and storage capability of the wide-angle fundus visualization systems, which include Retcam 120 (Massie Research Laboratories, Dublin, CA), Optomap (Optos, Marlborough, MS), and Panoret-1000 (CMT Medical Technologies Inc., Valley Stream, NY). The risk of general anesthesia is balanced by the benefit of improved survival of the patient and preservation or maximization of vision. The currently recommended schedule for surveillance among persons in whom a nongermline mutation is proved by genetic screening may perhaps be relaxed in the future, but in today's clinical practice, multiple

EUAs within the first 5 years of life is the standard of care. Additional tests, although not always necessary, may be performed to confirm the diagnosis, but ocular biopsy in retinoblastoma is not done for histopathologic confirmation because of the fear of carrying tumor cells to extraocular tissues.[115]

Ocular A- and B-scan ultrasonography or CT may demonstrate a solid intraocular tumor with characteristic calcifications. CT also may be required to exclude a concomitant primitive neuroectodermal tumor (PNET) in the midline (i.e., the so-called trilateral retinoblastoma, which consists of bilateral retinoblastomas and concomitant pineal PNET).[116–118]

Spontaneous regression of retinoblastoma is an exceptionally rare occurrence. If the tumor is not treated, it will rapidly enlarge to occupy the entire globe and extend into adjacent orbital, periorbital, and intracranial tissues[119] (Fig. 71-14). The most common routes of extension are by direct infiltration of the optic nerve or sclera and spread via the choroid.[120] The risk of neural spread depends on the level of the invasion of tumor cells into the optic nerve. Mortality rates of up to 85% and 70% have been reported if tumor cells have reached the surgical transaction margin of the optic nerve and posterior to the lamina cribrosa, respectively. Additional routes of spread include dispersion of the tumor cells through the subarachnoid space into the CNS, lymphatic dissemination of the tumor anteriorly into the conjunctiva and eyelids, and hematogenous metastases to distant organs such as the bone, liver, and brain.

MRI can be particularly helpful in those cases with possible extension into the optic nerve or choroid; fat suppression and gadolinium contrast techniques constitute the best imaging choice[121] (see Fig. 71-14). If imaging provides evidence of tumor outside the eye, a metastatic workup should be pursued.[122] Metastatic disease is rarely suspected at the time of initial presentation, and the usual tumor staging studies such as bone marrow biopsy, lumbar puncture, radionuclide bone scan, or PET usually are not performed. In the usual case of endophytic retinoblastoma in which the optic nerve can be seen, the morbidity associated with metastatic screening tests outweighs their likely value.[123] Symptoms and signs of metastatic disease may include weight loss, vomiting, headache, neurologic impairment, orbital mass, or enlarged neck nodes.[124] Preoperative bone scan is not justified in patients with intraocular disease even when it is advanced. Bone scan should be done only in patients with documented extraocular metastatic disease.[125]

The Reese-Ellsworth classification, still the most widely used retinoblastoma organization system, is based on intraocular tumor staging and globe salvage prediction after EBRT; survival is not taken into account in this categorization.[126] A newer proposed organization for the disease, the International Intraocular Retinoblastoma Classification (the "ABC classification"), is more suitable to current management senarios for this tumor.[127,128] This classification stages intraocular tumors according to their prognosis after chemoreduction and adjuvant focal therapy. It consists of five groups—A, B, C, D, and E—in descending order of favorable prognosis (Table 71-7).

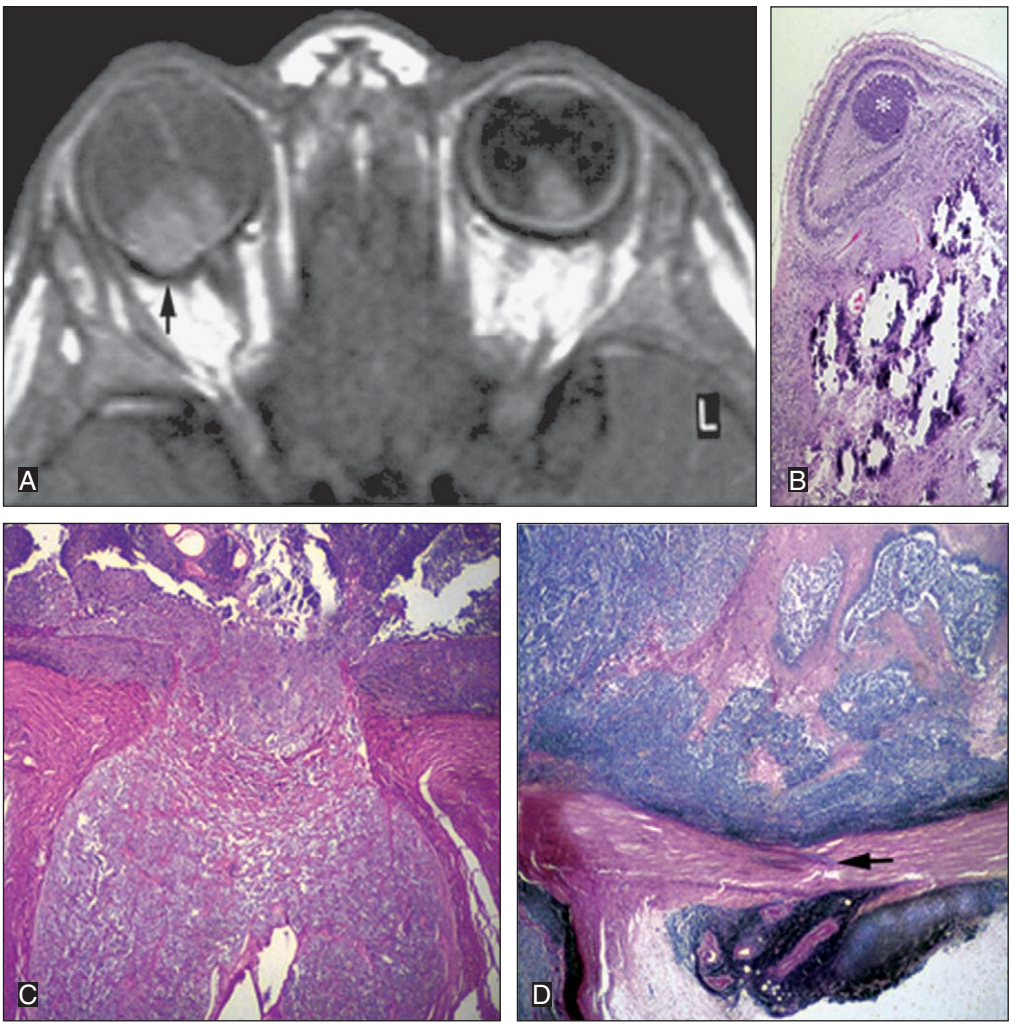

Figure 71-14 • A, T_1-weighted axial magnetic resonance image shows the extraocular extension of retinoblastoma into the orbit (*black arrow*). **B,** Contrasting histopathologic appearance of viable (*asterisk*) versus calcified tumor after external beam irradiation. **C** and **D,** Images reveal extension of the tumor into the optic nerve and then to the orbital soft tissues through scleral blood vessels (*black arrow*).

Table 71-7 International Intraocular Retinoblastoma Classification

Group	Quick Reference	Specific Features
A	Small tumor	Retinoblastoma ≤3 mm*
B	Larger tumor	Retinoblastoma >3 mm *or*
	Macula	Macular retinoblastoma location (≤3 mm to foveola)
	Juxtapupillary	Juxtapupillary retinoblastoma location (≤1.5 mm to disc)
	Subretinal fluid	Additional subretinal fluid (≤3 mm from margin)
C	Focal seeds	Retinoblastoma with
		Subretinal seeds ≤3 mm from retinoblastoma
		Vitreous seeds ≤3 mm from retinoblastoma
		Both subretinal and vitreous seeds ≤3 mm from retinoblastoma
D	Diffuse seeds	Retinoblastoma with
		Subretinal seeds >3 mm from retinoblastoma
		Vitreous seeds >3 mm from retinoblastoma
		Both subretinal and vitreous seeds 3 mm from retinoblastoma
E	Extensive retinoblastoma	Extensive retinoblastoma occupying >50% globe *or*
		Neovascular glaucoma
		Opaque media from hemorrhage in anterior chamber, vitreous, or subretinal space
		Invasion of postlaminar optic nerve, choroid (>2 mm), sclera, orbit, anterior, chamber

*Refers to 3 mm in basal dimension or thickness.

Differential Diagnosis

Other causes of leukocoria such as Coats disease, persistent hyperplasic primary vitreous, retinopathy of prematurity, *Toxocara* endophthalmitis, large retinal detachments, and rarely unilateral congenital cataracts may be confused with retinoblastoma.[129,130] Most of these pathologic conditions can be differentiated easily from retinoblastoma with today's advanced diagnostic technologies. Coats disease, however, may still be a problem when it presents in young children. MRI or IVFA can be helpful, particularly when Coats' disease with retinal detachment is in the differential diagnosis.[131,132]

Management

Retinoblastoma is now considered a "curable" tumor if it is diagnosed early. Early treatment of the disease is effective at a reasonable cost, saving both life and vision. Undertaken at a late stage, however, treatment is very costly, with poor outcome, particularly for vision. This underlines the call for early diagnosis and the importance of public and professional awareness of this deadly disease.[133] The hereditary form is associated with increased risk of second nonocular primary malignancies that are even more lethal than the retinoblastoma itself.[134]

Management of retinoblastoma should be tailored to the individual patient. All parameters should be taken into account, including the size, location, and laterality of the tumors; threat of metastases; risks for second malignancies; and projected visual prognosis. Today's treatment methods include chemotherapy (i.e., chemoreduction) with intravenous carboplatin, etoposide, and vincristine; subconjunctival carboplatin injection; TTT; cryotherapy; laser photocoagulation; plaque brachytherapy; EBRT; and enucleation or exenteration[135] (Fig. 71-15). In general, eyes classified as group A are treated with cryotherapy or laser photocoagulation, or both. Eyes classified as group B or C typically receive chemoreduction; unilateral cases without seeding may be managed with plaque brachytherapy. Eyes with diffuse vitreous seeding (group D) are treated with either chemoreduction, EBRT, or enucleation, depending on the laterality of the disease. Chemoreduction usually reduces tumor volume by more than 50% within a few weeks and dries out most of the retinal detachment. The choice of antimetabolic agents, dosage, and the duration of treatment will vary from one hospital to another; however, most centers make use of vincristine, carboplatin, and an epipodophyllotoxin (etoposide or teniposide).[136] The tumor-related disadvantage of chemoreduction is the recurrence of vitreous or subretinal seeding or appearance of new crops of retinoblastomas elsewhere (in approximately one fourth of cases) in the eye after the discontinuation of therapy.[137] A permanent response is almost never achieved with chemoreduction alone, so the response to this treatment should be monitored closely and other focal therapies should be implemented before the recurrent tumor gets a chance to reach a large size. Also, chemoreduction is not without its systemic side effects, such as

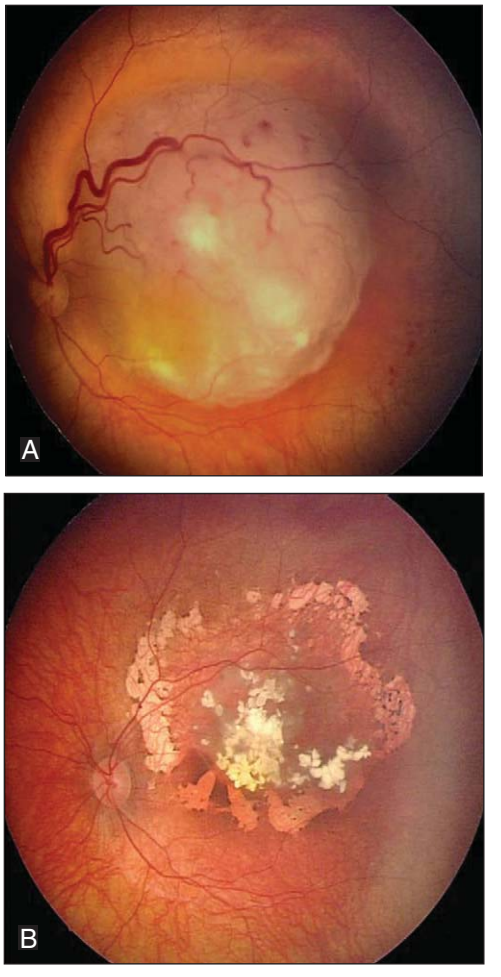

Figure 71-15 • **A** and **B,** Prechemoreduction and postchemoreduction appearance of a large solitary retinoblastoma nodule.

bone marrow suppression, loss of hair, and, possibly more serious, long-term complications such as development of second malignancies. Final data on chemoreduction are not yet available.

Plaque radiotherapy is a form of brachytherapy in which a radioactive seed carrier (i.e., plaque) is surgically sutured over the wall of the eye at the base of a tumor focus for transscleral irradiation (see Fig. 71-8). Placement of radioactive plaques (^{125}I, ^{106}Ru) is limited to tumors measuring approximately less than 15 mm in cord diameter and 8 mm in thickness and can be used for the primary treatment of medium-sized tumors. When a retinoblastoma focus reaches these sizes, however, it usually breaks down, with seeding into the vitreous and subretinal spaces. Therefore, the plaques more often are used as a secondary measure after other forms of treatment. Currently, the most widely used plaque is the ^{125}I plaque, which delivers unidirectional low-energy gamma rays that can be shielded well. The old cobalt 60 plaques have been largely abandoned because their high-energy gamma rays cannot be shielded effectively. When plaque radiotherapy is given in cases with extensive subretinal or vitreous seeding, it has a high failure rate.[138] On the other hand, when this method is used as a primary treatment of RB, it provides long-term tumor control in almost 90% of cases. It also is very effective in those eyes in which a focus of RB recurs after chemoreduction. Of note, although plaque radiotherapy is much safer than EBRT in terms of local radiation toxicity, it may lead to localized radiation effects such as radiation vasculopathy, maculopathy, or papillopathy, depending on the location of the lesion.

EBRT is no longer considered to be first-line conservative treatment owing to its important long-term side effects. It may still be needed, however, in advanced bilateral disease or for control of recurrent tumors inaccessible to focal treatment methods. The customary total radiation dose is 40 to 50 Gy, delivered in fractions of 1.8 Gy through a lateral or anterior port. The use of other delivery techniques for external beam irradiation such as stereotactic conformal radiotherapy and accelerated proton beam irradiation are not commonly used in retinoblastoma.

The other form of treatment to be taken into account for retinoblastoma is enucleation. Although enucleation has become less common with early diagnosis and better alternative therapies for this tumor, it remains the treatment of choice for advanced disease in eyes with no visual potential or with high risk of metastasis. For unilateral tumors, enucleation is required in approximately two thirds of cases.[139] This stems from the fact that most cases of unilateral sporadic retinoblastoma are detected by the affected child's parents, who notice leukocoria or strabismus when the disease is advanced.[140] For those patients with less advanced unilateral disease, chemoreduction with focal consolidation of each focus of tumor with thermotherapy or cryotherapy or the use of plaque brachytherapy is helpful. The great majority of group E cases are managed by enucleation or more extensive surgical procedures such as exenteration with or without EBRT to the socket and adjuvant chemotherapy. Children with dissemination of retinoblastoma to the CNS or metastatic disease remain incurable and die of progressive disease despite the aggressive treatment.[124,141]

CONJUNCTIVAL TUMORS

Conjunctival tumors comprise neoplasms originating from cells of all germ layers, including epithelial, melanocytic, glandular tissue, vascular, and other soft tissue elements, and other cells.[142] This section covers only the commonly encountered malignancies, including melanoma, squamous cell carcinoma, and Kaposi's sarcoma.

Conjunctival Squamous Cell Carcinoma

Squamous cell carcinoma is the most frequently encountered malignancy of the conjunctiva; the incidence of this tumor varies, ranging from 0.025 to 3.5 per 100,000 population, depending on the geographic location.[143,144] The mean age of affected patients is approximately 60 years. Although this tumor is considered to be a low-grade malignancy, local extension into the globe and underlying eyelid structures may be seen. Regional and distant metastases are rare, but the tumor may show local aggressiveness.[145]

Pathogenesis

The etiology of conjunctival squamous cell carcinoma is multifactorial, involving such factors as age, fair pigmentation, ultraviolet light exposure, and exposure to human papillomavirus (HPV). Ultraviolet radiation is considered to be the most important cancerogenic factor for conjunctival squamous cell carcinoma.[146]

In the past, HPV infection and impairment of p53 function have been identified as frequent events in conjunctival squamous cell carcinoma.[147] Recent studies, however, indicate that the role of HPV in the pathogenesis of conjunctival and eyelid tumorigenesis may be auxiliary. The p53 protein probably is involved in the development of conjunctival and eyelid carcinomas, owing to its frequent presence in both benign and malignant neoplasms of the eyelids.[148,149]

It seems that human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) and other forms of immunosuppression-related conjunctival squamous cell carcinoma and virus-associated tumors are increasing in Africa and elsewhere in the world. Recent studies have described conjunctival tumors that behave more aggressively and are seen in younger patients.[150,151]

Clinical Features

The most common presenting signs and symptoms of conjunctival squamous cell carcinoma are redness and irritation of the eye with or without foreign body sensation. The bulbar conjunctiva, particularly the limbus, is the frequent site for the occurrence of a slow-growing, elevated pinkish gray lesion with a pearly or gelatinous appearance with surrounding feeding vessels. Similar to squamous epithelial neoplasms elsewhere in the body, conjunctival tumors evolve through morphologic advances of dysplasia, to carcinoma in situ, to the invasive stage (Fig. 71-16). The degree of dysplasia in these lesions cannot be determined by clinical examination; therefore, it is absolutely necessary that they be biopsied and examined histopathologically.[152,153] Although most lesions manifest as a localized mass formation, atypical presentations of squamous cell carcinoma as a diffuse growth or a masquerade lesion mimicking scleral keratitis or scleromalacia also have been reported.[154] Both carcinoma in situ and the invasive form are considered to be low-grade malignancies that are locally invasive but rarely manifest with distant metastases. Once the neoplasm breaks through the basement membrane of the conjunctival epithelium and invades the subepithelial tissues and episclera, however, it behaves in a locally aggressive fashion.[155] Although squamous cell carcinomas are slowly growing tumors, under certain conditions they are known to extend into the underlying structures, including the globe and the orbit[156] (see Fig. 71-16).

Differential Diagnosis

Conjunctival squamous cell carcinoma should be differentiated from pingueculum or pterygium, foreign body granuloma, and other tumors of the conjunctiva such as lymphoma, melanoma, and metastatic tumors.

Management

The treatment of of conjunctival squamous cell carcinoma varies depending on the age and the extent of development. The management of superficial disease (carcinoma in situ, superficially invasive tumor) include surgical excision of the lesion with lamellar scleral keratoconjunctivectomy and cryotherapy.[157,158] Although other treatments and immunotherapy with dinitrochlorobenzene and photodynamic therapy have been used, most of these regimens do not offer

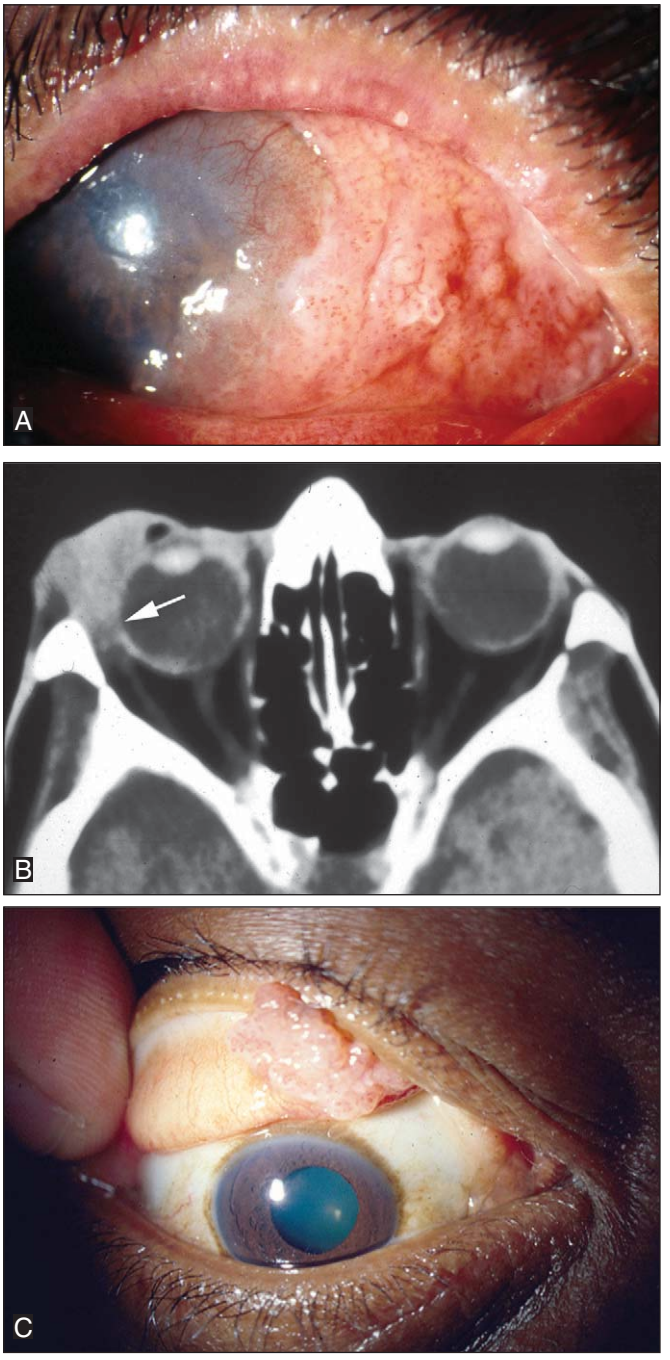

Figure 71-16 • **A** and **B,** Slit-lamp photograph and axial computed tomographic scan showing advanced-stage conjunctival squamous cell carcinoma originating from bulbar conjunctiva. Notice that the tumor extends into the orbital soft tissue laterally (*white arrow* in **B**). **C,** Squamous cell carcinoma originating from a conjunctival inverted papilloma of tarsal conjunctiva of the upper eyelid.

a very good prognosis.[159] Topical chemotherapy with mitomycin C and 5-fluorouracil has been reported to yield good results in superficial cases. A literature review reported that the use of mitomycin C, 5-fluorouracil, and interferon alfa-2b offers tumor regression rates for carcinoma in situ and squamous cell carcinoma ranging from 80% to 96%. Side effects of keratitis, redness, and irritation occurred most often with mitomycin C, followed by 5-fluorouracil and interferon alfa-2b.[160,161] Radiation treatment with brachytherapy and EBRT may be considered in recurrent cases with or without globe invasion.[162] Current knowledge of the efficacy of EBRT is limited; however, proton beam therapy may be considered as a possible alternative to enucleation for the treatment of invasive conjunctival squamous cell carcinoma, although it has serious side effects.[163]

Conjunctival Melanoma

Conjunctival melanoma is a rare ocular malignancy, with an estimated incidence of 5 cases per 1 million population annually; the incidence of melanoma is much lower in the nonwhite population, but the tumor may be seen exceedingly rarely.[164,165] Although conjunctival malignant melanoma is a rare disease, it is life-threatening, and complete tumor excision and other treatments are mandatory to prevent local recurrence and metastasis.

Pathogenesis

Conjunctival melanoma originates from dendritic melanocytes of the basal layer of the conjunctival epithelium. It is estimated that about 20% of conjunctival melanomas arise from pre-existing nevi, another 70% develops from primary acquired melanosis (PAM), and the rest is considered to develop de novo without a pre-existing lesion.

Conjunctival melanoma refers to the development of excessive melanocytic pigmentation as either an epithelial or a subepithelial lesion. Grayish blue subepithelial lesions occur congenitally and do not become malignant. PAM usually develops in the later decades of life and may be due to simple hyperplasia of conjunctival melanocytes, or to atypical melanocytic hyperplasia, which eventually progresses to malignant acquired melanosis and melanoma.

Clinical Features

Clinically, PAM areas form unilateral, tannish brown or black, flat, localized or patchy lesions (Fig. 71-17). Clinical experience indicates that approximately one third of these lesions may eventually become melanomas, but the process is slow, usually taking several decades.[166] Malignant PAM lesions appear as darkly pigmented, irregularly thickened, nodular foci, arising within pre-existing flat lesions. The rapid growth, high vascularity, spontaneous bleeding, and fixation to underlying tissues of melanomas differentiate malignant transformation from benign PAM and cyst-containing nevi. Any long-standing conjunctival nevus that suddenly changes in size, color, or overall appearance should be excised for histopathologic examination.

In early stages, conjunctival melanoma lesions are not deeply invasive into the underlying tissues, and surgical excision is easy. With growth of the tumor, however, fixation to underlying structures may occur, and eventually the tumor invades the lacrimal drainage system, globe, or orbit.[167] Survival time after primary diagnosis of conjunctival melanoma averages approximately 6 years, with death ensuing from postregional metastasis within a median of approximately 12 months. Regional metastasis after treatment is associated with a poor prognosis.[168,169]

Differential Diagnosis

The significant issues in the differential diagnosis lie in distinguishing between ordinary PAM and PAM with atypia, and between a nevus and conjunctival melanoma. Other masses such as conjunctival lymphoma, carcinoma, and granulomatous lesions also are seen occasionally. In most instances, the biopsy findings are conclusive. An anterior uveal melanoma with extrascleral extension may manifest as an epibulbar pigmented tumor mass; this should not be confused with conjunctival melanoma. If the clinical findings are suggestive, a high-resolution echographic examination with A and B scans or MRI will be helpful.

Management

Current management for early conjunctival melanoma is surgical excision under frozen section control whenever possible, followed by

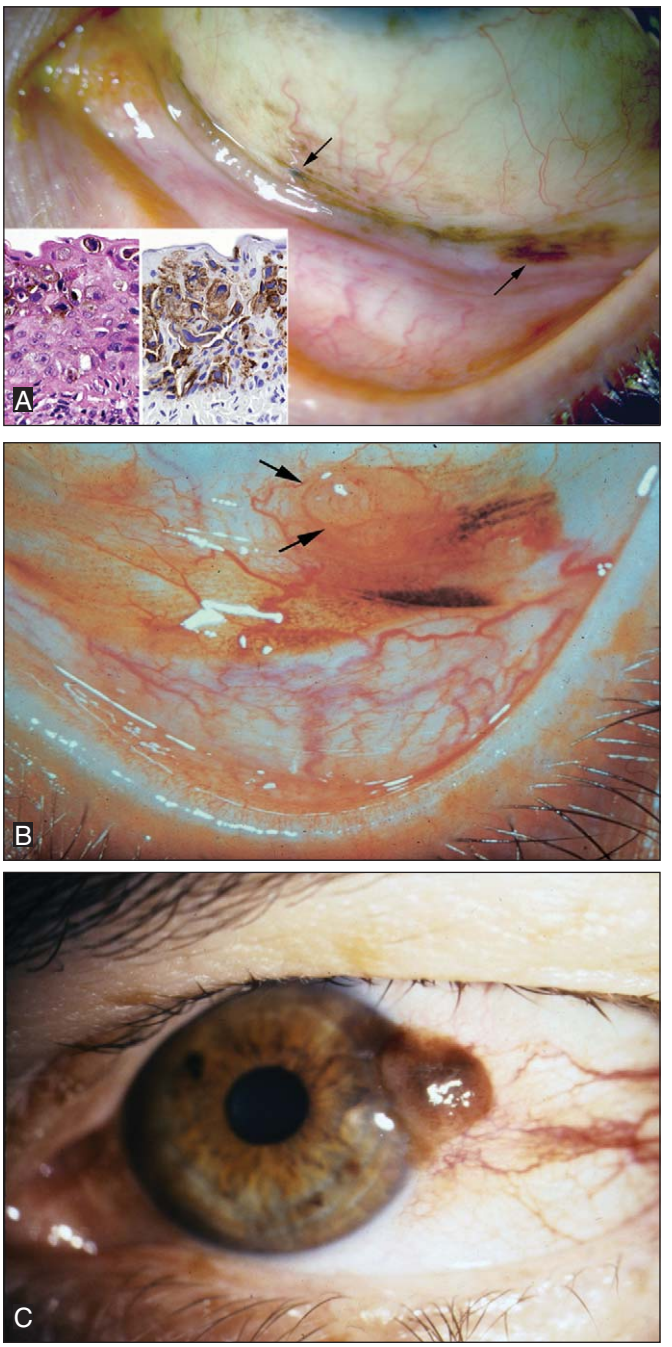

Figure 71-17 • Conjunctival pigmented lesions. **A,** Recurrent primary acquired melanosis (PAM) (*arrows*). *Inset*: The histopathologic appearance of the atypical melanoctes in hematoxylin-eosin and Melan-A stains. **B,** Transition of PAM to elevated but not pigmented lesions of conjunctival melanoma (*arrows*). **C,** Pigmented conjunctival melanoma at the limbus.

alcohol epitheliectomy and cryotherapy to the margins of excision. With larger tumors, the surgical technique should include wider and deeper excision for melanomas on the surface of the eye. Enucleation or exenteration should be considered for tumors with ocular or orbital invasion. In patients with large tumors, the regional lymph nodes should be biopsied for staging purposes. Some histopathologic features observed in the biopsy indicate the likelihood of recurrent and disseminated tumor. These include invasive melanoma thickness more than 0.8 mm, lack of inflammatory cell response at the invasive front, five or more mitotic tumor cells per 10 high-power fields (HPFs), and involvement of orbital soft tissues with melanoma and positive lateral and deep margins of the excisional biopsy. With one or more of these findings, the patient should undergo clinical evaluation every 2 to 3 months for 1 to 2 years to detect recurrent tumor. Recurrent cases should be evaluated for regional lymph node involvement and metastatic disease.

Once the tumor extends into the orbit, local resection of the lesion is no longer feasible and exenteration may be indicated. According to some physicians, exenteration should only performed for tumors involving the fornices or extending to the eyelid skin and for tumors which do not respond to EBRT. Recent investigation of regional lymph node metastasis in conjunctival melanoma performed with sentinel lymph node mapping and biopsy indicate that preauricular lymph nodes are most commonly involved. The sentinel lymph node biopsy may be used as a piece of information in decision making for exenteration. Other clinical features reported as predictive of orbital extension of conjunctival melanoma include visual acuity of 20/200 or worse, extralimbal location, amelanotic tumors, caruncular lesions, and tumors that manifest with histopathologic invasion deeper than 1 mm. Paridaens and coworkers reported mortality rates between 33% and 50% for melanomas thicker than 1-mm invasion despite exenteration.[170] The same investigators indicated that invasion of the lymphatics, blood vessels, and sclera, as well as the incomplete excision at the time of initial treatment, indicated very poor outcomes.

Topical mitomycin treatment also shows considerable promise, particularly in the treatment of diffuse PAM with atypia. Long-term data are lacking, however.[171,172]

Although radiotherapy has been tried on conjunctival melanomas, these tumors are not very responsive to radiation, and EBRT may lead to various complications. Proton beam irradiation can serve as an alternative therapy to exenteration in cases of conjunctival melanoma with a large, diffuse, or multilocular growth pattern.[173] In extended tumors, ocular surface toxicity can result after therapy. Some physicians suggest that brachytherapy may offer better therapeutic outcomes with these tumors.[174]

Kaposi's Sarcoma of the Conjunctiva

With the advent of the HIV/AIDS epidemic, the incidence of conjunctival or eyelid Kaposi's sarcoma has increased, with development of these tumors in approximately 10% of HIV-infected male patients.[175] This rate varies among patient populations, however. An important point is that Kaposi's sarcoma is a multifocal disease, affecting, for example, the skin, mucous membranes, lung, and gastrointestinal tract; dissemination of the lesions carries significant morbidity and mortality.

Clinical Features

Conjunctival tumors appear as flat or slightly elevated, dark reddish plaques or larger, circumscribed nodular masses (Fig. 71-18). These mass lesions can cause local irritation, chemosis and lid edema, trichiasis, ptosis, and visual problems.

Pathogenesis

Current evidence suggests that Kaposi's sarcoma is not a true tumor but rather represents a dysregulation of the inflammatory response. It is associated with viral infections, and the lesion's growth depends on numerous cytokines and growth factors, including the *tat* gene from the HIV genome.[176]

Differential Diagnosis

Conjunctival lesions may be confused clinically with pyogenic granuloma, hemangioma, subconjunctival hemorrhage, and inflamed pinguecula or bacillary angiomatosis from *Bartonella henselae* infection. Eyelid lesions may be confused with melanocytic tumors.

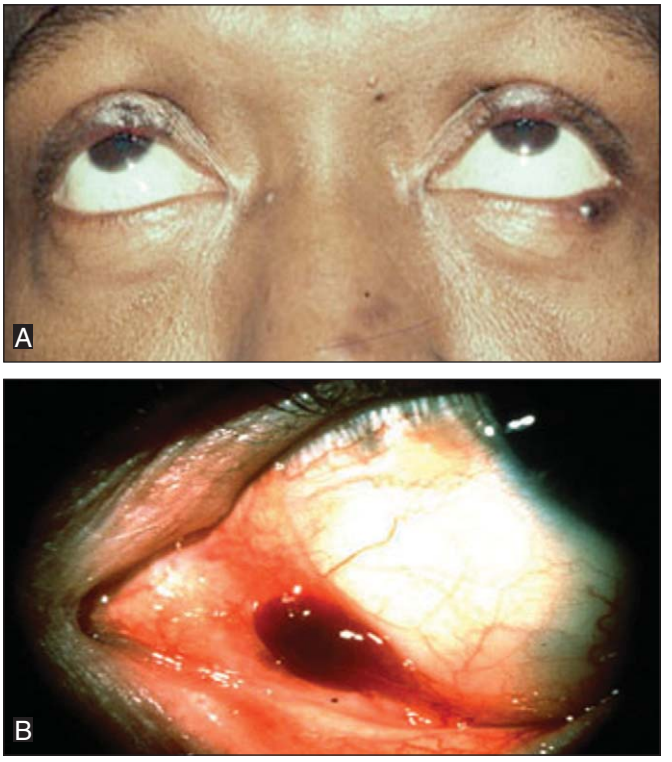

Figure 71-18 • Multiple foci of skin, eyelid, and conjunctival Kaposi's sarcoma in a patient with acquired immunodeficiency syndrome.

Management

Because of their apparent location, many lesions are discovered early and can be observed without treatment. Others can be surgically removed with 1- to 2-mm margins, but recurrence is common. Cryotherapy and local injections of antimetabolites and immunomodulators such as interferon-α and human chorionic gonadotropin have been reported to be effective in some patients. If the systemic antiretroviral therapy has favorably affected the course of HIV infection with normalized $CD4^+$ levels, the associated Kaposi's sarcoma may regress.[176]

Radiotherapy also has been used effectively to treat ophthalmic Kaposi's sarcoma, but it is associated with numerous side effects and a high recurrence rate. It has been reported that a single dose of 800 cGy is a safe and effective palliative therapy for ophthalmic Kaposi's sarcoma.[177] Conjunctival and eyelid Kaposi's sarcomas seem to be more radiosensitive when compared with these tumors in other cutaneous sites, with a higher remission rate; an approximately 95% remission rate was reported with use of single doses ranging from 10 to 20 Gy.[178]

EYELID TUMORS

Eyelid tumors originate from many tissue components, including skin, glandular structures, vascular and other mesenchymal elements, lymphoid tissue, and other types of cells. This section covers the commonly encountered malignancies, including basal cell carcinoma, squamous cell carcinoma, sebaceous gland carcinoma, and melanoma.

Basal Cell Carcinoma of the Eyelid

Basal cell carcinoma accounts for greater than 90% of malignant eyelid tumors.[179] It rarely metastasizes, but may lead to significant morbidity and mortality by invading contiguous structures around the eye and the orbit. The mortality rate from basal cell carcinoma is approximately 10%, which is due mostly to intracranial extension. The typical patient is an elderly person who has been exposed to actinic radiation. Despite its prevalence in adults, it is extremely rare in children.[180]

Pathogenesis

The factors accounting for the development of basal cell carcinoma are complex and still not completely understood. Ultraviolet light (UV) exposure is a major influence, but its relationship to clinical phenotype is not yet clear. In addition, immunosuppression has been shown to be a significant risk factor.[181] UV radiation not only induces DNA damage in epidermal cells but also interferes with the pattern of the apoptosis process in the epidermis. Excessive UV exposure can mutate the p53 tumor suppressor gene, leading to the loss of its repair function and thus creating an apoptosis resistance. If the DNA damage is not repaired or the damaged cells are not eliminated by apoptosis, the result is uncontrolled proliferation and eventual formation of basal cell carcinoma. An additional pathway has also been identified for tumor formation.[182] A number of hereditary syndromes including basal cell nevus syndrome of Gorlin-Gotz,[183] linear unilateral basal cell nevus,[184] Rombo syndrome,[185] and Bazex syndrome[186] are associated with basal cell carcinoma.

Clinical Features

The most common sites for basal cell carcinomas on the eyelids are, in order of frequency, the lower eyelid, the medial canthus, the lateral canthus, and the upper eyelid. Four main subtypes of this tumor are recognized, each with a different clinicopathologic pattern and with distinct biologic behavior: nodular ("rodent ulcer"), sclerosing (morphea-like type), superficial, and basosquamous.

The nodular subtype accounts for 75% of all tumors. This lesion usually begins as a small translucent papule. As it gets larger, it forms a zone of central necrosis and ulceration as the tumor outgrows its blood supply. The periphery of the tumor is raised with pearly margins and the vessels course over the surface.

The morphea-like, or sclerosing, subtype is a plaque-like lesion that accounts for 15% of all basal cell carcinomas and is responsible for a majority of tumors invading the orbit. It may be difficult to diagnose and delineate, because the margins are clinically indistinct. Morphea-like basal cell carcinomas are characterized by deep invasion into the deeper tissues and loss of the eyelashes. The superficial subtype may appear as a scaly area that resembles chronic dermatitis, which may be difficult to differentiate from an inflammatory lesion.

The basosquamous subtype of basal cell carcinoma, which manifests with squamous differentiation, may not be clinically distinguishable from the nodular type. Biologically, however, it behaves in a more aggressive fashion, with perineural invasion and distant metastatic potential. Long-standing basal cell carcinomas may develop necrotic changes and manifest as cysts.[187]

Orbital invasion may develop with all subtypes of basal cell carcinoma, although it is more common in the diffuse morphea-like type. Delay in diagnosis and incomplete excision of the initial tumor are critical factors in the development of orbital invasion.[188] The most common presentation of orbital basal cell carcinoma is as a mass lesion and incomitant strabismus. Perineural spread, although more commonly reported with squamous cell carcinoma, can also occur in basal cell carcinoma and should be suspected if the patient complains of burning or stinging pain, numbness, or formication.

Differential Diagnosis

Basal cell carcinoma may mimic all other types of skin tumors and inflammatory conditions, including keratoacanthoma, sebaceous gland carcinoma, amelanotic malignant melanoma and metastatic tumors, and granulomas and fungal infections of the eyelids.

Management

Complete surgical excision monitored with frozen-section control of the margins of the lesion offers the lowest tumor recurrence rate.[189]

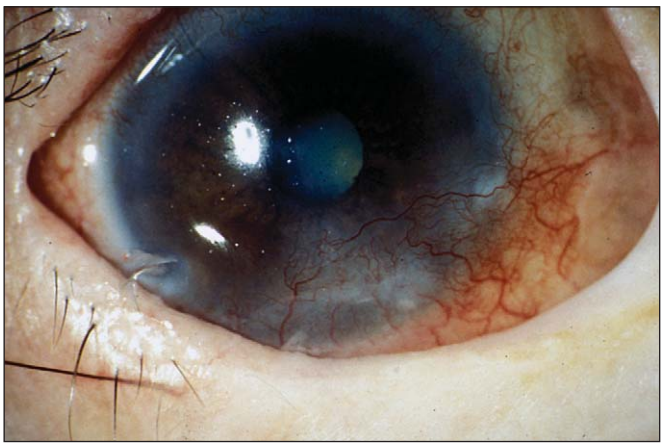

Figure 71-19 • Eyelid and external eye complications after radiation treatment of basal cell carcinoma. Although the tumor was successfully eradicated, conjunctiva and cornea were scarred, with neovascularization. Radiation cataract also is seen through the pupil. The lower eyelid shows loss and misdirection of the cilia secondary to irradiation. Also, the eye was extremely dry.

Reports from tertiary care hospitals indicate approximately 25% of initially incomplete excisions lead to recurrent tumors in approximately 5% of patients.[190]

In many cases with orbital invasion, cure is possible only with exenteration. If the patients cannot undergo or refuse exenteration, other treatment modalities including EBRT may be offered. Radiotherapy is a useful measure, although in light of the significant recurrence rate, it is not to be recommended as an effective initial treatment. EBRT also causes significant complications in the eye and eyelids[191] (Fig. 71-19). Brachytherapy with ^{125}I has been reported as an alternative to exenteration and EBRT for orbital invasion by the tumor.[192] Results appear to be better for untreated tumors than for incompletely excised tumors or tumors recurring after surgery.[193]

Squamous Cell Carcinoma of the Eyelid

Squamous cell carcinoma is the second most common form of skin cancer. It represents less than 2% of all eyelid malignancies.[194,195] A majority of patients (75%) with squamous cell carcinoma are older than 60 years of age. The distinct male predominance (65% versus 35%) probably represents increased occupational sunlight exposure by men rather than a genetic predisposition. It tends to occur in fair-skinned persons with a history of exposure to UV light. The incidence of developing invasive squamous cell carcinoma increases with increasing proximity to the equator.

The incidence of squamous cell carcinoma has been on the rise for the last 3 to 4 decades. The annual incidence in the United States is approximately 100 per 100,000 population; Australia has the highest incidence of SCC in the world, with an annual incidence of approximately 200 per 100,000 population.[196]

The squamous proliferations of the eyelid and periorbital skin manifest with a spectrum of premalignant lesions, carcinoma in situ and invasive squamous cell carcinoma. Premalignant lesions are defined as dysplastic epidermal changes that harbor the potential for transformation into invasive squamous cell carcinoma. These lesions include actinic (solar) keratosis, epidermal dysplasia, radiation dermatoses, and xeroderma pigmentosum.

Pathogenesis

Squamous cell carcinoma may arise from a precancerous condition or de novo. The mechanism of UV-induced photocarcinogenesis appears to involve the inactivation of the p53 tumor suppressor gene, as with basal cell carcinoma. It is a potentially fatal neoplasm that can metastasize to regional lymph nodes and also exhibit aggressive local spread. Other predisposing factors for the development of squamous cell carcinoma are Bowen disease; solar keratosis; keratoses resulting from arsenic, tar, or irradiation[23]; xeroderma pigmentosum; therapeutic ultraviolet light treatments such as psoralen plus ultraviolet A (PUVA); fair skin; immunosuppression; and chronic inflammation.[197,198]

Clinical Features

The lower lid is the most common site for squamous cell carcinoma, accounting for approximately 60% of lesions; the upper lid is the least common site.

Carcinoma in situ and actinic solar keratosis are similar clinically, although the average size of carcinoma in situ is larger than average actinic keratosis. Carcinoma in situ manifests as erythematous scaly patches or small placoid lesions, which may or may not show increased pigmentation.[199] Actinic keratosis may occasionally manifest as a nodular lesion. Left alone, all cases of carcinoma in situ develop into invasive squamous cell carcinoma, but the exact incidence of malignant transformation in actinic keratosis is not definitely known.

Once the epidermal neoplastic proliferation violates the epidermal-dermal interface and extends into the subepidermal tissues, the tumor is known as "invasive" squamous cell carcinoma, which may manifest as plaques, large ulcerated lesions, or papillomas. Squamous cell carcinoma is the second most common malignancy of the eyelid and periorbital skin. Invasive squamous cell carcinoma usually occurs in the sun-exposed skin areas of elderly persons with lightly pigmented skin. The most common histologic subtype of invasive tumors is the well-differentiated kind. High incidence rates of peripheral nerve involvement (25%) and orbital invasion (45%) have been reported.[200] Squamous cell carcinoma of the eyelid and periorbital skin is a malignant tumor with potential of invasion into the full thickness of the lid, underlying globe, and orbit. It also may spread into regional lymph nodes and to distant viscera. Regional lymph node metastasis is detected in approximately 5% of cases at initial examination. Some studies indicate that the overall rate of regional lymph node metastasis in patients with squamous cell carcinoma of the eyelid or periocular skin may be as high as 25%.[201]

Patients with squamous cell carcinoma require long-term follow-up because of the risk of new skin cancer formation. It has been reported that new foci of nonmelanotic skin cancer developed in about 60% of the patients every 3 years. The main risk factor for new cancer formation is the number of previous skin cancers that a patient had; those who had three or more cancers were at significantly greater risk than those with fewer than three.[202]

Differential Diagnosis

Periocular squamous cell carcinoma manifests with variable clinical features ranging from plaque-like scaly lesions to nodular growths.[203] Occasionally, the tumor may be totally or partially covered by pearly keratin or may show central or peripheral ulcerations.

The wide variation in clinical appearances of squamous cell carcinoma presents great difficulty in differentiating these lesions from basal cell carcinoma; approximately 30% are clinically diagnosed as basal cell lesions at presentation.[204] Other malignancies, such as sebaceous gland carcinoma and deep fungal infections, also should be considered in the differential diagnosis for squamous cell carcinoma.

Management

Before decisions regarding specific treatment, the patient with squamous cell carcinoma should undergo careful workup to assess for orbital and ocular invasion, as well as intrasinusoidal and intracranial extension of the tumor. Consultation with a medical oncologist is in order, to rule out distant metastasis. Orbital ultrasonography and cranial CT and MRI may be very useful to determine the extent of the tumor before any treatment preferences are selected. PET and radionuclide scans and microdissection of the sentinel

lymph nodes also may be helpful to determine the extent of the disease.[205]

Some physicians firmly believe that all in situ and invasive squamous cell carcinomas should be treated with surgical excision.[206–208] If surgical treatment is not feasible, radiation therapy, carbon dioxide laser, or cryotherapy may be considered alternative treatment modalities. The essence of surgical treatment is to obtain tumor-free margins either with conventional frozen-section control or using the Mohs microsurgery technique (Fig. 71-20). Although the Mohs technique has been very popular lately, the rates of tumor cure it offers are not distinctly different from those achieved with conventional frozen-section monitoring.[209,210] Five-year survival rates greater than 95% have been reported with use of Mohs microsurgical excision for primary and recurrent squamous cell carcinoma.[211]

These surgical techniques, however, are mostly reliable with surface tumors; once the tumors extend into the orbit, both methodologies become unreliable. If the tumor extends into the underlying soft tissues and bone, it is extremely difficult to remove surgically with tumor-free margins. Squamous cell carcinoma with bone involvement also responds poorly to radiotherapy.

Squamous cell carcinoma is responsible for approximately 10% of carcinomas involving the orbit, mainly as a result of direct spread from surrounding tissues. Like orbital invasion by basal cell carcinoma, invasion by squamous cell carcinoma tends to result from a delayed diagnosis, inadequate prior treatment with surgery or irradiation, and frequent recurrences. When perineural spread has extended to the orbit and beyond to the base of the skull or the cavernous sinus, the prognosis is extremely guarded. Radical surgery may be attempted to be followed by radiation but only after extensive consultation with the patient and the family.

On the other hand, some physicians believe that radiotherapy also offers high tumor regression with good cosmesis in squamous cell carcinoma as well as in basal cell carcinoma with local control rates of 75% and 91%, respectively. Recurrent tumors after other therapies are controlled by irradiation less effectively.[212,213] The radiation treatment techniques employed to treat squamous cell carcinoma of the lids and the underlying structures include use of superficially penetrating orthovoltage x-rays, superficially penetrating electrons, or more deeply penetrating megavoltage x-rays and implantation of radioactive sources depending on the location and the extent of the tumor. The radiation is delivered over 1 to 7 weeks, depending on the site, size, and cosmetic requirements. Irradiated skin cancers may continue to regress for weeks after the end of therapy. Desquamation with erythema and peeling of the epidermis at the treatment site commonly develops, which may be more severe in the eyelids because of the thinness of the skin.[214]

The radiation fields usually include surrounding margins of normal-appearing skin to incorporate microscopic extension of tumor. It has been reported that the extent of microscopic extension of tumor beyond the grossly visible lesion averages approximately 5 mm, and a margin of 10 mm is required to provide a 95% chance of obtaining clear resection margins. The extent of the microscopic tumor correlates well with the size of the gross lesion.[215]

The advantages of radiation treatment include relative sparing of normal tissue with good cosmetic outcome, cure rates comparable to surgical treatment, and avoidance of hospitalization and surgery in elderly, debilitated, or anticoagulated patients or those in whom medical conditions make the tumor inoperable. The potential for complications and side effects such as alopecia and more serious ocular toxicity, particularly in upper lid lesions, and rarely occurring soft tissue and bone necrosis, also should be taken into account. The risk of complications is related to tumor size. Complications develop in approximately 5% of the patients with skin lesions smaller than 1 cm, but in up to 15% of patients who have lesions larger than 5 cm.[216]

Brachytherapy has also been recently advocated for fascial squamous cell carcinomas that pose problems of surgical reconstruction with a claim to provide a high level of local control and good cosmetic results. The results were particularly better for untreated tumors than for incompletely excised tumors or tumors recurring after surgery.[217] Topical and systemic chemotherapy and immunotherapy have limited applications in advanced cases.

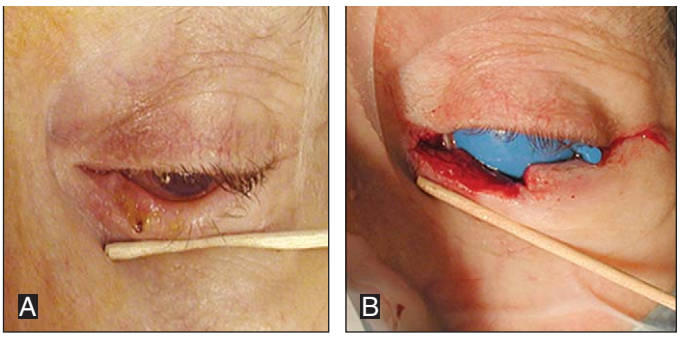

Figure 71-20 • **A,** Preoperative appereance of squamous cell carcinoma of the lower eyelid. **B,** The appearance of the eyelid tissue defect at the end of excision under frozen section control. Note that although the tumor appears to be innocuous, the extent of the invasion is far greater than could be appreciated on clinical examination alone.

Sebaceous Gland Carcinoma of the Eyelid

Sebaceous gland carcinoma is a relatively rare eyelid adenocarcinoma that originates from the meibomian or Zeis glands, or both, or from the sebaceous glands in the eyebrow or carbuncle.[218] Sebaceous gland carcinoma accounts for approximately 5% of all malignant eyelid tumors. It affects mainly elderly patients in the sixth to seventh decades of life and is encountered predominantly in women; no explanation is evident for its predilection for females. It is seen more often in the upper eyelid than in the lower, probably because meibomian glands are more abundant in the upper lid.[219]

Pathogenesis

Development of sebaceous gland carcinoma has been reported in patients who underwent irradiation for facial acne, hemangioma, or eczema, regardless of their age. Moreover, eyelid sebaceous carcinoma developed in children with hereditary retinoblastoma who received EBRT in their teenage years. It has been reported recently that sebaceous gland carcinoma also may be seen in younger age groups of immunosuppressed patients.[220]

Clinical Features

The tumor initially appears as a tarsal nodule in approximately 40% of the cases and as a diffuse thickening of the eyelids in 60%. The mean duration of symptoms or signs before diagnosis is approximately 2 years. The diffuse tumors usually simulate blepharoconjunctivitis. In patients who present with a chronic inflammatory condition, sebaceous gland carcinoma often exhibits "pagetoid" spread or conjunctival intraepithelial invasion. Of those with diffuse conjunctival involvement, the superior tarsal and conjunctiva and fornix are involved in almost all cases. Direct orbital invasion occurs in about 10% to 15% of the cases (Fig. 71-21). Another point to keep in mind is that sebaceous gland carcinoma may be associated with Muir-Torre syndrome, which is a rare genodermatosis of autosomal dominant inheritance associated with mutations in mismatch repair proteins, which predispose affected patients to GI and genitourinary tract malignancies.[221] Almost half of the patients with sebaceous gland carcinoma have been reported to have additional visceral neoplasms.[222]

Differential Diagnosis

Known as a masquerader, sebaceous gland carcinoma may mimic other benign and malignant conditions such as chronic blepharoconjunctivitis or chalazion, as well as squamous cell carcinoma, often

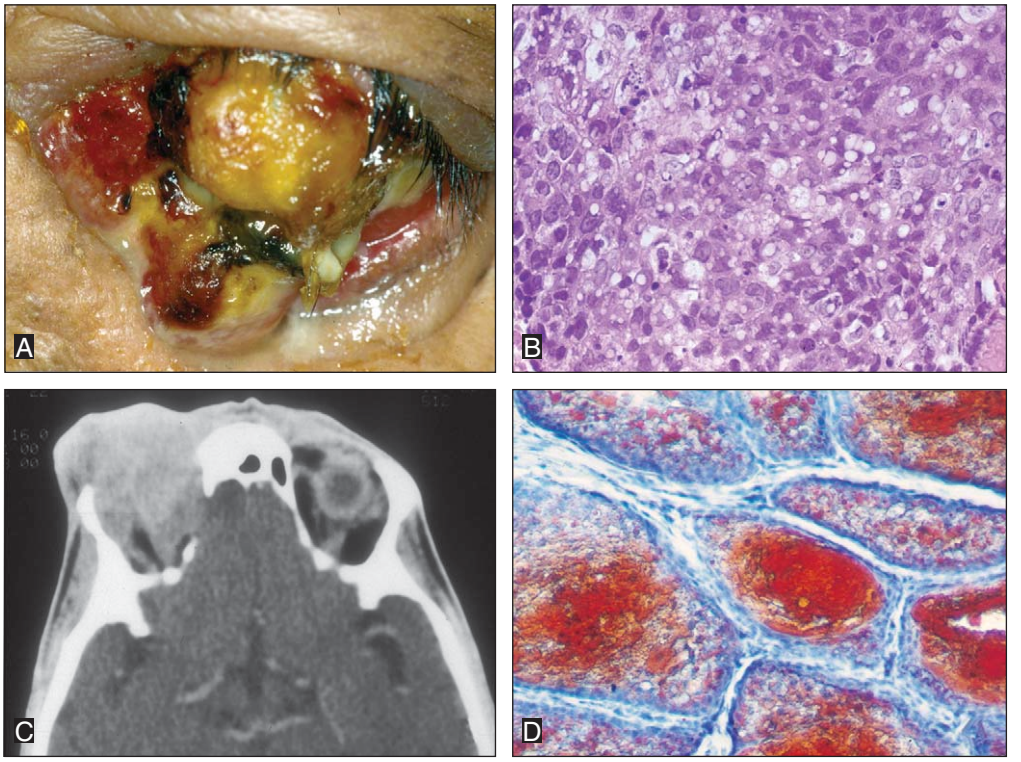

Figure 71-21 • Sebaceous gland carcinoma. **A** and **C,** External photograph and axial computed tomographic scan showing massive growth of the tumor anteriorly and posteriorly into the orbital soft tissues and bone. **B** and **D,** Histopathologic appearance of the tumor, with infiltration of markedly pleomorphic tumor cells with mitotic figures. In better-differentiated areas of the tumor, positive staining with oil red O is seen (**D**).

resulting in delayed diagnosis, which can lead to higher morbidity and mortality.[223,224] Sebaceous gland carcinoma should be considered in any unilateral chronic inflammatory condition of the eyelids in the elderly.

Management

Treatment should be individualized on the basis of the extent of the tumor and the specific needs of the patient.[225] If the lesion is diffuse and without a nodular component, multiple mapping biopsy specimens should be obtained and submitted for histopathologic examination, with fixation of permanent slides. Currently, the mainstay of treatment of tumors without orbital involvement has been wide local excision, with monitoring of margins with both permanent and frozen sections.[226] In a majority (75%) of the cases, the initial treatment method is surgical excision with or without cryotherapy. In cases with orbital involvement, exenteration often is warranted.

Topical antimetabolites, brachytherapy, and EBRT also are used in some cases. EBRT with an appropriate delivery system is reported to be a curative treatment for eyelid sebaceous cell carcinoma when a radiation dose greater than 55 Gy is used.[227] Moreover, brachytherapy should be considered for patients seeking an alternative to surgical excision.[228] Some sebaceous gland carcinomas present a challenge to surgical excision because of the cosmetic and functional impairment. According to some experts, interstitial radiation with ^{19}Ir may very well be an effective alternative treatment to surgical excision.[229] Treatment complications include symblepharon formation, irregular eyelid and conjunctival scarring, and eyelid malpositions as the result of multiple surgical procedures, cryotherapy, and radiation of the eyelids and conjunctiva.

TUMORS OF THE ORBIT

A variety of tumors and pseudotumors can involve the orbit. Approximately two thirds are benign and one third are malignant. The percentage of malignant tumors increases with age because of the higher incidence of lymphoma and metastasis in the elderly.[230]

Tumors that most commonly are treated with radiation are covered in this section; for more extensive literature coverage, the reader is referred to ophthalmic oncology and orbit textbooks.[2,4–7,231–233]

Orbital Lymphoma

Lymphoproliferative tumors are the most common primary orbital neoplasms in adults yet constitute only approximately 2% of all lymphomas.[234] Lymphoid tumors constitute approximately 10% of all orbital tumors. A majority of orbital lymphomas are of the non-Hodgkin's type and are seen mostly in adults during the fifth and the seventh decades of life.

Pathogenesis

Malignant lymphoma is diagnosed when diffusely arranged populations of immature and mitotically active lymphocytes are found in the orbit. Monoclonal populations of B cells confirmed by immunohistochemical studies, with prominent nucleoli, chromatin margination, nuclear membrane irregularities, and cellular atypia are histologic hallmarks of this disease.[235]

Different theories regarding the pathogenesis of lymphomas have been proposed. Although no specific agents have yet been identified, new trends hypothesize an infectious etiology. A possible seasonal variation for a greater incidence of lymphomas also has been suggested.[236]

A higher risk of lymphoma has been noted in patients with rheumatoid arthritis or those on anti-inflammatory drug therapy.[237] The relationship between viruses and lymphomas, particularly Epstein-Barr virus (EBV) and Hodgkin's lymphoma, has been described.[238]

Clinical Features

Orbital lymphomas usually are unilateral, with a predilection for the superior and anterior orbits, but also may be seen in both orbits. The patient usually presents with a painless proptosis of insidious onset, downward displacement of the globe, a palpable nontender orbital mass, with or without exraocular motility problems, and ptosis.

Imaging studies usually confirm the presence of a mass. On CT, lymphomas appear homogeneous in texture, are isodense to muscle, and show mild enhancement with contrast. A diffuse or well-defined orbital mass with molding to the globe, optic nerve, and orbital bones strongly suggests the diagnosis of orbital lymphoma; molding usually is associated with indolent histology, whereas bone destruction is associated with aggressive histology (Fig. 71-22). MRI commonly reveals intermediate signal intensity on T_1- and T_2-weighted images and moderate signal intensity with gadolinium enhancement.[239]

In the orbit, the distinction between "primary" and "secondary" orbital lymphoma is to some extent arbitrary. Primary lymphomas are considered to be limited to the orbit. Thus, by definition, "primary" orbital lymphomas are stage I. In secondary orbital lymphomas, the orbit is considered as a secondary extranodal site of involvement. In these cases, the systemic disease is either known previously or it is diagnosed at the same time as the discovery of orbital lymphoma.[240] With application of the more advanced diagnostic tools such as PET, bone marrow biopsy, and monoclonal antibodies for detecting small foci of systemic lymphoma as part of the staging workup, it appears now that the incidence of truly "primary" orbital lymphoma is lower than was suggested in the past.[241]

Lacrimal gland lymphomas, which are considered in the category of orbital lymphomas, are B-cell tumors that develop in older adults. A majority of these tumors have mucosa-associated lymphoid tissue (MALT) characteristics and carry a favorable prognosis.[242]

Accurate histopathologic evaluation is the most critical diagnostic step in the management of orbital lymphomas.[243] Ideally, the biopsy tissue should be delivered to the laboratory fresh (without preservatives) and sterile. Current laboratory workup for lymphoma includes immunohistochemistry, flow cytometry, cytogenetics, and molecular studies.[241] Approximately 85% to 90% of orbital lymphomas are categorized as diffuse, low-grade proliferations of small, monoclonal B-cell lymphocytes. The remaining 10% to 15% have follicular or nodular characteristics. Lesions displaying high mitotic activity are most likely to be associated with extraorbital, systemic disease; follicular lesions with germinal centers are more likely to be indicative of localized disease.[244] The advances in the detection of monoclonal antibodies, which identify surface antigens on lymphoid cells, led to the classification of lymphomas based on their immunophenotype. In addition, the chromosomal and molecular characteristics of lymphomas are now studied routinely and correlated with their clinical behavior. The Revised European-American Classification of Lymphoid Neoplasms (REAL) is the most recently and widely used diagnostic classification system and is based on morphology, immunophenotype, genotype, and clinical features of the lymphoma[245] (Table 71-8). In this classification, lymphomas are grouped as indolent, aggressive, and highly aggressive types.[246]

A thorough staging workup with a complete history and physical examination, including gastrointestinal endoscopy, orbital and systemic imaging, barium studies of the gastrointestinal tract, and morphologic studies, is necessary for patients with orbital lymphoma in order to recognize systemic disease.[247] PET has replaced bone and gallium scans for detecting small foci of lymphoma throughout the body because of its high sensitivity.[248] PET/CT is another new and useful tool for the diagnosis and staging of orbital lymphoma.[249] Today, the Ann Arbor Staging System most commonly is used to assign a stage for lymphomas (Table 71-9).

Differential Diagnosis

So long as the orbital lymphoma is associated with a conjunctival component, which presents a salmon-colored "fish flesh" appearance, the differential diagnosis is not difficult. Pure orbital tumors, however, may mimic other localized or diffuse space-occupying masses in the orbit, including some inflammatory conditions such as Graves' disease and idiopathic orbital inflammation.

Management

Current treatment of lymphoma is based on the use of EBRT or systemic chemotherapy, or both, for the treatment of primary orbital lymphomas.[250,251]

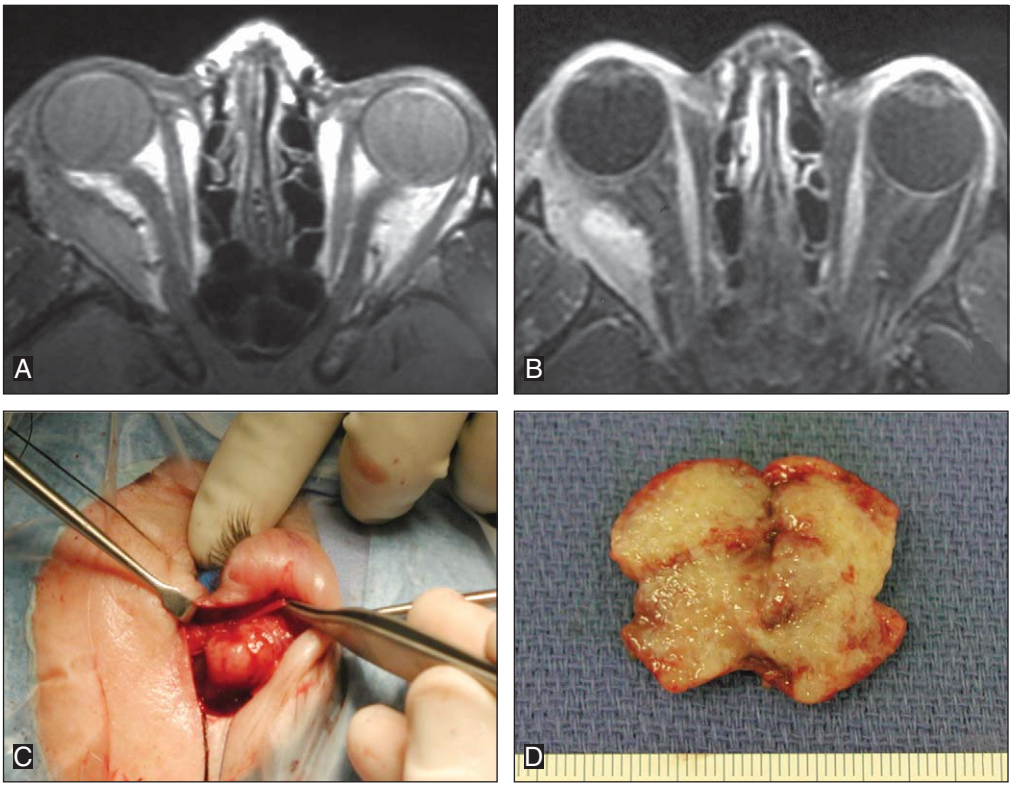

Figure 71-22 • Lymphoma. **A** and **B,** B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type depicted on T_1- and T_2-weighted axial magnetic resonance images. **C,** Intraoperative appearance of the well-encapsulated, firm tumor located in the lateral orbit. **D,** The "fish flesh" gross appearance of the cut surface of the tumor.

Table 71-8 Revised European-American Classification of Lymphoid Neoplasms

INDOLENT LYMPHOMAS
Follicular lymphoma
B-CLL/small lymphocytic lymphoma
Lymphoplasmacytic lymphoma
Marginal zone lymphoma (nodal and/or extranodal)
T/NK large cell granular lymphocyte leukemia
T-CLL
AGGRESSIVE LYMPHOMAS
Mantle cell lymphoma
Diffuse large B-cell lymphoma
Peripheral T-cell lymphoma (unspecified)
Peripheral T-cell lymphoma (angioimmunoblastic, angiocentric)
T/NK cell, hepatosplenic, intestinal T-cell lymphoma
Anaplastic large cell lymphoma
HIGHLY AGGRESSIVE LYMPHOMAS
Precursor T- or B-cell lymphoblastic leukemia/lymphoma
Burkitt and Burkitt-like lymphoma
Adult T-cell leukemia/lymphoma

CLL, chronic lymphocytic lymphoma; NK, natural killer.

The therapeutic approach should be individualized for each patient based on the histologic classification and staging of the disease. Lymphomas are radiosensitive; although EBRT at a 30-Gy dose may be successful in controlling local orbital disease in a majority of patients with low-grade indolent lymphoma, intermediate-grade lymphomas are more appropriately treated with higher doses of up to 40 Gy.[252,253] Some reports have stated that with localized mucosa-associated lymphoid tissue (MALT)-type lymphomas, excellent control and prognosis can be achieved even after lower doses (15 to 25 Gy) of radiation.[254]

Distant relapse has been observed in approximately 25% of patients with low-grade lymphoma and 50% of those with higher grade lymphomas. For orbital lymphomas, the risk of distant relapse is significant with radiotherapy alone.[255] In patients with more aggressive orbital lymphoma for which widespread systemic involvement is likely, combining systemic chemotherapy with local radiation treatment is a safer approach[256] (Fig. 71-23).

Table 71-9 Ann Arbor Staging System for Lymphoma

Stage	Description
I	Single lymph node region or lymphoid structure (e.g., spleen or Waldeyer ring)
II	Two or more lymph node regions on the same side of the diaphragm OR localized involvement of an extranodal lymphoid structure AND of one or more lymph node regions on same side of diaphragm
III	Lymph nodes on both sides of diaphragm ± extranodal sites
IV	Two or more extranodal sites or liver or bone marrow

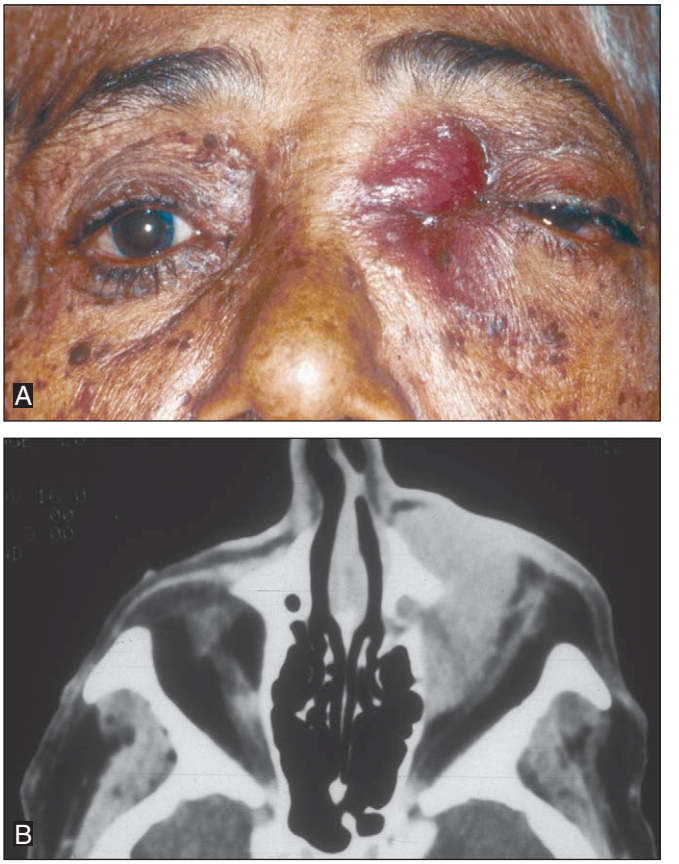

Figure 71-23 • **A,** Large cell lymphoma of the orbit, with involvement of the skin, underlying soft tissues, and bone. **B,** The invasion of bone is not a typical feature of orbital lymphoma but may be seen in long-standing cases or in more malignant types of lymphoma.

Low-dose external beam irradiation (at a dose of 20 Gy) also is used with good results in orbital pseudotumor (idiopathic orbital inflammatory disease) as well.[257] This regimen is recommended in patients with moderate to severe active orbital inflammation but contraindicated in young and diabetic patients because of the risk of secondary malignancies and aggravation of diabetic retinopathy.[258]

In most patients, radiotherapy for primary orbital lymphoma induces minimal acute ocular toxicity, but long-term follow-up can document the usual ocular side effects, including dry eye syndrome and occasionally cataracts.[259] A cumulative dose of 16.5 Gy or higher is likely to lead to formation of lens opacities. Adequate shielding can decrease the risk of cataract formation, but shielding usually does not prevent dry eye syndrome, which frequently occurs after EBRT for orbital lymphoma. Severe radiation vasculopathy of the retina and optic nerve does not commonly occur with the typical total dose used for orbital lymphoma.

Newer approaches in radiation delivery, such as conformal therapy, promise isodose delivery to tumors with minimal ocular radiation toxicity.[260]

Chemotherapy usually is indicated for the more aggressive histologic subtypes of orbital lymphoma and may have potential for subsequent or existent disseminated disease. Combined chemotherapy and radiation therapy may be an appropriate option for intermediate- to high-grade lymphomas. The rationale for combined-modality therapy originates from observations that systemic relapse is common after EBRT alone. Relapse-free 5-year survival rates of approximately 95% for stage I lymphomas and 75% for stage II disease have been reported.[261]

Low-grade lymphomas are very sensitive to both single-agent chemotherapy, such as cyclophosphamide, and combination chemotherapy, which usually is with a doxorubicin-containing regimen such as cyclophosphamide, doxorubicin (i.e., hydroxydaunomycin), vincristine, and prednisone (CHOP) or cyclophosphamide, vincristine, doxorubicin (Adriamycin), and dexamethasone (CVAD).

Recent reports have suggested that monoclonal antibody therapy also may be effective in the treatment of low-grade non-Hodgkin's lymphomas. The availability of active monoclonal antibodies has altered the treatment paradigms for patients with non-Hodgkin's lymphomas. Many patients do not respond, however, and almost all of those who do eventually relapse and require conventional treatment.[262–264] Thus the search for more effective treatment alternatives has led to the development of radioimmunotherapy (RIT). RIT entails the administration of a monoclonal antibody in combination with a radioactive ligand.[265] Beta particles emitted by commonly used radioisotopes are tumoricidal over a distance, allowing eradication of antigen-negative tumor cells by radioactive "crossfire" from neighboring antigen-positive antibody-coated cells. This additional mechanism for tumor lysis leads to more effective treatment than is possible using the nonradioactive antibody. Monoclonal antibodies labeled with radionuclides have become an important therapeutic tool in the treatment of patients with non-Hodgkin's lymphomas. RIT is an attractive option because of the inherent radiosensitivity of most NHLs. Yttrium 90 ibritumomab tiuxetan and ^{131}I tositumomab are two radioimmunoconjugates currently available for clinical use. Toxicities primarily include myelosuppression, with a potential risk of treatment-associated myelodysplastic syndrome and acute myelogenous leukemia. Further development of RIT may be expected to lead to a prolongation of survival for patients with non-Hodgkin's lymphoma.[266,267]

Lacrimal Gland Tumors

The lymphomas and pseudotumors of the lacrimal gland, which are two to three times more common than its epithelial neoplasms, are discussed earlier under "Orbital Lymphoma." Although many carcinomas, including malignant mixed tumor, acinic cell carcinoma, mucoepidermoid carcinoma, and others, develop in the lacrimal fossa, the primary epithelial malignancy of the gland is adenoid cystic carcinoma, which accounts for approximately half of the epithelial malignancies.[268,269]

The mean age at presentation in patients with adenoid cystic carcinoma is approximately 40 years, with a range of 7 to 80 years. A bimodal peak of distribution has been noted in the fourth and the sixth decades of life.

Pathogenesis

It has been proposed that allelic loss for microsatellite markers at 1p36 may be a common and an early event in formation of adenoid cystic carcinomas.[270]

Histopathologically, adenoid cystic carcinoma manifests in five different patterns: cribriform ("Swiss cheese"), basaloid, sclerosing, comedocarcinomatous, and ductal, in order of frequency. The Swiss cheese pattern has been associated with longer survival. The basaloid pattern may be seen more frequently in patients older than 40 years and is associated with a poor prognosis.[271] Perineural invasion of the peripheral nerves frequently is observed in exenteration specimens, accounting for the symptoms of pain and numbness.

Clinical Features

Lacrimal gland carcinomas typically manifest with upper eyelid fullness and rapidly developing downward and medial displacement of the globe with diplopia. In later stages of the disease, proptosis may be associated with pain and visual loss. Adenoid cystic carcinoma extends perineurally and into adjacent bone; therefore, periorbital pain and rarely numbness are associated with this tumor.[272]

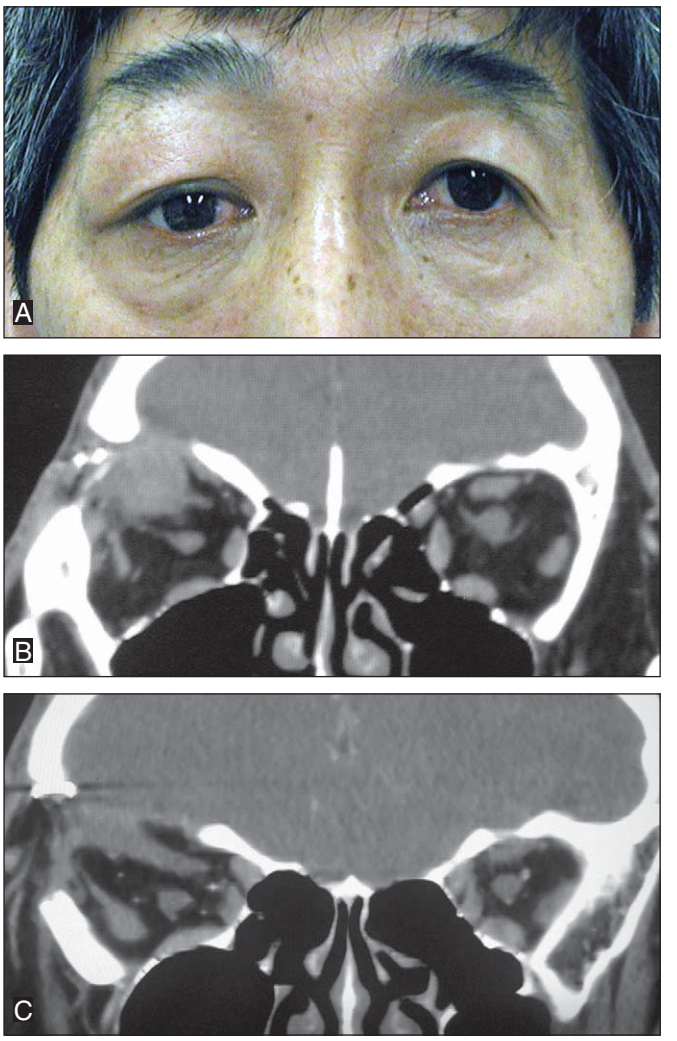

Figure 71-24 • Adenoid cystic carcinoma of the lacrimal gland. Mild proptosis of the right eye is present (**A**), but the destruction of the bony orbit seen on the computed tomographic scans is extensive (**B** and **C**). (Courtesy of Dr. Yoon-duck Kim, Republic of South Korea.)

On high-resolution CT, an elongated mass is seen to extend along the lateral orbital wall, with expansion of the lacrimal fossa with bone invasion. Calcifications more commonly are seen in malignant tumors. Immediate tumor biopsy is indicated in such cases. High-resolution CT typically shows a round or irregular mass lesion extending along the lateral orbital wall with expansion of the lacrimal fossa and bony invasion (Fig. 71-24). Contrast enhancement helps to reveal involvement of the dura and intracranial extension.

MRI will reveal the tumor as hypointense on the T_1-weighted images and hyperintense on the T_2-weighted images with contrast enhancement. This diagnostic modality also is useful for assessing invasion by tumor into the cavernous sinus and brain.

Differential Diagnosis

Acute onset of swelling, periorbital pain, chemosis, or an erythematous indurated lid indicates an inflammatory process. CT or MRI may reveal a diffuse glandular enlargement with irregular margins, frequently demonstrating contrast enhancement and no bone changes. Most cases of bacterial dacryoadenitis resolve rapidly with appropriate systemic antibiotics. Idiopathic acute inflammation can be treated with a short course of corticosteroids. Failure to respond to treatment over a few weeks should prompt incisional biopsy, because acute and

subacute inflammatory episodes may be related to an underlying carcinoma.

As mentioned, orbital lymphoproliferative lesions are another common cause of glandular enlargement. It is characterized by an insidious and painless onset in a slightly older patient and often can be bilateral. Imaging shows that most lymphoid tumors mold themselves around existing orbital structures, such as the globe and the bony orbit, without eroding bone or enlarging the orbit.

When painless swelling in the upper lid without inflammatory symptoms and signs manifests more than 12 months, benign mixed tumor (pleomorphic adenoma) should be suspected. Most patients with malignant epithelial tumors present with painful swelling in the upper eyelid in less than 1 year. Imaging of pleomorphic adenomas usually shows a rounded, well-circumscribed mass with expansion of the lacrimal fossa without invasion of overlying bone. Biopsy of pleomorphic adenoma should be avoided. If biopsy is done before excision, the 5-year recurrence rate is estimated to be 30%, and many recurrent tumors undergo malignant transformation.

Management

Surgical tumor removal with postoperative radiotherapy constitutes the most common treatment for adenoid cystic carcinoma. The surgical techniques of tumor removal include local resection, en bloc removal, exenteration, and orbitectomy. Even with very radical surgical approaches, the survival rate with this tumor does not go beyond 20% at 10 years, and the median survival period is 5 years.[273] Patients usually die of intracranial spread. Orbitectomy with bone removal may help to achieve local control in advanced cases of adenoid cystic carcinoma of the lacrimal gland, but such surgery does not decrease the risk of distant metastases.[274] The use of brachytherapy has been tried in patients with adenoid cystic carcinoma, yielding reasonably good results.[275] The long-term results are unknown, however. The preliminary data suggest that intra-arterial cytoreductive chemotherapy (IACC) is potentially effective in improving local disease control and overall disease-free survival in lacrimal gland adenoid cystic carcinoma. Intracarotid cisplatin and intravenous doxorubicin were used before and after exenteration and irradiation, with long-term survival periods of 9.5 and 7.5 years, respectively.[276] Adenoid cystic carcinoma also is known to grow slowly and to exhibit recurrence and metastasis years after the initial treatment.

Orbital Rhabdomyosarcoma

Rhabdomyosarcoma makes up approximately 5% of all cancers in the pediatric population, but it is significant in ocular oncology as the most common malignant mesenchymal orbital tumor of childhood.[277]

Orbital tumors account for about 15% of the cases of rhabdomyosarcoma; males are more often affected than females, and the mean age at diagnosis is 8 years. A confirmed or unclear history of trauma frequently is associated with the clinical presentation of the tumor.[278]

Pathogenesis

Rhabdomyosarcoma, which is considered to originate from primitive mesenchymal cells, manifests in various histopathologic forms that usually differ among age groups. These lesions appear to be separate biologic entities as well as morphologic categories, with embryonal tumors manifesting genetic lesions related to loss of heterozygosity and aberrant parental imprinting, alveolar tumors containing fusions between *PAX* and *forkhead* genes, and pleomorphic tumors showing an accumulation of genetic lesions similar to those with other adult high-grade sarcomas.[279,280] Infants and young children tend to have embryonal tumors, adolescents and young adults tend to have alveolar tumors, and older adults tend to have pleomorphic forms, although some overlap is recognized. A fusion-positive rhabdomyosarcoma has a distinct molecular signature, which may lead to successful genetic testing for diagnosis and staging in the near future.

Clinical Features

The most characteristic presenting feature of orbital rhabdomyosarcoma is its rapid onset and progression with proptosis and displacement of the globe.[281]

Rhabdomyosarcoma should always be suspected whenever the clinical presentation is that of a rapidly progressive unilateral exophthalmos in a child (Fig. 71-25). Signs and symptoms depend on the site and histologic type of the tumor. With posterior tumors, rapid development of edema of the optic disc and loss of color vision, choroidal folds, and some degree of ophthalmoplegia are characteristic. When the tumor is situated in the inferior and anterior regions of the orbit, it often causes chemosis and edema of the eyelids and motility limitation.

The histopathologic types of rhabdomyosarcoma in the orbit consist primarily of embryonal and alveolar tumors. The embryonal type is the most common; the alveolar is less common and carries the worst prognosis.[282,283] Tumor locations within the orbit usually correlate with histologic type: Embryonal and differentiated tumor types more commonly are located in the superior and superonasal regions, whereas the alveolar type originates from the mid- and posterior orbit. CT and MRI play important roles in the preoperative evaluation to determine the location and size of the tumor and also in evaluating residual or recurrent disease on follow-up examinations.[284,285] Intracranial and sinonasal invasion are rather uncommon

Figure 71-25 • **A** and **B,** Two children with superiorly (**A**) and inferiorly (**B**) located rhabdomyosarcomas in left and right orbits, respectively.

at presentation, whereas changes in the adjacent bone frequently have been reported.[284] CT depicts a moderately well-delineated, homogeneous orbital mass isodense to the extraocular muscles, which often shows enhancement after contrast administration (Fig. 71-26). On MRI, on T_1-weighted images, the tumor may appear isointense to hyperintense with respect to the extraocular muscles and hypointense with respect to orbital fat. Proton density and T_2-weighted images are not very distinct. On T_1-weighted, contrast-enhanced images, rhabdomyosarcoma exhibits moderate to marked enhancement, to a degree that its highly vascular internal architecture may resembles that of a capillary hemangioma.[286]

Differential Diagnosis

Considerations in the clinical differential diagnosis for rhabdomyosarcoma include most disorders that lead to rapidly developing proptosis in childhood, including orbital cellulitis, vascular tumors, Burkitt tumor, and metastatic tumors, particularly neuroblastoma in younger patients. The differential diagnosis has become simpler than in previous years because of the use of myogenic factors in immunohistochemistry studies, nevertheless, in some cases, it may still be challenging. Diagnosis and management of orbital rhabdomyosarcoma require close collaboration among the radiologist, the ophthalmologist, and the medical and radiation oncologists.[287]

Management

No matter how typical the clinical imaging features are, the ultimate diagnosis, staging, and the management plan are based on the histopathologic diagnosis. If the tumor is located within the posterior orbit, excision biopsy or open core biopsy should be performed; fine-needle aspiration biopsy usually does not yield enough information, and findings may be misleading.[288] After the biopsy, the tumor should be staged according to the schemes of the Intergroup Rhabdomyosarcoma Study (IRS) and American Joint Commission on Cancer (AJCC).[289,290]

Simplification of the staging system by Shields and coworkers is a practical approach that can be applied to orbital rhabdomyosarcomas. Because most orbital tumors are biopsied without attempt at resection, gross residual disease is inevitable (group III); thus, most tumors will be stage I or group III; a minority will be stage I or group I or II, and rarely a primary orbital RMS will be found to be stage IV.[278]

Current treatment for rhabdomyosarcoma consists of surgery, chemotherapy, and EBRT, based on the recommendations of the IRS.[291,292] Some surgeons limit the therapeutic role of surgery to excisional biopsy only; others, however, perform extensive surgery to remove or debulk the tumor. The surgical approach should be planned according to the clinical and imaging findings. We recommend that tumor excision be pursued if it can be done without damaging the vital structures of the orbit. It has been shown that 4000 cGy in fractionated doses provides satisfactory tumor control.

Children with orbital rhabdomyosarcoma treated on IRS protocols have had an extremely high cure rate. The 5-year survival rate for children with alveolar tumors was 74%; infants diagnosed with an alveolar rhabdomyosarcoma die very young. The 5-year survival rate for children with embryonal tumors, on the other hand, was approximately 95%.[293] Multiple malignant neoplasms in rhabdomyosarcoma survivors has become of increasing concern over the last 2 decades or so. These tumors, which occur in higher numbers after EBRT, may be benign or malignant and usually develop in a different site from that of the primary tumor several years after treatment.[47,294] The ongoing IRS-V study uses actinomycin D and vincristine combined with a decreased dose of EBRT (4500 cGy compared with 5000 cGy) for patients with low-risk rhabdomyosarcoma, including group III orbital disease. Further reduction in radiation complications may result from the use of three-dimensional conformal radiation therapy techniques by minimizing the inclusion of normal tissues in the treated volume.

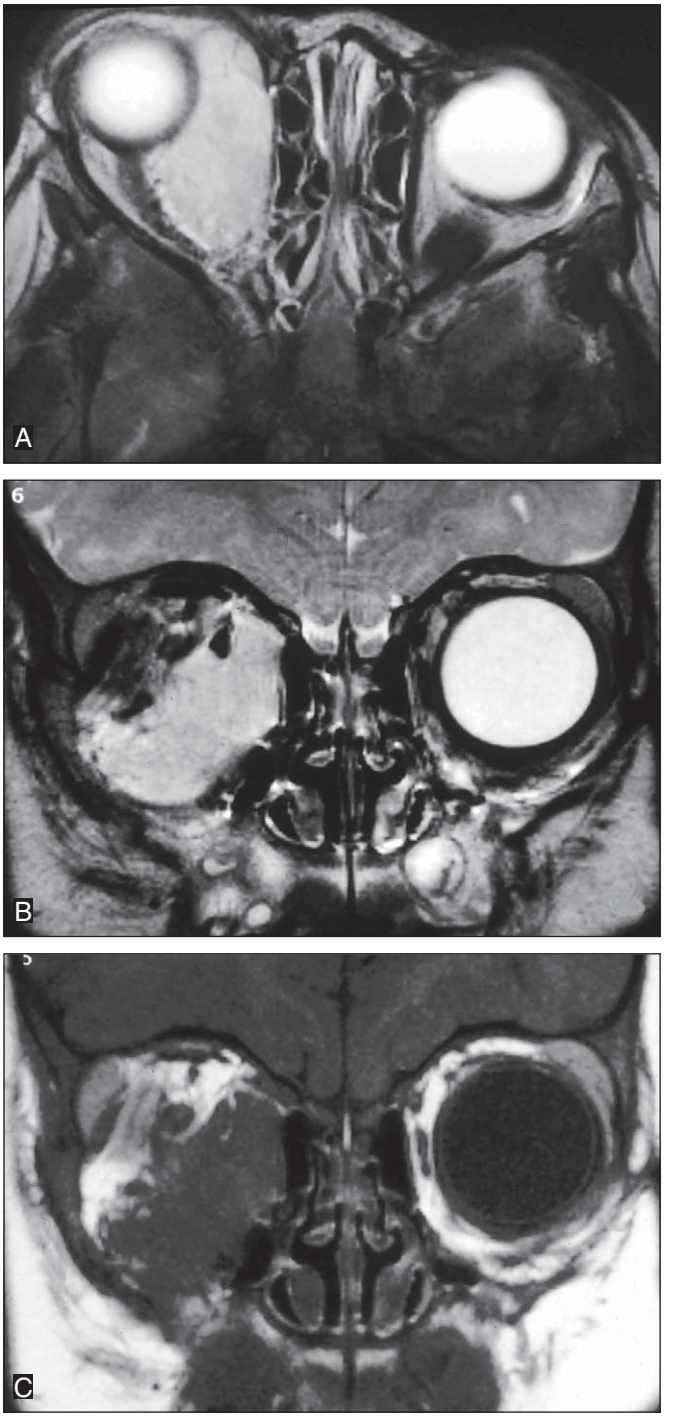

Figure 71-26 • Large inferomedial rhabdomyosarcoma seen on magnetic resonance imaging. **A,** Axial T_2-weighted image; **B** and **C,** coronal T_1- and T_2-weighted images.

Ocular and Orbital Histiocytosis

Histiocytic cell dysfunctions and proliferations are important to the ophthalmic oncologist because these "pseudotumors" are encountered in many ophthalmic disorders of the eye and the orbit.[295]

Pathogenesis

Histiocytes are divided into two major types: macrophages and dendritic cells. Both types are nonlymphoid mononuclear cells

involved in immune and nonimmune inflammatory responses. *Macrophages*, which derive from the bone marrow, are tissue phagocytes that serve both antigen processing and effector functions in T cell-mediated immunity. *Dendritic cells* are nonphagocytic immune accessory cells that also appear to originate from the stem cells of the bone marrow.[296] Dendritic cells are further divided into *Langerhans cells* (LCs) and *non-Langerhans cells* (nLCs). Both cell types express CD1 and CD45 antigens and S-100 protein and contain high levels of adenosine triphosphatase (ATPase). The distinct feature differentiating these two cell types is the presence of an intracytoplasmic organelle called a Birbeck granule in the LC but not in the nLC; Birbeck granules can be demonstrated only with electron microscopic examination.

Clinical Features

LC histiocytoses are class I histiocytoses (histiocytosis X in old terminology), including eosinophilic granuloma, Letterer-Siwe disease, Hand-Schüller-Christian disease, and Hashimoto-Pritzker disease.[297]

Current thinking is that LC histiocytosis is a clonal, "tumor-like" proliferation with variable biologic behavior that occurs most often in children aged 1 to 3 years, with a 2:1 male predominance; LC histiocytosis is rare in adults. An increased incidence of LC histiocytosis has been reported in patients with leukemia and solid tumors. Furthermore, these tumors, particularly acute lymphoblastic leukemia (ALL), commonly are reported in patients who received treatment for LC histiocytosis with chemotherapy and irradiation. Ophthalmic manifestations, which are seen in approximately 10% of cases, occur more often in eosinophilic granuloma and Hand-Schüller-Christian disease. The latter typically manifests with the triad of orbital lesions, diabetes insipidus, and bone lesions. Eosinophilic granuloma is the localized variant of LC histiocytosis, most often involving the orbit in the superior temporal area with lytic or sclerotic bone lesions. Solitary lesions of eosinophilic granuloma manifest only in the cranium. Multifocal LC histiocytosis manifests with multiple bone lesions scattered throughout the skeleton.

Necrobiotic xanthogranuloma is another non-LC disorder that manifests with destructive skin and soft tissue lesions of the periorbital region. In approximately 50% of the patients, other ophthalmic manifestations also develop, including proptosis due to orbital masses, ptosis, lid-apposition abnormalities, scleritis, and uveitis.[298] Necrobiotic xanthogranuloma frequently is associated with immunoglobulin G (IgG) monoclonal gammopathy, hepatosplenomegaly, plasma cell dyscrasias, and, less commonly, cryoglobulinemia and lymphoproliferative tumors.

Juvenile xanthogranuloma is an infantile disease with serious ophthalmologic consequences; it currently is considered to be a neoplasm of the non-LC. This disorder manifests with small papules of the skin in the head and neck region and tends to be self-limiting.[299] When the iris and anterior chamber are involved, which occurs in less than 1% of the cases, the intraocular histiocytic nodules easily break down, leading to hyphema, secondary glaucoma, cataracts, and corneal damage. Juvenile xanthogranuloma may occur on the external eye, on the eyelids, or in the orbit as a localized mass as well.[300]

Another type of non-LC proliferation is adult-onset xanthogranuloma, which occurs as a localized or systemic disease.[301] The localized form usually involves the eyelids and the orbit and consists of dense infiltrates of histiocytes intermingled with occasional multinucleated giant cells (Fig. 71-27). These lesions show CD68 immunoreactivity. In its systemic form, known as Erdheim-Chester disease, the long bones, heart, lung, brain, and other organs may be involved, with histiocytic proliferations leading to serious, sometimes fatal symptoms.[302]

Differential Diagnosis

The differential diagnosis is based on morphologic features. The histologic pattern in LC histiocytosis consists primarily of proliferation of large histiocytes surrounded by neutrophils, eosinophils, lymphocytes, and plasma cells. Specialized cells such as mast cells and multinucleated foreign body giant cells, called Touton cells, also may be seen. Definite characterization of the cell type should be done by identification of Birbeck granules with electron microscopy. Immunohistochemical identification is not dependable because non-LC disorders also may show positivity with markers such as CD-68, HAM-66, and CV1a.[303]

Figure 71-27 • Two patients with bilateral orbital xanthogranuloma. The patient in **A** had diffuse xanthomas (yellow plaque lesions) of the eyelids, which responded well to bilateral external beam irradiation, without any recurrence. The patient in **B** failed to respond to any kind of treatment, including surgical excision, steroid injection, irradiation, and interferon alfa-2B treatment. Orbital, eyelid, and skin lesions recurred.

Management

Because these histiocytic lesions occur in a variety of ocular and adnexal locations, the details of treatment will depend on the anatomic site. In general, however, chemotherapy with adjuvant radiotherapy is the currently preferred modality of treatment.[304] Chemotherapy protocols consisting of systemic steroids, vinca alkaloids, antimetabolites, and antifols produce a variable response and have a high morbidity. The treatment of recurrent eosinophilic granuloma is challenging.[305] Necrobiotic xanthogranuloma does not respond well to medical, surgical, or radiation therapy; topical, regional, or oral corticosteroids are of no benefit. Minimal surgery consisting of gentle débridement is recommended.

Non-LC proliferations are treated with localized or systemic steroids, excisional surgery, radiation, or chemotherapy. Localized lesions respond well to treatment; diffuse or disseminated lesions, however, are difficult to control with any form of treatment.[306,307]

Orbital Meningioma

Orbital meningiomas may develop primarily from the meninges of the optic nerve sheath or extend into the orbit secondarily from the intracranial cavity.[308,309]

Meningiomas usually occur in middle-aged patients, with a female-to-male ratio of 3:1, and and whites are affected more often than blacks.[309] An increased incidence of this tumor is associated with neurofibromatosis types 1 and 2 (NF-1 and NF-2); multiple meningiomas and bilateral optic nerve sheath meningiomas (ONMs) may occur in these patients, particularly those with NF-2.[310]

Meningioma usually is a benign neoplasm; a malignant histologic pattern is very rare but is known to occur with metastatic potential. The most frequent sites of metastasis are the lung and bone. Histologic grading is the most important predictor of malignancy. Some physicians suggest that, in patients with a history of relapsed meningioma, a total-body CT scan should be performed in order to assess for other possible sites of disease.[311,312]

Pathogenesis

Meningioma originates from the meningoendothelial cells of the meninges. Loss of the *NF2* tumor suppressor gene in a biallelic fashion is believed to be central to the pathogenesis of NF-2-associated and sporadic meningiomas. The mechanism includes nonsense or missense mutation in the *NF2* gene and loss of the other *NF2* allele as a part of chromosomal losses on 22q.[313]

Clinical Features

The primary clinical manifestation of a meningioma affecting the anterior visual pathway is painless and gradually progressive loss of visual acuity or visual field. Patients with frontal or olfactory meningiomas may exhibit mental status changes. Ocular motility impairment, with or without diplopia, may occur with extraocular muscle, orbital, or cavernous sinus involvement. Other clinical findings include loss of color perception and ipsilateral afferent pupillary defect. Optic disc edema and optic atrophy may be seen on fundus examination; the disc, however, may look normal in early cases, particularly with posteriorly located lesions. Optociliary collateral ("shunt") vessels may be present on the optic nerve head secondary to increased choroidal and retrobulbar venous pressure.[314]

Imaging of the orbit in general shows typical but not necessarily pathognomonic features of meningioma. MRI usually is superior to CT in the evaluation of patients with meningioma; however, a CT scan may show hyperostosis of adjacent bone or foci of calcification within the lesion, which are consistent with meningioma (Fig. 71-28). MRI typically shows an isointense lesion on T_1-weighted images with homogeneous gadolinium enhancement.[315] ONMs have a more diagnostic radiographic appearance and may display a classic "railroad track" appearance of enhancement of the optic nerve sheath.

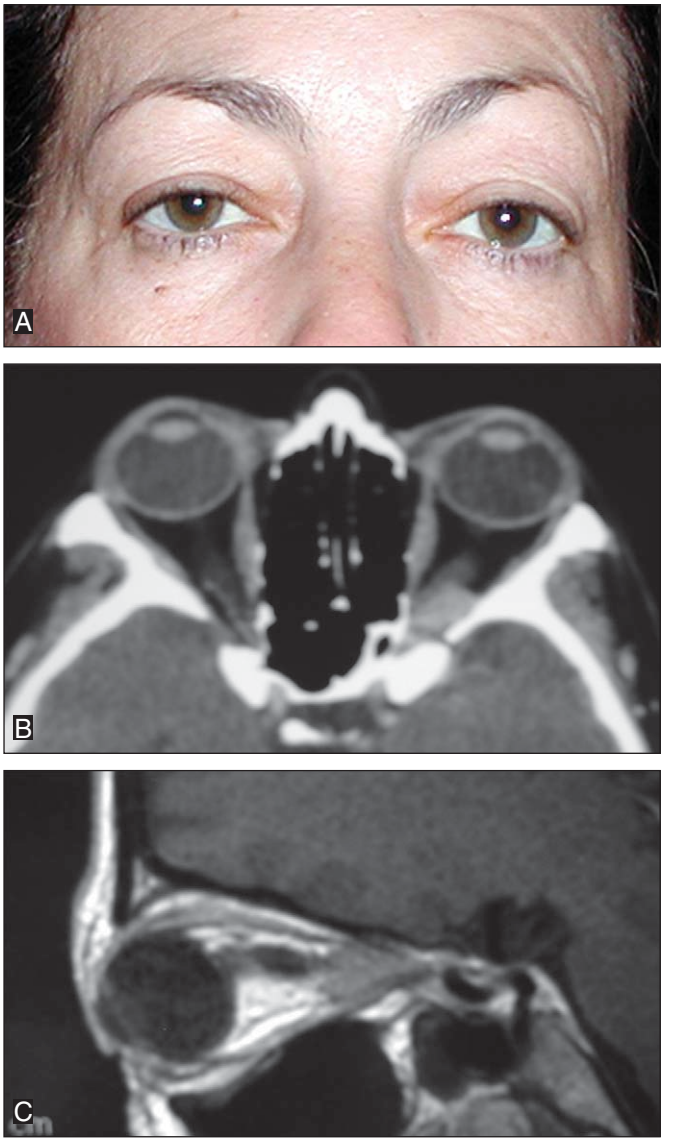

Figure 71-28 • Orbital meningioma. **A,** The patient had minimal proptosis of the left eye with diplopia at extreme left and upper gazes. The vision was severely diminished. **B,** The axial computed tomography reveals the apical location of the tumor with focal calcification. **C,** The sagittal T_1-weighted magnetic resonance image depicts extension of the tumor into the optic canal.

Differential Diagnosis

Metastatic tumors to the optic nerve are exceedingly rare and usually can be differentiated from ONM easily because of their rapid growth. However, occasional metastatic carcinomas are known to mimic ONM owing to their initial radiologic appearance and minimal growth on serial imaging.[316]

Imaging features considered characteristic of ONM, such as the "railroad track" sign or central optic nerve lucency seen on CT, also may be seen with metastases to the optic nerve.[317] Although typically more sensitive than CT, MRI also can be inconclusive because the appearances of these two pathologic conditions on ophthalmic imaging overlap considerably. Other rare lesions that may mimic an ONM include meningoceles and arachnoid cysts.[318,319] Arachnoid cysts are cystic lesions filled with a cerebrospinal fluid-like content within the leptomeninges. Usually they represent congenital malformations.[320]

Management

The management of symptomatic intracranial meningiomas must be individualized. The tumor usually is benign but may compress adjacent vital structures. In general, total surgical resection is attempted if the patient is a good surgical candidate, and if the surgery is technically possible. If the meningioma encases vital structures, such as a cavernous sinus or internal carotid artery, a subtotal excision may be considered. Sequential neuro-ophthalmic evaluations and neuroimaging studies are recommended to detect postoperative recurrence or progression. Postoperative irradiation may be employed for malignant or aggressive pathologic processes or for residual, recurrent, or nonresectable meningiomas.

ONMs usually do not require biopsy for diagnosis if the typical clinical and radiographic features are present; tissue diagnosis may be needed in rapidly growing tumors to rule out an aggressive

histopathologic type. Observation for progression is a reasonable first step in management. Surgical excision of ONM usually produces irreversible visual loss and generally is reserved for eyes without visual potential or cosmetically unacceptable proptosis. In patients with severe disk edema and rapid vision loss, however, surgery may serve an adjuvant role to fractionated stereotactic radiation therapy.[321] Orbital decompression by transnasal endoscopic ethmoidectomy has been reported to delay the visual loss in sphenoid wing meningiomas for some years. Some patients require additional radiotherapy for progressive tumor growth.[322] Rare patients with acute visual deterioration also may benefit from optic nerve sheath fenestration.[323]

If no tumor growth is observed, an ideal monitoring protocol is repeated MRI of the head and orbits with gadolinium and fat suppression every 6 months for 2 years and then yearly. On the other hand, if visual acuity and visual field are lost, even in the absence of tumor enlargement, most physicians would consider radiation therapy to be the treatment of choice.[324,325] Improved techniques for delivery of radiotherapy (e.g., conformal, three-dimensional, or intensity-modulated radiotherapy) may decrease the risks of radiation side effects. Stereotactic radiotherapy currently is the most effective method for treatment of primary ONM. It provides tumor control and visual preservation with low risk of complications.[325,326] In some patients, the visual improvement may take place early, even before completion of a standard course of radiation therapy.[327]

Turbin and coworkers offered a comparison of treatment (observation, surgery only, radiotherapy only, or surgery and radiotherapy) outcomes in 64 patients with ONM after a minimum of 50 months of follow-up. Of 59 patients with vision better than no light perception at diagnosis, 13 patients were observed only, 12 had surgery only (4 biopsies or partial resections, 8 total resections), 18 received irradiation alone, and 16 had surgery and irradiation (14 biopsies or partial resections and irradiation, 2 total resections and irradiation). Irradiated patients received 4000 to 5500 cGy of conventional multiport or conformal external beam therapy, typically fractionated over 6 weeks. Visual acuity measurements at diagnosis were not different among the four groups. Visual acuity fell significantly for the observation-only, surgery-only, and surgery plus irradiation groups. Patients with ONM receiving radiation alone had the best visual outcome during the follow-up period. The investigators recommended that fractionated external beam irradiation (at a dose of 5000 to 5500 cGy) be considered for initial treatment in adults when preservation of visual function is the therapeutic goal.[328] Other workers also reported very promising CyberKnife radiosurgery results, with high rates of tumor control and preservation of visual function in patients with these tumors. In one study in which the radiation was delivered in two to five sessions to an average tumor volume of 7.7 cm^3, with a cumulative average marginal dose of 20.3 Gy, 94% of the patients retained or improved pretreatment vision.[329]

Orbital Glioma

Optic pathway gliomas, which are tumors of childhood, account for approximately 1% of all CNS tumors.[330] No sex predilection has been noted, and although these tumors can manifest at any age, most patients are less than 10 years old. The presentation of this tumor in adulthood may suggest a more malignant behavior.[331,332]

The incidence of optic gliomas in children with NF-1 is as high as 15%, with symptomatic visual loss in approximately 20% of affected patients.[333] Any part of the optic pathway may be occupied with tumor. In approximately 25% of the cases, one or both optic nerves alone are involved; in the remaining 75%, the optic chiasm or tract contains glioma.

Pathogenesis

A majority of optic pathway gliomas are low-grade astrocytomas. The astrocytic nature of the tumor can be confirmed using immunohistochemical techniques with antibodies against glial fibrillary acidic protein (GFAP; molecular weight of 15,000). Although this protein also may be present in some schwannomas, increased GFAP expression is typical for astrocytic tumors.

Clinical Features

Gliomas that develop in the orbit produce painless proptosis, ophthalmoplegia, and progressive visual loss.[332] Visual loss is noted at presentation in approximately 90% of the patients. Optic disc swelling (35%) or atrophy (60%) generally is present, and rarely optociliary shunts may be observed. In children with NF-1 and optic pathway gliomas, the likelihood of visual loss depends on the extent and location of the tumor as determined by MRI.[334]

Hypothalamic symptoms and endocrine abnormalities may occur with chiasmal-hypothalamic tumors.[335]

On CT, the glioma manifests as a fusiform enlarged, uncalcified optic nerve mass with frequent kinking and cystic areas. MRI with gadolinium is superior to CT to display the tumor and monitor intracranial extension. The imaging typically reveals intrinsic enlargement of the optic nerve with variable contrast enhancement. On T_1-weighted images, the lesion usually is isointense to the cerebral gray matter. When the tumor is large, it may show marked enhancement centrally without peripheral enhancement; this appearance is consistent with ectactic or hyperplastic arachnoid around the nerve. On T_2-weighted images, fusiform lesions reveal high signal intensity, whereas large, lobulated tumors tend to have a more heterogeneous signal. A double-intensity "tubular thickening," with kinked and elongated optic nerves, suggests, but does not confirm, a diagnosis of glioma in patients with NF-1 (Fig. 71-29). Enlargement of the chiasm or the optic tracts is a sign of intracranial involvement.[336]

Differential Diagnosis

Considerations in the differential diagnosis for optic nerve glioma include idiopathic optic neuritis, sarcoidosis, demyelinating disease, and other tumors and cysts of the optic nerve and its sheath, including metastatic tumors.[337–339]

Management

A period of observation for progression prior to initiation of therapy is recommended by most authorities, because gliomas often are static or slowly growing lesions.[340] Non-NF-1 patients usually have larger and more rapidly progressive tumors. Rapidly progressive chiasmatic tumors are best treated by radiotherapy and respond well by regression.[341]

EBRT generally is reserved for patients older than 5 years of age with progressive imaging findings or worsening clinical signs and symptoms.[342] The risks of radiation are substantial and include cerebral atrophy, cerebrovascular disease, moya moya disease, subnormal intelligence or learning disabilities, and secondary primary malignancies, cataracts, radiation damage to the retina and optic nerve, endocrinopathy, and hypothalamic dysfunction. These risks generally are higher in younger patients.[343] The usefulness of surgical therapy generally is limited. An optic nerve glioma in a patient with no useful vision or that demonstrates progression may be resected. However, chiasmal, hypothalamic, or optic tract gliomas cannot be completely resected because of unacceptable ocular and CNS morbidity.

Chemotherapy frequently fails in a majority of patients but serves to delay implementation of radiotherapy or surgery until the child has progressed neuropsychologically. In infants or children younger than 3 years of age, however, chemotherapy with carboplatin and vincristine is emerging as a possibly safer alternative to EBRT. Surgical debulking does not appear to enhance chemotherapy effectiveness.[344] The prognosis of optic pathway gliomas is quite variable and is primarily based upon location; the more anterior the location, the better the prognosis. The 10-year overall survival rate is between 85% and 100%. In approximately 80% of patients with gliomas, vision stabilizes after an initial period of visual loss.[345] The natural history of the optic pathway glioma usually is more indolent in patients with

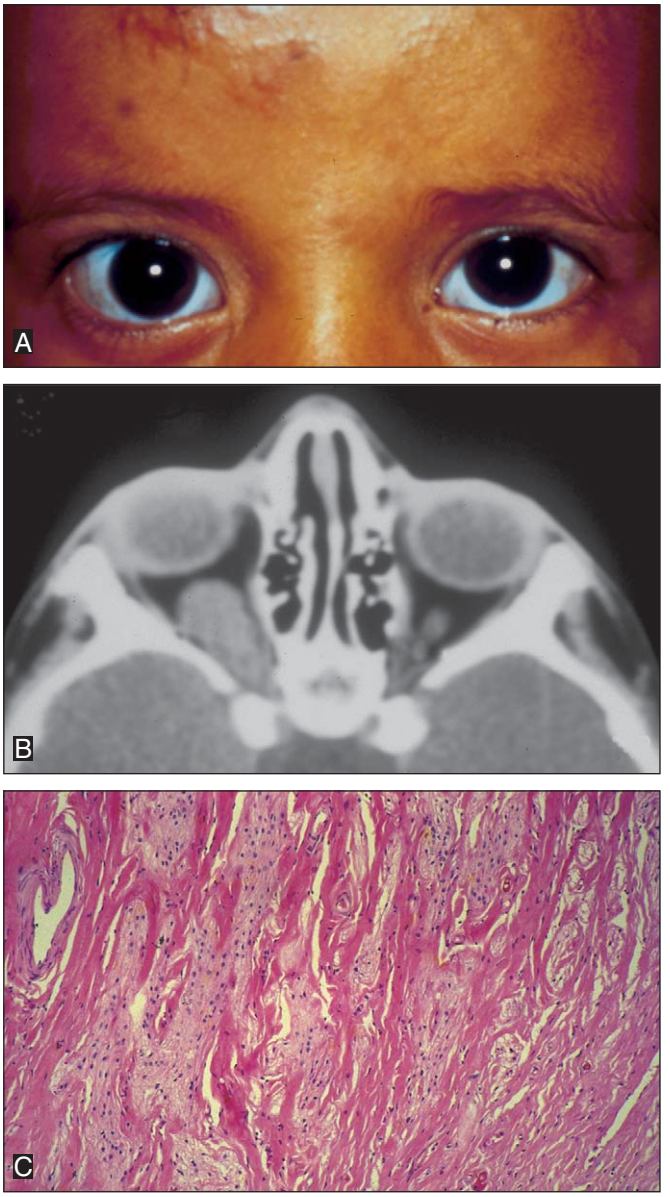

Figure 71-29 • Optic nerve glioma. **A,** Barely noticeable proptosis of the right eye in a child with long-standing optic nerve glioma. Because of the very slow growth of these tumors, proptosis is subtle in a majority of affected children. This patient also has multiple skin neurofibromas of neurofibromatosis type 1. **B,** Optic nerve glioma seen on axial computed tomography (CT) scan. Although the tumor is clearly seen on the CT scan, magnetic resonance imaging is preferred to monitor for extension of tumor into brain. **C,** Histopathologic appearance of a low-grade astrocytoma of the optic nerve.

NF-1 than in the others, and regressions are observed.[346] The prognosis with these tumors also is dependent on the patient's age at presentation. Those tumors that manifest before the age of 6 years have a tendency to grow fast and must be followed closely.[347]

Metastatic and Secondary Tumors

Metastatic Tumors

Systemic malignancies may metastasize to the orbit, with a frequency ranging from 2% to 10% of all orbital tumors.[348] Although almost, any human neoplasm has been reported to metastasize to the orbit, the most frequent primary tumors in adults include *breast*, *lung*, *prostate*, and *gastrointestinal tract carcinomas* and *cutaneous melanoma*.[349] Most orbital metastases appear as solitary nodules, rather than infiltrating tumors, and approximately 10% are bilateral. Bilateral orbital and sino-orbital disease most frequently is seen with metastasis from breast carcinoma. Approximately 50% of orbital metastatic tumors were reported to have concurrent involvement of other metastatic sites, including the eye. Patients with metastatic orbital tumors most frequently present with rapidly developing unilateral motility disturbance, painful proptosis, and occasionally, a palpable mass.[350] Imaging studies with CT and MRI provide information regarding the location of the tumor and the pattern of orbital involvement (Fig. 71-30); however, they rarely offer any clues in terms of the primary site. Fine-needle aspiration biopsy is an effective method for histopathologic confirmation of orbital metastasis.[351] Carcinoid tumors in the orbit may be primary or metastatic; the latter type is reported to be a slowly growing tumor associated with long survival after surgical treatment.[352]

In approximately 10% of metastatic orbital tumors, the site of the primary lesion is unknown; this condition is known as *occult primary malignancy*.[353]

In children, metastatic neoplasms to the orbit are predominantly small, round, blue-cell tumors, including neuroblastoma, Ewing sarcoma, granulocytic sarcoma, and Wilms tumor. Neuroblastoma is the most common malignant tumor in infants, with an approximate incidence of 1 per 1000 live births, and it is the most common metastatic tumor of the orbit in this age group. Neuroblastoma, which originates from primitive neuroectodermal cells, most often is diagnosed during the first year of life. On histopathologic examination it is seen to be made of round or oval, small round cells with hyperchromatic nuclei and minimal cytoplasm containing numerous mitotic figures. Differentiating neuroblasts and ganglion cells, as well as rosette formations (Homer-Wright rosettes), may be seen in primary tumors. Approximately 75% of affected children excrete increased amounts of catacholamine byproducts, including vanillyl-

Figure 71-30 • Multiple orbital and brain metastases from an abdominal neuroblastoma on an axial T_1-weighted image.

mandelic acid (VMA), norepinephrine, homovanillic acid (HVA), and dopamine, in the urine; assays for these substances are very helpful in diagnosis.

Secondary Tumors

Tumors extending into the orbit range from congenital malformations, hamartomatous and teratomatous lesions, and reactive proliferations to most malignant neoplasms such as retinoblastoma. Secondary orbital tumors may originate from the cranial bones and CNS tissues (*meningioma*, *pituitary adenoma*, *craniopharyngioma*), periorbital bones (*osteoma* and *osteogenic sarcoma*, *giant cell-rich reactive lesions*), paranasal sinuses and nasal cavity (*squamous cell carcinoma*), nasolacrimal drainage apparatus (*squamous cell carcinoma*), globe (*uveal melanoma*, *retinoblastoma*) and conjunctivae and the eyelids (*squamous cell carcinoma*, *basal cell carcinoma*, *melanoma*, and *sebaceous gland carcinoma*).

72 Cancer of the Head and Neck

Harry Quon

SUMMARY OF KEY POINTS

Incidence
- More than 37,000 estimated new cases of head and neck cancer are diagnosed each year in the United States.
- More than 11,000 estimated deaths due to head and neck cancer occur annually in the United States.

Epidemiology and Risk Factors
- The dominant risk factors for the development of head and neck cancers are tobacco and alcohol use.
- Other risk factors may include immunosuppression and viral infection (human papillomaviruses and Epstein-Barr virus [EBV]).

Pathology and Tumor Biology
- A majority of head and neck cancers are squamous cell carcinomas with a well-delineated local-regional spread pattern.

Clinical Findings
- The clinical presentation in head and neck cancer depends on the anatomic site of involvement.
- Common symptoms may include hoarseness of voice, dysphagia, odynophagia, and referred otalgia.

Differential Diagnosis
- Considerations in the differential diagnosis include lymphoma, sarcoma, and other solid malignancies.

Staging
- Clinical evaluation should include endoscopic evaluation of the upper aerodigestive tract.
- Local-regional anatomic imaging is accomplished by computed tomography (CT) or magnetic resonance imaging (MRI).
- Chest radiography also is indicated.
- Ultrasound examination of the neck is indicated in select cases.
- Chest CT, bone scan, or positron emission tomography (PET) may be indicated as well.
- Complete blood count (CBC) also is part of the workup.

Primary Therapy, Salvage Therapy
- *Early-stage definitive therapy*: Subsite-specific with either definitive surgery or radiotherapy. Involvement of sites important for speech or swallowing function or sites in which surgical risks are prohibitive may favor therapy that provides functional organ preservation. This often favors primary radiotherapy.
- *Advanced-stage definitive therapy*: Subsite-specific with either definitive surgery with postoperative radiotherapy as indicated or chemoradiotherapy with concurrent chemoradiotherapy often favored. Involvement of sites important for speech or swallowing function may favor therapy that provides functional organ preservation. This often favors chemoradiotherapy. Altered fractionated radiotherapy may be used in patients not able to receive chemotherapy or as a alternative therapeutic option for nonbulky primary but advanced-stage disease.
- *Advanced-stage palliative therapy*: Treatment options may include radiotherapy. Systemic chemotherapy or treatment on protocol with systemic chemotherapy often is favored owing to a more favorable toxicity profile.
- *Local-regional recurrent salvage therapy*: For resectable disease with no prior irradiation, surgery with postoperative radiotherapy is favored; for resectable disease with prior irradiation, surgery with considerations for re-irradiation with or without brachytherapy implant is favored. For unresectable disease without prior irradiation, chemoradiotherapy is favored; for unresectable disease with prior irradiation, re-irradiation on protocol or systemic chemotherapy is favored.

Complications
- *Surgical* complications may include: nerve injury, hematoma formation, and organ dysfunction.
- *Radiotherapy-related* complications seen acutely may include skin desquamation, mucositis, dysphagia, odynophagia, xerostomia, and taste alterations; late complications include xerostomia, skin–soft tissue–mucosal atrophy, soft tissue fibrosis, permanent swallowing dysfunction, hypothyroidism, transverse myelitis, and blindness.
- *Chemotherapy-related* complications may include bone marrow suppression.

Prognosis
- Prognosis is both subsite-specific and histology-specific. For locally advanced head and neck cancers of the squamous cell type, the long-term disease control rate is less than 40%.

Future Directions
- Further improvements in local-regional management with the integration of novel targeted agents in combination with current chemotherapy and radiotherapy regimens may lead to better outcomes.
- Continued development of novel radiotherapy techniques, including intensity-modulated radiotherapy (IMRT) and proton radiotherapy, is essential.

INTRODUCTION

In the United States for the year 2003, cancers of the head and neck accounted for 2.8% of all new cancer cases and 2% of all cancer deaths.[1] Because these tumors are relatively uncommon, misdiagnosis along with patient neglect not uncommonly contributes to an advanced stage at presentation and limited survival.[2] Despite their relatively low numbers in clinical practice, research and management of head and neck cancers continue to receive significant emphasis owing to the rich anatomic and functional complexity of this body site, which is critical to issues of self-esteem, communication, and social integration. Although squamous cell carcinomas constitute a majority of adult histopathologic patterns (95%)[3] that may be seen in head and neck cancers, the variation in histopathologic types and the differing features of the possible anatomic subsites of involvement result in tremendous discordant variability in the natural course of the diseases for this small anatomic region.

The site begins at the base of the skull and extends only to the clavicles and includes the base of the skull, temporal bone (external auditory canal, middle and inner ear), paranasal sinuses, nasopharynx, oropharynx (soft palate, tonsil structures, base of tongue, oropharyngeal wall), larynx, hypopharynx (pyriform sinuses, postcricoid, posterior pharyngeal wall), oral cavity (lips, buccal mucosa, alveolar ridges, floor of mouth, oral tongue, retromolar trigone), major and minor salivary glands, skin, and the neck.

Accordingly, management of head and neck cancers has evolved to require a multidisciplinary approach with effective integration of various skills and treatment modalities to achieve the desired goals of cure and functional organ preservation. Despite improvements in the diagnosis and local-regional management of head and neck cancer, few significant increases in long-term survival rates over the past 30 years have been realized. The desire for more effective yet organ-preserving therapies with acceptable toxicity is currently being addressed with recent technological advancements in surgical and radiotherapy techniques and the development of novel biologic agents. These agents are particularly attractive because they have been demonstrated in cell model systems to target various aberrant molecular proteins that appear to have dominant roles in mediating biologic aggressiveness or therapeutic resistance. These advances, coupled with tremendous clinical research activity, have resulted in a number of therapeutic options for patients with head and neck cancer.

EPIDEMIOLOGY

An estimated 37,000 new cases of head and neck squamous cell carcinoma (HNSCC) were diagnosed in the United States in 2003, with 68% being diagnosed in males, accounting for approximately 11,000 cancer deaths, with 71% in males.[1] Additionally, cancers of the oral cavity and oropharynx represent 3% of all malignancies in men and 2% in women in the United States.[4] Worldwide, 15% of male cancers, 600,000 cases annually, are HNSCCs. Head and neck cancers affect both sexes and all races, but a preponderance continues to be seen in males, African Americans, and Asians.[4] Oral and pharyngeal cancers have decreased significantly in white males over the past 20 years and in white females younger than 65 years of age.[5] Conversely, the incidence and mortality rates have significantly increased in African-American males but have decreased in black women. The incidence of laryngeal cancer appears to mimic that of lung cancer; a small decline in the incidence in white men younger than 65 has been noted, but the incidence continues to increase in white and black males older than 65 and in women in all age groups.[6]

Limited knowledge exists concerning the epidemiology of in situ head and neck cancers (lip, oral cavity, larynx, and pharynx). Data extrapolated from population-based cancer registries in the National Cancer Institute's (NCI) Surveillance, Epidemiology, and End Results (SEER) program revealed that annual age-adjusted incidence rates for in situ HNSCC rose from 6.33 per 1 million person-years in 1976 to 8.04 per 1 million in 1995 (a 35% change).[7] The predominant anatomic sites of change were the larynx and lip, with this significant rise thought to be attributable to improved surveillance.

Of significant concern are the rising trends of head and neck malignancies in the pediatric population and younger adults. Again, according to data from SEER, the average annual rate in children younger than 15 years of age rose 35% from 1.10 to 1.49 between 1973 to 1975 and 1994 to 1996, respectively.[8] This incidence reflects a greater increase than for childhood cancer in general, which increased 25% during that same period. In a selected population at the M.D. Anderson Cancer Center, the percentage of adults younger than 40 years with oral tongue squamous cell carcinomas rose from 4% to 18% between 1971 and 1993.[9] This finding has been substantiated by SEER data indicating that the incidence of tongue cancer (oral cavity and oropharynx) increased by 60% in adults younger than 40.[10] The prognosis tended to be worse in black than in white males in the same age category. Trends in laryngeal cancers, documented most accurately in the Veterans Affairs (VA) system increased as well between 1983 and 1993 but more notably among those older than 65 years.[11]

Successful therapy for HNSCC may be limited by the recognized risk of second primary malignancies in the aerodigestive tract. Using data from a population-based cancer registry, investigators from the United Kingdom observed 5.5% of males and 3.6% of females to have developed a second primary cancer after an initial diagnosis of head and neck cancer.[12] They also noted a significantly increased risk for a second cancer in most of the upper aerodigestive tract sites commonly associated with tobacco exposure, with a standardized incidence ratio for subsequent oral cancer of 5.56 in men and 15.31 in women. Excluding these tobacco-associated sites resulted in a nonsignificant risk for a second malignancy. Patients with a first detected pharyngeal cancer experienced the highest incidence of a second malignancy. The relative risk for multiple primary cancers was higher in younger patients and among patients who received radiotherapy for their first primary malignancy. These investigators estimated that within 20 years of diagnosis of the first primary HNSCC, subsequent primary malignancies would develop in 30% of males and 20% of females.

ETIOLOGY AND PATHOGENESIS

Tobacco and alcohol continue to remain the two major risk factors for HNSCC in developed countries, with their carcinogenic risks summarized in several working group reports by the International Agency for Research on Cancer (IARC).[13,14] It is estimated that 75% to 90% of all head and neck carcinomas are attributable to tobacco consumption, particularly cigarette smoking.[15,16] The cumulative evidence easily fulfills the criteria for causality between cigarette smoking and the development of HNSCC.[17,18] Supporting a causal relationship has been the demonstration that the risk of developing HNSCC rises with increasing numbers of cigarettes smoked per day and increasing years' duration of the habit.[3,19] Current smokers have an approximate 20-fold higher risk of oropharyngeal and laryngeal cancers than that in lifelong nonsmokers.[19,20] The relative risk of developing head and neck cancer in the heaviest smokers is quoted as 20 to 40 times that of nonsmokers.[19–21] Even light or occasional cigarette smoking leads to an increased risk of cancer.[3,19,21] In addition to the duration of smoking and number of cigarettes, the type of cigarettes and the age, sex, and race of the smoker also influence the relative risk. By contrast, it has been estimated that the relative risk of developing head and neck cancer for heavy consumers of alcohol is two- to sixfold.[22]

Approxiamtely 300 known carcinogens are present in tobacco, with tobacco-specific *N*-nitrosamines (TSNAs) being the most harmful.[23] These substances are metabolites of nicotine, the major

alkaloid responsible for addiction to tobacco.[17] TSNAs are known to bind to DNA and to cause mutations that can activate proto-oncogenes or inactivate tumor suppressor genes.[24] Other harmful mutagenic compounds found in tobacco include polycyclic aromatic hydrocarbons (PAHs), carbon monoxide, and hydrogen cyanide.[23]

Despite limited data, an association between cigar and pipe smoking and an increased risk for HNSCC also is recognized. Cigar consumption in the United States has increased substantially since 1993. Cigars are known to contain even higher concentrations of TSNAs than in cigarettes.[25] With regard to environmental smoke, compared with cigarettes, cigars emit 20 times the carbon monoxide and twice the PAHs, owing in large part to their greater size.[25] The increased risk of HNSCC associated with cigar smoking is between 1.9 and 10.3 times that in nonsmokers.[15,25–28] Smoking more than 4 cigars per day increases the risk more than 20-fold.[29] A recent study analyzed prospectively the rates of cancer deaths among cigar-smoking men. Men who never smoked cigarettes or pipes were excluded. Risk of death from oral cavity or pharynx and larynx cancers was 4.0 (95% confidence interval [CI], 1.5 to 10.3) and 10.3 (95% CI, 2.6 to 41.0), respectively.[26] Although fewer dedicated studies have been performed, pipe smoking has been similarly implicated.[15,30,31]

Active cigarette smoking is not the only form of tobacco exposure that poses a risk. Exposure to secondhand, or environmental, smoke also has been implicated in several publications as a risk factor for the development of head and neck cancer.[32–34] A recent study of more than 300 patients and control subjects found that secondhand smoke increased the risk of HNSCC, with a confirmed dose-response pattern. Persons who were exposed to the highest levels of environmental cigarette smoke were up to four times more susceptible to the development of HNSCC.[34]

Tobacco is consumed in a smokeless form in many cultures around the world. In the West, the most common form of smokeless tobacco is termed snuff, whereas in parts of Asia, it often takes the form of betel quid. Betel quids consist of a betel pepper leaf wrapped around a mixture of areca nut, slaked lime, and tobacco; the slaked lime releases an alkaloid that causes a sense of euphoria in the user. Approximately 200 million persons throughout the western Pacific basin and south Asia regularly chew betel quid.[35] Habitual use of betel quid can lead to a progressive scarlike formation known as oral submucous fibrosis. The data regarding an increased risk of oral cancer in persons who chew betel are incontrovertible, with an estimated odds ratio of 17 for the development of HNSCC.[35–38]In Europe and the Americas, a large variation has been found in the amounts of TSNA among the various brands and forms of smokeless tobacco available.[39] Therefore, a discrepancy exists between estimated cancer risks associated with smokeless tobacco consumption in Europe and in the Americas.[18,39] Recent studies of Swedish moist snuff users showed no increase in cancer incidence over that in control subjects,[18,40] which may be due to the lower concentrations of TSNA in Swedish snuff.[39] The link between other forms of smokeless tobacco and oral cancer is well established, however.[41–43] A recent review of the known literature found relative risks ranging between 0.6 and 13, depending on the type of smokeless tobacco studied.[42]

Alcohol consumption also is a known independent risk factor for HNSCC.[19,44–47] For those individuals that drink heavily but do not smoke, the increased relative risk reportedly ranges from 5.0 to 11.6, increasing in significance with higher numbers of drinks consumed.[45,46] When alcohol and tobacco are consumed together, the risk increases multiplicatively, rather than additively.[15,19,48] Extremely high odds ratios have recently been quoted for heavy consumers of both tobacco and alcohol.[19,44] Franceschi and colleagues reported an odds ratio of 228 for oral cancer in consumers of more than 25 cigarettes per day and more than 11 drinks per day.[44] One other report noted an odds ratio of 177 for laryngeal cancer in heavy tobacco and alcohol users.[19]

The mechanism for alcohol-induced carcinogenesis is not fully understood. Pure ethanol has been shown not to be carcinogenic.[49] Alcohol, however, often is regarded more as a cocarcinogen, facilitating carcinogenesis rather than initiating it.[50] Several mechanisms for this effect have been proposed. It has been suggested that alcohol may increase the penetration of carcinogens across the oral mucosa,[51] as well as causing mucosal atrophy, which may result in an enhanced susceptibility to chemical carcinogens.[52] It also has been suggested that alcohol may have an effect on DNA repair mechanisms.[53] Other suggested mechanisms include nutritional deficiencies associated with heavy drinking, the effects of contaminants and congeners in alcoholic beverages, and the induction of microsomal enzymes that enhance the metabolic activation of tobacco or other carcinogens.[3] These mechanisms also may explain the observation of an increased risk of cancer with heavy alcohol consumption in nonsmokers. Several reports suggest that women may be more susceptible than men to alcohol-induced carcinogenesis in the head and neck.[46,54,55]

Several studies have implicated the lack of vitamin and fresh fruit intake as a risk factor for head and neck cancer.[56–61] It often is difficult, however, to separate malnutrition from other confounding variables, including alcohol consumption and cigarette smoking. Related to malnutrition is the problem of poor oral hygiene, which also has been found to be associated with HNSCC.[62–64]

It has been proposed that patients with HNSCC have increased chromosomal sensitivity to carcinogen exposure that predisposes them to developing cancer.[65–68] In vitro laboratory studies have shown that cells from these patients suffer more chromosome breaks on exposure to a mutagen than are seen in normal control cells.[67,69] In addition, mucosa from young patients with HNSCC who were nonsmokers was particularly mutagen sensitive.[70]

Immunosuppression may predispose individuals to an increased risk of HNSCC. The risk of carcinomas of the lip is particularly increased in renal transplant recipients.[71–73] Cutaneous malignancies including lip cancers appear to be increased in cardiothoracic transplant recipients.[74] Other sites of malignancies may include the oral cavity, although the risk does not appear to be as significantly increased as it is with cutaneous malignancies including the lip in transplant recipients. An increased risk of oral cavity carcinomas has been reported in human-immunodeficiency virus (HIV)-infected patients.[75] These tumors generally are more aggressive, with decreased patient survival[74,76] and a demonstrated association between the degree of medical immunosuppression, most notably involving prednisone, and advanced-stage presentation and an adverse survival.[76]

A potential causal relationship is believed to exist between viral infections and carcinomas of the head and neck. Human papillomaviruses (HPVs) have been associated with a risk for oral cavity[77,78] and oropharyngeal carcinomas.[78,79] Of interest, these carcinomas may carry a better prognosis[80,81] and may respond better to therapy such as radiotherapy.[79] A nested case-control study suggested that the risk may be with the HPV-16 serotype, with 50% and 14% of oropharyngeal and oral tongue carcinomas, respectively, containing HPV-16 DNA. In a large retrospective study, 90% of HPV-positive tumors were of the HPV-16 subtype. Two oncoproteins encoded by HPVs, E6 and E7, are known to inactivate p53 and the tumor suppressor protein for retinoblastoma, presenting potential mechanisms of action.[82,83] The EBV is a human herpesvirus that has been implicated in a number of human malignancies, including nasopharyngeal carcinoma (NPC). A consistent association between EBV and less differentiated types of NPC has been reported.[84–86] Although the extent to which EBV infection may contribute to NPC carcinogenesis has not been completely elucidated, an early role is supported by evidence of clonal EBV infection in preinvasive lesions (carcinoma in situ).[87] The expression of various viral gene products, EBV nuclear antigen (EBNA), and latent membrane proteins (LMP1, LMP2) has been demonstrated to have the capacity to induce transformation in vitro, consistent with a carcinogenic role for EBV infection.

PATHOLOGY

Squamous Cell Carcinoma

Oral Cavity

Squamous cell carcinoma accounts for 95% of all malignant tumors in the oral cavity. Other malignancies involving the oral cavity include malignant salivary gland lesions, mucosal melanoma, lymphoma, and sarcoma. Although squamous cell carcinoma can occur anywhere in the oral cavity, the most common locations include the floor of the mouth, tongue, and hard palate. In the earliest recognizable stage, squamous cell carcinoma appears as firm, pearly plaques or as irregular, roughened, or verrucous areas of mucosal thickening, which can be mistaken for leukoplakia, a premalignant lesion. Larger lesions seldom are mistaken for leukoplakia and form either exophytic masses (Fig. 72-1A) or endophytic lesions, often with associated ulceration and heaped-up edges (see Fig. 72-1B).

Histologic examination frequently reveals an association with in situ lesions, sometimes with surrounding areas of epithelial dysplasia of varying degrees (see Fig. 72-1C). Histologically, these tumors range from well-differentiated keratinizing neoplasms to poorly differentiated squamous cell carcinoma without keratinization to anaplastic and sometimes sarcomatoid growth patterns (see Fig. 72-1D). Less common patterns include verrucous carcinoma.

Larynx

Epithelial changes in the larynx include a spectrum of pathologic changes beginning with hyperplasia and progressing through dysplasia, carcinoma in situ, and invasive carcinoma.[88] As in the oral cavity, these early pathologic lesions appear as white (leukoplakia) or reddened (erythroplakia) thickenings and cannot be reliably distinguished from early invasive carcinoma. The earliest lesions (hyperplasia) have little or no malignant transformation potential, whereas mild dysplasia progresses to carcinoma in 1% to 2% of cases over a 10-year period and rises to 5% to 10% with high-grade dysplasia over a similar time span. In general, the more severe the dysplasia, the greater the risk of progression to carcinoma.

Approximately 95% of laryngeal carcinomas are the typical squamous cell carcinoma. Squamous cell carcinoma may develop on the vocal cords, but it also may develop in a supraglottic or subglottic location. Similar to oral squamous cell carcinomas, these lesions begin as in situ carcinoma and, left untreated, grow into infiltrating, ulcer-

ated, and fungating lesions (Fig. 72-2A–C). The degree of differentiation of squamous carcinoma is highly variable and similar to that in tumors of the oral cavity. Rare cases show sarcomatoid differentiation.

Nasal Sinus and Nasopharynx

Epithelial carcinomas in the nasal sinus are grouped under the entity of NPC. Within this clustered entity are three distinct histopathologically recognizable tumor patterns: (1) keratinizing squamous cell carcinoma; (2) nonkeratinizing squamous cell carcinoma; and (3) undifferentiated carcinoma, also referred to as the lymphoepithelial type of NPC. The nonkeratinizing and undifferentiated carcinoma is most closely associated with EBV infection.

Keratinizing and nonkeratinizing squamous cell carcinoma in the nasopharynx is morphologically similar to lesions found in the larynx and oral cavity. The nonkeratinizing forms also may take the appearance of transitional epithelium—hence the designation of some nasal carcinomas as transitional type. The undifferentiated form of NPC, by contrast, shows a unique morphology characterized by the growth of large tumor cells with round to oval nuclei, prominent nucleoli, fine vesicular chromatin, and indistinct cell borders (which produces a syncytial appearance). An abundant lymphoid response is seen within this tumor, sometimes obscuring the malignant epithelial cells. EBV genome frequently is found within the epithelial tumor cells (Fig. 72-3A–C).

A rare and highly aggressive variant of squamous cell carcinoma, the so-called basaloid squamous cell carcinoma, can be found in the upper aerodigestive tract and nasopharynx and less commonly in other sites within the head and neck.[89,90] This tumor is characterized by cells infiltrating in small to large nests with prominent central comedo-type necrosis. At the edges of the nests, the tumor cells form an organized palisade. In addition, variable areas of the tumor show malignant squamous cell morphology with keratinization. Cytologically, the tumor cells show marked nuclear pleomorphism with single cell necrosis and high mitotic rates (see Fig. 72-3D).

A rare and highly aggressive carcinoma found within the nasal sinus is the sinonasal undifferentiated carcinoma (SNUC) believed to originate from the schneiderian mucosa.[91] These lesions may manifest with or without neuroendocrine differentiation but without evidence of squamous or glandular differentiation. SNUCs are distinguished from undifferentiated nasopharyngeal carcinoma by the absence of a surrounding lymphoid reaction. SNUC cells are medium in size and grow in nests. Cytologically, the tumor cells show a fine chromatin pattern, hyperchromasia, and variably sized nucleoli. Mitotic rates are high, and necrosis is common.

Malignant Salivary Gland Neoplasms

Salivary gland tumors constitute a rare and interesting heterogeneous group of tumors. The vast majority of salivary gland tumors are benign and develop in the parotid gland. A subset of salivary gland tumors is malignant, however. Malignant salivary gland tumors are more common in the minor salivary glands (50% to 60%) and sublingual salivary glands (80% to 90%) in contrast to the parotid (20% to 30%) and submandibular (30% to 40%). A brief discussion of the major types of malignant salivary gland tumors follows.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinomas are the most frequent type of malignant salivary gland tumor. Although occurring most often in the parotid gland, they also can be seen with high frequency in the minor salivary glands. These tumors, as their name implies, are composed of a mixture of squamous cells (epidermoid component) and mucus-secreting cells (mucoid component). A third cell type found within these lesions is the intermediate cell.

Mucoepidermoid carcinomas vary in size and lack a well-defined capsule. Microscopically, the tumor shows a pushing or infiltrative border. They vary in appearance from white to gray and frequently contain small to microscopic mucinous cysts (Fig. 72-4A). Microscopically, the tumor is composed of cells arranged in cords, nests, and sheets with varying amounts of squamous, mucous, and intermediate cells. These tumors can vary from well differentiated to highly aggressive, poorly differentiated histopathology. Various grading schemes to account for these differences cluster tumors into low-, intermediate-, and high-grade categories based on the amount of mucinous cells, solid squamous nests, mitotic rate, necrosis, and pleomorphism.[92,93] These tumor grades also correlate with patient outcome. Low-grade tumors (see Fig. 72-4B) rarely metastasize, often are locally infiltrative, and recur in 10% to 15% of cases, and therefore have an excellent 5-year survival rate of greater than 90%. By contrast, high-grade tumors (see Fig. 72-4C) are highly infiltrative, recur in 30% to 40% of cases, and have metastasized in 30% to 40% of cases at presentation, producing 5-year survival rate of only 50%.[94–96] Grading appears to have less prognostic importance when the submandibular glands are involved. Involvement of this site appears to be associated with an increased risk of distant relapse regardless of grade.[96,97]

Adenocarcinoma, Not Otherwise Specified

These tumors are now restricted to lesions that do not show histopathologic patterns of the other salivary gland tumor types. These

tumors can occur in the parotid gland as well as minor salivary glands and typically present in the sixth to eighth decade of life. At presentation, varying histologic patterns including tubular, papillary (with varying degrees of differentiation from well to poorly differentiated), and adenocarcinoma may be observed. Important in the workup for these patients is to exclude an adenocarcinoma from another body site because salivary gland adenocarcinomas can mimic adenocarcinomas from other organ sites.

Adenoid Cystic Carcinoma

Adenoid cystic carcinomas account for some 20% of malignant salivary gland tumors. They are frequently located in the minor salivary glands (40% to 50% of cases) and less often in the parotid gland (20% to 30%). The most common histologic pattern is the classic cribriform type or "Swiss cheese" pattern, characterized by neoplastic cells forming oval or circular spaces or nests. Within these nests is dark, eosinophilic, hyaline-like basement membrane material. The amount of the hyaline material can distort the cell nests and produce a small acinar- or cord-like appearance to the tumor nests (see Fig. 72-4D). Perineural invasion is almost invariably observed in these tumors (see Fig. 72-4E) and a diagnosis of adenoid cystic carcinoma without finding perineural invasion should be carefully reconsidered. Adenoid cystic carcinomas are graded into low-, intermediate- and high-grade tumors based on the amount of solid growth, mitoses, necrosis, and pleomorphism[98]; as with mucoepidermoid carcinoma, the degree of differentiation is correlated with long-term survival.

Acinic Cell Carcinoma

More than 90% of acinic cell carcinomas arise in the parotid gland. These tumors occur between the ages of 50 to 70, with men affected more than women (2:1 male-to-femael ratio). The gross appearance of these tumors varies, but they often are white-tan in color and present as a well-circumscribed but unencapsulated mass. Microscopically, the most common histologic pattern consists of solid sheets of cells with low-grade cytology and granular basophilic cytoplasm similar to the serous acinar cells of a normal salivary gland. Less common variants include a cystic and microcystic pattern, in which the tumor cells are arranged at the edges of the cyst, and cells with granular basophilic cytoplasm are arranged among cells, with a tombstone appearance and capitation-type secretion, as well as cells with a bubbly vacuolated appearance. Rare cases of acinic cell carcinoma have been reported to undergo dedifferentiation into a high-grade aggressive malignancy[99]; most acinic cell carcinomas, however, behave in a more indolent fashion.[100,101]

Figure continues on following page.

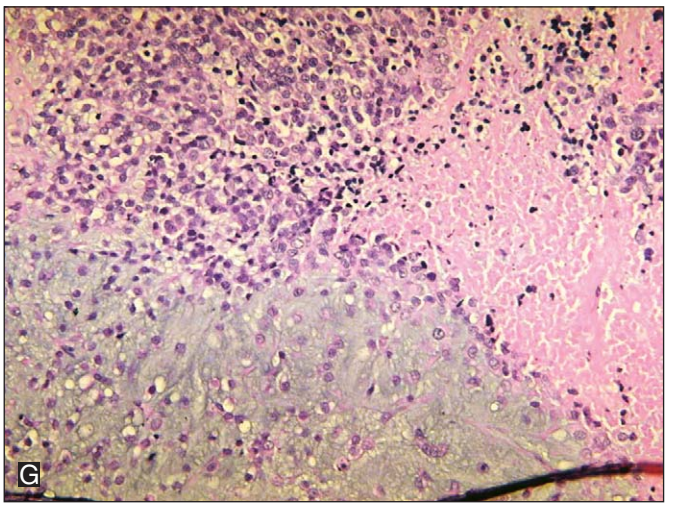

Figure 72-4, cont'd • G, Parotid gland with carcinoma ex pleomorphic adenoma showing adenocarcinoma not otherwise specified, with comedo-type necrosis.

Malignant Mixed Tumor (Carcinoma ex Pleomorphic Adenoma)

Malignant mixed tumors of the salivary gland are predominantly tumors that started as pleomorphic adenomas in which the epithelial tumor component subsequently underwent malignant transformation. This transformation may be confined to the adenoma, resulting in the noninvasive carcinoma ex pleomorphic adenoma.[102] A majority of carcinomas that arise out of pleomorphic adenomas, however, are infiltrative and aggressive lesions (see Fig. 72-4F and G). The transformation to a malignant phenotype is heralded by a change in the behavior of the patient's underlying pleomorphic adenoma characterized by sudden enlargement of an otherwise stable adenoma, or by the onset of pain in a previously asymptomatic adenoma. Morphologically, the malignant transformation can take on any malignant epithelial salivary tumor phenotype, the most common being adenocarcinoma not otherwise specified.[103] Occasionally, multiple recognizable histologic patterns may be present. These tumors are highly aggressive, with 5-year survival rates as low as 25%. Another form of the malignant mixed tumor is the true carcinosarcoma, which again often arises from a pleomorphic adenoma background. These tumors have both malignant epithelial and malignant stromal elements.

Polymorphous Low-Grade Carcinoma

Polymorphous low-grade adenocarcinoma (PLGA) is a rare low-grade carcinoma of minor salivary glands. These tumors grow as infiltrative masses and are composed of uniformly low-grade tumor cells arranged in a variety of histologic patterns, including tubular, solid, papillary, microcystic, cribriform (with true lumina), pseudoadenoid cystic (without true lumina), fascicular, single file, and cordlike.[104] Perineural invasion is common. In contrast with adenoid cystic carcinoma, PLGA stains positively for EMA, which may be relied on to distinguish between these two pathologic lesions. Rare cases of PLGA have metastasized, and these cases have been associated with more than focal areas of papillary growth. Rare cases have dedifferentiated into high-grade aggressive carcinomas.[105]

Salivary Duct Carcinoma

Salivary duct carcinomas are rare tumors with a male predilection. These are rapidly growing tumors that can produce pain and nerve palsies. Morphologically, these tumors resemble comedo-type duct carcinoma of the breast and also may grow in a cribriform or papillary pattern. Cytologically, these tumors tend to be high grade, with nuclear pleomorphism, single-cell necrosis, and high mitotic rate. Clinically, these tumors behave in an aggressive fashion, with poor long-term survival.[106,107]

Lymphoid Tumors of Head and Neck

Extranodal Lymphoma

Extranodal lymphomas of the head and neck can take on the same morphologic spectrum as that seen anywhere in the body. Large cell lymphoma predominates, but any morphologic pattern can be seen. Although many of these lymphomas arise in association with lymphoid tissue within Waldeyer's ring, they are not limited to this location.

Angiocentric Lymphoma

Formerly called by a variety of terms (polymorphic reticulosis, lethal midline granulomatosis), this lymphoid malignancy manifests as an aggressive destructive lesion characterized by ulceration and tissue necrosis. The tumor cells are visible, growing in an angiocentric location. Immunophenotypically, these tumors often are either NK or T cells, with rare B cell phenotype reported.[108–110] It is important to distinguish this entity from nonmalignant sinonasal processes, such as Wegener's granulomatosis, that also can produce an ulcerating and necrotizing lesion.

Plasmacytoma

Extramedullary plasmacytomas occur in the area of Waldeyer's ring of lymphoid tissue. These tumors represent clonal plasma cell tumors. Some 30% of patients with plasmacytomas will eventually develop multiple myeloma if followed for 20 years. Cytologically, the plasma cells can vary from well-differentiated plasma cells to very atypical-appearing plasmablasts. Occasionally, plasmacytomas with increased plasmablasts are misdiagnosed as poorly differentiated carcinoma, unless the pathologist considers plasmacytoma in the differential diagnosis and orders the appropriate immunohistochemical studies.

Olfactory Neuroblastoma

Olfactory neuroblastomas or esthesioneuroblastomas are rare tumors that arise from the olfactory neuroepithelium. This epithelium can be found along the roof of the nasal cavity to the midportion of the nasal septum and onto the superior turbinate. These tumors appear to be morphologically similar to neuroblastomas that arise in the adrenal gland. They are characterized by proliferation of small round blue cells arranged in nests and surrounded by a vascular network in a loose connective tissue stroma. Rosette formations can be seen as well as neurofibrillary material in the center of the rosette and within the connective tissue matrix. These tumors stain for neuroendocrine markers including S100, NSE, chromogranin, and Leu-7, which aids in distinguishing them from poorly differentiated carcinoma.[111,112]

Melanoma

In addition to cutaneous melanomas that can occur anywhere on the head and neck, melanomas may also involve the mucosal surface of the oral cavity or nasal sinus. These tumors often manifest in the fifth or sixth decade of life. Mucosal melanomas often appear histologically similar to their cutaneous counterparts and may display a similar range of architectural and cytologic variability to that exhibited by cutaneous melanomas. One interesting exception is that some mucosal melanomas display a small cell phenotype that on biopsy can easily be mistaken for a nonkeratinizing squamous cell carcinoma (Fig. 72-5A and B).

Sarcomas

Angiosarcoma

Angiosarcomas may occur in the head and neck and most commonly manifest on the face and scalp, usually in the sixth or seventh decade

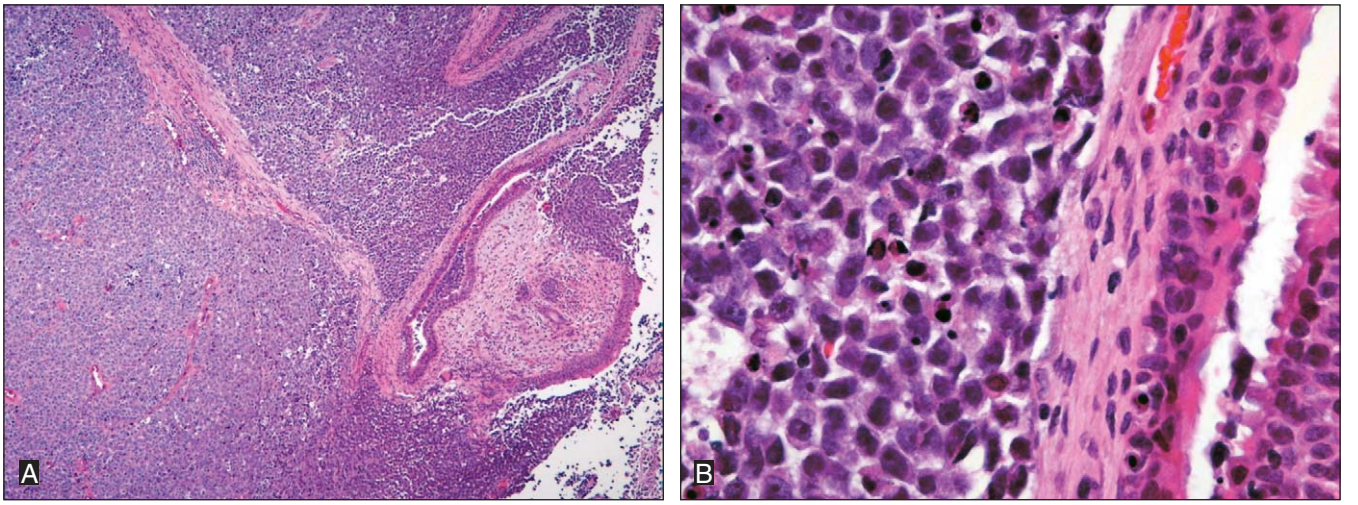

Figure 72-5 • **A,** Sinus with primary mucosal melanoma showing infiltrative destructive growth by large epithelioid cells beneath respiratory mucosa. **B,** Sinus with primary mucosal melanoma showing infiltrative destructive growth by large epithelioid cells beneath respiratory mucosa. Cells exhibit a blastic appearance, with prominent single-cell necrosis and high mitotic rate.

of life. Angiosarcomas of the oral or nasal cavity are exceedingly rare. Morphologically, these tumors show anastomosing vascular channels, with varying degrees of nuclear atypia in the malignant endothelial cells. Those with better differentiation are associated with a better prognosis.

Chondrosarcoma

Chondrosarcomas may arise in any bone within the head and neck as well as within the larynx. They are typically seen in the sixth or later decade of life. As with chondrosarcomas occurring in other areas, malignancy is defined by infiltrative, permeative growth as nuclear crowing and atypia within cartilage lacunae.

Osteosarcoma

Osteosarcomas may occur in any bone of the head and neck. This lesion often is seen in younger patients, with a peak in the third decade of life. In addition, osteosarcomas have been seen after radiation therapy or in association with Paget's disease.[113,114] Morphologically, these tumors are characterized by infiltrative and destructive growth of surrounding bone and soft tissue.

Chordoma

Chordomas are low-grade tumors derived from notochord remnants. The two most common locations for the tumors are at the base of the skull (spheno-occiput) and sacrum. In the head and neck area, these tumors may involve the clivus, sphenoid, upper nasopharynx, occipital bone, maxilla, ethmoid, pterygoids, or cervical vertebrae.[115] These tumors grow as lobulated, infiltrative lesions that destroy adjacent normal structure. Microscopically, a myxoid matrix predominates with epithelioid cells growing singly or in small nests. These epithelioid cells are granular or vacuolated (physalipherous cells) and show staining for both keratin and S100 on immunohistochemistry studies, helping to differentiate them from low-grade chondrosarcomas, which are keratin negative.

TUMOR BIOLOGY

In the simplest terms, cancer formation can be regarded as the escape of cells from the normal regulatory mechanisms of the cell cycle. Consequently, the cells proliferate without regard to their surroundings. Their progeny often become less differentiated, and they become able to invade surrounding tissues and spread to distant sites.

The genetic alterations associated with these changes are myriad. With regard to head and neck squamous cell carcinoma, much of the seminal work has elucidated the potential role of the tumor suppressor gene in the pathogenesis of cancer. These genes are expressed at appropriate levels in normal tissue and have a negative effect on cellular growth. If one or more of these genes is inactivated through mutation, chromosomal deletion, or DNA methylation, however, the loss of negative regulatory control may lead to unregulated growth and subsequently to cancer. The tumor suppressor genes encoding p53, p16, and $p19^{ARF}$ are the major tumor suppressor genes involved in HNSCC pathogenesis. The p53 gene lies on the short arm of chromosome 17 (17p), and p53 is a negative regulator of the cell cycle by means of the cyclin/cyclin-dependent kinase complex. The p53 gene frequently is mutated in HNSCC, with 40% to 70% of tumors harboring mutations.[116,117] The proteins p16 and $p19^{ARF}$ also are cell cycle inhibitors, and these genes also frequently are inactivated in HNSCC.[118] The mechanism of inactivation, however, includes not only gene mutation but also chromosomal deletion and promoter methylation.[119] Approximately 70% to 80% of cancers have allelic loss of the chromosomal region 9p, where p16 resides.[120,121] The loss of these cell cycle inhibitors is thought to contribute to progression from normal mucosa to preneoplastic lesions to invasive cancer.[122]

Certain genes are overexpressed in HNSCC as well. These oncogenes include those encoding cyclin D1, C-myc, and epidermal growth factor (EGF), and their increased expression also can contribute to the pathogenesis of HNSCC.[123–125] More recently, attention has turned to cell adhesion receptors such as integrins and E-cadherin with regard to tumor invasion and recurrence.[126,127] E-cadherin has been shown to be highly underexpressed in oral tongue carcinomas, and weak expression of the molecule was significantly correlated with a higher recurrence rate and worse 5-year survival.[127] Integrin expression is closely tied to the invasiveness of HNSCC cell lines.[126]

Theoretically, many of these genetic alterations should result in the expression of altered proteins that the host immune system would recognize as foreign. The cells would then be identified and targeted for immune-mediated destruction. It is clear, however, that tumor cells are able to escape from the host immune system through a variety of mechanisms.[128] A significant proportion of tumor cells have decreased expression of human leukocyte antigen (HLA) class I, a molecule necessary for the presentation of foreign peptides to the immune system.[129] Furthermore, T lymphocytes that infiltrate the

tumor are not as competent at killing tumor cells, presumably due to factors within the tumor microenvironment.[128]

New technologies will soon enable researchers to analyze further the genetic and immunological changes that occur in HNSCC. Complementary DNA microarrays allow for large-scale analysis of gene expression. Researchers have already identified hundreds of genes that are either overexpressed or underexpressed in HNSCC.[130,131] Future studies will elucidate the relationship of these genes to the pathogenesis of cancer, and novel tumor markers will be identified against which new chemotherapeutic and immunotherapeutic modalities can be targeted.

CLINICAL PRESENTATION AND PATIENT EVALUATION

Patients with head and neck cancers present with certain symptoms according to the location of the tumor. Some signs and symptoms and patient characteristics are common to many of these patients regardless of the site of tumor origin, however. Patients with head and neck cancer are mostly male and in their sixth decade of life or older. Most have a history of tobacco and alcohol use. They often present with cachexia due to dysphagia, tumor burden, or malnutrition. Rapid weight loss is sometimes reported. Hemoptysis also is frequently found. Pain, either primary or referred to the ipsilateral ear, also is often encountered. Many tumors manifest with cervical metastasis as the first sign of disease, and a thorough examination must be performed to identify the primary site.

More specifically, signs and symptoms associated with oral cavity tumors include bleeding, dysphagia, dysarthria, and halitosis. The patient may complain of ill-fitting dentures that previously fit properly. Oropharyngeal tumors cause similar signs and symptoms. In addition, pain often is experienced at the site within the oropharynx or is referred to the ear. A neck mass is often the presenting sign of an oropharyngeal tumor. Supraglottic tumors can manifest with dyspnea, dysphagia, and voice change. Glottic and subglottic tumors are likely to cause hoarseness and dyspnea. Dysphagia and ear pain often is experienced by patients with hypopharyngeal cancer.

Initial Head and Neck Examination

An initial examination of the head and neck should be performed with the patient sitting upright in a chair. A standard and complete head and neck examination should then be conducted. All 12 cranial nerves are assessed. Otoscopy and anterior rhinoscopy also are indicated. Examination of the oral cavity is preferably done using a head light to allow bimanual examination of the lips, buccal mucosa, gingiva, floor of the mouth, and oral tongue. Palpation of the tongue and the base of the tongue often is forgotten but is crucial for a thorough evaluation. The tongue base can be further examined using a mirror and a flexible fiberoptic laryngoscope. The larynx also is visualized using these instruments. While viewing the larynx fiberoptically, the physician should ask the patient to perform several maneuvers: vocalization to allow assessment of vocal cord motion; tongue protrusion to aid in viewing the vallecula; and filling the cheeks with air to help visualize the pyriform sinuses. After the subglottis is evaluated, the laryngoscope can be removed and the examination completed with palpation of the neck for masses. The size, mobility, and consistency of any mass should be carefully noted.

Staging Investigations

Radiography is a necessary component of the evaluation. It is now standard practice to order a CT scan of the head and neck for any patient with suspected cancer. Not only does this examination help to evaluate the size and location of the primary, but also any possible metastasis. An MRI scan can provide useful additional information in certain cases, such as in previously treated patients or in those lesions in which skull base involvement must be ruled out. Routine preoperative laboratory values should be obtained, as well as appropriate medical consultations as indicated.

If accessible in the clinic, biopsy of any suspicious mucosal lesion should be undertaken after local administration of anesthetic. Generally, oral cavity lesions and selected oropharyngeal lesions are easily biopsied in the clinic. For most lesions of the tongue base, larynx, and hypopharynx, direct laryngoscopy with biopsy under anesthesia is required. During this procedure, flexible esophagoscopy should be undertaken to rule out tumor spread into the cervical esophagus. In addition, a tracheostomy or gastrostomy tube should be placed at this time if indicated. If no primary tumor is identified, but a firm node 1 cm or greater is present, the node should be sampled by means of fine-needle aspiration (FNA). An open biopsy of a neck node in an adult suspected of head and neck cancer should be undertaken only after FNA diagnosis is inconclusive and a primary site cannot be identified.

Based on this extensive clinical and radiologic evaluation, the cancer is assigned a stage. Generally, T1, T2, and T3 represent increasing tumor size, whereas T4 is defined by invasion of a surrounding structure (skin, nerve, vessel, cartilage). The node, or N, stage is identical for all head and neck cancer sites and is defined in Table 72-1. The absence or presence of distant metastases is defined as M0 or M1. The T, N, and M stages are combined into overall groupings that are presented in Table 72-1. Because the natural history of head and neck cancer varies somewhat according to specific anatomic location of the primary disease and since stages III and IV include a large number of different T and N stages, it is customary to refer to specific head and neck cancers by their individual T, N, and M stage and the primary site.

Follow-up Program

After completion of initial treatment, patients are seen every 4 to 6 weeks for 2 years in the office; during this period a complete set of

laboratory data and chest radiographs are obtained every 6 months to look for metastatic disease or second malignancies. It is important to monitor levels of thyroid-stimulating hormone, because many patients who have received therapeutic irradiation to the neck will become hypothyroid and will require thyroid hormone supplementation. A baseline post-treatment CT scan (or MRI after skull base procedures) is obtained approximately 2 months after the end of postoperative radiation therapy as a reference point for comparison in the event that disease recurs.

During the third year, the patient is seen every 3 months, and every 4 months during the fourth year. After 5 years, the patient should be examined once per year.

PROGNOSIS

Prognostic and treatment-predictive factors play a central role in the treatment decision-making process, because the current therapeutic approach uses a risk stratification paradigm. This approach recognizes that currently accepted treatment modalities are associated with significant risk and a spectrum of toxicities. Identification of these factors facilitates this risk assessment and helps to guide decisions on whether to initiate therapy and also may influence what type of therapy to administer. An ideal prognostic factor would provide information about the biologic behavior of a tumor, permitting the prediction of the outcome and response to therapy. The use of such factors has become confusing, however, owing to the spectrum of factors reported, often with conflicting results. This dilemma has led to efforts to systematically classify head and neck prognostic factors based on the level of significance and reliability, including a recent meta-analysis.[132]

This heterogeneity results from several sources, including statistically underpowered studies, absence of statistical modeling for independent prognostic effects, variability in the nature of the therapy applied, the composition of prognostic factors as represented in the study group, and the inherent biologic heterogeneity of cancer. The heterogeneity is compounded further by the heterogeneity associated with the tests and instruments that often are used to measure aspects of the tumor biology. Although it may be said that clinical prognostication often is imprecise, several clinical factors have an established role. In the head and neck, tumor site is a strong prognostic factor for survival, regardless of the treatment modality, and reflects the precision with which it can be identified by the clinician, although exceptions may exist, particularly for large tumors that overlap anatomic subsites.[133–135] Within each subsite, the current American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM > staging criteria have been demonstrated to have prognostic significance and continue to evolve through efforts to stratify further the staging classification based on prognosis.[136] Most problematic are patients who constitute the heterogeneous locally advanced AJCC stage IV group.

The sixth edition of the TNM classification introduces a distinction of the heterogeneous T4 disease group based on the probability of disease control, with T4a disease representing a reasonable probability and T4b disease representing such extensive disease that an adverse outcome is certain. In essence, the watershed between T4a and T4b reflects for most subsites the transition to unresectable disease that has been a recognized prognostic factor. Criteria for T4 subclassification by each anatomic subsite have been developed.[137] Consideration of this subclassification scheme in the context of N and M staging facilitates recognition of three distinct prognostic groups: advanced lower-risk stage IVA (potentially curable); advanced high-risk stage IVB (of dubious curability); and stage IVC with distant metastatic disease (undoubtedly incurable).[137] The critical distinction is the definition of IVB as N3 disease or T4b with any N category (excluding the nasopharynx subsite), for which aggressive local-regional therapy may be undertaken but with a potentially low expectation of success—a philosophical view that has been termed "aggressive palliation." In this subgroup, other patient-based prognostic factors, such as performance status, comorbid conditions, and the patient's ability to tolerate and comply with local-regional aggressive therapy, may have significant effect on the anticipated outcome and hence treatment decisions. Although the committee acknowledges that comparative outcome data do not exist for these new stage IV groupings, these groupings are likely to be surrogate groupings for tumor volume and resectability that have established prognostic effects and form the basis for the current therapeutic paradigm.

Within each subsite, various tumor features, noteworthy for their prognostic impact and not necessarily reflected in the new TNM staging criteria, warrant additional comments. In the oral cavity, tumor thickness or depth of invasion has been well recognized to influence the risk of nodal metastases[138,139] and to reflect biologic aggressive disease with an adverse survival.[138,139] Po and colleagues recently demonstrated that tumor thickness in oral tongue carcinomas was the only significant factor that had significant predictive value for subclinical nodal metastasis, local recurrence, and survival in multivariate analysis. With the use of 3-mm and 9-mm division, tumor of up to 3 in mm thickness is associated with an 8% risk of subclinical nodal metastasis, zero local recurrence, and 100% 5-year actuarial disease-free survival; tumor thickness of more than 3 mm and up to 9 mm carried a risk of 44% subclinical nodal metastasis, 7% local recurrence, and 76% 5-year actuarial disease-free survival; tumor of more than 9 mm carried a 53% risk of subclinical nodal metastasis, 24% local recurrence, and 66% 5-year actuarial disease-free survival.[139] With disease of the nasopharynx, the staging classification reflects the prognostic importance of soft tissue extension beyond the nasopharynx, particularly the presence and the degree of extension into the parapharyngeal space.[140] In this regard, MRI is superior to CT imaging for such prognostication. For well-differentiated thyroid carcinomas, young age (younger than 45 years) is an important favorable prognostic factor such that patients with other favorable prognostic factors including small tumors (1 to 1.5 cm) that are well encapsulated and confined to the thyroid, may be monitored by observation, with no adjuvant therapy recommended.[141] Anaplastic thyroid carcinomas carry an adverse prognosis irrespective of the local disease extension at the time of presentation.

For patients with HNSCC treated with radiotherapy, CT-based tumor volume assessment[142–146] and the presence of anemia[144,147–151] appear to be prognostic for local-regional control and survival. Of interest, in a series of 258 patients with T1 to T4 glottic carcinoma treated with surgery only, anemia and positive surgical margins were independently associated with an adverse 5-year local-regional control rate.[151] Protracted overall treatment duration for a course of radiotherapy is well established as an adverse prognostic factor for local-regional control.[152–156] Limited data suggest that this adverse prognostic factor also may be important in patients receiving concurrent chemoradiotherapy, when the risk of toxicity and treatment interruptions is increased.[157] For early-stage glottic larynx carcinomas treated with radiotherapy, a dose per fraction less than 2 Gy appears to be associated with poor local control rates in various univariate analyses, but this has not been conclusively demonstrated to be independent of other time-dose parameters.[156,158,159] Nevertheless, current consensus recommendations are for dose per fraction of 2 to 2.25 Gy.[160] Tumor response to radiotherapy has been demonstrated in a large prospective series of 228 patients with HNSCC treated uniformly with conventionally fractionated radiotherapy to be associated with local control. Multivariate analysis showed that the probability of local relapse was significantly and independently increased for minor regression at 5 weeks (less than 75%) (relative risk, 2.3), for nonlaryngeal tumors (relative risk, 2.4) and for T3-T4 disease (relative risk, 2.4).[134]

In patients requiring postoperative radiotherapy who demonstrate high-risk adverse prognostic features, the time interval between

surgery and radiotherapy and the overall treatment time from the time of surgery to completion of the radiotherapy appear to be important.[161] Investigators from the M.D. Anderson Cancer Center have previously demonstrated that the most adverse prognostic postoperative risk factor is the presence of extracapsular extension.[162] These investigators have proposed and prospectively validated a risk stratification criterion that identifies patients as high-risk if extracapsular extension is present or two or more pathologic risk factors are present. These include oral cavity primary, mucosal margins close or positive, nerve invasion, more than one positive lymph node, more than one positive nodal group, the largest node greater than 3 cm, and treatment delay longer than 6 weeks.[161,162] Cooper and colleagues noted similar risk factors in a review of the Radiation Therapy Oncology Group (RTOG) database.[163] In the high-risk group of patients, progressively protracted treatment time was associated with worsening local-regional control rates ($P = 0.005$) and overall survival ($P = 0.027$), with the most favorable outcome noted when the overall treatment time was less than 11 weeks.[161] Other retrospective studies have reported similar observations.[164,165]

The heterogeneity and imprecision of clinical prognostic factors have encouraged recent efforts to evaluate the potential prognostic significance of various molecular factors[166] and various quantitative measures describing functional tumor imaging such as magnetic resonance spectroscopy.[167,168] Grandis and colleagues reported a strong independent prognostic value for the epidermal growth factor receptor (EGFR) and its ligand, transforming growth factor-α (TGF-α), in a mature but heterogeneous group of 91 patients with a mixture of stages and sites treated with surgery and adjuvant therapy. Of the 91 patients, 56 (62%) received postoperative external beam radiation therapy (EBRT) and 16 (18%) received adjuvant chemotherapy. Protein expression was quantitated by computer immunohistochemistry image analysis on paraffin-embedded specimens. Increasing levels of overexpression of either EGFR or TGF-α were associated with an increasing adverse disease-free and cause-specific survival. Other investigators using various quantitative assays of this surface receptor also have demonstrated an independent prognostic effect of EGFR overexpression.[169–172] These series are noteworthy for the strong prognostic significance observed in multivariate analysis, possibly owing to the reduced test heterogeneity with such quantitative assays and the biologic significance of EGFR overexpression.

PRIMARY TREATMENT AND TREATMENT COMPLICATIONS

General Principles

Effective management of head and neck cancers requires comprehensive consideration of several often-competing treatment goals. This routinely requires the efficient integration of various treatment modalities and supportive services for appropriate patient care. Accordingly, representation from disciplines including head and neck surgery, reconstructive surgery, radiation oncology, medical oncology, pathology, neuroradiology, dentistry, oral and maxillofacial surgery, nutrition, nursing, rehabilitation medicine, social services, and psycho-oncology is routinely required.

Before the start of any therapy, it is important not only to evaluate issues of histologic diagnosis and the anatomic extent of disease but also to review issues that may have an impact on treatment compliance. This assessment should include a review of the level of social support a patient has, with appropriate referrals to support services as indicated. Similarly, effective attention to nutritional support and pain management can significantly improve patient compliance to any subsequent therapeutic plan. Depending on the treatment modalities that are required, pretreatment evaluation by oral and maxillofacial services may be indicated. If radiotherapy is indicated, prophylactic enteral tube placement for nutritional support may be appropriate, especially if concurrent chemoradiotherapy will be given. Whenever possible, review of a patient's case within the context of a multidisciplinary tumor conference is strongly advocated.

On establishment of a histologic diagnosis of cancer in the head and neck, subsequent treatment decisions follow from a hierarchy of considerations. Because treatment for head and neck cancer is associated with significant risk and spectrum of toxicities, it becomes important to identify patients with a poor prognosis, for whom treatment may be appropriately tailored. Determining a poor prognosis can be complex and imprecise, influenced not only by the anticipated clinical outcome but also by various patient factors including treatment tolerance and toxicity. In large part, the imprecision of prognostication results from the clinical heterogeneity of established prognostic and treatment predictive factors, as already discussed. When a poor prognosis is uncertain, it may be appropriate to adopt a curative intent, but the potentially low expectations of treatment success should be discussed with the patient.

In tailoring treatment to the prognosis, it is the hope that patients with a poor prognosis will only be subjected to treatment toxicities that are appropriate for the goals of any palliative treatment. Hence, palliative (or curative) intent should be clearly distinguished from palliative (or curative) treatment goals. Unfortunately, palliative treatment goals for advanced head and neck carcinomas (HNSCCs) often require achieving some degree of local-regional disease control but with constraints to minimize toxicity. Although various palliative radiotherapy schedules have been reported, in general, it may be more appropriate to consider the role of systemic chemotherapy to minimize the adverse quality of life that results from radiotherapy-induced xerostomia and taste alteration. In appropriate circumstances, surgical intervention including the use of high-dose rate brachytherapy implants may achieve treatment goals with the most favorable therapeutic ratio. When and how best to achieve such palliative treatment goals become issues of judgment that follow from engaging a thoughtful dialogue between various members of the multidisciplinary team and the patient and family members.

In treating patients thought to be appropriate candidates for potentially curative therapy, a higher threshold for unacceptable toxicity on the part of the treating physician and patient is implicitly accepted. As a result, an evidence-based approach in deciding between various treatment options is preferred to justify the increased tolerance of toxicity. This has favored a systematic categorization of the quality of clinical reports reflecting the study methodology employed and the confidence that the results reported are free of biases and random variability. In general, randomized trials with sufficient statistical power provide the greatest unbiased level of evidence and confidence that the results are reproducible. Not uncommonly, treatment effects often are smaller than anticipated, leading to variable results among similar randomized trials, which limits consensus treatment recommendations. For head and neck carcinomas, competing comorbid conditions and the risk of second malignancies contribute to underpowered trials in demonstrating improvements in patient survival. As a result, prospective and retrospective comparative analyses of different treatment options often are relied on to provide significant treatment guidance. These studies are, however, subject to potential biases from patient selection and the generalizability of the reported results may be limited by the nature of the patients selected. Attempts often are made to match groups by stage to ensure their comparability, leaving only the treatment to vary. This strategy may be limited, however, by the effects of stage migration and should be carefully reviewed for this potential influence. For HNSCC, this is particularly important in light of the significance of anatomic tumor extent on treatment prognosis[137] and the recent evolution of various sensitive imaging modalities. Finally, the usefulness of data from institutional series, case series, and reports also may be limited by the size of the sample study population and the absence of comparative analysis of different therapeutic strategies. Such data often

provide insight into the management of rare histologic diagnoses, however. When insufficient evidence-based literature exists, consensus treatment principles have evolved to further guide treatment recommendations. Alternative systematic quantitative tools such as decision tree analysis techniques and cost-effectiveness analysis have not been well studied and remain limited in their impact on the management of head and neck cancers.

For HNSCC, therapeutic principles traditionally have considered competing treatment goals of local-regional control and the level of risk and spectrum of toxicity in defining the concept of a therapeutic ratio. Both quantitative and qualitative issues in toxicity must be considered, because a severe but low-probability toxicity may be important in defining what is an acceptable therapeutic ratio for the patient. This concept of a therapeutic ratio is important, because a dose-response relationship exists for both disease control and toxicity in several treatment modalities, including chemotherapy and radiotherapy, and may even be extended conceptually to surgery. Although treatment toxicity is an important consideration in evaluating treatment options, the emphasis remains on local-regional control as a principal measure of treatment success. This focus underscores the natural history of the disease and the cosmetic and functional impact of cancer in this body site. Accordingly, definitive therapeutic decisions often involve evaluation of surgery- or radiotherapy-based strategies. Although rigorous randomized comparisons of these two treatment approaches are extremely limited, several generalizations may be noted.

When local-regional control rates appear comparable between competing treatment modalities, such as surgery and radiotherapy, the use of a single modality associated with the most favorable therapeutic ratio is preferred. This principle is most applicable to the use of surgery or radiotherapy for early-stage disease (typically T1-2N0-1). For early-stage disease, local-regional control rates reported from surgical and from radiotherapy institutional series appear to be comparable, with the possible notable exception of the oral tongue subsite, for which anecdotal experience suggests that local control rates with EBRT are inferior. (Rather, the incorporation of a brachytherapy implant appears to provide comparable results to surgery.) Surgery is often preferred for disease involving sites that are readily accessible, such as the oral cavity site, to minimize the risk of complications. By contrast, early-stage NPC typically is treated with radiotherapy owing to the risks associated with surgery in this location.

Radiotherapy has traditionally been considered to be more attractive for early-stage tumors involving sites at which surgical resection may compromise organ function, such as involvement of the oropharynx, larynx, and hypopharynx. Again, this consideration is appropriate when local control rates appear comparable. Evolving experience and sophistication with various organ-preserving surgical techniques, however, offer the potential for good function preservation with no apparent compromise in oncologic results. Examples include various innovative larynx preservation techniques, including the supracricoid laryngectomy.[173,174] These techniques are influenced by patient and tumor selection, with some techniques being very operator-dependent and thus not necessarily generalizable. When available, these techniques provide a potential single-treatment modality for patients in the early stage of disease that involves critical sites of organ function, such as the larynx, without the issues of radiotherapy-induced late complications. It also allows radiotherapy to be reserved for the management of relapses and second head and neck malignancies. Currently, the relative efficacy with regard to oncologic results and organ function between these surgical options and radiotherapy remains unexplored.

This single-modality principle for treatment of early-stage disease attempts to minimize toxicity and emphasizes the importance of patient and tumor selection. When postoperative radiotherapy appears likely, definitive radiotherapy may be more appropriate, particularly for small volume disease, as it is unclear that combined-modality therapy is superior to radiotherapy alone. This consideration is particularly relevant when initial definitive en bloc resection may, in combination with postoperative radiotherapy, further complicate treatment toxicity and organ function. Not uncommonly, these issues arise with more extensive early-stage HNSCC or in cases in which the anatomic location limits achieving adequate surgical margins. For these and more advanced lesions, the role of debulking surgery also has been proposed.[175] This has been favored as a strategy for efficient reduction of the number of tumor clonogens without the surgical morbidity of more extensive tissue resection. Altough attractive, the value of this approach remains controversial, because it has not been subjected to critical scientific scrutiny and remains ill defined in the literature.

For more advanced primary lesions (typically defined as T3 and T4 disease), increased treatment-related toxicities generally have been accepted owing to inferior local control rates attained. Accordingly, a combined-modality approach typically has been employed. Traditionally, this approach has included surgery and radiotherapy with either preoperative or postoperative conventionally fractionated radiotherapy. A postoperative protocol typically has been favored because the radiotherapy can be delayed until more accurate delineation of the tumor extent of disease and histopathologic stratification of patients requiring postoperative radiotherapy (PORT).[176] When evaluated in a randomized trial in 277 patients with supraglottic larynx and hypopharynx carcinomas (RTOG 73–03), PORT demonstrated superior mature local-regional control rates although the results were confounded by use of a higher dose delivered in the postoperative setting.[177] Recent randomized trials have permitted optimization of not only selection of patients requiring PORT[161] but the dose required,[162] as well as the identification of prognostic factors adversely influencing the outcome particularly in high-risk patients.[161] Of greater significance, it is now clear that the time from surgery to the start of PORT and the overall treatment time of PORT are important determinants of local-regional control in patients with high-risk features. Because the issue of patients with more extensive disease undergoing higher risk surgical resection may confound these observations, the magnitude of benefit from manipulating these time variables remains to be determined. Nevertheless, it remains prudent to regard these observations, emphasizing the importance for effective coordinated management, which is best achieved in the context of a multidisciplinary team of health care providers. Strategies to improve the results of surgery and PORT have included adjuvant chemotherapy, concurrent postoperative chemoradiotherapy, and altered fractionated radiotherapy schedules such as various accelerated radiotherapy schedules. These strategies remain subjects of ongoing study to further define their role and efficacy in patients with resectable locally advanced HNSCC.

For unresectable advanced disease, conventionally fractionated radiotherapy alone has been traditionally recommended. Results of suboptimal local-regional disease control in the absence of surgical options, however, have favored an acceptance of intensifying treatment with increased treatment toxicities. Of note, however, the increased toxicity associated with this strategy warrants careful patient selection, because the therapeutic ratio is clearly reduced. This has included the use of concurrent chemotherapy with daily-fractionated radiotherapy,[178] altered fractionated radiotherapy alone,[179] and recently developed combinations of concurrent chemotherapy with altered fractionated radiotherapy schedules.[180] In general, modest success has been realized with both daily-fractionated chemoradiotherapy and altered fractionated radiotherapy, and they are regarded as acceptable therapeutic options. For concurrent chemoradiotherapy, determining the optimal agents and schedule remains largely undefined and is the subject of ongoing evaluation. Although a recent updated patient-based meta-analysis has demonstrated a modest survival benefit with concurrent chemoradiotherapy,[181] the generalizability of these results to current popular taxane-based chemoradiotherapy regimens is unclear.[157,182] Randomized data currently also support the use of either a dose-escalated hyperfractionated schedule

or an accelerated schedule reducing the overall treatment time by 1 week with twice daily treatments in the final 2.4 weeks for this group of patients.[179] The relative efficacy and indications for these two treatment strategies also remain largely undefined. Despite the improvements in local-regional control rates observed with the various altered fractionated schedules, the predominant relapse pattern continued to be local-regional (approaching 50%), with distant relapse rates of less than 20%, leading current opinion to favor the use of concurrent chemoradiotherapy for large volume disease manifesting at the primary site or in the neck.[183] The integration of chemotherapy has been particularly favored for bulky neck disease, because the risk of distant relapses is increased with some chemoradiotherapy regimens, demonstrating an impact on this risk.[135]

In recent years, treatment decisions have been progressively influenced by obligations to achieve functional organ preservation for advanced but resectable HNSCC. This treatment goal has been buoyed by the fact that the superiority of altered fractionated radiotherapy schedules[179] and concurrent chemoradiotherapy[178] demonstrated in randomized trials has, in general, been observed in study populations that have been unselected based on the resectability of the disease.[184] This treatment goal has been particularly paramount for disease in the larynx[185,186] and oropharynx subsites[187] and continues to evolve; the optimal definitions, methodology, and instruments for studying functional organ preservation remain to be defined. Because surgical resection for more advanced disease often results in greater normal tissue extirpation and loss of function, radiotherapy-based management strategies typically have been favored. It is noteworthy, however, that the oncologic efficacy of surgical resection, often followed by PORT, relative to these radiotherapy-based strategies has not been rigorously evaluated. In fact, studies have demonstrated that patients will prioritize length of life if compromises in speech or swallowing function are required.[188] Accordingly, surgical resection remains an appropriate treatment consideration, particularly when organ function already has been compromised by tumor. Invasion of bone or cartilaginous structures by advanced HNSCC has been also considered an indication for surgery on the basis of historic experience of poor responsiveness to radiation therapy, although this is debated.[189] Recent results with treatment intensive intra-arterial chemoradiotherapy strategies have challenged this indication.[190]

In general, two therapeutic paradigms involving radiotherapy have been adopted for organ preservation. A nonselective strategy may be adopted whereby the tumor response serves as an in vivo test for radiosensitivity reserving surgery for salvage.[191] This strategy poses increased risks of difficulties and complications with salvage surgery but increases the number of patients achieving organ preservation. It also is limited by the recognition that not all patients who fail at the primary site after radiotherapy are amenable to surgical salvage. Alternatively, selecting tumors and patients who may have a more favorable probability of local control with radiotherapy minimizes the proportion of patients subjected to increased surgical complication rates, but may subject patients with radiosensitive lesions to unnecessary surgery. A hybrid strategy that continues to have proponents is based on treatment response to either chemotherapy[187,192,193] or an intermediate radiotherapy dose, typically between 50 and 55 Gy.[134,135] Responses to chemotherapy have been argued to predict for biologically favorable and responsive disease to subsequent radiotherapy. It also has been argued that significant radiotherapy responses possess sufficient predictive power, allowing for the selection of patients who are destined to require salvage surgery, in turn limiting the subsequent toxicity from cumulative therapy with higher radiotherapy doses. A large prospective radiotherapy series has demonstrated this to have independent prognostic value for local control.[134]

Early experiences of organ preservation with conventionally fractionated radiotherapy were limited to the larynx, and the results were disappointing.[143,194–197] Salvage surgery was possible in 50% to 80% of patients with early-stage disease treated with radiotherapy.[194–196] Inferior local-regional control rates were reported for bulky disease such that a majority of patients required salvage surgery, with a success rate of 50%, and also were associated with increased surgical complication rates.[191,197] This gave rise to the use of various neoadjuvant chemoradiotherapy regimens in attempts to achieve organ preservation. The value of the neoadjuvant chemotherapy in contributing to local disease control was questioned, however. In a recently completed randomized trial, it was subsequently demonstrated to have minimal value and the trial indicated that intensive local-regional therapy was a more appropriate strategy.[198] Recent studies have now demonstrated that the use of an altered fractionation schedule (hyperfractionated and accelerated schedules)[179] or the use of concurrent chemotherapy[135,198] in combination with daily-fractionated radiotherapy offers superior local-regional control rates. This gain in local-regional control rate, however, may still come at the increased risk of surgical complications with salvage surgery. The risk of pharyngocutaneous fistula increased from 15% to 30% in patients randomized to receive radiotherapy alone or concurrent chemoradiotherapy with cisplatin for larynx preservation, respectively.[185] It remains to be demonstrated whether this risk is observed with other treatment-intensive regimens (and for other head and neck disease sites) that aim to improve on local-regional disease control.

Accordingly, patients deciding between initial surgical therapy and organ preservation therapy must balance the issues of immediate organ loss with lower complication rates and a reduced probability of delayed organ extirpation but at an increased risk of surgical complications. To guide these decisions, attention has focused on the probability of organ preservation with radiotherapy-based strategies and the degree of function that will be achieved. To date, radiotherapy predictive factors remain limited to considerations of clinical tumor features such as tumor volume.[142,143,146] Although predictive factors of organ function remain in evolution, it is clear that when nonexisting pretreatment function is observed, successful radiotherapy is unlikely to restore function.

In the evolution of organ preservation as a curative treatment goal, several additional concerns have been raised. Initial concerns focused on the potential risk of an adverse outcome due to the potential risk of ongoing tumor metastasis. Early randomized trials comparing surgery and PORT with neoadjuvant chemoradiotherapy have demonstrated that organ preservation can be achieved without immediate surgical extirpation and with no compromise in overall survival.[192,193] The second trial has centered on treatment toxicity, especially with recent evidence favoring the concurrent integration of chemoradiotherapy for organ preservation.[185,186,198]

With concurrent chemoradiotherapy, increased swallowing dysfunction and secondary risks of aspiration, events contrary to the goal of functional organ preservation have been observed.[187,199] The mechanisms contributing to these events remain to be fully understood but in general may relate to the severity and location of the treatment-induced mucosal edema with subsequent fibrosis and damage to peripheral nerves, all compounded by significant radiotherapy-induced xerostomia. Despite these concerns, preliminary data suggest that patient quality of life may still be improved as a consequence of organ preservation.[200]

Traditionally, the management of the primary tumor site dictated the treatment modality for the neck as a strategy to facilitate efficient management of HNSCC. Treatment decision-making for the neck has adopted a similar therapeutic paradigm of risk stratification to optimize the therapeutic ratio, but the decision-making becomes more complex as a result of the primary treatment considerations. Conceptually, the issue of functional organ preservation also may be extended to the neck, because neck dissection may result in cosmetic changes and compromised neck and shoulder function. Similarly, radiotherapy-induced edema and fibrosis may compromise the goal of functional neck preservation and may be exacerbated by a neck dissection.

Typically, single-modality treatment is favored for early-stage neck disease and combined-modality strategies for advanced neck disease. In the clinically negative neck, when surgical resection has been elected for the primary site management, elective neck dissection may be omitted if preoperative evaluation determines a high risk of requiring PORT and the risk of occult nodal metastasis is sufficiently high to warrant elective management. When radiotherapy has been selected for management of the primary site, neck dissection in the clinically negative neck is not indicated. In fact, preradiotherapy neck dissection may alter the lymphatic flow of the neck, necessitating larger volumes of the neck to be irradiated and requiring surgical wounds to be irradiated to higher doses. It also may contribute to delays in the delivery of radiotherapy, which have been reported to contribute to an adverse overall survival when compared with postradiotherapy neck dissection in a retrospective analysis.[201]

In the clinically positive neck with adverse risk features, combined-modality therapy (surgery and radiotherapy) also has been favored owing to the increased recurrence risk and morbidity associated with regional relapses and the limited salvage options. Postoperative radiotherapy after a neck dissection is indicated in accordance with the presence of adverse pathologic nodal risk factors such as extracapsular extension. Again, delays in the start of PORT may be detrimental, particularly when high-risk nodal factors are present.

When conventionally fractionated radiotherapy alone has been employed for locally advanced HNSCC, suboptimal regional control rates coupled with the morbidity and the limited success of subsequent salvage neck dissection have prompted the incorporation and general acceptance of a planned neck dissection. This approach, generally accepted in the presence of residual adenopathy after radiotherapy, also has been selectively applied to patients with adverse risk factors such as large nodal size (typically 3 cm or greater). This risk stratification follows from radiotherapy series demonstrating an inverse relationship between nodal size and control rate.[202,203] In a study of radiotherapy alone for treatment of HNSCC in 1251 patients, Dubray and colleagues noted 3-year neck control rates, by maximum nodal size, of 0.5 cm, 77%; 2 cm, 67%; 4 cm, 60%; 6 cm, 52%; 8 cm, 37%; and 10 cm, 7%. Multivariate analysis revealed that regional relapses independently increased with increased nodal size ($P = 0.0001$), decreasing radiation dose ($P = 0.0001$), T4 primary disease ($P = 0.0001$), node fixation ($P = 0.02$), bilateral neck disease ($P = 0.03$), and geographic miss ($P = 0.0001$).[203]

Controversy continues, however, regarding the benefit of a planned neck dissection in the setting of a complete clinical response in the neck, particularly in large pretreatment lymph nodes, after completion of radiotherapy.[204] Treatment with conventionally fractionated radiotherapy has demonstrated that the prognosis of large neck nodes with a complete response is associated with a prognosis comparable with that of smaller nodal metastases, and that the risk of relapse is low.[202,205] This suggests that perhaps the subgroup of patients with a complete response in the neck may have more radiosensitive disease and may not require a neck dissection. A neck dissection continues to be favored, particularly for advanced neck disease, however, because the likelihood of achieving a complete response with radiotherapy alone is limited. The efficacy of this approach is further supported by several retrospective series demonstrating improved regional control rates,[205–207] with a possible improvement in survival[208] despite the absence of a randomized trial. Attempts to definitively treat advanced neck disease also increase the risk of subsequent wound complications with any subsequent salvage neck dissection,[209] if that is even possible given that salvage options are almost always limited owing to disease encasing critical structures such as the carotid artery.[210,211]

This issue has been further compounded by the use of concurrent chemoradiotherapy strategies that have reported improved local-regional control rates. One trial of concurrent hyperfractionated chemoradiotherapy versus hyperfractionated radiotherapy suggested a lower frequency of residual disease in the dissected neck specimen in favor of concurrent chemoradiotherapy (21% for chemoradiotherapy versus 37.5% for radiotherapy).[212] No neck relapses occurred in either arm in cases for which a planned neck dissection was performed. McHam and colleagues retrospectively reported on 109 patients who received concurrent chemoradiotherapy with or without a neck dissection for indications of residual neck disease or as a planned procedure.[211] Residual neck disease was observed in 33% of the neck specimens (25% and 39% of neck specimens with complete clinical responses or partial clinical responses, respectively). Neck relapses were observed in 5 out of 76 (6.6%) and 4 out of 33 (12%) patients receiving and not receiving a neck dissection, respectively. The only factor significantly correlating with neck relapses was the presence of residual disease (5 out of 25 versus 0 out of 51). These findings suggest that both chemoradiotherapy and neck dissection are contributing to high neck control rates, with clinical evaluation of the neck not possessing sufficient predictive power to select for a subgroup of patients for whom a planned neck dissection may be held. The role of PET imaging, which carries a risk of false-negative results, remains to be defined.[213,214] Although there is no appreciable increased risk of surgical complications with the addition of concurrent chemotherapy,[215–217] increased neck and mucosal edema, particularly with bilateral neck dissections, may contribute significantly to treatment morbidity.

Management of patients with HNSCC is further complicated by the risk for development of second primary carcinomas and relapses within an aerodigestive tract that may have been extensively exposed to prior treatment. This challenging scenario further emphasizes the single-modality treatment principle when appropriate and favors surgery alone when possible. An irradiated aerodigestive tract not only limits re-irradiation but also may preclude an effective surgical salvage, because concerns of residual microscopic disease often exist in cases that would otherwise warrant consideration of postoperative radiotherapy. In general, repeat surgery is associated with fewer normal tissue toxicity constraints but greater immediate functional consequences than are seen with re-irradiation. Accordingly, when a second primary or relapse occurs within a previously irradiated field, surgical resection should be the primary treatment option.[218] Experiences with various repeat EBRT strategies, including the integration of chemotherapy, have unfortunately demonstrated limited success, often at the risk of significant toxicities.[218] The exception appears to be NPCs that are more radiosensitive. Even then, significant late complications may arise but may be more accepted in view of the limited surgical options.

Institutional series have demonstrated that higher repeat radiation doses are more likely to be successful; this has favored the incorporation of conformal radiotherapy techniques when possible. Such techniques may include stereotactic radiosurgery or radiotherapy, three-dimensional conformal radiotherapy, IMRT, and brachytherapy techniques. The first option has been used as a preferred strategy with nasopharyngeal cancer in which infiltrative disease extends beyond the limits of an intracavitary brachytherapy implant. The last has been particularly favored when the disease is well defined and for its ability to deliver a biologically effective dose to a limited volume. In fact, limited institutional series have reported on the efficacy of a brachytherapy implant for the base of tongue and tonsil for selected well-defined lesions as an alternative to surgery for lesions that also are suitable for surgical resection. In general, a coordinated brachytherapy implant at the time of complete gross surgical resection of either the second primary relapse or in the dissected neck may facilitate successful re-irradiation. When surgical reconstruction and wound closure incorporate unirradiated tissue, the risk of complications from brachytherapy re-irradiation may be reduced. This approach is limited by the ability to define the extent of microscopic disease in the head and neck when normal anatomic barriers and lymphatic drainage patterns have been altered from prior therapies. It thus becomes important to apply a brachytherapy implant appropriately, because these results are not necessarily generalizable.

Treatment Modality Considerations

Surgery

GENERAL. The decision to treat HNSCC with surgical therapy must be undertaken carefully. To assess whether a patient is a surgical candidate, the input of a multidisciplinary team is invaluable. Of the many issues to be considered, among the most important is the medical condition of the patient. Severe cardiac or pulmonary disease, profound malnutrition, and generalized debilitation are relative contraindications to immediate surgical intervention. Therefore, a detailed assessment by an experienced internist or cardiologist is mandatory when a major resection is planned.

The next important consideration is whether the lesion can be removed safely with adequate margins. The resectability of a tumor is assessed via physical examination and radiographic studies. In general, tumor involvement with certain anatomic landmarks, including the base of skull and the prevertebral fascia, renders the lesion unresectable. This is due to the inability to achieve an adequate normal tissue margin in these areas. In addition to tumor location, massive tumor size also can preclude total extirpation. In such cases, tumor-free margins may be impossible to obtain. In addition, adequate reconstruction may be exceedingly difficult, and other forms of therapy should be considered.

Postoperative function also is a primary concern in considering surgical therapy. The ability to speak clearly and swallow effectively is greatly affected by surgery in the head and neck region. Although complete resection of the malignancy is of paramount importance, reconstruction of the surgical defect must be designed so that the patient has an opportunity to regain as much speech and swallowing function as possible. Site-specific considerations are discussed in the following sections.

The cognitive ability of the patient to participate in postoperative rehabilitation should be reviewed as well. Patients who are neurologically or emotionally unable to participate should be identified early in the decision-making process. They may be better served with different forms of therapy. The social situation of the patient also should be considered. Patients who live alone may require admission to a nursing home or skilled nursing facility to ensure adequate postoperative care.

In general, primary surgical therapy is reserved for patients with tumors of the oral cavity, selected early staged larynx cancer, skin cancer, salivary gland tumors, paranasal sinus tumors, and thyroid neoplasms. Patients with very advanced tumors invading bone, destroying cartilage, or extending into the soft tissues of the neck are considered for primary surgical therapy. When patients have severe organ dysfunction as a consequence of cancer infiltration, surgery also should be considered since functional restoration with nonsurgical therapy is unlikely.

NECK DISSECTION. It is important to understand the different types of neck dissections that can be performed (Fig. 72-6). The radical neck dissection is a procedure wherein the lymph nodes from all five levels of the neck, the sternocleidomastoid muscle, the internal jugular vein, and the spinal accessory nerve are all removed. The specimen is removed en bloc, theoretically so that there is no spillage of tumor and so that there is a complete resection of any metastases. This procedure is indicated only in the setting of massive neck metasases involving most of the levels of the neck as well as the nonlymphatic structures.

A modified radical neck dissection removes all of the lymph nodes in the neck but spares one or more of the nonlymphatic structures. Three types of modified radical neck dissection are in general use:

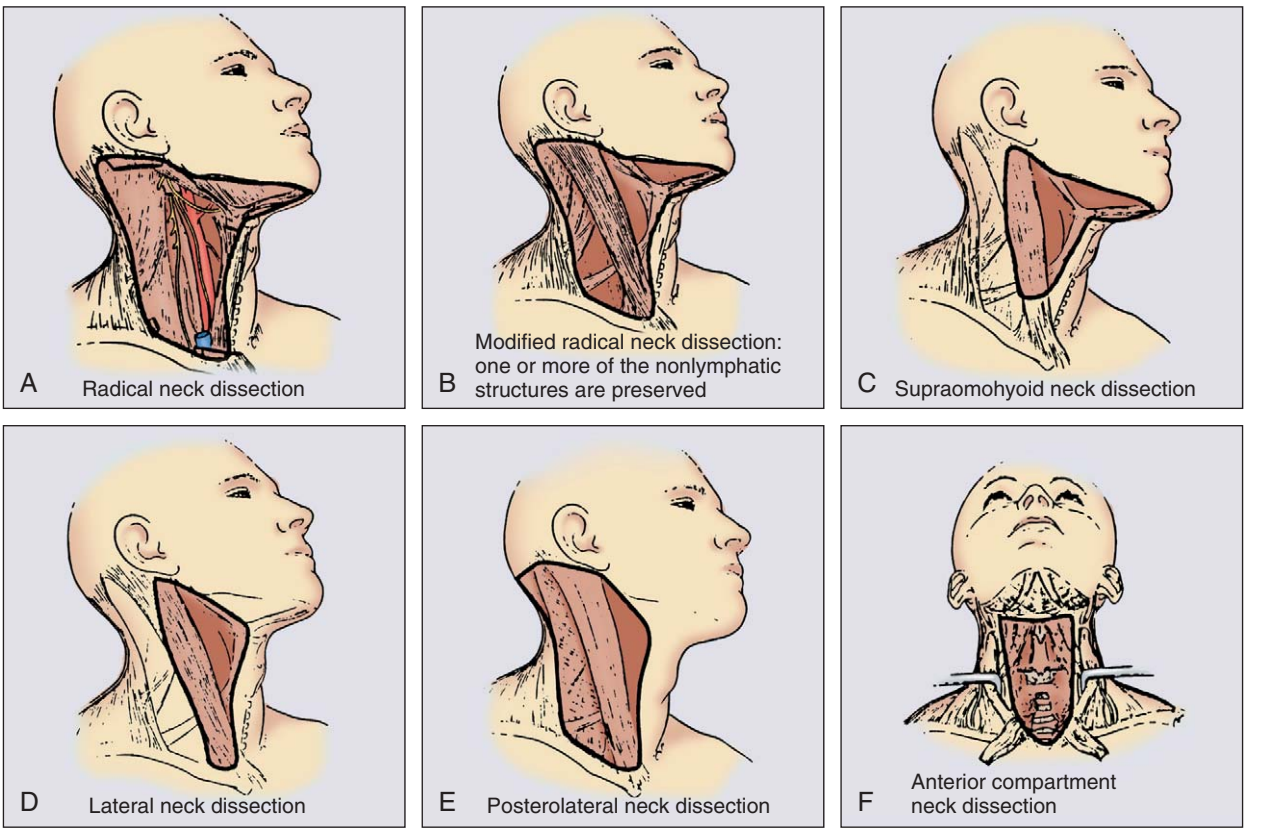

Figure 72-6 • Types of neck dissection. **A,** Radical. **B,** Modified radical: One or more of the nonlymphatic structures are preserved. **C,** Supraomohyoid. **D,** Lateral. **E,** Posterolateral. **F,** Anterior compartment.

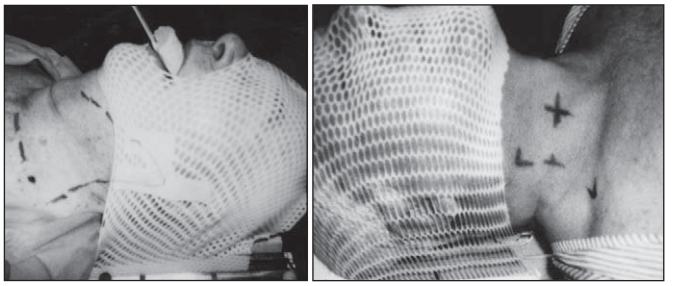
Type I spares the spinal accessory nerve, type II spares the nerve and the internal jugular, and type III spares the nerve, vein, and sternocleidomastoid muscle. A type III dissection also is termed a functional or Bocca neck dissection, named after the Italian surgeon who pioneered the surgery.[219]

Selective neck dissections do not involve the resection of all five levels of lymph nodes but usually involve three or more according to the site of the primary cancer. These neck dissections are usually perfomed in the setting of the N0 neck. There is some controversy regarding the use of a selective neck dissection versus a modified radical or radical neck dissection when known metastases are present, although a consensus is forming that a selective neck dissection is appropriate for patients with N1 and selected N2 disease.[220–222]

Radiotherapy



GENERAL. Historical experiences with EBRT have demonstrated that acute treatment-limiting radiotherapy-induced dermatitis may be limited by fractionation and the use of higher energy radiotherapy. which results in less surface dose. Accordingly, current standard radiotherapy practices have evolved to utilize a fractionated radiotherapy prescription using modern linear acceleration (linac)-model radiotherapy machines that can produce a spectrum of beam energies. With fractionation, issues of patient immobilization and treatment setup reproducibility become important considerations. For the head and neck, several critical normal tissue structures such as the spinal cord and optic chiasm often are in close proximity to the irradiated target. For these reasons, a prerequisite treatment simulation whereby patients are immobilized with various devices including a custom-made face mask and frame, with the setup referenced to a laser light coordinate system in the treatment rooms, is required before treatment can be initiated (Figs. 72-7 and 72-8).

Various immobilization devices exist, achieving different degrees of immobilization. Immobilization addresses the issue of the precision of the treatment delivery as a strategy to optimize the therapeutic ratio. The most examples of this are recently described stereotactic radiotherapy and radiosurgery techniques that involve immobilization of the patient in a rigid head frame system that may be removed daily for fractionated treatments in the former case or bolted to the cranium for a single large dose of radiation in the latter case.

More sophisticated treatment planning may involve obtaining axial images, typically with a dedicated CT scanner, of the immobilized referenced patient to facilitate non-coplanar three-dimensional beam arrangements or the use of IMRT techniques. The former utilizes geometric shielding to effect shaping of the radiotherapy beam; the latter utilizes various approaches that result in modulation of the radiotherapy beam fluence to achieve additional degrees of radiotherapy beam conformality. Increasing the conformality provides an additional strategy to optimize the therapeutic ratio, separate from the issue of radiotherapy beam precision. Radiotherapy beam conformality, however, often is dependent on achieving beam precision for it to be successful. This again places emphasis on achieving sufficient reproducible patient immobilization.

Figure 72-7 • Linear accelerator with reference laser lights shown for reproducible patient setup.

A B

Figure 72-8 • Patient in mask in the treatment position. **A,** Supraglottic carcinoma. **B,** Glottic cancer. (From Liebel S, Phillips TL (eds): Clinical Radiation Oncology, p 503.)

Although these new conformal techniques often are advantageous in the sparing of dose to critical head and neck normal structures, it is important to recognize that this benefit comes at the expense of increasing the volume of normal tissue that is exposed to low doses of the entry and exit radiotherapy beams. This issue is particularly emphasized with the IMRT technique, which often may dose many small segments of a radiotherapy beam or exploit the automated delivery process to deliver many more radiotherapy beams to achieve the degree of conformality sought. Concerns have been raised with regard to the potential long-term consequences of exposing larger volumes of normal tissue to low doses of radiation. In particular, a genotoxic and possibly carcinogenic effect has been speculated. These concerns remain to be fully evaluated, but they emphasize the importance of judiciously and appropriately applying these techniques in counseling young patients, particularly those with an anticipated good prognosis.

The success of these techniques is also dependent on the ability to accurately identify anatomic sites that may harbor subclinical disease. Currently, the basis for this determination is derived from surgical and clinical documentation of disease extension that is often unique to each head and neck subsite. Recent functional imaging techniques, such as PET-based studies, remain promising active areas of investigation. As a result, the transition to the use of axial images for radiation treatment planning places a significant emphasis on the knowledge and experience of the radiation oncologist with regard to the natural history of the disease as it pertains to axial anatomy. In particular, the identification of nodal groups that typically are at risk for harboring subclinical nodal metastases may be more problematic. To aid in this regard, several reports have been published delineating axial anatomic structures that may be used to delineate the various nodal groups (Table 72-2).[223] The incidence of nodal metastases has also been summarized and can significantly aid the radiation oncologist (Table 72-3). Of note, however, when prior treatment to the neck has occurred, altered flow of lymphatics is a significant concern. As with the head and neck surgeon, skill and judgment must be exercised with these precise treatment techniques. The alternative may be particularly detrimental.

a total dose of 70 Gy) has permitted the delivery of higher radiotherapy doses that currently are limited by normal tissue tolerances, such as in the mandible. Conceptually, radiotherapy failures may result from insufficient doses of radiotherapy relative to the number of tumor clonogens or may be due to cellular mechanisms of radioresistance. The former has proved to be more amenable to therapeutic manipulation with studies of various altered fractionation schedules, which may be generalized into two groups: hyperfractionation and accelerated fractionation (Fig. 72-9). Various randomized trials have been conducted and have been recently summarized.[183]

A *hyperfractionation* schedule, or the use of lower doses per treatment fraction, has been hypothesized to reduce the risk of late radiotherapy-induced complications associated with an increase in the total radiotherapy dose. Typically, the dose per fraction is reduced to 1.15 to 1.2 Gy and exploits a differential radiosensitivity between normal late-responding tissues and most cancers, including HNSCC. To ensure that the overall treatment time is not adversely protracted, fractions often are delivered twice a day, with an interfraction period of 6 hours.

Several randomized trials support the concept of hyperfractionation as a strategy to increase the biologically effective dose delivered without a significant increase in the risk of late radiotherapy-induced complications[179,224–226] (Table 72-4). In general, improved local-regional control rates were observed, with improved survival rates, in two trials.[225,226] The largest trial (RTOG 90–03) of radiotherapy fractionation schedules randomized over 1000 patients with locally advanced AJCC stage III and IV HNSCC (greater than 60% stage IV) for all subsites except nasopharynx (stage II disease permitted for base of tongue and hypopharynx) to one of four fractionation schedules including hyperfractionation to a dose of 81.6 Gy in 1.2 Gy per fraction twice daily in 68 fractions over 7 weeks, treated every Monday to Friday.[179] The standard control regimen consisted of 70 Gy in 2 Gy per day in 35 fractions over 7 weeks. With a median follow-up period of 23 months, the 2-year local-regional control rate, 2-year disease-free survival rate, and 2-year overall survival rate were 54.4% (versus standard arm of 46%; $P = 0.045$; Fig. 72-10), 37.6% (versus 31.7%; $P = 0.067$) and 54.5% (versus 46.1%; not significant), respectively. The modest but superior local-regional control rates in the hyperfractionated schedule reflected a 2-year local relapse and 2-year regional relapse rates of 37.8% (versus 43.7% in the control arm) and 26.6% (versus 32.1%), respectively. A planned neck dissection was permitted for residual neck abnormalities and for N2 and N3 neck disease regardless of the response. The 2-year distant relapse rate was 16.8% (versus 17.8%).

Increased acute mucositis was the predominant acute toxicity in patients receiving the hyperfractionated protocol in the RTOG 90-03 trial. No increased risks of late toxicities were observed through the follow-up at the time of report, although this report would be regarded as immature for this endpoint. Of note, however, a prior prospective dose-escalation hyperfractionation study (also using 1.2 Gy per fraction twice daily) conducted by the RTOG (83-13) demonstrated that the risk of late toxicities was significantly increased with an interfraction time of less than 4.5 hours.[227] A large retrospective review also observed the importance of interfraction time.[228] Because this strategy can be logistically demanding for the patient, it becomes important to recognize that the current recommended interfraction time of 6 hours should be maintained.

Alternatively, an *accelerated fractionation* radiotherapy schedule attempts to deliver the prescribed total dose over a shorter treatment duration. This strategy is founded on observations of adverse local-regional control rates with protracted treatment durations (with conventional fractionated schedules) such that higher total doses are required to maintain the same probability of tumor control. These results have been interpreted to be consistent with a model whereby tumor clonogens surviving each daily radiotherapy fraction undergo an accelerated rate of repopulation. As a consequence, a larger tumor burden would be expected with increasing duration of treatment interruptions. It has been rationalized that by reducing the overall treatment time, the opportunity and impact of accelerated tumor repopulation would be minimized. As the severity of acute toxicities is increased, some accelerated schedules studied have attempted to

modify the risk of unacceptable acute toxicities by modifying either the dose per fraction or the total dose as a strategy to achieve an acceptable therapeutic ratio. Accelerated radiotherapy schedules may therefore be categorized into two groups: schedules that do not modify the dose per fraction or the total dose (pure accelerated schedules)[229–232] (Table 72-5) and those that do (hybrid accelerated schedules)[179,233–236] (Table 72-6). Examples of the former are two fractions delivered per day on some or all treatment weekdays and daily treatments for 6 to 7 days per week. A variety of hybrid schedules reflecting a spectrum of dose modifications has been studied. Conceptually, the success of these hybrid schedules is dependent on the dose equivalent of the reduction in the overall treatment time being greater than the biologic equivalent dose reduction in the fractionation schedule.

A review of the 4 randomized trials of pure accelerated fractionation demonstrates that the overall treatment time may be reduced by 1 week without unacceptable acute and late toxicities, achieving modest improvements in local-regional control with no evidence of consistent survival gains.[229–231,237] The most aggressive of these schedules was conducted at the BC Cancer Agency, where the experimental treatment protocol consisted of 66 Gy in 33 fractions with twice-daily fractions of 2 Gy, with an interfraction time of 6 hours, resulting in an overall treatment time of 3.4 weeks (versus 6.6 weeks). Patients receiving the accelerated schedule were more likely to experience RTOG grade 3–4 acute toxicity (seen in 27 of 41 versus 8 of 41; $P = 0.00005$). Increased grade 4 late toxicity (seen in 8 of 41 versus 2 of 41) resulted in premature termination of the study, which precluded definitive conclusions regarding the therapeutic efficacy of this schedule. Of the eight cases of late toxicity, four occurred after salvage surgery, two were soft tissue necroses, and two followed from persistent acute toxicity. Investigators at the Sklodowska-Curie Institute observed similar observations of consequential late effects involving the mucosa in their experimental arm of 70 Gy in 35 fractions with daily fractions of 2 Gy 7 days per week with an overall treatment

Table 72-5 Phase III Trials of Pure Accelerated Fractionation in Patients with Head and Neck Cancer

Study	Tumor Site and Stage	No. of Patients	Dose per Fraction (Gy)	Fractions per Day	Total Dose (Gy)	Overall Treatment Time (weeks)	Tumor Response	Complications
Jackson et al, 1997	Various sites, stage III–IV	82	2.0	2 (at least 6 h apart)	66.0	3.4	CR, 35% vs 29%	Grade 3–4 reactions
			2.0	1	66.0	6.8	No difference in 3-year relapse-free survival	Grade 4 late toxicity ($P = 0.10$)
Skladowski et al, 2000	Various sites, T2–4, N0-1	100	1.8–2.0	1	–70.0	5.0	3-year LC, 82% vs 37% ($P < 0.0001$); 3-year OS, 78% vs 32% ($P < 0.0001$)	Severe mucositis, 62% vs 26%; late complications, 10% vs zero
			1.8–2.0	1	–70.0	7.0

time of 5 weeks. These investigators observed no additional late toxicities when the dose per fraction was reduced to 1.8 Gy per day. Although a significant gain in local-regional control and overall survival was observed, concerns regarding the validity of these observations have been raised owing to the unexpected poor outcome of the control arm, especially when the study did not include patients with N2 or N3 disease.

In contrast, investigators from both the Danish[232] and Polish[238] Cooperative Groups conducted randomized trials accelerating treatment with six treatments per week, either as an additional treatment on the weekend[232,238] or as a single second daily fraction, with no evidence of any increased late toxicities.[232] Acute toxicities were increased, as would be expected. Significant improvements in local-regional control rates were observed, but with no survival gains. Hence, the evidence to date suggests that late toxicities, possibly resulting from severe acute pathologic processes that exceed normal tissue repair capacities, limit the increased biologic effect to only an approximately 1-week reduction in overall treatment time. It may be possible to realize additional therapeutic gains with a modest reduction in the dose per fraction to 1.8 Gy, but this needs to be further validated.

Various hybrid accelerated radiotherapy schedules have been studied as strategies to further achieve increased biologic effects with greater reductions in the overall treatment time (see Table 72-6).[179,233–236] These schedules may be further differentiated depending on whether or not the total dose was reduced (type A versus types B and C). Typically, the total dose has been reduced where more than a 2-week treatment time reduction (from a conventional 7-week course) has been attempted. The most aggressive schedule was the CHART schedule, which reduced the treatment time by 4.5 weeks by delivering 1.5 Gy three times a day with an interfraction time of 6 hours over a total duration of 2 weeks to a total dose of 54 Gy (representing an 18% dose reduction).[233] In a randomized trial of 918 patients with stage II to IV HNSCC involving various sites (a majority had laryngeal carcinomas), no improvement in local-regional control or overall survival was observed. Although this trial did demonstrate increased acute toxicities that occurred earlier, it is noteworthy that fewer late radiotherapy toxicities were observed in the accelerated arm. Poulsen and colleagues performed a randomized trial of 350 patients with stage III or IV HNSCC through the Trans-Tasman Radiation Oncology Group (TROG) studying a schedule with a 3.5-week reduction in the treatment time and a total dose reduction of 10.6 Gy (15%).[234] The experimental arm consisted of twice-daily1.8 Gy (6-hour interfraction time) to a total dose of 59.4 Gy. No improvement in local-regional control rates, disease-free survival, or survival was noted. Again, acute toxicities were more severe and occurred earlier, but no increased late toxicities were observed. Lastly, a French Cooperative Group Study (GORTEC 94–02) reported the preliminary results of a randomized trial of 268 patients with the majority having advanced T4 oropharyngeal carcinomas with the experimental arm receiving a 4-week reduction in treatment time and a modest 10% (7 Gy) reduction in the total dose.[235] The schedule used consisted of 2 Gy twice daily over 3 weeks to 62 Gy versus 70 Gy in 2 Gy per day. With only a median follow-up period of 28 months, a significant improvement in 2-year actuarial local-regional control rate was observed (58% versus 34%; $P < 0.01$) with no difference in overall survival. Increased acute mucosal toxicities were reported with no increased late toxicities noted with the limited follow-up. Hence, the data to date suggest that with only a modest total dose reduction of 10%, reducing the overall treatment time by more than 3 weeks may achieve improvements in local-regional control. With only a modest total dose reduction, however, it remains to be seen if late toxicities are increased.

Two other randomized trials have attempted to accelerate the overall treatment but without reductions in the total dose. The European Organization for Treatment of Cancer (EORTC) Radiotherapy

Table 72-6 Phase III Trials of Hybrid Accelerated Fractionation in Patients with Head and Neck Cancer

Study	Tumor Site and Stage	No. of Patients	Dose per Fraction (Gy)	Fractions per Day	Total Dose (Gy)	Overall Treatment Time (weeks)	Tumor Response	Complications
ACCELERATED FRACTIONATION WITH TOTAL DOSE REDUCTION								
Dische et al, 1997	Various sites, mainly stage II–IV	918	1.5	3 (every 6 h)	54.0	2.0	No difference in LRC, disease-free interval, or ulceration	More acute mucositis, less epidermal telangiectasia, mucosal ulceration, and edema with AF
			2.0	1	66.0	6.5		
Poulsen et al, 2001	Various sites, stage III–IV	350	1.8	2 (at least 6 h apart)	59.4	3.5	5-year LRC, 52% vs 47% ($P = 0.30$); 5-year DFS, 41% vs 35% ($P = 0.32$); 5-year DSS, 46% vs 40% ($P = 0.40$)	More severe acute mucositis ($P = 0.00008$) but lower frequency of grade ≥2 late soft-tissue effects ($P < 0.05$) with AF (except for mucosal late effect)
			2		70.0	7.0		
Bourhis et al, 2000	All sites, 75%; T4, 70%	269	2.0	2	–63.0	3.3	2-year LRC, 68% vs 34% ($P < 0.01$)	Grade 3–4 mucositis, 83% vs 28% ($P < 0.01$); similar late toxic effects
			2.0	1	70.0	7.0	No difference in OS	
ACCELERATED FRACTIONATION WITH SPLIT-COURSE (TYPE B) OR CONCOMITANT BOOST (TYPE C)								
Horiot et al, 1997	Various sites, T2–4 N0-1	500	1.6	3	72.0	5.0	5-year LRC, 59% vs 46% ($P = 0.02$); trend for higher 5-year DFS ($P = 0.08$); no difference in OS ($P = 0.95$)	More severe acute mucositis and higher frequency of severe late morbidity ($P < 0.001$) with AF
			2.0	1	70.0	7.0		
Fu et al, 2000	Various sites, stage III–IV; stage II of tongue base, hypopharynx	1073	1.8*	1–2	72.0	6.0	LRC, higher with CB and HF ($P = 0.06$ and 0.045); DFS, strong trend in favor of CB and HF ($P = 0.054$ and 0.067); no difference in OS	More acute mucositis with all altered fractionations: no difference in late complication rate
			1.2	2	81.6	7.0		
			1.6	2	67.2	6.0		
			2.0	1	70.0	7.0		

AF, accelerated fractionation; CB, conconstant boost; DFS, disease-free survival; DSS, disease-specific survival; HF, hyperfractionation; LRC, locoregional control; OS, overall survival.

From Nguyen LN, Ang KK: Radiotherapy for cancer of the head and neck: altered fractionation regimens. Lancet Oncol 2002;3:693–701.

Cooperative Group randomized 512 patients with T2 to T4 HNSCC of all sites excluding the hypopharynx to conventional arm of 70 Gy in 35 fractions daily over 7 weeks or 72 Gy in 45 fractions over 5 weeks (EORTC 22851).[236] The experimental arm introduced a split in the treatment duration with the first half delivering 28.8 Gy in 18 fractions over 8 days with 1.6 Gy per fraction three times a day. This was followed by a 12- to 14-day treatment interruption, followed by a second course of 43.2 Gy in 27 fractions over 17 days again with 1.6 Gy per fraction three times a day. Although the 5-year local-regional control rate improved by 13% (59% versus 46%; 95% CI 3% to 23%), with a 24% reduction in local failure rate, this treatment regimen was associated with unacceptable toxicities including twice as many grade 3 or 4 acute morbidities, with grade 5 toxicity reported. Significantly more grade 3 fibrosis ($P < 0.001$) and severe neurologic complications, including permanent peripheral neuropathy, occurred in the accelerated arm. In contrast, the RTOG conducted a four-arm randomized trial in 1073 patients with stage III or IV HNSCC (stage II base of tongue and hypopharynx permitted), with one of two accelerated schedules also using a treatment interruption and a 4% total dose reduction (RTOG 90-03).[179] This treatment protocol consisted of 1.6 Gy twice daily (6-hour interfraction time) to a dose of 67.2 Gy in 42 fractions over 6 weeks. No improvement in local-regional control or overall survival was noted, suggesting that the treatment interruption employed also contributed to the absence of treatment benefit that was not sufficiently compensated in the dose intensity of fractionation schedule.

In the RTOG 90-03, a second accelerated schedule consisted of twice-daily fractions in the final 2.4 weeks, with the second fraction delivered with a 6-hour interfraction interval and limited to only the boost volume.[179] A total dose of 72 Gy was delivered, with the morning fraction 1.8 Gy and the afternoon boost fraction 1.6 Gy in the final 2.4 weeks of a 6-week treatment schedule. This limitation in volume was developed as a strategy to minimize the toxicity with the twice-daily fractionation. The timing of the concomitant boost followed from prior work by Ang and colleagues, who demonstrated slightly better local control rates than if the concomitant boost was delivered at the beginning of the radiotherapy schedule.[239] The results of the RTOG 90–03 demonstrated that the local-regional control rate was significantly improved (2-year survival rate of 54.2% versus 46.1%), with a trend to improved disease-free survival (see Fig. 72-10). The modest but superior local-regional control rates with this delayed concomitant boost accelerated schedule reflected a 2-year local relapse rate and 2-year regional relapse rate of 36.9% (versus 43.7% in the control arm) and 33.3% (versus 32.1%), respectively. A planned neck dissection was permitted for residual neck abnormalities and for N2 and N3 neck disease regardless of the response. The 2-year distant relapse rate was 16.6% (versus 17.8%). No improvement in overall survival was observed. Comparable increased

acute toxicities were observed as with the other altered fractionation schedules including the hyperfractionated arm. No significantly increased late toxicities were observed though the incidence of late toxicities was higher in the accelerated schedule. Because the benefits from this fractionation schedule appear to be comparable to the hyperfractionated schedule reported in RTOG 90-03, investigators have concluded that an accelerated schedule with a delayed concomitant boost may be preferred due to the more favorable logistical treatment delivery issues.[183]

Although the use of an altered fractionated radiotherapy schedule offers an improved local-regional control rate of approximately 15%, this comes at the price of increased acute toxicities. Most notable is the increased mucositis, which can occur earlier and be more severe depending on how the various dose and time parameters are manipulated. The results from the Conventional Accelerated Irradiation (CAIR) trial highlight the potential for excessive mucosal toxicities to exceed their normal repair capacity, leading to consequential late effects.[238,240] A similar potential for increased mucosal toxicities with consequential late effects also appears to have emerged with various concurrent chemoradiotherapy schedules including both conventionally fractionated[187,199] and altered fractionated schedules.[241] These results highlight that a limit to local-regional intensive therapy does in fact exist and have led to interest in the development of normal tissue protectants.

TREATMENT TOXICITIES AND NORMAL TISSUE PROTECTANTS. The most developed of these normal tissue protectants is amifostine. This thiol-containing compound and its metabolite, WR-2721, are believed to function as free radical scavengers and appear to have preferential normal tissue uptake, with the highest concentration found in salivary glands and kidneys.[242,243] Amifostine has been shown to reduce cisplatin-induced nephrotoxicity.[244] It has been the subject of tremendous clinical interest, initially for the protection of salivary glands from radiotherapy-induced xerostomia, and most recently as a mucosal normal tissue protectant. To date, clinical trials have reported improvements in the rate and severity of radiation-induced xerostomia[245–248]; reduced hematologic effects, particularly with concurrent chemoradiotherapy[245]; and reduced radiotherapy-induced mucositis with altered fractionated radiotherapy and from concurrent chemoradiotherapy.[246,249] No compromise in treatment outcome has been reported, either by a small randomized trial using definitive chemoradiotherapy[246] or by a larger randomized trial containing a mixture of patients receiving postoperative radiotherapy and definitive therapy.[247] The latter trial led to the current approved indication for amifostine limited to the postoperative setting, owing to concerns of potential tumor protection that may not be adequately detected.

This trial randomized 315 patients undergoing conventionally fractionated radiotherapy to receive an intravenous 3-minute infusion of amifostine (200 mg/m^2) 15 to 30 minutes before each daily fraction.[247] The main toxic effects were nausea (any grade, 44% versus 16%; $P < 0.001$), vomiting (any grade 37% versus 7%; $P < 0.001$), hypotension (any grade, 15% versus 2%; $P < 0.001$), and a hypersensitivity reaction (any grade, 5% versus 0%; $P = 0.003$) with 21% discontinuing the amifostine before completing the scheduled treatment. The mean quantity of unstimulated saliva 1 year after treatment was significantly higher, correlating with a lower frequency of late grade 2 or higher xerostomia in the group receiving amifostine. In this trial, mucositis was not reduced (grade 3 or higher, 35% with amifostine versus 39% no amifostine; $P = 0.48$), in contrast with to the results of other randomized trials.[246,249] It has been postulated that this discrepancy may relate to dose, becuase Buntzel administered 500 mg as a flat dose and only on the days during which daily concurrent carboplatin was administered (days 1 to 5 and days 21 to 26).[246] Ongoing trials are under way to verify these results. It is clear, however, that the toxicities related to amifostine are dose-related, particularly the emetogenic side effects. These concerns along with logistical issues with coordinated daily administration have prompted studies with a subcutaneous schedule of administration.

A French Cooperative Group study (GORTEC) compared intravenous amifostine as a 3-minute infusion of amifostine (200 mg/m^2) 15 to 30 minutes before each daily fraction with a subcutaneous schedule delivering 500 mg 20 to 60 minutes before each daily fraction.[248] Preliminary results have been promising. Early reporting describes reduced incidence of hypotension (6% versus zero, in favor of the subcutaneous route), with nausea and vomiting remaining dominant side effects in both treatment groups. The rates of acute xerostomia appeared to be similar in both treatment groups, offering a potential alternative schedule for administration.

INTENSITY-MODULATED RADIOTHERAPY. In recent years, significant technological advances have enabled the ability to vary the fluence of the radiotherapy beam, permitting an additional degree of dose conformality and some exciting potential therapeutic applications. These may include an improved therapeutic ratio with irradiation near the base of skull, parotid sparing to minimize the risk of xerostomia, and manipulation of the effective radiotherapy dose per fraction that is delivered to the tumor or surgical bed. Coupled with promising advances in functional imaging, there exists the potential to manipulate the dose to critical areas within the tumor that may harbor radioresistant cells. In particular, interest has focused on identifying areas of tumor hypoxia that may be amenable to in vivo hypoxia imaging with various promising compounds including Cu-ATSM[250] and EF-5.[251] Although this technique remains promising, it is important to recognize its evolving nature and the potential for geographic tumor "misses," particularly areas of subclinical tumor extension, which also may be complicated by a lower dose per fraction delivered. In addition, successful sparing of normal tissues requires knowledge of the dose and volume constraints that are associated with acceptable risks for toxicities. This knowledge base remains in evolution. The generalizability of not only the technique but also target delineation is the subject of several ongoing trials through the RTOG. Nevertheless, early reports are promising.

Several prospective reports demonstrated that with IMRT, dose and volume constraints to the parotid glands may be successful in reducing the xerostomia associated with radiotherapy to the head and neck.[252–255] Quality of life instruments have been used and suggest that there may be additional benefits resulting from reduced xerostomia.[256] These investigators noted that the probability of a geographic tumor miss was low,[255,257] with the majority of relapses within field, emphasizing the importance to identify potential radioresistant subvolumes.[254,257] Lee and colleagues reported a promising 4-year local-regional progression free rate of 98% without any increased acute toxicities for 67 patients with stage I to IV NPC, with stage III or IV disease in 70%.[255] Although toxicities to important critical structures may be manipulated, this may come at the expense of increased skin toxicities,[258] as a result of increased radiation dose resulting from multiple complex beam arrangements that expose more normal tissue that would otherwise have been excluded with conventional techniques. It is this observation that has led to concerns regarding potential long-term adverse effects and a call for prudence in the application of IMRT.[259]

POSTOPERATIVE RADIOTHERAPY. The indications for postoperative radiotherapy (PORT) may follow a risk-stratification paradigm that identifies patients as low, intermediate, or high risk for local-regional relapse, based on the absence, presence of one, or presence of two or more risk factors, respectively (Fig. 72-11). These risk factors include: oral cavity primary, mucosal margins close or positive, nerve invasion, more than one positive lymph node, more than one positive nodal group, largest node greater than 3 cm, and treatment delay longer than 6 weeks.[161,162] In addition, the presence of nodal extracapsular extension by itself placed patients in the high-risk group.[162,163] Although no randomized trial exists to demonstrate

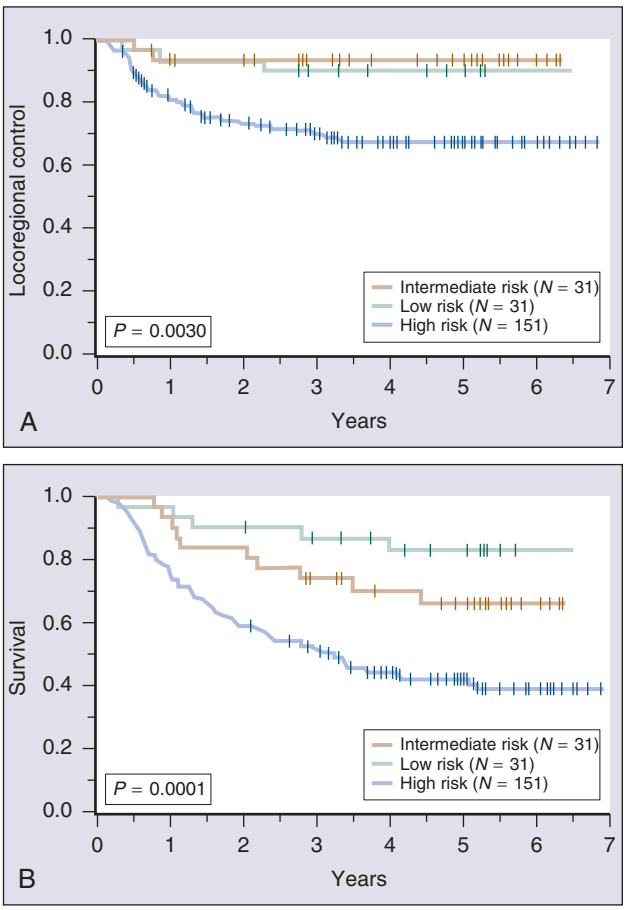

Figure 72-11 • Actuarial local-regional control rates **(A)** and overall survival **(B)** by postoperative risk stratification. (Ang KK, Trotti A, Brown BW, et al: Randomized trial addressing risk features and time factors of surgery plus radiotherapy in advanced head-and-neck cancer. Int J Radiat Oncol Biol Phys 2001;51:571–578.)

the efficacy of postoperative radiotherapy, Ang and colleagues demonstrated in a prospective trial in patients with an intermediate risk of relapse a local-regional control rate (greater than 90%) comparable to that in patients with no adverse risk factors, deemed to be low risk, and not subjected to PORT (see Fig. 72-11).[161] The overall survival for the intermediate group appeared to be inferior to that for the low-risk group; nevertheless, PORT continues to be recommended owing to the importance of local-regional control.

Peters and colleagues previously reported on a dose-finding randomized trial demonstrating that a minimum tumor dose of 57.6 Gy to the whole operative bed should be delivered, with a boost of 63 Gy to sites of increased risk, especially regions of the neck in which extracapsular nodal disease is present.[162] These investigators did not find any benefit with dose escalation above 63 Gy at 1.8 Gy per day and postulated that this might be offset by tumor repopulation. Accordingly, Ang and colleagues recently reported the results of a multi-institution prospectively registered trial of 288 patients with HNSCC deemed to require PORT.[161] Of these 288 patients, 151 patients were stratified as high-risk and subsequently randomized to receive radiation therapy in either a conventionally fractionated schedule or an accelerated schedule using the delayed concomitant boost technique, with a total dose of 63 Gy delivered in each arm. These investigators report in this mature trial a nonsignificant trend for higher local-regional control ($P = 0.11$) and survival ($P = 0.08$) in favor of the accelerated schedule that appeared to result from an underpowered sample size (Fig. 72-12). Acute confluent mucositis (62% versus 36%) was significantly greater in the experimental arm as would be expected. The actuarial probability of a patient sustaining one or more late complications between the two fractionation schedules ($P = 0.94$) did not significantly differ between the two arms. These investigators therefore concluded that the benefits of an accelerated PORT schedule had not been definitively established, but comment that, in practice, an accelerated PORT schedule may be used to keep the overall treatment time to less than 11 weeks in unavoidable situations where there has been protracted time before PORT. The latter follows from the demonstration of a significant adverse impact on both local-regional control and survival rates when analyzed by the overall treatment time (Fig. 72-13). These results must be interpreted with caution, however, as the study design did not stratify by the time interval before starting PORT.

Care should be exercised in the use of an accelerated schedule as concern has also been raised of a possible increased risk of late toxicities in the postoperative setting.[260] Rather, patients anticipated to require postoperative radiotherapy should be appropriately identified with the appropriate arrangements made for the patient so as to prevent unnecessary interruptions to starting PORT. In a prospective comparative trial with a median follow-up period of 6 years Trotti and colleagues demonstrated that patients initiating PORT within 4 weeks had a significantly lower rate of crude in-field relapses (seen in 0 of 10 versus 10 of 32).[260]

It has also been proposed that the integration of chemotherapy with postoperative radiotherapy be favored in light of the increased risk of distant relapses also observed in the high-risk group. Ang and colleagues noted a 5-year actuarial distant relapse rate of 33% (versus

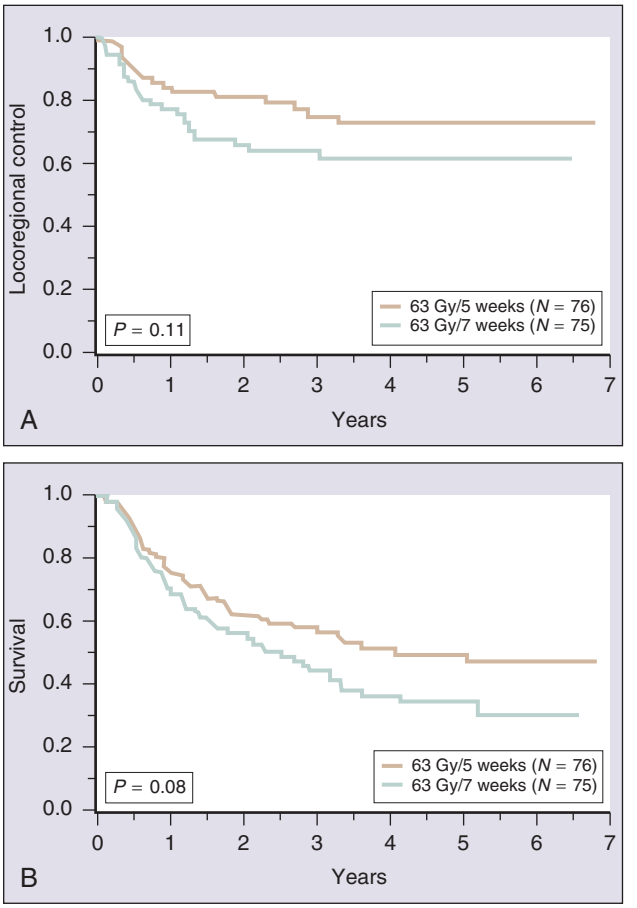

Figure 72-12 • Actuarial local-regional control rates **(A)** and overall survival **(B)** for high-risk patients according to the postoperative radiotherapy fractionation schedule. (Ang KK, Trotti A, Brown BW, et al: Randomized trial addressing risk features and time factors of surgery plus radiotherapy in advanced head-and-neck cancer. Int J Radiat Oncol Biol Phys 2001;51:571–578.)

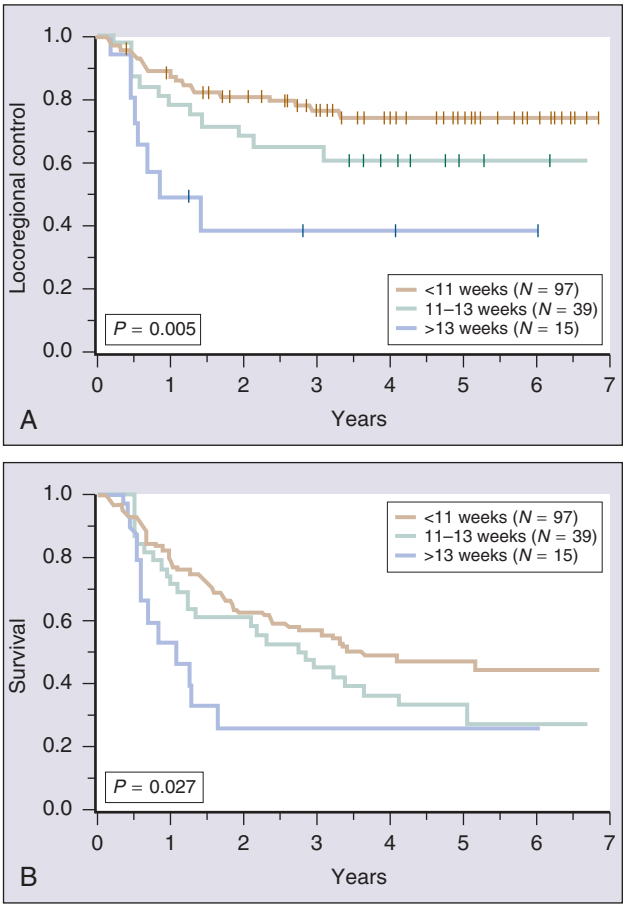

Figure 72-13 • Actuarial local-regional control rates **(A)** and overall survival **(B)** for high-risk patients according to the overall treatment time (from the time of surgery to the completion of radiotherapy). Int J Radiat Oncol Biol Phys 2001;51:571–578.)

3% in the low-risk group). Although attractive, this remains an active area of investigation with no established chemoradiotherapy regimen. Two randomized trials of postoperative chemoradiotherapy with concurrent cisplatin and daily fractionated radiotherapy have been reported.[261,262] Bachaud and colleagues reported the results of a randomized trial prematurely closed due to poor patient accrual, demonstrating improved local-regional control rate, disease-free survival, and overall survival with weekly concurrent cisplatin. Only 88 patients with stage III or IV disease with the presence of extracapsular extension were were accrued, however, so the authors suggest that these results require validation in a larger study. Recently, the RTOG presented the preliminary results of a randomized trial of 459 patients with high-risk postoperative features including extracapsular extension receiving radiotherapy or radiotherapy and bolus cisplatin on weeks 1, 4, and 7 (RTOG 9501).[262] Modest improvement in local-regional disease control and disease-free survival (54% versus 43%; $P = 0.049$) in favor of the chemoradiotherapy arm, with no difference in overall survival, was reported.

Several institutional retrospective reports have suggested that the addition of a brachytherapy implant to postoperative radiotherapy when surgical margins are positive or close may improve the local control rates for a mixture of tumor sites.[263–267] This strategy may be particularly attractive for management of early oral cavity lesions, for which the risk of nodal metastasis is low, thereby avoiding the morbidity associated with EBRT. Site-specific indications for the floor of the mouth[263] and the oral tongue[264] have been reported. Pernot and colleagues reported a 5-year local control rate of 89% for 97 patients who received either postoperative EBRT followed by an implant or brachytherapy with an implant alone for oral cavity tumors.[265] Self-resolving grade 1 and 2 complications occurred in 19% and 12%, respectively, with only 6% of complications requiring surgical intervention (grade 3). These results are particularly promising in light of the fact that one third of the patients who received this treatment had T3 and T4 lesions. Accordingly, this therapeutic may be considered when the surgical margin of concern can be located and when experience exists for the safe administration of the implant.

BRACHYTHERAPY. Brachytherapy has a significant role in the management of head and neck squamous cell carcinomas[268,269] with various techniques described.[270] Owing to the unique physical properties of this region, treatment morbidity is minimized as a result of reduced irradiation in the surrounding normal tissues. An implant may be used in the definitive setting for several tumor sites including the tonsil and soft palate,[271–276] oral tongue,[277–280] base of tongue,[281–288] and lip.[289,290] The use of an implant in the base of tongue has the advantage of being a functional organ-preserving treatment strategy validated with quality of life instruments,[291,292] with the results suggested to be superior to those achievable with EBRT alone and comparable with those for surgery with PORT.[284] It may be used as an alternative to surgery for selected cancers of the floor of mouth in specific circumstances. In early-stage lesions, for which the risk of nodal metastases is low, brachytherapy may be employed definitively or in an adjuvant fashion after surgery. In more advanced lesions, it often is combined with external irradiation of the head and neck. The ability to provide specific high local irradiation also permits the selective use of brachytherapy in the setting of recurrent[293,294] or second HNSCC occurring within a previously irradiated region.[295]

Appropriate application of a brachytherapy implant begins with patient selection. This process requires assessment of the patient's understanding and ability to comply with the inherent radiation precautions associated with brachytherapy implants, especially for continuous low dose rate (LDR) implants. Patients should be selected for their ability to provide for their baseline self-care needs, in addition to the treatment-related needs such as the care of a tracheostomy, nasogastric feeding tube, and patient-controlled analgesic pump as indicated. Patients subject to periods of confusion and disorientation may not be suitable for this mode of therapy.

Several considerations influence the decision of a permanent or a temporary implant. Permanent implants, emitting radiation over the lifetime of its radioactivity, use sources that provide LDR irradiation. Suboptimal placement of a permanent implant and the potential adverse dosimetric effects of organ swelling and movement pose potential risks for an unfavorable therapeutic ratio. A permanent implant affords the delivery of a very high total dose delivered, however, and may be advantageous when implanting complex and irregular surfaces not amenable to placement of temporary catheter-based implants where chinking of the catheters is a significant risk. The judicious use of permanent sources with low-energy photons, such as iodine 125 (^{125}I), may be advantageous when critical normal structures, such as the spinal cord, are adjacent to the implant.

Temporary implants more commonly are applied in the head and neck because they permit a more deliberate and accurate placement of the implant applicator system without the radiation exposure concerns that occur with a permanent implant. Typically, nylon catheters are placed, approximating the desired position of the radioactive sources, which then may be subsequently afterloaded with LDR radioactive seeds embedded at defined positions within a nylon strand. This technique affords optimization of the implant dosimetry after placement of the implant applicator system. Commonly, this has involved obtaining orthogonal plain x-ray films of the implant with dummy seeds placed within the selected applicator system, with digitization of the relative seed positions into a treatment planning software. Variations in the activity, number of radioactive sources, and loading duration and, for high dose rate (HDR) computer-

guided remote afterloading systems, variations in the dwell time and position allow for dosimetric optimization. Optimization cannot obviate the adverse dosimetry associated with poor implant geometry, however.

Temporary LDR implants also offer several radiobiologic advantages, including a reduced treatment time, the capability to irradiate a potentially less hypoxic tumor bed early in the postoperative period, a reduced adverse influence of hypoxia itself, and exploitation of cell cycle-specific radiosensitization. These implants further exploit the differential repair capacities between tumor and normal tissues, reducing the risk of normal late complications. The risk of radiation exposure to personnel, however, necessitates good source-handling skills and strict radiation precautions. Alternatively, HDR sources with computer-guided remote afterloading significantly reduce the exposure risks and required precautions. Fractionated radiotherapy is delivered with a single iridium 192 (^{192}Ir) source fixed to the end of a cable wire that may be variably stepped along the length of each catheter. HDR implants confer greater flexibility in conforming the implant dosimetry to the target volume, yield a relatively more homogeneous dose distribution to those of LDR implants, and, because the delivery of the radiation occurs over a shorter time period, are less subject to the effects of organ movement. These advantages may yield a lower complication rate as a result of this precise geometric sparing. Concerns remain, however, with regard to the risk of increased late complications from the higher dose rate of radiation.[296] This has prompted ongoing studies to define the optimal fractionation schedules to reduce this risk. Several other promising but investigational techniques include the use of pulsed dose rate (PDR) radiation, which has been studied as a technique to exploit the logistical advantages and reduced radiation exposure of remote afterloading and the LDR biologic advantages that may be expected with this technique.[268,297,298] HDR intraoperative radiation therapy (HDR-IORT) remains a promising investigational technique that has the advantage of accurately delivering radiation to the areas at risk for tumor recurrence potentially at a time when the tumor burden is the lowest.[299]

Chemotherapy

GENERAL. The role of chemotherapy in the primary treatment of locally advanced disease became more prominent in the 1970s due to the poor outcome of stage III and IV disease treated with surgery or radiation, or both. Definitive treatments with chemotherapy emerged in nasopharyngeal cancer and in organ preservation protocols for the larynx,[193] the hypopharynx,[192] and, most recently, the oropharynx.[300] Systemic chemotherapy continues to have a role for palliation in patients with locally advanced-stage disease, locally recurrent disease beyond salvage techniques such as surgery, and metastatic disease.

PROGNOSTIC FACTORS. The decision to treat with chemotherapy remains dependent on various factors that can contribute to response. Those factors include the patient's performance status, nutritional status, the tumor burden and extent, disease stage, degree of tumor differentiation, and primary cancer site.[192,301–303]

NEOADJUVANT AND INDUCTION CHEMOTHERAPY. Over the last 10 to 15 years, approaches to the treatment of patients with stage III and IV disease began to include the use of chemotherapy as induction therapy before planned surgical resection and, more recently, before radiotherapy. The concept of induction chemotherapy arose from several principles. It has been postulated that chemotherapy may promote regression of tumor, enhancing local-regional therapy through sensitization, and also may identify patients who may be candidates for a more conservative surgical approach as the need for improved quality of life through functional preservation has arisen. Thus, organ preservation, rather than extensive, potentially morbid surgical procedures, came into vogue as a philosophical consideration in the management of advanced-stage disease. An additional attractive feature with this approach was the conceptual ability to treat micrometastatic disease in hopes of reducing distant failure rates, which can be 40% or greater with conventional local-regional surgical/radiation approaches. Finally, it was felt that the use of chemotherapy before the tumor and vascular bed are altered by surgery or irradiation may improve the ability to identify responding tumors for which adjuvant chemotherapy may be beneficial.

Nonrandomized phase II trials in the 1970s used single-agent chemotherapy based on strategies used in the recurrent and metastatic setting. These single-agent trials reported 30% to 40% response rates.[304] Induction strategies subsequently involved multiple chemotherapy regimens. The first reported trials by Wittes and colleagues[304] showed a 71% response rate with complete responses noted in 21% of patients using cisplatin and continuous infusion bleomycin in 21 patients. Other studies followed, using cisplatin/bleomycin with other drugs such as hydrea and revealing increased toxicity with no improvement in response rates or survival.[305] Investigators from Wayne State University reported the first trial using neoadjuvant cisplatin with infusional 5-fluorouracil, with an overall response rate of 88% and a complete response rate of 54%.[306] The investigators reported that 120-hour infusional 5-fluorouracil showed improvement over 96-hour infusions and that complete response rates after three total cycles were double those achieved after two.[305–307] More recent studies appear to confirm that complete response rates will increase after three to five cycles; other studies have confirmed the activity of this combination but at varied response rates (38% to 100%) and complete response rates (13% to 54%).[308,309] A 38% complete response rate also was achieved by the RTOG.[310] Numerous other combinations reported have included high-dose cisplatin with fixed-dose 5-fluorouracil, high-dose 5-fluorouracil with fixed-dose cisplatin, intra-arterial cisplatin, and additional drugs, such as bleomycin, cyclophosphamide, mitoguazone, taxanes, and methotrexate, have been given with the cisplatin plus 5-fluorouracil regimen, with significant toxicity and no overall difference in response or survival.[307,310–312] Trials using carboplatin with 5-FU have shown similar response rates of 70% to 80% and complete response rates of 30% to 40%, which are similar to those with cisplatin plus 5-fluorouracil.[313]

Although these experiences with chemotherapy plus irradiation included several randomized trials with neoadjuvant chemotherapy, many were characterized by methodological problems. In 1985, the increasing interest in laryngeal preservation coupled with disappointing experiences with upfront radiotherapy for advanced disease, laid the foundation for the Veterans Affairs Cooperative Studies Program (VACSP) to initiate a multi-institutional randomized trial of neoadjuvant chemotherapy as an organ preservation strategy.[193] Patients with previously untreated, locally advanced but potentially resectable stage III (T2-3N1 or T3N0) or stage IV (T1-3N2-3 or T4N0-1) disease of the supraglottic or glottic larynx were randomized either to receive neoadjuvant chemotherapy or to undergo surgical resection (Fig. 72-14). The chemotherapy regimen was cisplatin (CDDP) with continuous-infusion 5-fluorouracil for 5 days with response after 2 cycles used to stratify patients to either continue with an additional cycle of chemotherapy followed by radiotherapy or, for nonresponders, salvage surgery followed by postoperative radiotherapy. In total, 332 patients were enrolled: 216 patients with T3, 85 with T4, and 240 patients with N0-1 disease. Laryngeal preservation was achieved in 64% of patients enrolled in the chemotherapy arm. The local failure rate was significantly higher in the chemotherapy plus irradiation arm, but the distant failure rate was significantly lower in this arm. The long-term overall survival rate was approximately 30% in each arm. On subset analysis, sequential chemotherapy plus irradiation was less effective in the T4 tumors or those with N2 or greater disease; 50% of these patients required salvage laryngectomies. Although this trial demonstrated that laryngeal conservation was achievable in 64% of

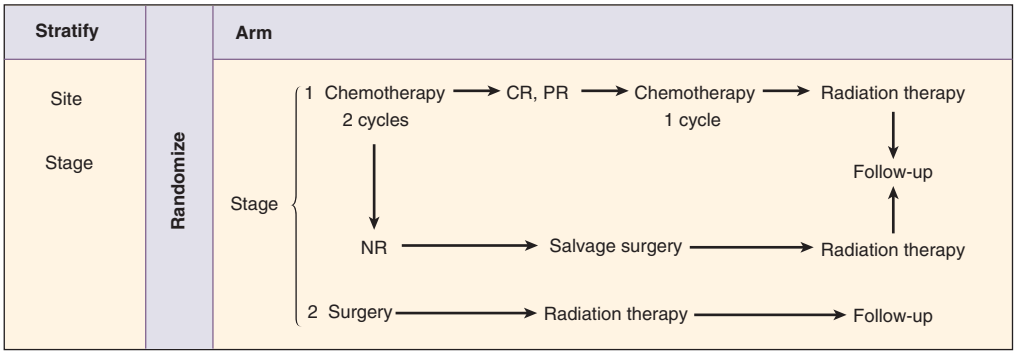

Figure 72-14 • Study schema of Veterans Affairs larynx preservation trial. CR, complete response; NR, no response; PR, partial response. (From Department of Veterans Affairs Laryngeal Cancer Study Group: N Engl J Med 1991;324:1685–1690.)

patients with advanced laryngeal carcinoma, the incremental role neoadjuvant chemotherapy contributed to this is unclear. This laryngeal preservation rate appears to be comparable to the results achieved with radiotherapy alone followed by salvage surgery, which ranged from 50% to 73%.[191,197] The value of neoadjuvant chemotherapy has also been questioned as only a subset of patients with advanced laryngeal cancers had chemoresponsive tumors.

These results subsequently were approximated in a similar randomized trial conducted by the EORTC.[192] The EORTC randomized a smaller population of 194 patients with locally advanced hypopharyngeal cancer (6% with stage II, 57% with stage III, and 37% with stage IV) to receive either cisplatin plus 5-fluorouracil or total laryngectomy, partial pharyngectomy or radical neck dissection with adjuvant radiation therapy. Only patients who achieved a complete response received radiation alone; 54% had a complete response at the primary site, 51% at the nodal site, and 43% achieving a complete response both at the primary and nodal site. Treatment failures at the local, regional, and second primary sites occurred at approximately the same frequencies in the immediate surgery arm (12%, 19%, and 16%, respectively) and in the induction chemotherapy arm (17%, 23%, and 13%, respectively). By contrast, there were fewer failures at distant sites in the induction chemotherapy arm than in the immediate surgery arm (25% versus 36%, respectively; $P = 0.041$). The median duration of survival was 25 months in the immediate surgery arm and was 44 months in the induction chemotherapy arm, which the investigators concluded were equivalent. The 3- and 5-year estimates of retaining a functional larynx in patients in the induction chemotherapy group were 42% (95% CI, 31% to 53%) and 35% (95% CI, 22% to 48%), respectively. It would appear that with a more stringent response to chemotherapy, fewer local relapses may be anticipated, in contrast with the results of the VA study.[193]

Recently, a French Cooperative trial (GETTEC) reported the randomized results using a neoadjuvant chemotherapy approach for organ preservation for the oropharynx site.[300] Patients with a squamous cell carcinoma of the oropharynx for whom curative radiotherapy or surgery was considered feasible were randomized to undergo either three cycles of neoadjuvant chemotherapy, followed by local-regional treatment determined by the treating physician, or the same local-regional treatment without chemotherapy. The local-regional treatment consisted either of surgery plus radiotherapy or of radiotherapy alone. The chemotherapy regimen consisted of cisplatin (100 mg/m^2) on day 1, followed by a 24-hour intravenous infusion of fluorouracil (1,000 mg/m^2 per day) for 5 days delivered every 21 days. A total of 318 patients were enrolled in the study between 1986 and 1992; the study was prematurely closed as a result of a loss of clinical equipoise, because the treating physicians believed that neoadjuvant chemotherapy was efficacious. The investigators note, however, that this decision was independent of any knowledge of the trial results, minimizing the impact of any bias. Overall survival was significantly better ($P = 0.03$) in the neoadjuvant chemotherapy group than in the control group, with a median survival of 5.1 years versus 3.3 years in the no chemotherapy group. The effect of neoadjuvant chemotherapy on event-free survival was less and of borderline significance ($P = 0.11$). In summary, it is clear that systemic chemotherapy can have an impact on the risk of distant relapses, with possible improvements in overall survival.

The preceding studies led to the more recent intergroup trial, RTOG 9111, conducted in patients with stage III or IV resectable disease of the larynx.[198] Patients were randomized to three treatment groups: chemotherapy (cisplatin plus 5-fluorouracil) followed by radiation therapy; concurrent chemoradiation therapy with high-dose cisplatin as the radiosensitizer; or standard fractionated EBRT daily. Patients with T4 lesions were not included in this trial. If a patient initially had N2 or N3 neck disease, a modified neck dissection was performed independent of response. Two-year laryngectomy-free survival was superior in the group of patients receiving concurrent chemoradiotherapy ($P = 0.018$), reducing the number of laryngectomies performed by approximately 50%, with the number of laryngectomies performed identical in the other two treatment arms (43 versus 21 versus 49, respectively). Two-year local-regional control rates were also superior in the concurrent chemoradiotherapy arm (61%, 78%, and 56%, respectively), with the overall survival (approximately 75%) not differing among the treatment arms.

Efforts continue to improve on the clinical efficacy of neoadjuvant chemotherapy in hopes of achieving significant activity to yield consistent survival benefits.[314] Recent strategies have focused on the use of neoadjuvant chemotherapy followed by concurrent chemoradiotherapy. Various phase II studies[187,301,315–318] have been reported. These also include variations of the "gold standard" chemotherapy regimen, cisplatin and 5-fluorouracil, incorporating leucovorin rescue (Platinol-fluorouracil-leucovorin [PFL] regimen), with or without interferon-α, efforts pioneered by Vokes and colleagues in Chicago.[301,317] A recently completed Eastern Cooperative Oncology Group (ECOG) phase II trial of neoadjuvant carboplatin and paclitaxel followed by concurrent weekly paclitaxel and daily-fractionated radiotherapy for oropharynx carcinomas included functional swallowing assessments as a measure of functional preservation. This trial follows from promising preliminary data reported by Machtay and colleagues, who noted a major clinical response rate of 89% after induction chemotherapy, with a 90% complete response rate after concomitant chemotherapy.[187] The 3-year survival and 3-year progression-free survival rates were 68% and 60%, respectively. Local-regional control was 82%, and the 3-year distant failure rate was reported at 18%. Organ preservation was achieved in 77% of all patients. In general, increased toxicities have been observed in these trials with promising activity that will require study in the context of a randomized trial. These strategies offer the promise of not only improved local-regional control rates with organ preservation but also a reduced risk of late distant relapses and more consistent improvements in overall survival. Recent results from a large patient-based meta-analysis, however, have drawn attention to the potential

negative effects of neoadjuvant chemotherapy when used as a larynx preservation strategy, because a nonsignificant hazard ratio of death (1.19; range, 0.97 to 1.46) was noted.[181]

CONCURRENT AND CONCOMITANT CHEMORADIOTHERAPY. A significant body of literature exists, including numerous randomized trials of concurrent chemotherapy that have been systematically summarized by several investigators.[181,319–321] These independent reviews have consistently favored the concurrent integration of chemotherapy. Pignon and colleagues reported the largest and recently updated of these meta-analyses.[181] This patient-based meta-analysis of more than 10,000 patients derived from 63 randomized trials confirmed an absolute survival benefit of 4% at 2 and 5 years, with the greatest benefit of 8% observed in the group receiving concurrent chemotherapy. The group that contributed to this survival benefit was found to be the group of studies that used radiotherapy as the local-regional treatment. The survival benefit was found to be significantly greater with multiagent versus single-agent concurrent chemotherapy. A nonsignificant increase in the risk of death was noted with multiagent chemotherapy regimens containing a platinum agent (Fig. 72-15). When results were analyzed with covariants, a significant decreasing benefit on survival for concurrent chemotherapy was noted with increasing age, which may be partly explained by lower compliance and higher toxicities (Fig. 72-16). These results are consistent with anecdotal clinical experiences and highlight the importance of patient selection for concurrent chemoradiotherapy in light of the small incremental benefit. No survival benefit was observed with either neoadjuvant or adjuvant chemotherapy, leading the study investigators to recommend its use only within the context of a clinical trial.

Although concomitant chemoradiotherapy is probably the most promising and feasible approach in locally advanced patients, there remain several issues including the generalizability of these survival benefits to specific subsites, specific chemoradiotherapy regimens, including recent popular taxane-based regimens, and whether or not, differences exist between resectable and unresectable disease. The latter distinction becomes important, because concurrent chemoradiotherapy has emerged as a popular strategy to achieve functional organ preservation.[198] Because the addition of concurrent chemotherapy increases mucosal toxicity and poses the potential of adversely affecting swallowing function,[187,199] if the survival benefits, particularly with multi-agent regimens, are generalizable to those patients with resectable disease, compromises in organ function may result. Even if survival benefits are not observed, multi-agent regimens may still be preferred, as recently noted by Adelstein and associates.[135] In their mature report of 100 patients with resectable HNSCC at various tumor sites, improved local-regional control rates without surgical salvage (77% versus 45%; $P < 0.001$), although with no survival benefit, were observed with concurrent chemotherapy (both 5-fluorouracil [1000 mg/m^2 per day] and cisplatin [20 mg/m^2 per day] given as a continuous intravenous infusion over 4 days beginning on day 1 and again on day 22). Successful primary salvage surgery was possible in 73% of cases, which contributed to the absence of any demonstrable survival benefit.

Although concurrent chemoradiotherapy has been studied in patients with stage III and IV HNSCC, often without selection for resectability, it becomes important to recognize the narrowed therapeutic ratio in its application.[184] In this regard, the relative efficacy of altered fractionated radiotherapy schedules is an important consideration, because the randomized trials establishing their efficacy have used comparable selection criteria. To date, limited randomized data exist comparing conventionally fractionated radiotherapy with concurrent chemotherapy with altered fractionated radiotherapy. Olmi and colleagues recently reported the results of a three-arm multi-institutional randomized trial of concurrent chemoradiotherapy versus altered fractionated radiotherapy versus conventionally fractionated radiotherapy alone.[322] These investigators randomized 192 patients with previously untreated, stage III and IV oropharyngeal carcinoma (excluding T1N1 and T2N1) to undergo one of three therapy regimens described as arms A, B, and C: for arm A, conventionally fractionated radiotherapy to a dose of 66 to 70 Gy in 33 to 35 fractions, 5 days a week over 6.5 to 7 weeks; for arm B, altered fractionated radiotherapy to a dose of 64 to 67.2 Gy, in two fractions of 1.6 Gy every day, with an interfraction interval of at least 4 hours and preferably 6 hours, 5 days a week with a 2-week split at 38.4 Gy, with radiotherapy resumed at the same fractionation after the split (arm B); or for arm C, chemotherapy in a regimen consisting of carboplatin and 5-fluorouracil (CBDCA 75 mg/m^2, days 1 to 4, plus 5-fluorouracil 1000 mg/m^2 given by intravenous infusion over 96 hours, days 1 to 4, every 28 days [at weeks 1, 5, and 9]), plus radiation therapy using the same daily fractionation schedule as described for the standard arm (arm A). No significant differences were detected in overall survival ($P = 0.129$): 40% of patients in arm A, 37% of those in arm B, and 51% of those in arm C were alive at 24 months.

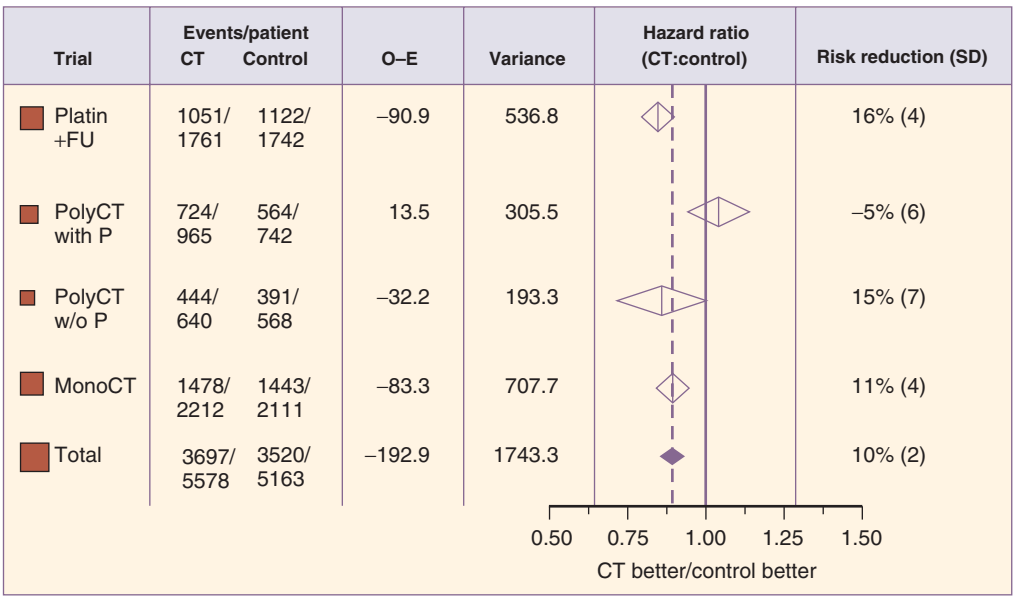

Figure 72-15 • Hazard ratio of death with local-regional treatment plus chemotherapy (CT) with local-regional treatment by chemotherapeutic regimen: Platin (cisplatin or carboplatin) + fluorouracil (FU), combination CT with platin (polyCT + P), combination CT without platin (polyCT w/o P), single-agent CT (monoCT) including platin. Test for heterogeneity between types of chemotherapy ($P = 0.02$). (From Pignon JP, Bourhis J, Domenge C, Designé L: Chemotherapy added to locoregional treatment for head and neck squamous-cell carcinoma: three meta-analyses of updated individual data. MACH-NC Collaborative Group. Lancet 2000;355:949–955.)

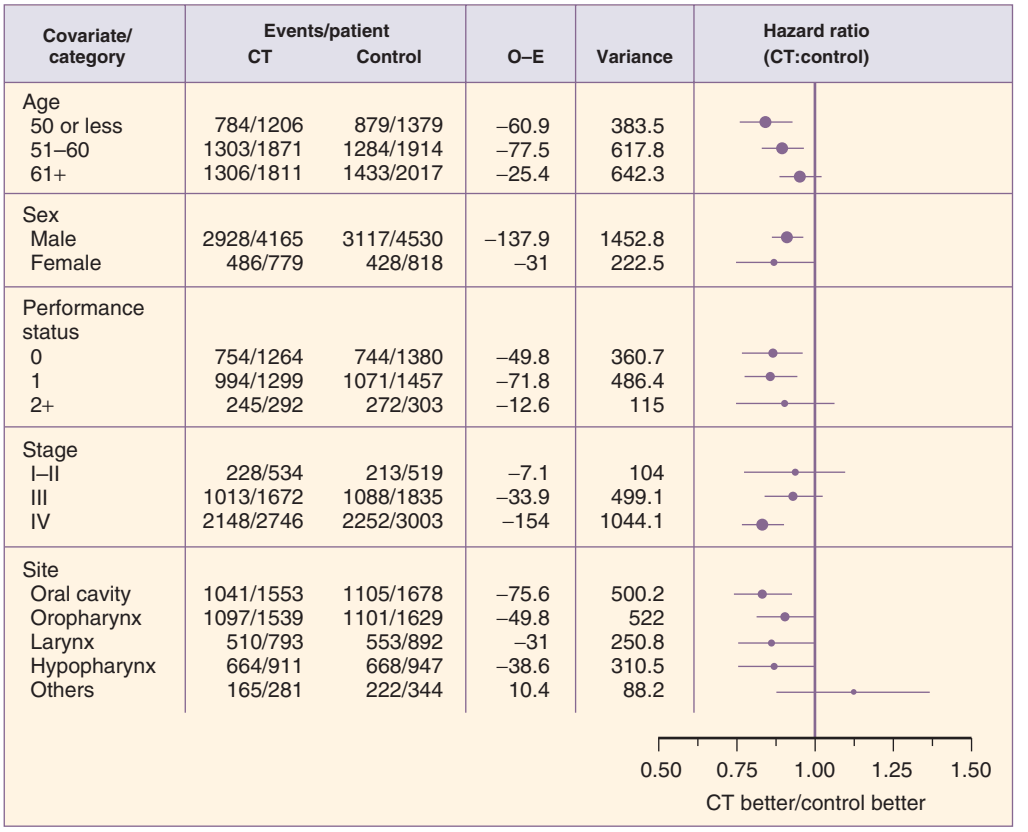

Figure 72-16 • Hazard ratio of death with local-regional treatment with or without chemotherapy (CT) by age, sex, performance status, stage, or tumor site. Test for trend for age was significant ($P = 0.05$). (From Pignon JP, Bourhis J, Domenge C, Designé L: Chemotherapy added to locoregional treatment for head and neck squamous-cell carcinoma: three meta-analyses of updated individual data. MACH-NC Collaborative Group. Lancet 2000;355: 949–955.)

The 2-year disease-free survival rates, however, were significantly different among the three arms ($P = 0.022$), with the highest rate in the chemoradiotherapy arm. At 24 months, the proportion of patients without relapse was 42% for arm C, 23% for arm A, and 20% for arm B. Increased grade 3 skin and mucosal toxicities were noted in the concurrent chemoradiotherapy arm and the altered fractionated schedule. A suggestion of increased late skin and mucosal toxicities was noted in the chemoradiotherapy arm. Nguyen and Ang also have favored concurrent chemoradiotherapy in patients who are able to tolerate the increased toxicity, particularly in the setting of advanced T3 or T4 primary disease or in patients with advanced N2 or N3 neck disease, stratifying patients with T2 or exophytic T3N1 disease to altered fractionated radiotherapy.[183]

Multi-agent regimens continue to be favored over single-agent regimens owing to concerns of late distant failures that have become more evident with improved local-regional management. A favorable effect for many multiagent regimens on the risk of distant relapses, however, remains to be clearly established.[178,323] A reduced risk of distant relapse has been suggested in several reports[135,324] and may indicate that the local-regional therapy is effective in addressing micrometastases, but control of the local-regional disease is necessary for this benefit to manifest. Accordingly, significant interest has been focused on the incorporation of altered fractionated radiotherapy schedules with concurrent chemotherapy (Table 72-7). In total, six randomized trials have been reported and may be characterized by the type of altered fractionation used.[212,241,323–326] In the trials combining an accelerated schedule, acute mucosal toxicities were significantly increased, with two trials demonstrating unacceptable toxicity,[241,326] one of which included a high rate of chronic swallowing dysfunction.[326] Jeremic and colleagues reported an improved 5-year local-regional control rate (50% versus 36% at 5 years; $P = 0.041$), 5-year overall survival (46% versus 25% at 5 years; $P = 0.0075$), and distant metastasis-free survival (86% vs. 57% at 5 years; $P = 0.0013$) with the concurrent administration of daily cisplatin (6 mg/m^2) with a hyperfractionated schedule delivering 77 Gy as 1.1 Gy twice daily in 70 fractions over 7 weeks compared with this same hyperfractionated schedule alone.[324] No significantly increased acute or late toxicities were reported. This remains a promising aggressive regimen that requires further validation of the concept of daily radiosensitization with an altered fractionation schedule. Finally, both 5-fluorouracil and cisplatin with or without leucovorin have been administered concurrently with a split-course schedule. Wendt and colleagues demonstrated improved local-regional control rates with an accelerated split-course schedule with concurrent bolus schedule of cisplatin, 5-fluorouracil, and leucovorin, but the results were overall disappointing (36% versus 17%; $P = 0.004$).[323] A significant reduction in the total dose was used. Brizel and colleagues administered concurrent cisplatin and 5-fluorouracil with a split-course hyperfractionated schedule of 1.25 Gy twice daily over 47 days with a 7- to 10-day treatment interruption after 40 Gy.[212] Improved local-regional control rates with no difference in overall survival were noted, with increased risk of sepsis and enteral feeding noted in the experimental arm. To date, the generalizability of any of these regimens is limited not only by the increased toxicity, but also by the intensive resources required on the part of the treating team and the patients.

POSTOPERATIVE AND ADJUVANT CHEMOTHERAPY. The use of postoperative adjuvant chemotherapy in patients at high risk for local and regional recurrence from HNSCC remains under evaluation.[181] Patients with two or more positive regional nodes, extracapsular extension of disease, positive resected margin, or perineural or perivascular invasion are considered to be in a high-risk category. Ang and colleagues noted a 5-year actuarial distant relapse rate of 33% (versus 3% in the low-risk group).[161] A comparable level of risk for distant relapses in various chemoradiotherapy series with patients treated nonsurgically has been described ranging from 15%

Table 72-7 Phase III Trials of Concurrent Chemotherapy and Altered Fractionation in Patients with Head and Neck Cancer

Study	Tumor Site and Stage	No. of Patients	Therapy Regimens	Tumor Response	Complications
ACCELERATED FRACTIONATION PLUS CHEMOTHERAPY					
Dobrowsky and Naude, 2000	Various sites, T1-4 N0-3	188	55.3 Gy over 17 days (2.5 Gy on day 1, then 1.65 Gy, twice a day) ± mitomycin; conventional fractionation, 60 Gy over 7 weeks	Combination treatment yielded higher LRC ($P < 0.05$) and survival ($P < 0.03$)	More mucositis than in the combination group but not intensified by mitomycin; late toxic effects not reported
Staar et al, 2001	Various sites, stage III–IV	240	69.9 Gy over 5.5 weeks plus carboplatin (70 mg/m^2 per day) and fluorouracil (600 mg/m^2 per day) for 2 cycles of 5 days; 69.9 Gy over 5.5 weeks (1.8 Gy once daily for 3.5 weeks, then, individual fractions of 1.8 Gy and 1.5 Gy, daily for 2 weeks)	2-year OS, 48% vs 39% ($P = 0.11$); 2-year LC, 51% vs 45% ($P = 0.14$); patients receiving radiochemotherapy had worse LRC	Grade 3–4 mucositis, 68% vs 52% ($P = 0.01$); grade 3–4 vomiting, 8.2% vs 1.6% ($P = 0.02$); late swallowing problems and feeding tube dependency, 51% vs 25% ($P = 0.02$)
Bourhis et al, 2001	Various sites, advanced-inoperable	109	62.64 Gy over 5 weeks plus cisplatin (100 mg/m^2 on days 1, 16, and 32) and fluorouracil (1 g/m^2 on days 1–5 and 31–35); 62–64 Gy over 3 weeks	Not yet reported	Early stopping due to higher number of treatment-related deaths in the combined-treatment group
HYPERFRACTIONATION PLUS CHEMOTHERAPY					
Jeremic et al, 2000	Various sites, stage III–IV	130	77 Gy over 7 weeks plus cisplatin (6 mg/m^2 per day); 77 Gy over 7 weeks (1.1 Gy, twice daily)	5-year LRPFS, 50% vs 35% ($P = 0.04$); 5-year PFS, 46% vs 25% ($P = 0.007$); 5-year DMFS, 86% vs 57% ($P = 0.001$); 5-year OS, 46% vs 25% ($P = 0.008$)	No significant difference in acute morbidity (except for leucopenia, $P = 0.006$) or late toxic effects
SPLIT-COURSE ALTERED FRACTIONATION PLUS CHEMOTHERAPY					
Wendt et al, 1998	Various sites, stage III–IV	270	70.2 Gy over 51 days plus cisplatin, fluorouracil, and leucovorin; 70.2 Gy over 51 days (23.4 Gy in 1.8-Gy fractions, twice daily × 3 cycles with a 10-day break)	3-year LRC, 36% vs 17% ($P < 0.004$); 3-year OS, 48% vs 24% ($P < 0.0003$)	Grade 3–4 acute mucositis, 38% vs 16% ($P < 0.001$); serious late side effects, 10% vs 6.4% (NS)
Brizel et al, 1998	Various sites, T2–4 N0–3	122	70 Gy over 47 days as 1.25 Gy, twice daily (7- to 10-day break after 40 Gy) plus cisplatin and fluorouracil in weeks 1 and 6; 75 Gy over 42 days as 1.25 Gy, twice daily	3-year LRC, 70% vs 44% ($P = 0.01$); 3-year RFS, 61% vs 41% ($P = 0.07$); 3-year OS, 55% vs 34% ($P = 0.07$)	Similar mucositis; increased enteral feeding and sepsis with combination therapy; similar late complications

to 30%.[135,178,212] Laramore and colleagues reported the results of a randomized trial conducted through the Intergroup (0034), randomizing patients after surgical resection to either three cycles of cisplatin and 5-fluorouracil chemotherapy followed by postoperative radiotherapy (CT/RT) or postoperative radiotherapy alone (RT). Patients were stratified as having either low-risk or high-risk treatment volumes depending on whether the surgical margin was greater than or equal to 5 mm, there was extracapsular nodal extension, and/or there was carcinoma in situ at the surgical margins. Radiation doses of 50 to 54 Gy were given to low-risk volumes and 60 Gy were given to high-risk volumes. A total of 442 patients were analyzable with no difference noted in the overall survival (4-year actuarial survival rate was 44% on the radiotherapy arm and 48% on the chemotherapy plus radiotherapy arm [P = not significant]), 4-year disease-free survival (38% versus 46%, respectively), and 4-year local-regional control rates (29% versus 26%, respectively). The overall incidence of distant metastases, however, was 23% on the radiotherapy arm, compared with 15% on the chemotherapy-radiotherapy arm ($P = 0.03$), again confirming activity as noted in trials employing neoadjuvant chemotherapy, but with no improvement in overall survival as noted in the recently updated meta-analysis reported by Pignon and colleagues.[181] A limited number of other randomized trials have been conducted. These include a small randomized trial of adjuvant chemotherapy for oral cavity lesions reported in abstract only that favored the control arm,[327] and a second trial also limited to the oral cavity that did not demonstrate any improvement in disease-free survival or overall survival.[328]

CHEMOPREVENTION. Retinoids have been increasingly used in the treatment of oral leukoplakia and dysplasia of the head and neck since the 1960s. Studies have been published using retinoids in the treatment of head and neck cancers in conjunction with interferon. 13-*Cis*-retinoic acid also has been looked at in the adjuvant setting. More recently, retinoids have been evaluated in the "preventive" setting after definitive therapy.

A phase I/II study looked at *cis*-retinoic acid, cisplatin, and ifosfamide in patients with advanced or recurrent HNSCC.[329] Patients were given cisplatin at 20 mg/m^2 per day for 5 days every 3 weeks, with *cis*-retinoic acid at 0.5 mg/kg orally for 5 days per week and dose-escalating ifosfamide at 1000 to 1500 mg/m^2. A response rate

of 72% was reported, with median time to progression of 10.4 months and overall survival time of 13 months.

The combination of retinoids and interferons has synergistic effects in modulating proliferation, differentiation, and apoptosis. A German study evaluated 30 patients after treatment for stage IV HNSCC in which adjuvant "chemopreventive" *cis*-retinoic acid and interferon were administered for 6 months.[330] The dose of *cis*-retinoic acid was 0.5 mg/kg per day given orally, and the dose of interferon was 3 million IU per week given subcutaneously. Sixteen patients remained disease free 1 year after definitive treatment. Associated side effects were weight loss, flushing, cachexia, worsening xerostomia, and dysphagia from *cis*-retinoic acid. Interferon side effects were reported as pyrexia and hematologic changes.

Based on the preceding data, a phase II study was conducted in this country using *cis*-retinoic acid, alpha-tocopherol, and interferon as adjuvant therapy in patients receiving definitive treatment for locally advanced HNSCC.[331] Three million units of interferon were given subcutaneously three times weekly with alpha-tocopherol at 1200 IU per day orally and *cis*-retinoic acid at 50 mg/m^2 per day orally for 12 months. Forty-five patients were enrolled; 38 completed the 1-year trial. On follow-up evaluation at a median of 24 months, the local-regional failure rate was 9%, with 5% failing distantly. Median survival at 2 years was reported as 84%. This adjuvant regimen is being tested at the phase III level.

Celecoxib is a novel compound that specifically inhibits the inducible form of the enzyme cyclooxygenase (COX-2) (prostaglandin G/H synthase). Celecoxib is an oral anti-inflammatory agent indicated for the treatment of rheumatoid arthritis and osteoarthritis. Nonsteroidal anti-inflammatory drugs (NSAIDs) and related drugs such as COX-2 inhibitors are attractive candidates for prevention based on recent epidemiologic and case-control studies suggesting that the risk of several malignancies such as colon, esophagus, gastric, and bladder is reduced in chronic NSAID users.[332–336] Many tumors, both human and animal, express elevated levels of COX-2 compared with normal tissue. [337,338] This elevation also is noted in premalignant lesions.[339] In the head and neck area, COX-2 overexpression is seen in oral leukoplakia as well as in squamous cell carcinomas. Increased levels of COX-2 can contribute to carcinogenesis by modulating xenobiotic metabolism, apoptosis, immune surveillance, and angiogenesis. In animal models, selective COX-2 inhibitors suppress the formation of tumors, including tongue cancer. Selective COX-2 inhibitors also can suppress the growth and metastasis of established tumors and enhance the anticancer activity of both radiation and chemotherapy agents. Celecoxib is now being evaluated for efficacy and safety as an adjunct in the prevention of cancer and the prevention of recurrence and metastasis after therapy. Thus, COX-2 inhibition may be a promising strategy to prevent and treat HNSCC.

Targeted Therapy and Novel Approaches

Novel biologic agents have been developed to target multiple specific regions of cancer cells. Protein tyrosine kinases are major components of cell signaling pathways. Various subfamilies of these kinases include receptors for the epidermal growth factor (EGFRs), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), fibroblast growth factor, and hepatocyte growth factor. EGFR is one of four receptors involved in cellular proliferation, differentiation, and survival and is widely expressed in many malignant tissues. EGFR inhibitors such as anti-EGFR monoclonal antibodies, tyrosine kinase inhibitors, ligand conjugates, and antisense oligonucleotides have received significant attention in patients with HNSCC, because the EGFR commonly is overexpressed in 80% to 90% of patients.

EPIDERMAL GROWTH FACTOR RECEPTOR. EGFR–erb-B1 is part of the erb-B family of receptor tyrosine kinases, which includes erb-B2/Her2/neu, erb-B3/Her3, and erb-B4/Her4.[340,341] EGFR is composed of three domains: an extracellular ligand-binding domain, a transmembrane lipophilic region, and an intracellular protein tyrosine kinase domain.[342,343] Endogenous ligands to EGFR include EGF, TGF-α, and heparin-binding EGF. When activated, phosphorylation of the intracellular tyrosine residues results in a cascade of protein phosporylations, resulting in turn in the activation of various downstream signal transduction pathways, including ras/MAP kinase, phosphatidylinositol-3 kinase, and STAT-3. The signal transduction pathway can lead to cell proliferation, tumor growth, and progression of invasion and metastasis signals.[344,345] Based on its overexpression in many cell types (particularly HNSCC cell lines) and the fact that EGFR-based signals can mediate resistance to chemotherapy and radiotherapy, it has been hypothesized that inhibition of EGFR may result in a synergistic antitumor effect.

Numerous EGFR inhibitors have been evaluated, including anti-EGFR monoclonal antibodies, tyrosine kinase inhibitors, ligand conjugates, immunoconjugates, and antisense oligonucleotides. Small molecules such as the tyrosine kinase inhibitors target intracellular tyrosine kinase signaling and inhibit EGFR; antibodies are more directed at the extracellular domain.

IMC-C225 (ImClone Systems, Somerville, New Jersey) is a monoclonal antibody targeting the EGFR and has been studied in several tumor types. In vitro, this antibody appears to enhance the antitumor activity of chemotherapy such as cisplatin (CDDP) and doxorubicin as well as the radiosensitivity of HNSCC cell lines.[346] Similar in vitro data have shown C225 to enhance radiosensitivity.[347,348]

Recent evidence now supports a role for EGFR to mediate a cytoprotective stress response to ionizing radiation. Therapeutically relevant doses of ionizing radiation have been demonstrated to increase expression of EGFR[349] and cytosolic release of TGF-μ from its membrane-bound form,[350] modulate an activated EGFR autophosphorylation profile,[350–353] with increased mitogenic signals involving the MAPK pathway with cellular proliferation,[352,354] and protect from radiation-induced cell death.[350] In a series of experiments with the radioresistant vulva squamous carcinoma cell line A431, inhibition of EGFR with the tyrosine kinase inhibitor tyrphostin AG1478 was associated with reduced MAPK activation and reduced EGFR-mediated tumor cell proliferation.[352] When these findings are taken collectively, it is intriguing to postulate that such a response may serve to mediate the clinical phenomenon of accelerated tumor repopulation during radiotherapy for HNSCC.[152] This hypothesis may be particularly relevant in HNSCC in light of the significant body of clinical data supporting the notion of tumor clonogen repopulation contributing to radiation failure.[179,238]

Early phase I trials of C225 alone and in combination with CDDP were reported. Fifty-two patients were initially treated with dose-escalation of C225 as well as CDDP weekly.[355] C225 was dose escalated to 200 to 400 mg/m^2, but CDDP dosing was found to be optimal only at 60 mg/m^2, owing to toxicity at higher doses. One patient experienced a humoral response. Toxic manifestations included acneiform rashes, gastrointestinal distress, seborrheic dermatitis, flushing, asthenia, and transaminitis. This led to subsequent studies in the metastatic setting.

In a phase I trial, 12 patients with metastatic HNSCC with high levels of EGFR expression were given three doses of C225 with 100 mg/m^2 of CDDP every 3 weeks.[356] Weekly maintenance of C225 was given at 250 mg/m^2. Responses were seen in 67% of the 12 patients enrolled, with minimum toxicity. The specifics for a follow-up study of the use of C225 plus CDDP in patients with recurrent HNSCC were presented at the American Association for Cancer Research (AACR) in 2001. Sixty-three patients were evaluated and given a loading dose of 400 mg/m^2 of C225, followed by weekly maintenance at 250 mg/m^2, plus CDDP at 75 or 100 mg/m^2. The overall response was 24%. Use of C225 by itself has produced response rates of 10%, which is encouraging. ECOG recently compared single-dose CDDP and CDDP plus C225 in a doubleblind randomized trial in patients with previously untreated recurrent or metastatic HNSCC, with 35% to 40% stable disease in both treatment groups.[357]

Anti-EGFR antibodies have radiosensitization properties in cell cultures and preclinical animal studies. A phase I study with C225 and radiation in 16 patients with locally advanced disease (13 with stage IV) was recently reported with an overall clinical response rate of 100% and a complete response rate of 87%.[358] The impressive complete response rate has been interpreted to be consistent with radiosensitization. A multi-institutional phase III trial comparing radiation therapy alone with radiation therapy plus C225 in locally advanced HNSCC has recently closed to accrual with results currently being analyzed.

TYROSINE KINASE INHIBITORS. ZD1839 (Iressa, AstraZeneca Pharmaceuticals LP, Wilmington, Delaware) is a selective EGFR tyrosine kinase inhibitor, recently approved by the U.S. Food and Drug Administration (FDA) as palliative therapy in non-small-cell lung cancer. Preclinically, ZD1839 potentiates the antitumor and apoptotic effects of several cytotoxic agents, including CDDP and taxanes.[359,360] In combination with radiation, ZD1839 shows dose-dependent inhibition of cellular proliferation in human SCC cell lines. ZD1839 also can inhibit tumor angiogenesis in tumor zenograft models in vivo.[348]

Four phase I trials using ZD1839 as monotherapy mostly in patients with prostate, lung, colorectal, ovarian, and head and neck cancer have reported modest toxicity such as diarrhea, nausea and vomiting, transient transaminitis, and rash. Most patients had been heavily pretreated and most were lung cancer patients. The results of the non-small-cell lung cancer monotherapy trial were presented. The overall response rate in 208 patients was 53% and the median progression-free survival rate was 84 days.[361] This study, as well as several other trials, led to recent FDA approval.

The role of ZD1839 as a radiosensitizer is the subject of an ongoing NCI-sponsored multi-institutional trial in combination with a delayed concomitant boost accelerated radiotherapy schedule and with concurrent chemoradiotherapy. The chemoradiotherapy incorporates a weekly cisplatin schedule. The use of oral tyrosine kinase inhibitors may be particularly attractive for its flexible daily dosing schedules. It is hypothesized that this may permit continued arrest of tumor repopulation during any unplanned radiotherapy treatment interruptions. Accordingly, this clinical trial seeks to continue daily dosing of ZD1839 during these unplanned interruptions and during the weekends in light of the provocative positive results with an accelerated schedule that delivered radiotherapy through the weekends.[238]

A phase II trial in recurrent or metastatic squamous cell carcinoma of the head and neck also was recently published.[362] Fifty-two patients who previously received treatment with only one other strategy were allowed to enroll. Patients were given the higher dose of 500 mg per day orally; 250 mg per day is the approved dose based on phase I data in non-small-cell lung cancer. Patients were able to tolerate this drug through feeding tubes. The observed response rate was 10.6%. Median time to progression and overall survival time were 3.4 and 8.1 months, respectively.

OSI-774 (Genetech, San Francisco, California) also is an orally active quinazoline and potent selective inhibitor of EGFR tyrosine kinase. This results in cell cycle arrest at G_1. Phase I studies with OSI-774 were well tolerated, again with toxicities including diarrhea, skin rash, and gastrointestinal upset. OSI-774 in a dose of 150 mg per day has been tested in patients with HNSCC refractory to chemotherapy. In a phase II trial in 114 patients, 13% of patients had a partial response and 29% exhibited disease stabilization.[363] Toxicities were as previously noted and included acneiform rash, diarrhea, nausea, vomiting, headache, and fatigue.

RAS INHIBITORS. It has been suggested that oral cavity cancers have a 27% mutation rate in H-*ras*.[364] Farnesyl transferase inhibitors (FTIs) inhibit a critical enzymatic step in the post-translational modification of ras, allowing the constitutive expression of mutated *ras* genes. Several FTIs are available in the study setting: R115777 (Janssen Pharmaceutica); BMS214662 (Bristol-Meyers Squibb); and SCH66336 (Schering Plough, Kenilworth, New Jersey).

R115777 is a nonpeptidomimetic orally available FTI. Clinically, it can be used alone or in combination with chemotherapy. Toxicity has been minimal. Reversible myelosuppression is the most common dose-limiting toxicity, as well as fatigue, nausea, renal dysfunction, and peripheral neuropathy. A phase I trial using R115777 with irinotecan was reported.[365] Another trial with docetaxel is being conducted, as is a third with gemcitibine.[366,367]

BMS214662 has preferential cytotoxicity against nonproliferating cells. Combination chemotherapy from preclinical human colon cancer cell lines has exhibited synergy with paclitaxel, irinotecan, gemcitabine, and an epothilone analog, BMS247550.[368] Phase I studies are ongoing in advanced solid tumors, including using this drug with CDDP at 75 mg/m^2 every 3 weeks.

p53 TARGETS. As discussed elsewhere in this chapter, p53 mutations occur in 45% to 70% of patients with HNSCC and are associated with continual tobacco and alcohol use.[29,30] p53 is a multifunctional protein that can be induced by DNA damage and plays a significant role in the detection and repair of damaged DNA. P53 can induce apoptosis in severely damaged cells and has been associated with both carcinogenesis and poor prognosis in many cancers, including HNSCC.

ONYX-015 is an E1B-55kD gene-deleted replication-selective adenovirus that replicates and causes cytopathogenicity in certain cancer cell lines.[369,370] Selective intratumoral replication and tumor-selective tissue destruction of ONYX-015 have been demonstrated in phase I and II trials in patients with refractory or recurrent HNSCC.[371,372] Clinical benefit was seen in 15% of patients. A phase II multicenter trial of intratumoral ONYX-015 in combination with CDDP and 5-fluorouracil in patients with recurrent HNSCC was reported.[373] Forty patients received injections, 30 for 5 consecutive days and 10 twice daily for 2 weeks. Responses and stable disease were noted in both groups. Pain was noteworthy in the twice-daily injection group, but otherwise this was well tolerated.

Thus, novel modalities involving molecular targets are actively being investigated. Cytotoxic agents have limited efficacy as demonstrated throughout many sections of this chapter, so targeted therapies may improve treatment in the setting of recurrent and metastatic disease and, eventually, for definitive treatments.

Site-Specific Treatment Considerations

Nasopharynx

The nasopharynx is a cuboidal structure bounded by the sphenoid bone superiorly, the posterior choanae anteriorly, the clivus and the first two cervical vertebrae posteriorly, and the soft palate inferiorly. The eustachian tube enters through the lateral wall, with the posterior portion of the tube being cartilaginous and forming the portion of the lateral nasopharyngeal wall known as the torus tubarus. Just posterior to this is the fossa of Rosenmuller.

The vast majority of malignancies in the nasopharynx are epithelial neoplasms and arise from the lateral wall, particularly from the fossa of Rosenmuller. Local spread may include extension anteriorly through the submucosa including the nasal cavity, laterally and superiorly through the foramen lacerum with cranial nerve involvement, and inferiorly into the oropharynx. Extension into the cavernous sinus commonly results in a sixth cranial nerve palsy. Two cranial nerve syndromes have been characterized. The *petrosphenoidal syndrome* describes involvement of the third, fourth, fifth, and sixth cranial nerves. The *retroparotidian syndrome* describes involvement of cranial nerves IX, X, XI, and XII. Metastatic spread to the adjacent upper cervical lymph nodes and to the retropharyngeal lymph nodes that are located in the retropharyngeal space that lies between the lateral border of the posterior nasopharyngeal wall and medial

to the carotid artery may extend inferiorly to the level of the hyoid bone.

Both the tumor stage and the histologic grade of epithelial malignancies are prognostic. The World Health Organization (WHO) identifies three histopathologic types: type 1, differentiated; type 2, nondifferentiated; and type 3, undifferentiated or lymphoepithelial, which highlights the presence of numerous infiltrating lymphocytes. The presence of keratin is an adverse prognostic feature for local control and overall survival. Other malignancies may include lymphoma, plasmacytomas, melanomas, and, in the pediatric population, juvenile angiofibromas and rhabdomyosarcomas. Approximately 60% to 90% of patients with nasopharyngeal cancer present with palpable adenopathy and up to 50% of patients with involved nodes have bilateral disease.[374–376] Patients with adenopathy at the mastoid tip require exclusion of a malignancy in the nasopharynx due to the characteristic lymphatic drainage pattern from the retropharyngeal space. Staging follows the sixth edition of the AJCC TNM criteria. No modifications have been recommended, including subdivision of the T4 stage that is new to this sixth edition.[137] Both MRI and CT scans are complementary in this tumor site, with the former favored in most cases and the latter beneficial when bone invasion or destruction has occurred.

Because of the anatomic location of the nasopharynx, surgical resection typically has not been recommended owing to the inherent surgical complication rates with surgery in this area, including the inability to achieve tumor-free margins. Accordingly, radiation therapy is the treatment of choice. Fortunately, NPCs are both sensitive and responsive to radiotherapy and chemotherapy, the two principal treatment modalities that are used. For early-stage disease, radiotherapy alone may be used, with excellent results reported, with 3-year overall survival rates ranging from 70% to 100%[374,377–379] and 65% to 100%[374,377–379] for stage I and II disease, respectively, based on the AJCC 1997 staging system. Typical local control rates to current treatments have been summarized by Lee[380]: approximately 80% (72% to 90%) for T1 and approximately 70% (5% to 100%) for T2. Even with locally confined disease (T1), generous initial radiotherapy margins are advised.

Unfortunately, a majority of patients present with locally advanced disease. Local control for T3–4 disease may be expected to be approximately 50% (39% to 72%).[380] For locally advanced-stage III and IV disease, concurrent chemoradiotherapy has emerged as the standard treatment option following from the results of the Intergroup 0099 (IG0099) study reported by al-Sarraf and coworkers.[381] These investigators reported the results for 147 evaluable patients of 193 registered randomized to receive radiotherapy alone or radiotherapy with concomitant cisplatin (100 mg/m^2 given intravenously on days 1, 22, and 43) followed by adjuvant chemotherapy with cisplatin 80 mg/m^2 on day 1 and fluorouracil 1000 mg/m^2 per day on days 1 to 4, administered every 4 weeks for 3 courses. An improvement in the 3-year progression-free survival rate (69% versus 24%; $P < 0.001$) and overall survival (76% versus 46%; $P = 0.001$) was observed on interim analysis, prompting premature study closure. These results are not without debate, however.[380]

Several investigators have questioned whether this positive study may have resulted from inferior outcomes in the control arm rather than a therapeutic effect. Chow and coworkers from the Princess Margaret Hospital recently published the results of a large institutional series using radiotherapy alone administered in a homogeneous manner to 172 patients with advanced-stage disease, demonstrating 5-year disease-free survival and overall survival rates of 48% and 62%, respectively.[382] Although these investigators acknowledge that direct comparisons with the control arm of IG0099 have limited validity, these observations made during a similar time period as the IG0099 provide a context within which the positive results of the IG0099 should be interpreted. In a similar report by Cooper and colleagues, 86 patients with locally advanced disease treated with radiotherapy alone had a 3-year actuarial disease-free survival and overall survival rates of 43% and 61%, respectively.[383] These investigators also observed that in 35 patients undergoing the IG0099 protocol, the projected 3-year disease-free survival and overall survival rates were 63% and 93%, respectively, suggesting benefit. Recently, Cheng and colleagues reported the results for 107 patients with NPC treated with concurrent 5-fluorouracil and cisplatin (weeks 1 and 6) and radiotherapy followed by two cycles of adjuvant 5-fluorouracil and cisplatin. The 5-year overall survival rate, disease-free survival rate, and local-regional control rate were 84.1%, 74.4%, and 89.8%, respectively. The 3-year overall survival rates for stage II, III, and IV were 100%, 92.8%, and 69.4% ($P = 0.0002$), and the 3-year disease-free survival rates were 96.9%, 87.7%, and 51.9% ($P = 0.0001$). Although a confirmatory randomized trial is noted to be under way,[384] the current consensus opinion continues to recommend concurrent chemoradiotherapy. These results further suggest that Asian patients also may benefit from concurrent chemoradiotherapy, which has been questioned owing to geographic differences in the histologic subtype between North America and Asia. A pilot trial of a modified schedule of the IG0099 regimen (reduced cisplatin dose) has been demonstrated to be safe and has given rise to a phase III trial to confirm the generalizability of these results to the Asian population.[384]

With concurrent chemoradiotherapy, toxicities clearly are increased. In addition, the late toxic effects with concurrent chemoradiotherapy have not been well described. Increased acute toxic effects include not only mucosal toxicity, further compounded by the large volume of normal mucosa that is irradiated, but also the asthenia and emetogenic side effects of concurrent high-dose cisplatin. As Cooper describes,[383] the observations by Cheng and colleagues may suggest that other alternative regimens may be equally if not more effective. The impact of these toxicities is important to consider in patient management, because treatment interruptions during radiotherapy also have been demonstrated to result in inferior local-regional control and disease-free survival rates.[385] These investigators estimated that local-regional relapses increased 3.3% per day of treatment interruption. The timing of the interruption, including interruptions early in the course of treatment, appeared to be equally detrimental. Although it is unclear if NPC tumor kinetics may be different with concurrent administration of chemotherapy, close attention to the toxicities of treatment and causes for interruption during a course of radiotherapy may be prudent.

One attractive strategy to minimize toxicities associated with concurrent chemoradiotherapy has been to employ lower but more frequent doses of chemotherapy. Chan and colleagues recently reported the results of a randomized trial of concurrent weekly cisplatin (40 mg/m^2) with daily fractionated radiotherapy in 350 patients.[386] Although no improvement was observed overall for the primary endpoint of progression-free survival, subgroup analysis demonstrated benefit in Ho's T3 stage owing to an improved time to first distant failure. The treatment was well tolerated. The results of a second randomized trial of concurrent 5-fluorouracil and cisplatin, however, showed a significant improvement in progression-free survival.[387]

Despite the improved outcome that appears to have been realized with concurrent chemoradiotherapy for locally advanced NPC, a proportion of patients may continue to have persistent disease that is slow to respond. The therapeutic options recommended have been further irradiation and observation. A limited number of studies have reported on the role of an implant in patients with persistent disease after standard therapy.[388–393] These studies have suggested that further irradiation in early-stage disease that is amenable to intracavitary and interstitial techniques may result in local control rates comparable to those achieved in patients demonstrating a prompt complete response.[389] Hence, dose escalation may be adequate in compensating for tumors demonstrating a low radioresponsiveness. The optimal dose schedule remains to be determined, with both 60-Gy LDR and 22.5- to 25-Gy HDR schedules reported. Stereotactic radiosurgery has been used with preliminary data, suggesting that up to 70% of

patients with organ-confined recurrences may achieve local control for up to 2 years.[394] Late toxicity does not appear to be increased. In light of the poorer local control rates and survival rates in patients managed for local recurrences, a brachytherapy implant or stereotactic radiosurgery may be considered in the management of patients demonstrating persistent disease.

Neck control for NPC is unique for its increased sensitivity to radiotherapy compared with the typical HNSCC.[395] In the clinically negative neck, elective irradiation is recommended owing to the high probability of subclinical nodal metastases, with a risk of 40% neck relapse if untreated, which is associated with a significantly higher incidence of distant failure (21% versus 6%) despite successful nodal salvage.[396,397] With appropriate doses of radiation (50 Gy), the probability of relapse is less than 5%.[398] In the clinically positive neck, doses of 60 Gy or greater are typically recommended; average regional control rates of 90% (range, 86% to 96%) and 75% (range, 71% to 87%) might be expected for neck nodes 3 cm or less and greater than 6 cm, respectively.[380] Accordingly, a planned neck dissection typically is not recommended but may be appropriate. When a residual abnormality remains, a neck dissection typically is recommended. This approach may be complicated, however, by the recognition that in some NPC lesions, gross disease response can be slow at both the primary site and in the neck. As well, the integration of a neck dissection can create conflicts with regard to the prompt initiation of adjuvant chemotherapy. In light of the association between local-regional relapses and the subsequent risk of distant metastases,[397] a neck dissection continues to be a prudent recommendation at this time.

Various strategies have been used in attempts to improve upon the survival rates, particularly for locally advanced disease. The first is to optimize local-regional control, not only because this is a major pattern of relapse in this group of patients but also for the potential impact on the risk of distant metastases. The second is the integration of various chemotherapy agents with definitive radiotherapy. Because a dose-response relationship appears to exist for local control,[399] and the overall treatment time[385] also appears to have an adverse impact on treatment outcome, several institutions have reported their results using altered fractionation for locally advanced NPC with[400] or without concurrent chemotherapy.[401] Jian and colleagues used the same chemotherapy regimen as that described by Cheng and colleagues, with cisplatin and 5-fluorouracil on weeks 1 and 6, with concurrent hyperfractionated radiotherapy to a total dose of 74.4 Gy, in 48 patients. With a median follow-up period of 57 months, 3-year local-regional control rate was 93%, the disease-free survival rate was 71%, and the overall survival rate was 72%. In particular, patients with T4 disease had a 3-year local-regional control rate of 91%, disease-free survival of 62%, and an overall survival of 63%. The major acute toxicity was grade 3 mucositis in 73% and grade 2 weight loss in 31% of patients. These investigators concluded that the treatment was well tolerated, with 88% of patients completing their radiation treatment within 8 weeks.[400] These promising results require further validation of the results and definition of the increased toxicity risks, particularly in light of the unacceptable toxicities observed in other non-nasopharyngeal concurrent chemoradiotherapy series employing altered fractionation.[326]

Various randomized trials incorporating various sequences of chemotherapy and radiotherapy have been reported. To date, a number of randomized trials have failed to demonstrate a benefit with either neoadjuvant[402–406] or adjuvant chemotherapy.[404,407,408] These results are consistent with a recent large patient-based meta-analysis.[181] Accordingly, the use of adjuvant chemotherapy, particularly with definitive chemoradiotherapy, should be judiciously applied.

Because NPCs are radiosensitive, locally recurrent carcinomas may be amenable to re-irradiation. The risk of late complications, including soft tissue and brain necrosis and neuropathies, is highly dose- and volume-dependent with re-irradiation, so the general strategy has been to incorporate conformal radiotherapy techniques for the boost component of the re-irradiation regimen. As with treatment for persistent disease, this may take the form of either brachytherapy or stereotactic radiosurgery boost.[409] In a series of over 891 patients undergoing re-irradiation, the extent of the recurrence was prognostic. Overall, approximately 30% achieved local disease control with local control best seen when a repeat radiation dose of 60 Gy or greater was delivered.[410] The selection of small EBRT fraction size and the use of a brachytherapy implant was associated with a reduced risk of late complications. Several other institutional series have reported sustained local control rates of 20% to 60%, with the variability due to the extent of initial disease presentation and at recurrence and the dose of re-irradiation.[388,390–392] In selected series treating only disease confined to the nasopharynx mucosa amenable to management by either intracavitary or interstitial implant, sustained local control rates of 50 to 60% may be realized. These series also have demonstrated, however, a significant risk of developing late radiation-related complications including soft tissue and bone necrosis, trismus, fistula formation, and neurologic complications such as radiation myelitis and temporal lobe necrosis.

Salvage surgery is now being performed in Taiwan for NPC in selected patients. Large prospective studies are needed to determine efficacy, but small retrospective studies have demonstrated feasibility and success in local control.[411,412] Hsu and colleagues studied 60 patients who underwent salvage surgery, and showed that the results of surgical resection in terms of local control and overall survival were slightly better than those in patients undergoing high-dose re-irradiation for local relapse, with fewer late complications.[412] These investigators favored salvage surgery for rT1–2 and limited rT3 disease, owing to the lower complication rate. This therapeutic option may be considered for selected lesions and in appropriate centers with expertise in this technique, as its relative efficacy to high-dose re-irradiation remains to be defined.

Locally recurrent and metastatic nasopharyngeal cancers generally remain chemosensitive. Many patients have been previously treated with combined modality strategies involving a platinum agent and 5-fluorouracil. Several phase II trials have evaluated carboplatin and paclitaxel in this setting. Carboplatin at an area under the curve (AUC) value of 7 with 3-hour infusional paclitaxel at 200 mg/m^2 revealed an overall response rate of 57% in the metastatic setting.[413] Another phase II study investigated carboplatin at AUC 6 with 135 mg/m^2 paclitaxel infused over over 3 hours, with an overall response rate of 59%.[414] Two other phase II studies, again using similar dosing schedules of carboplatin AUC 6 or 5.5 with 175 mg/m^2 paclitaxel, demonstrated 75% and 25% response rates, with median overall survival rates of 12 and 9.5 months, respectively.[415,416]

Paranasal Sinus and Nose

Malignant tumors of the sinonasal tract are relatively rare, constituting approximately 3% of upper respiratory tract cancers. Accordingly, the scientific literature is limited to multiple small retrospective reports describing the treatment and outcome of these patients. This has limited progress in defining the optimal management for these malignancies. Although squamous cell carcinoma is the most common, several other types of epithelial tumors are less commonly found, including melanoma, adenocarcinoma, adenoid cystic carcinoma, and esthesioneuroblastoma.[417] Nonepithelial malignancies arising in the sinonasal tract include sarcomas and lymphoma.

Among the different subsites within the paranasal sinuses, squamous cell carcinomas occur most commonly in the maxillary sinus.[418] The second most common location is the nasal cavity. The ethmoid sinus is more frequently the site of adenocarcinoma or esthesioneuroblastoma. Cancer arises rarely in the frontal and sphenoid sinuses.[418] The prognosis with these lesions is based on staging classification, as well as on their relationship to Ohngren's line. This theoretical plane extends from the medial canthus of the eye to the angle of the mandible. Tumors anteromedial to this plane are thought to have a considerably better prognosis. Staging follows the sixth-edition AJCC

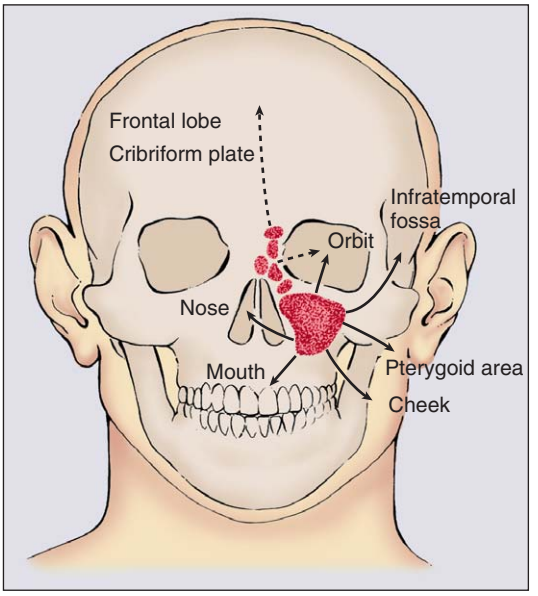

Figure 72-17 • Routes of spread of cancer of the paranasal sinuses. *Solid arrows*, maxillary sinus cancer; *dashed arrows*, ethmoid sinus cancer.

staging criteria. The nasoethmoid complex was added as a tumor site with subdivision of the T4 stage for both maxillary sinus and nasal cavity and ethmoid sinus.[137]

Most malignancies are advanced at presentation and commonly involve one or more adjacent structures (Fig. 72-17). Orbital invasion often occurs early with cancers of the maxilla and of the ethmoid sinuses, whereas it often is a late event for nasal cavity tumors. Malignancies beginning in the anterolateral infrastructure of the maxilla often erode through the inferolateral wall and extend into the oral cavity, with involvement of the maxillary gingival or the adjacent gingivobuccal sulcus. In general, the risk of cervical nodal metastases is low unless the tumor has progressed to involve mucosal surfaces with abundant lymphatics such as the oral cavity.

Management of paranasal sinus malignancies is primarily surgical, with adjunctive irradiation and possibly chemotherapy for advanced lesions.[419,420] For maxillary sinus tumors, a partial or total maxillectomy is required to excise the tumor with disease-free margins, depending on its location. The maxilla can be accessed through a variety of approaches. For smaller, medially based tumors, a medial maxillectomy can be performed using a mid-face degloving approach, in which incisions are made under the lip. For larger lesions, well-placed skin incisions in the nasal crease and upper lip often are required for access. Reconstruction in these cases usually involves a skin graft or acellular dermal graft to reline the mucosal surface, as well as a dental appliance to recreate the hard palate.

Tumors that involve the ethmoid sinuses frequently require a craniofacial resection for surgical access because of the proximity to the skull base. This procedure requires not only an anterior approach to the sphenoethmoid area but also a craniotomy by a skilled neurosurgeon to address the skull base and dura. Orbital exenteration must be considered if the tumor involves the periorbital fat or extraocular muscles. The surgical indications for this vary, however, with an inclination toward eye conservation and an evolving consensus that bone erosion is not an absolute indication. The decision is an intraoperative decision.

When surgical resection is not feasible, either medically or surgically, definitive radiotherapy may be used. It also has been favored as an organ preservation strategy to avoid an orbital exenteration. In this capacity, it may be used definitively, reserving surgery for salvage,[421] or as preoperative radiation as a strategy to downstage the tumor. In view of the proximity of these cancers to many critical normal structures, new radiotherapy techniques including IMRT, stereotactic radiosurgery, or fractionated stereotactic radiotherapy are recommended because they are likely to improve the therapeutic ratio. These techniques are an important consideration in light of evidence suggesting a potential dose-response relationship, with doses greater than 65 Gy recommended.[422] Other technical considerations include the use of computer image fusion software that can permit the use of MRI and the superiority of delineating soft tissue disease during the radiotherapy treatment planning process. Although the current literature does not necessarily support the potential incremental therapeutic efficacy, this is due to the relative rarity of this disease and not to the absence of any effect. As well, the value of concurrent chemotherapy as a radiosensitizer, including early interest in the use of intra-arterial chemotherapy, remains to be established.[423] The value of elective management of the neck remains unclear. Because this often increases the treatment morbidity, it may be omitted. Where considered, most nodal metastases occur in the level I and II regions.

The overall 5-year survival rate for patients with maxillary sinus cancer is 30% to 50%.[422,424,425] Cervical metastases occur in less than 10% of maxillary sinus cancers.[426] Therefore, a prophylactic neck dissection is not indicated in the N0 neck. Cervical metastases are associated with a very poor prognosis, with 5-year survival rates less than 10%.

Oral Cavity

The oral cavity (Fig. 72-18) is composed of the lip, anterior two thirds of the tongue (oral tongue), floor of mouth, buccal mucosa, gingiva, hard palate, and retromolar trigone. The floor of the mouth is bounded by the lower alveolar ridge anteriorly and laterally and the ventral tongue surface and anterior tonsillar pillar posteriorly. The oral tongue lies anterior to the circumvallate papillae. The buccal mucosa overlies the buccinator muscle, is bounded superiorly and inferiorly by the gingiva, and extends posteriorly to the retromolar trigone. The gingiva is the soft tissue overlying the alveolar ridges of the mandible and maxilla. The hard and soft palates form the roof of the mouth. The retromolar trigone mucosa overlies the mandibular ramus and is bounded anteriorly by the buccal mucosa and posteriorly by the anterior tonsillar pillar. As elsewhere in the head and neck, squamous cell cancer is the most common type, except in the hard palate, where most tumors originate in the minor salivary glands. For staging of cancers of the oral cavity, the AJCC classification system is used (Table 72-8). The principle management approach is surgical resection followed by postoperative radiotherapy. Carcinomas of the oral cavity have an adverse prognosis and often require postoperative radiotherapy.[162]

LIP. Surgical management of squamous cell carcinoma of the lip is complex, due to the challenges in reconstruction of this unique part of the body. Although secondary to the complete resection of the lesion, the preservation of speech, oral competence, and cosmesis must be considered. Surgical therapy is considered to be equal in effectiveness to irradiation for the treatment of early, T1, or T2 lesions.[427–430] Small lesions of the lip can be managed surgically by means of wide local excision and primary closure. The morbidity associated with this approach often is less than would be experienced with irradiation. With larger lesions that require resection of more than one half of the lip, local flap reconstruction will be necessary. These flaps involve the mobilization of remaining lip tissue, or even the use of tissue from the opposite lip.

Metatases from lip carcinoma is relatively rare, with the incidence reported at 12% or less.[431,432] In the N0 neck, occult metastases are estimated to occur in 5% to 10% of cases. Therefore, elective neck dissection is not routinely performed in the N0 neck. Neck dissections are generally performed when cervical metastases are clinically or radiographically apparent.

Table 72-8 American Joint Committee on Cancer Tumor Classification System for Staging Cancer of the Oral Cavity

Stage	Characteristics
Tis	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
	Tumor more than 4 cm in greatest dimension
T3	Tumor invades adjacent structures (e.g., through cortical bone, into deep [extrinsic] muscle of tongue, maxillary sinus, skin)

From the American Joint Committee on Cancer: Manual on Staging of Cancer, 4th ed. Philadelphia, JB Lippincott, 1992, with permission.

Predictably, the results of these procedures depend on the extent of disease. The 5-year survival rate for T1 and T2 cancers of the lip is greater than 90%, whether treated with surgery or irradiation.[428] For larger cancers, especially those that have metastasized, the cure rates are in the range of 40% to 50%.[428,433] Thus, for stage III and IV cancers, a combined approach with surgery and postoperative radiation is indicated. For smaller lesions, surgery and irradiation are equally effective; however, surgery often is recommended because of shorter treatment time and excellent rehabilitation with minimal morbidity.

BUCCAL MUCOSA. Malignant tumors arising from the buccal mucosa are rare, and early lesions are treated primarily with surgery. Although surgical management of T1 buccal mucosa lesions can be managed with transoral wide local excision, larger tumors may require more complex resections. Extension to the mandible or maxilla may lead to a partial mandibulectomy or maxillectomy. Reconstructive options for smaller lesions include primary closure, fat grafting, or a split-thickness skin graft. Larger defects would require local mucosal flaps, myocutaneous rotational flaps, or free flaps, depending on the size and extent of the lesion. Neck dissections are indicated only for

clinically positive cervical metastases. The treatment algorithm for carcinoma of the buccal mucosa is similar to that for other sites in the oral cavity, with surgery indicated for early lesions and combined therapy with surgery and irradiation for advanced lesions.

ORAL TONGUE. Oral tongue carcinomas represent approximately 25% of oral cavity carcinomas. These lesions are characterized by early infiltration into the underlying tongue musculature with an early and high risk for regional metastases. Surgical resection has been favored, because EBRT results alone have been disappointing.[434,435] Although it has been shown that irradiation and surgery are equally effective in treating early lesions,[436] a recent review of 332 patients revealed that disease-free survival was better with surgery alone than irradiation alone.[435] In general, surgery is often the treatment of choice for early lesions because of the ease of surgical access, excellent reconstruction options, and quick treatment time. For stage III and IV lesions, a combined treatment approach is favored. For select lesions, various series describe comparable results with the use of EBRT and a brachytherapy implant as definitive therapy.

Surgical management for squamous cell carcinoma of the oral tongue can take a variety of forms depending on the size and location of the lesion. Small T1 or T2 tumors are treated with a partial glossectomy accomplished through a transoral approach. Larger lesions may require a total or near-total glossectomy, often requiring a mandibulotomy or a cervical pull-through procedure. T4 lesions that involve the mandible require composite resection including either a marginal or segmental mandibular resection.

Reconstruction of the surgical defects also depends on their size and location. After resection of smaller lesions, allowing healing through secondary intention may best preserve function. For larger defects resulting from resection of T2 or T3 defects, healing is facilitated by primary closure, or split-thickness skin graft. For near-total or total glossectomy defects, a pedicled myocutaneous flap or free-tissue transfer is needed for reconstruction. For those patients with mandibular involvement, reconstruction options vary with the location of the defect. Mandibular defects that are large and are located near the mandibular symphysis often require vascularized composite free flaps to restore mandibular continuity with acceptable function and cosmesis.

Surgical or radiation treatment of the neck is indicated in most cases of oral tongue squamous cell carcinoma. The rates of occult cervical metastases exceed 30% for lesions T2 and greater.[277,278,433,437,438] Therefore, for the N0 neck, a selective neck dissection is indicated in T2–T4 lesions, or T1 lesions with depth of invasion greater than 3 to 4 mm.[139,438–440] Patients with clinical or radiographic evidence of cervical metastasis may require more radical procedures depending upon the number and size of nodal involvement.

A significant body of literature exists supporting a role for brachytherapy in the management of selected oral tongue carcinomas that tend to be well defined and thus probably less infiltrative. Brachytherapy has been used alone or in combination with EBRT, demonstrating local control efficacy. The largest experience, comprising more than 600 patients, from the Curie Institute reported local control rates of 86%, 78%, and 71% for T1, T2, and T3 lesions, respectively.[277] Early T1 and T2 lesions were treated with temporary interstitial LDR ^{192}Ir implants alone, delivering 70 Gy in 6 to 9 days. Larger T2 and T3 lesions were treated with EBRT (50 to 55 Gy), followed by an implant (20 to 30 Gy). Other investigators have demonstrated comparable results, demonstrating a high rate of local control.[280,296,441–445] Several series reported local control rates of 90% or greater for very selected lesions often amenable to a single-plane implant alone with a lesion thickness of less than 1 cm.[296,441] Mazeron and colleagues reported their series of 121 patients with T1 or T2N0 tumors treated with 60 to 70 Gy by the Paris system.[442] The crude local control rates for T1, T2a (2.1 to 3 cm), and T2b (3.1 to 4 cm) reported were 86%, 89%, and 74%, respectively. The dose prescribed was found to be significantly associated with the risk of local control, with doses less than 65 Gy associated with a fivefold risk of relapse. Selection by the growth pattern has been shown to influence the 5-year local control rates, with 85%, 79%, and 45% reported for superficial, exophytic, and infiltrative lesions, respectively.[445] Implant of the oral tongue has been associated with a 10% to 20% risk of mild to moderate self-limiting soft tissue ulceration and a low risk (less than 10%) of mandibular osteoradionecrosis in experienced hands. Custom lead-embedded mandibular prostheses and spacers are recommended and have been demonstrated to reduce the risk of bone complications.[441] A predicted 5-year probability of osteoradionecrosis of 38% was reduced to 4% with the use of a spacer. When implant brachytherapy is used in combination with EBRT, the overall treatment time and the proportion of dose delivered with the implant may be important.[446]

Several studies suggest that treating selected early-stage T1 and T2 node negative lesions with HDR brachytherapy alone may facilitate treatment delivery.[296,444,447] One promising schedule comes from a small randomized trial of 29 patients comparing LDR brachytherapy (70 Gy over 4 to 9 days) with an HDR schedule (60 Gy in 10 fractions of 6 Gy per fraction delivered twice daily over 6 days) for a selected group of patients with T1 or T2N0 squamous cell carcinoma of the lateral oral tongue.[444] The lesions had a thickness of 10 mm or less, allowing treatment with a single-plane HDR implant with the dose prescribed at 0.5 cm from the reference plane. The 1-year local control rates were 86% and 100% ($P = 0.157$) in the LDR ($N = 15$) and HDR ($N = 14$) groups, respectively. The 2-year local control rate was identical, although the median follow-up period of 24 months (10 to 32 months) limits this observation. One soft tissue ulceration and one bone exposure complication arose in the HDR arm, although a prosthetic spacer was not used in the latter case. Leung and colleagues have reported preliminary results in 8 patients subjected to the same HDR treatment schedule, showing a 100% local control rate with a median follow-up period of 26 months.[447] Alhough these results are promising, the short follow-up coupled with the significant risk of a false-negative error limits any definitive conclusions regarding the generalized application of HDR brachytherapy in place of standard LDR implants for the oral tongue.

In a subset of patients with a close or positive surgical excision margin and no indication for neck irradiation, treatment with a brachytherapy implant alone (^{192}Ir LDR to 60 Gy) has been used. This obviates the risk of further major surgery or EBRT-related toxicities, including xerostomia. A promising mature local control rate of 89% has been observed in a small retrospective series.[263] Similar results have been reported in other studies.[448,449]

FLOOR OF MOUTH. Most floor of mouth cancers are amenable to surgical treatment. T1 and T2 cancers that do not involve the mandible are often treated with wide local excision with 1 cm margins. In contrast to lip cancers, postoperative loss of speech and swallowing function is not as prevalent with small floor of mouth tumors. Therefore, reconstruction can be performed simply with primary closure, secondary intention, skin graft, or an acellular dermis graft. Although not always necessary, it is recommended that the patient undergo preoperative extraction of any decaying teeth close to the lesion.

For those tumors that approach the mandible, a more complex procedure is indicated. Tumors that involve in periosteum of the mandible require a marginal mandibulectomy, where the top half of the involved bone is removed. The overall continuity of the mandible remains intact. T4 tumors that have invaded the cortex of the mandible require a segmental resection of the involved bone. Reconstruction mandates either composite free-flap reconstruction or no reconstruction if the defect is laterally based.

Surgical management of the neck must take into consideration that occult metastases occur frequently in floor of mouth cancers. The incidence is between 23% and 35% of lesions.[277,278,450,451]

Therefore, most investigators recommend treatment of the node-negative neck in all patienrs with T2 or higher-grade lesions.[450–452] For T1 lesions, tumors greater than 2 to 4 mm in thickness have been found to have a high rate of metastasis, and treatment also is recommended.[453,454] If surgical rather than radiation treatment is pursued, a selective neck dissection that includes the first-echelon nodes (level I and upper level II regions of the neck) should be performed. Unless the lesion is clearly unilateral, a bilateral neck dissection is recommended. Treatment of floor of mouth primaries generally calls for a supraomohyoid neck dissection with resection of levels I, II, and III. Level IV should be included in performing a dissection for cancers of the oral tongue and oropharynx.[455] Levels I and V rarely are involved with laryngeal cancer; therefore, a lateral neck dissection of levels II, III, and IV is the procedure of choice for these lesions.[222]

The cure rates with surgical therapy for floor of mouth cancers have been quoted as 95% for stage I cancers and 86% for stage II cancers.[456] Another study in which the vast majority of patients were treated surgically also demonstrated cure rates of 80% or greater for early lesions.[457] The cure rates for similarly staged cancers treated with irradiation are reported by one study as 88% and 47% for T1 and T2 lesions, respectively.[265] Another study showed, however, that surgery and radiation are equally effective in treating early lesions, and that stage III and stage IV lesions should be treated with combined therapy.[458] In general, the early lesions of the floor of mouth are best managed surgically unless a contraindication exists. Combined therapy is necessary for larger lesions.

HARD PALATE. The type of surgical management indicated for lesions originating in the hard palate depends largely on the presence of bone involvement. With those lesions that do not involve the periosteum, the tumor can be excised without the underlying bone with an adequate mucosal margin. Tumors invading the periosteum, however, require full-thickness resection of the involved bone. Larger tumors may require partial or total maxillectomy. Reconstruction usually involves a skin graft and a dental prosthesis for large palatal defects. Neck metastases are rare and should be managed surgically with a neck dissection. The role of primary irradiation is limited in this disease, but postoperative irradiation is indicated for advanced lesions.

Oropharynx

Although radiation therapy plays a large role in the treatment of squamous cell carcinoma of the oropharynx, surgery often is indicated in combination with radiation for larger T3 and T4 lesions.[459] Although site-specific considerations are recognized, certain principles apply to surgery in the oropharynx whether the lesion is in the tonsil, base of tongue, or soft palate. Selected T1 tumors can be approached transorally. A transoral approach, however, may not provide the access necessary to excise larger lesions completely and safely. In these cases, an anterior or lateral mandibulotomy often is used to gain access. Mandibular involvement by oropharyngeal lesions necessitates marginal or segmental mandibular resection. A neck dissection can be performed in continuity with or separately from the primary tumor.

The goal of reconstruction in this region is to minimize the severe disfigurement and functional compromise that may result from oropharyngeal procedures. Reconstruction options for surgical defects of the oropharynx depend on the size and location of the lesion. Defects from small T1 lesions can be repaired via secondary intention, primary closure, or a split-thickness skin graft. Reconstruction options for larger lesions include a skin graft, a tongue flap, a myocutaneous flap, and free-tissue transfer. Reconstruction after segmental mandibular resection preferably includes osseous free-tissue transfer to replace the excised bone. If a marginal or small segmental resection is performed, however, the bone does not need to be replaced. The complications associated with surgical treatment of oropharyngeal tumors are similar to those encountered with the treatment of oral cavity tumors. Because the tongue base is critical to swallowing function, dysphagia and aspiration are frequent complications after tongue base resection; these problems can be managed with aggressive swallowing rehabilitation. Site-specific surgical and nonsurgical considerations within the oropharynx also are recognized.

TONSIL. Although T1 and T2 tonsil lesions generally are best treated with irradiation, large T2, T3 and T4 lesions are often treated with combined therapy. If the mandible is not involved, the procedure of choice is a radical tonsillectomy that includes the tonsil, the tonsillar pillars, and a portion of the underlying muscle. If the mandible is involved, a composite resection including a segmental mandibulectomy is required.

Some authors argue that early tonsil lesions are best treated with surgery. A recently published small study of 18 patients, cited a 5-year survival rate of 92% for surgically treated patients with T1 or T2 cancers of the tonsil.[460] Similar results are found in patients managed with irradiation alone, with less functional morbidity, however.[461,462] In addition, the use of radiotherapy alone for early tonsil lesions allows the retropharyngeal lymph nodes to be included in the treatment plan, particularly for progressively more posterior lesions and those involving the posterior pillar. Although early lesions are best treated with irradiation, advanced-stage III and IV cancers require combined surgical therapy with radiotherapy for best results.[459,463] The efficacy of this approach relative to an increasing role for concurrent chemoradiotherapy in advanced oropharyngeal carcinomas including tonsil carcinomas is unknown. With increasing involvement of the soft palate and of the pharyngeal wall, however, surgical resection becomes less favored (although often preferred owing to concomitant bulky tumor) because of the functional consequences and increased risk of complications, respectively. For more advanced lesions, with increasing posterior disease extension, the risk of parapharyngeal involvement and retropharyngeal lymph node metastases increases, necessitating radiotherapy as either definitive therapy or in the postoperative setting. When surgical resection is not indicated, concurrent chemoradiotherapy is emerging as a favored definitive strategy on the basis of recent randomized trials and meta-analyses.[181] This treatment approach is limited by the uncertainty with regard to the optimal chemoradiotherapy schedule and the potential for these results not to be generalizable to the tonsil site specifically. It also is recognized that salvage surgery, when chemoradiotherapy is used for potential organ preservation indications, is limited by the proportion of patients with recurrences able to undergo salvage surgery and then the proportion of those in whom salvage surgery can be expected to be successful.

Despite these concerns, several prospective studies have demonstrated high local-regional control rates (80% to 90%) when oropharyngeal and tonsil sites were the predominant tumor sites. It is not clear whether these results are superior to local-regional control rates that have been reported for treatment with radiotherapy alone. Several institutional series have outlined the results that may be expected with fractionated radiotherapy alone. It is recognized, however, that the fractionation schedule may in turn influence the results.

To address these concerns, Withers and colleagues reported the results of a remarkable collaborative retrospective multi-institutional study of carcinoma of the tonsil fossa treated with radiotherapy alone as part of the Patterns of Fractionation Study.[153] A total of 676 patients from 9 participating institutions provided sufficient treatment variability in fractionation schedules resulting from institutional treatment policies to permit study. Several noteworthy observations were made. With the exception of T1 disease, decreased local control rates were observed with the presence of clinically evident nodal disease across each T stage. Cox regression modeling demonstrated that T stage, N stage, total dose, and the overall treatment time were independent significant factors. Although the optimal fractionation schedule could not be identified, a nonsignificant reduction in local relapse was observed with altered fractionated

schedules consistent with the observations of RTOG 90–03.[179] Modeling of the relationship between local tumor control and the overall treatment time suggested that an accelerated growth rate may occur at approximately day 30 but did not significantly improve on the basic model of a constant tumor growth rate throughout the treatment duration. Whether or not these tumor kinetics differ with perturbations from the use of concurrent chemotherapy is unclear but should remain respected.

Hence, when radiotherapy is used as definitive therapy alone, an altered fractionation schedule is preferred, with particular attention paid to minimize any treatment interruptions at any time during treatment. Several reports provide a basis for selection of lesions appropriate for homolateral irradiation.[464–466] The advantages of homolateral irradiation include reduced acute toxicities, less risk of treatment interruptions, reduced dose to the contralateral parotid, and less risk of complete xerostomia. O'Sullivan and colleagues reported the results of a large retrospective analysis of data for 228 patients who received daily fractionated radiotherapy alone, with mature follow-up.[464] Based on an institutional policy of homolateral irradiation for lesions that did not cross midline structures, these investigators were able to demonstrate a spectrum of risk of contralateral neck relapses to guide treatment selection. Patients at low risk (less than 5%) for contralateral neck relapse include those with T1 or T2 lateralized lesions with involvement of even the lateral two thirds of the soft palate or lateral one third of the base of the tongue. With involvement of these structures, however, judicious use of ipsilateral irradiation will be required.

SOFT PALATE. Soft palate lesions that are large may require a partial maxillectomy for complete excision. In general, soft palate tumors are amenable to definitive radiotherapy for cure. The fields should cover the draining lymphatics and the retropharyngeal lymph nodes. With this modality, palatal function usually can be preserved. Reconstruction of this defect may include a skin graft along with a prefabricated prosthesis to maintain swallowing function. Irradiation has been shown to be effective in controlling early lesions, whereas combined-modality therapy is needed for stage III and IV lesions.[467–469]

Cervical metastases should be treated with surgery, or irradiation, or both. Neck dissections can be performed before or after radiation therapy. The decision to perform surgery or irradiation first depends on how the primary is to be treated, and on the size and extent of the neck metastasis. If the metastasis is of sufficient size to require a radical neck dissection, or if it encases the carotid artery, primary treatment with irradiation is preferred to shrink the neck mass to a more resectable size. Bilateral treatment should be considered in large oropharyngeal tumors or those that cross the midline.

Even with a clinically negative neck, treatment by surgery or irradiation is indicated when the primary malignancy originates from the oropharynx. The risk of occult disease is 30% or greater, and these nodes can be found anywhere in levels I to IV of the neck.[470–472] Therefore, if an elective neck dissection is performed rather than radiation therapy, a selective neck dissection exploring these levels is indicated. For midline lesions, bilateral treatment of the neck must be performed.

BASE OF TONGUE. Treatment options for carcinomas of the base of tongue may include surgery or radiotherapy-based strategies. Limited comparative studies have been published to guide the treatment decision-making process. In view of the functional impact of therapy to this site, the feasibility of functional organ preservation has received increasing consideration, because comparable local-regional control and survival rates have been suggested. In this regard, although radiotherapy typically has been preferred, several surgical issues are important to consider.

With regard to the tongue base, additional considerations relate to the size and location of the lesion. If a small tumor lies posteriorly and inferiorly in the base of tongue, a transhyoid approach through the neck can be considered rather than a mandible splitting approach. For small tumors that lie laterally in the tongue base or on the pharyngeal walls, a lateral pharyngotomy can be considered. For larger tumors, resection of a significant portion may result in chronic aspiration because the tongue base is critical to swallowing function. Recurrent pulmonary infections in the elderly or immunocompromised can be life threatening. Thus, a laryngectomy often is considered when more than half of the tongue base is to be removed, especially in high-risk patients. If the larynx is preserved, postoperative functional results can be optimized with swallowing therapy or a laryngeal suspension procedure.[473]

For base of tongue tumors, the data show that early tumors are best treated by radiotherapy or surgery while patients with advanced lesions should receive combined treatment. In one study of 173 patients, early primary tumors treated with surgery or radiotherapy gave a control rate of 83% (5 of 6 tumors) and 89% (40 of 45 tumors), respectively. For advanced primary tumors, definitive radiotherapy produced a local control rate of 55% (42 of 76 tumors), compared with 79% (23 of 29 tumors) for surgery and postoperative radiotherapy.[474] Radiotherapy is preferred for early lesions because of the decreased treatment morbidity compared with base of tongue surgery.

In this regard, data exist to demonstrate that the local control rates for EBRT followed by a brachytherapy implant are superior to those achieved with EBRT alone.[284] One retrospective review demonstrated comparable local control rates between EBRT with an implant and surgery, both of which were superior to EBRT alone.[287] Several independent investigators have consistently demonstrated that a brachytherapy implant boost (20 to 30 Gy) after EBRT (45 to 55 Gy) is associated with effective local control rates. No significant functional deficits with this organ-preserving strategy have been reported when several quality of life domains were studied, even for advanced lesions.[291,292] The most extensive experience has been with temporary interstitial LDR ^{192}Ir implants. Mature local control rates of 85% or greater may be expected for T1 and T2 lesions and 80% to 85% with T3 lesions.[281] Similar results have been reported in other series.[282–288,475,476] In general, selection of the more advanced lesions for treatment has been based on favorable exophytic growth patterns. The experience with a brachytherapy implant in T4 lesions remains limited.[281,283,284,288,475] Concurrent chemoradiotherapy techniques are favored, particularly for the more advanced T3 and T4 lesions. Puthawala and colleagues reported a mature crude local control rate of 67% with more relapses observed in patients with more advanced neck disease[288] and used a higher brachytherapy boost dose of 30 to 40 Gy, compared with 20 to 25 Gy for T1 and T2 lesions. The value of an implant for T4 lesions appears promising, but this approach requires further evaluation, particularly when combined with combination chemoradiotherapy, because late swallowing complications may compromise the benefits of an organ-preserving treatment strategy.

Larynx

From the standpoint of staging and treatment, the larynx is divided into supraglottic, glottic, and subglottic regions (Table 72-9; Fig. 72-19). The supraglottic region is composed of the epiglottis, arytenoid cartilages, aryepiglottic folds, false cords, and laryngeal ventricles. The glottic larynx includes the true vocal cords as well as the anterior and posterior commissures. The subglottic region extends to the inferior edge of the cricoid cartilage. Transglottic tumors involve the glottic level as well as another site within the larynx.

SUPRAGLOTTIC LARYNX. With regard to early lesions, surgical management of supraglottic tumors varies depending on the exact location of the lesion. T1 tumors of the suprahyoid epiglottis are readily managed endoscopically by CO_2 laser excision. Tumors of the infrahyoid epiglottis are not amenable to this type of resection because

Table 72-9 American Joint Committee on Cancer Classification for Staging Primary Laryngeal Cancer

Stage	Characteristics
SUPRAGLOTTIS	
T1	Tumor limited to one subsite of supraglottis, with normal vocal cord mobility
T2	Tumor invades more than one subsite of supraglottis or glottis, with normal vocal cord mobility
T3	Tumor limited to larynx with vocal cord fixation and/or invades postcricoid area, medial wall of pyriform sinus, or pre-epiglottic tissues
T4	Tumor invades thyroid cartilage and/or extends to other tissue beyond the larynx (e.g., to oropharynx, soft tissue of neck)
GLOTTIS	
T1	Tumor limited to vocal cord(s) (may involve anterior or posterior commissures) with normal mobility
T1a	Tumor limited to one vocal cord
T1b	Tumor involves both vocal cords
T2	Tumor extends to supraglottis or subglottis, or both, with or without impaired vocal cord mobility
T3	Tumor limited to the larynx with vocal cord fixation
T4	Tumor invades through thyroid cartilage and/or extends to other tissue beyond the larynx (e.g., oropharynx, soft tissue of neck)
SUBGLOTTIS	
T1	Tumor limited to the subglottis
T2	Tumor extends to vocal cord(s) with normal or impaired mobility
T3	Tumor limited to larynx with vocal cord fixation
T4	Tumor invades through cricoid or thyroid cartilage and/or extends to other tissues beyond the larynx (e.g., oropharynx, soft tissues of neck)

From the American Joint Committee on Cancer: Manual for Staging of Cancer, 4th ed. Philadelphia, JB Lippincott, 1992, with permission.

of the possibility of pre-epiglottic space invasion.[477] An open procedure is more oncologically sound in these cases.

Surgical treatment of early lesions of the false vocal folds often requires a supraglottic laryngectomy, which spares the true vocal folds. If a supraglottic tumor extends to the true cords, the patient may be a candidate for a supracricoid laryngectomy, which spares at least one arytenoid cartilage but not the true cords. Patients who undergo this procedure generally have excellent functional results with regard to speech and swallowing.[478,479]

Surgical treatment of T4 lesions requires a total laryngectomy in most cases. This procedure involves the resection of the entire larynx, including the epiglottis, the true and false vocal cords, the thyroid cartilage, one lobe of the thyroid gland, and the involved mucosa of the hypopharynx or base of tongue. The remaining pharyngeal mucosa is then closed, either primarily or with additional tissue from a free or rotational flap. The long-term functional swallowing results for this procedure generally are excellent, especially if the pharynx was closed primarily.[480–482] Speech rehabilitation is performed with a number of devices and techniques, including esophageal speech, an electrolarynx, or a tracheoesophageal puncture device.

Owing to the high rate of occult metastasis, bilateral treatment of the neck is recommended in most cases of squamous cell carcinoma of the supraglottis. In the clinically node-negative neck, surgical treatment includes a selective neck dissection including levels II, III, and IV, because these are the most likely locations for occult metastases.[221,483]

The decision to treat T1, T2, and T3 lesions with irradiation or surgery can be difficult. Recent studies in the surgical literature show good 5-year survival rates with either modality.[484–487] Irradiation with surgical salvage may be the best option for patients who have pulmonary disease who are at a high risk for severe complications from aspiration.

Salvage surgery often entails a total laryngectomy. Patients who are surgical candidates for a partial laryngectomy retain glottic function without compromising oncologic outcome.[488] The status of the cervical nodes also must be taken into consideration in deciding on treatment modality. Surgery certainly is indicated when large metastatic nodes are present, because this allows for combined therapy. Surgery or irradiation is sufficient to treat the node-negative neck.

GLOTTIC LARYNX. Early lesions of the true vocal cords that are not treated with irradiation can be treated surgically in a number of ways. Carcinomas in situ may be managed endoscopically with vocal cord stripping or with the CO_2 laser. T1 lesions of the true vocal cords may be treated surgically with cordectomy or CO_2 laser excision. T2 lesions often require open procedures for adequate surgical resection, although radiotherapy is an equally effective option. Operations geared toward organ preservation such as a vertical hemilaryngectomy or a supracricoid laryngectomy should be considered before total laryngectomy for T2 lesions. T3 and T4 lesions of the glottis almost always require a total laryngectomy if surgical management is chosen, although selected patients with T3 cancers are candidates for a supracricoid hemilaryngectomy.[489]

Management of the neck in glottic carcinoma differs from supraglottic carcinoma because the risk of occult metastasis is less, ranging from 3% to 21%.[490–493] Observation is the treatment of choice for the neck in T1 and T2 primary glottic cancers, but some authors recommend treatment of the N0 neck in T3 and T4 cancers.[494] If surgical management is chosen, a selective neck dissection of levels II to IV is the procedure of choice. In the node-positive neck, a selective or modified radical neck dissection may be indicated, depending on the size and location of the metastasis.

The oncologic results with treatment of T1 lesions of the glottis are good. Endoscopic cordectomy is equal in effectiveness to radiotherapy for most lesions, with cure rates greater than 90%.[495,496] Several factors should determine which modality to use. Patient concerns and health are of paramount importance. It must be made clear that although irradiation often can be used for salvage after surgery, the salvage procedure indicated after failed radiation therapy may be a total laryngectomy. Lesions of the anterior commissure, although classified as T1, are not as effectively treated with irradiation and are difficult to excise endoscopically.[497,498] An open partial laryngeal procedure such as a hemilaryngectomy or supracricoid laryngectomy can be considered, depending on the extent of the lesion.

T2 lesions can be managed with radiation or surgery equally well. The 5-year local control rate has been estimated to be greater than 80% after either primary surgical therapy or radiation therapy.[489,496,499–502] It is more likely, however, that an open partial laryngectomy approach rather than a simpler endoscopic approach will be needed for adequate surgical treatment.[489,496,501] Therefore, it becomes very important to choose surgical candidates carefully with regard to pulmonary function, intelligence, motivation, and home situation.

For advanced-stage tumors, it has been shown that survival is similar between patients managed with an organ preservation protocol and those managed with surgery.[503,504] It should be noted that in the landmark Veterans Affairs study, although 66% of patients in the organ preservation arm retained a functional larynx, 39% were tracheostomy-dependent. Patients should be offered chemotherapy and radiation therapy as an alternative to total laryngectomy, however. It recently has been shown that salvage laryngectomy after organ pres-

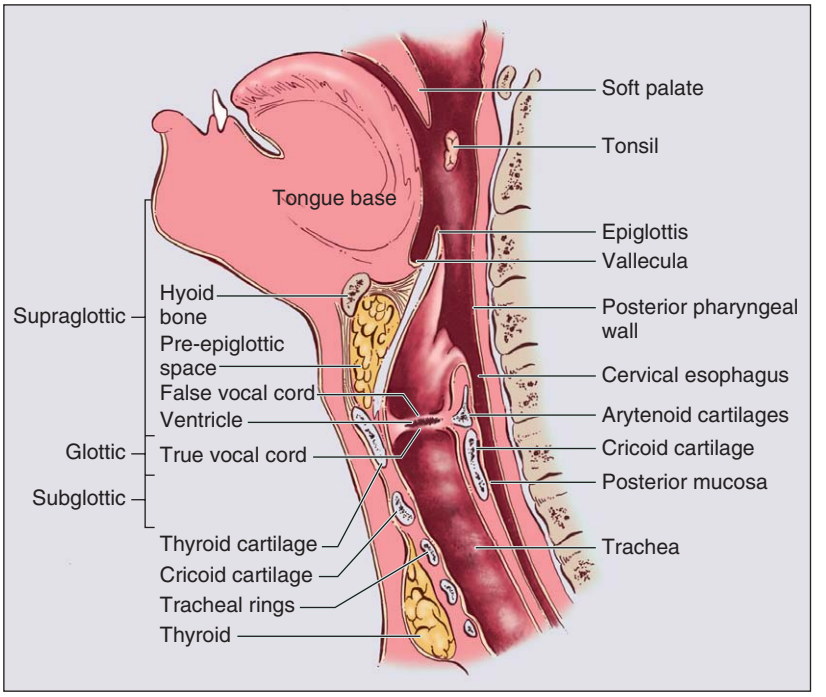

Figure 72-19 • Anatomy of larynx and hypopharynx: Sagittal view. (From Grégoire V, Coche E, Cosnard G, et al: Selection and delineation of lymph node target volumes in head and neck conformal radiotherapy. Proposal for standardizing terminology and procedure based on the surgical experience. Radiother Oncol 2000;56:135–150.)

ervation therapy is associated with acceptable morbidity, and that survival after the surgery was not affected by the initial organ preservation treatment.[185]

SUBGLOTTIC LARYNX. Primary cancers originating in the subglottis are relatively rare.[505] Because conservative endoscopic procedures would fail to clear the tumor, management of these tumors most often requires total laryngectomy. A paratracheal lymph node dissection and ipsilateral thyroidectomy also should be considered. Subglottic extension of T3 or T4 subglottic cancers should be managed similarly. Postoperative radiation therapy should be added to decrease the risk of a stomal recurrence.

HYPOPHARYNX. Surgical management of hypopharyngeal cancers is particularly challenging because the mucosa of the hypopharynx is vital to swallowing function. Thus, surgical extirpation of large tumors often requires complex reconstructions to minimize postoperative dysphagia.

The surgical options vary with the size and precise location of the tumor within the hypopharynx. Selected small tumors of the pyriform sinuses can be managed using conservation procedures that maintain laryngeal function. These procedures include the partial laryngopharyngectomy and supracricoid hemilaryngopharyngectomy.[506,507] To be a candidate for these procedures, a patient must have a small lesion that does not involve surrounding structures or impair vocal cord motion. In addition, the patient must have good pulmonary function and motivation to undergo rigorous swallowing rehabilitation.

For most tumors of the pyriform sinus staged as T2 and larger, a total laryngectomy with partial pharyngectomy is indicated. This procedure can carry significant morbidity, especially when performed as salvage after failed radiation therapy. To reconstruct the pharynx, surgical options include myocutaneous flaps such as the pectoralis flap, fasciocutaneous flaps such as the deltopectoral flap, and free-tissue transfer from the forearm or jejunum. A gastric transposition procedure, facilitated by a general surgeon in the operating room, also is used in cases in which a circumferential pharyngeal defect is present.

Tumors of the posterior pharyngeal wall are more accessible anatomically, making surgical management less complex than for pyriform sinus cancers. Most pharyngeal wall cancers can be resected directly, without laryngectomy, through a suprahyoid or lateral pharyngotomy approach. Reconstruction is often performed using a split-thickness skin graft or acellular dermal graft. Larger tumors may require myocutaneous or free flap reconstruction.

Cancers that involve the postcricoid region of the hypopharynx require an extensive procedure if they are to be managed surgically. A total laryngectomy, partial pharyngectomy, and cervical esophagectomy usually are required. A total esophagectomy may be indicated, depending on the inferior extent of the lesion.

Occult metastases from hypopharyngeal cancers are present in greater than 30% of N0 necks.[490,508] Therefore, selective neck dissection of levels II, III, and IV is indicated, even in patients with tumors staged N0. In addition, if the tumor approaches the midline, bilateral neck dissections should be performed.[508,509]

The outcome for patients with hypopharyngeal cancer is poor, especially if the tumor originates in the pyriform sinus. Marks and colleagues estimated the 5-year survival rate to be 14% for patients with advanced pyriform sinus cancers.[510] In the same retrospective study, it was demonstrated that surgery alone was significantly superior to radiotherapy, with or without chemotherapy, for treatment of the disease. Another retrospective study showed that surgery is superior to combined chemotherapy and radiation therapy, although the difference was not statistically significant.[511] A prospective study showed that organ preservation is superior in terms of survival, but again, the difference was not statistically significant.[192] The treatment of advanced hypopharyngeal cancer must be individualized for each patient.

MAJOR AND MINOR SALIVARY GLANDS. Surgical treatment is the mainstay of management of salivary gland cancer, whether arising from the parotid, submandibular, sublingual, or minor salivary glands. Surgery for parotid gland malignancy is perhaps the most challenging because of the location of the facial nerve coursing between the superficial and deep lobes. Most parotid tumors are located in the superficial lobe of the gland and therefore are treated with a superficial parotidectomy through a transcervical approach, sparing the facial nerve. Those tumors within the deep lobe of the gland require a total parotidectomy. The facial nerve is spared in these

cases if it is not involved with the malignancy. For deep lobe malignancies, additional access via a submandibular or, rarely for massive tumors, a mandible splitting approach.

Submandibular gland tumors usually are contained within the gland, so resection is limited to the submandibular triangle. The marginal mandibular, lingual, and hypoglossal nerves should be spared. If spread to the surrounding tissues has occurred, these structures, as well as surrounding bone, floor of mouth, and skin, may need to be removed surgically. The extent of surgery for malignancies of the sublingual glands and minor salivary glands depends on the size and location of the tumor within the oral cavity.

Combined therapy usually is recommended for high-grade malignancies of the salivary gland such as high-grade mucoepidermoid carcinoma. Postoperative irradiation has been shown to improve local-regional control in several studies.[512,513] Neck dissections are indicated in the event of known cervical metastasis.

Unknown Primary

The treatment for unknown primary squamous carcinoma may include neck dissection followed by postoperative radiotherapy alone or radiotherapy followed by a neck dissection. The relative efficacy of these two strategies has not been evaluated. No established role for the addition of concurrent chemotherapy has been recognized at this time, although this remains an attractive therapeutic strategy. The increased mucosal toxicity, including the potential for long-term swallowing dysfunction, however, must be balanced against unclear benefits including regional control and survival. Currently, irradiation may include the neck alone, or elective mucosal irradiation of potential primary sites may be performed. Weir and colleagues noted no survival benefits with elective mucosal irradiation,[514] although Reddy and colleagues continued to recommend elective mucosal irradiation owing to reduced risk of contralateral nodal and primary relapses.[515] The latter depends on the location of the nodal metastases. For level II nodal metastases, this may require elective irradiation of the oropharynx and laryngeal structures.

Recurrent Head and Neck Squamous Cell Carcinoma and Second Head and Neck Squamous Cell Carcinoma

The optimal management for recurrent non-nasopharyngeal HNSCC and second primary HNSCC remains to be defined and is complicated by retrospective series reporting on outcomes for heterogeneous groups of patients. Re-irradiation of the head and neck is possible, however, with increased but potentially acceptable toxicities. Various investigators have studied combinations of chemotherapy and radiotherapy in hopes of realizing significant radiosensitization such that the total required for re-irradiation is reduced. The results have been summarized by Kao and associates.[218] Unfortunately, only a select few demonstrate benefit with survival prolongation. Higher total doses appear to be important, with a re-irradiation dose of 60 Gy typically recommended.[516] Accordingly, the limited potential for gains must be balanced with an increased risk of complications, including soft tissue necrosis and neurologic damage. Currently, re-irradiation with EBRT and chemotherapy remains limited to clinical trials at centers with ongoing systematic experience with particular protocols. Various conformal radiotherapy techniques may facilitate safer re-irradiation. These include recent techniques such as IMRT. The use of brachytherapy implant for re-irradiation, however, can play an important role in improving the therapeutic ratio, because full-dose irradiation is required for any potential for cure.

Surgery is preferred and offered for resectable lesions in the absence of unacceptable functional and cosmetic sequelae. In this setting, management of microscopic residual disease with radiotherapy often is necessary. A planned introduction of nonirradiated tissue flaps with coordination of the implant placement and of the wound reconstruction can reduce the risk of wound complications. Both pedicled myocutaneous flaps[517] and microvascular free flaps have been described.[518] Nevertheless, complication rates of 20% to 50%, including a risk of carotid rupture during placement of the implant in the neck, have been reported. Factors other than the radiation may be contributing to this increased risk of complications. These considerations are tempered by local control rates of 44% to 80%, suggesting a limited therapeutic ratio.[519–522] Hence, patient selection is particularly important with this indication.

A brachytherapy implant alone may be used for treatment of selected second primary HNSCCs. Peiffert and colleagues reported the results with use of a ^{192}Ir implant alone for 73 patients with tonsil carcinoma treated at the Centre Alexis Vautrin.[295] A majority of the patients presented with early node-negative disease; a median dose of 60 Gy was prescribed according to the Paris dosimetry system. The 5-year actuarial local control rates for T1N0 and T2N0 lesions were 80% and 67%, respectively. Acceptable grade 2 self-resolving complications were observed in 10 cases (13%), with a majority of the complications being soft tissue necrosis due to a dose greater than 60 Gy. This appeared to be increased when compared with the same institution's series when tonsil implants were prescribed in unirradiated tissues.[272] The 5-year actuarial disease-specific survival and overall survival rates were 64% and 30%, respectively. No long-term survivors were observed, reflecting the increased risk of other malignancies and other alcohol- and smoking-related comorbid conditions in this patient population.

Other retrospective series have reported the results of re-irradiation with an implant, but include both patients with a second primary HNSCC and recurrent HNSCC, confounding the overall analyses. Treatment of recurrent HNSCC may be expected to give lower local control rates as a result of the presence of more radioresistant clonogens, an observation consistent with clinical data.[293,294,523] Langlois and colleagues reported the re-irradiation results for a larger and heterogeneous group consisting of 123 patients with T1 to T3 disease treated with a ^{192}Ir implant to a mean dose of 62 Gy at the Centre Alexis Vautrin.[294] A 5-year actuarial local control rate of 59% was observed. Local control correlated with tumor size less than 3 cm, second primary (versus recurrent lesion), dose greater than 60 Gy, and tumor site (oral cavity favorable compared with oropharynx). Only a 5-year actuarial survival rate of 24% was realized, with local control achieved, and a time interval between re-irradiation of more than 2 years associated with a better prognosis. Mucosal necrosis was observed in 28 cases (23%). Stevens and colleagues also noted favorable local control rates with second primary HNSCC, a re-irradiation dose of 60 Gy or greater for second primary HNSCC, a treatment interval longer than 1 year for recurrent lesions, and the use of an implant in addition to EBRT.[523] Mazeron and colleagues reported a 5-year actuarial local control rate of 69% for 70 patients with oropharyngeal carcinomas re-irradiated with a ^{192}Ir implant alone delivering a mean dose of 60 Gy with the Paris system.[524] Similarly, tumor site (glossotonsillar sulcus and base of tongue being unfavorable) and tumor size (larger than 2 cm) adversely influenced the local control rate, although larger lesions occurred more frequently in the base of tongue. Regional nodal irradiation was not intentionally treated, with only 7 of 69 (10%) developing nodal relapses. Soft tissue necrosis was the main complication (seen in 27%), was self-resolving in 13 of 14 patients, and appeared to be increased when a large lesion was implanted.

Levandag reported the results for 73 patients with either second primary HNSCC or recurrent HNSCC comparing EBRT re-irradiation with implant with or without EBRT re-irradiation (18 patients), although significant heterogeneity existed in the treatment applied in each of the patient cohorts, precluding definitive conclusions.[525] Selection bias was minimized because the two cohorts represented sequential treatment periods resulting from an institutional policy change. Crude local control rates of 29% and 50% were reported, respectively, suggesting improved control rates with an implant though this was confounded by the higher mean dose delivered in the implant cohort compared with the EBRT cohort. The

high rate of temporary mucosa ulcerations (in 13 of 18 versus 9 of 55) probably was related to the implant technique used. To reduce the increased risk of mucosal ulceration associated with an implant, Housset and colleagues employed a planned treatment interruption, delivering the intended dose using two separate implants with a source shift.[293] A total of 55 patients with both recurrent and second primary base of tongue squamous cell carcinomas underwent this implant protocol; 31 patients received a single-course implant delivering 60 Gy and 24 patients received a split-course implant delivering 35 Gy and then 30 Gy after a 1-month interruption. A significant reduction in the risk of mucosal necrosis was observed with the introduction of a treatment interruption (16% versus 43%), although a trend toward a lower crude local control rate (37.5% versus 52%) suggests that such a strategy warrants further investigation.

In summary, selective application of a brachytherapy implant for re-irradiation may be appropriate in view of the poor prognosis associated with this patient population. Favorable local control rates may be expected in patients with second primary HNSCC, small tumor sizes, tumor sites other than the base of the tongue, and the delivery of 60 Gy or greater. For recurrent HNSCC, treatment intervals of longer than 1 year appear to select for lesions that are less radioresistant. Soft tissue complications appear to be increased, with a frequency ranging from 20% to 30%; a majority of such complications are self-resolving.

SUMMARY AND FUTURE DIRECTIONS

A paradigm shift has occurred in the management of squamous cell carcinoma of the upper aerodigestive tract over the past 25 years. In the 1970s and 1980s, Fletcher and others demonstrated the ability to preserve function through the use of definitive radiation therapy for patients with cancers of the larynx and oropharynx. In the mid-1980s, Wolf and Hong introduced the concept of laryngeal preservation by combining induction chemotherapy and definitive radiotherapy for patients who demonstrated a significant response to the induction phase of treatment. For the first time, organ preservation was achieved without a deleterious effect on survival. After this favorable report by the Veterans Affairs Cooperative Group, treatment intensification trials were designed to increase the rate of organ preservation and to improve survival rates. Concomitant chemotherapy and radiation therapy were demonstrated to provide a survival benefit over neoadjuvant chemotherapy and irradiation, albeit with increased toxicity. The RTOG implemented a three-arm trial for laryngeal preservation in 1992 to test this concept. Preliminary results from this trial demonstrated a higher rate of organ preservation among patients receiving concomitant chemotherapy than among those receiving induction chemotherapy and radiation therapy or radiation alone. Despite an increased rate of laryngeal preservation, however, treatment intensification did not translate into improved survival.

Current therapeutic approaches have been designed to improve local-regional cancer control and survival through further treatment intensification. Phase III trials are evaluating different chemotherapeutic agents combined with altered fractionated radiation schemes and take advantage of the radiosensitizing effects of chemotherapy when administered concurrently with radiation. Although the outcome from these trials will not be reported for some time, the toxicity associated with aggressive combination therapy is of increasing concern. Anatomic organ preservation through nonsurgical means has been convincingly demonstrated; nevertheless outcome data that demonstrate effective functional preservation of the organ are lacking. Assessment of organ function and quality of life are now integrated into these trials and will provide longitudinal data on pre- and post-treatment organ function and how these relate to the patient's perceived quality of life. In the future, the success of anatomic as well as functional organ preservation will be clarified.

Further treatment intensification is likely to be associated with unacceptable toxicity and will require new approaches to ameliorate the side effects of cytotoxic therapy. Toxicity scoring schemes are being developed and implemented to provide a more quantitative assessment of early and late treatment side effects. Mucosal injury, an early treatment effect, and fibrosis, a late effect, will constrain further attempts to intensify treatment. Mucositis contributes to nutritional deficits and may lead to circumferential scarring and stenosis of the pharynx. Fibrosis contributes to laryngeal and pharyngeal dysfunction through loss of neuromuscular coordination and muscle function. IMRT to limit exposure of normal tissues and agents to mitigate these side effects are being studied in clinical trials. To date, none of the systemic agents intended to lessen toxic side effects has convincingly demonstrated effectiveness.

Although current therapeutic approaches destroy neoplastic cells, collateral damage to normal tissues is responsible for the toxic side effects and long-term functional impairment. Future directions may come from continued technological advancements including organ-preserving surgical techniques and the use of more precise radiotherapy techniques such as IMRT. The greatest potential for gain, however, comes from capitalizing on the molecular mechanisms specific to cancer cells that are responsible for tumor progression. The hope is for more cancer-specific therapy without the increased toxicity. The results from clinical trials conducted with several of these agents alone support the notion that there may be more specific tumor targeting, as the toxicity profiles have to date been very modest. Activity also has been modest, however, which has lead to the use of surrogate measures to determine if in fact these agents are inhibiting the molecular targets in vivo. Although the head and neck site lends itself to tissue biopsies for these assays, the hope is for the continued development of functional imaging to provide these answers. In view of the modest activity with these agents alone, the challenge of the moment is to develop novel strategies for combining these targeted biologic agents with cytotoxic drugs and radiation therapy in a rational manner. This will depend on successful translation of knowledge gained from laboratory investigations, particularly about the molecular mechanisms of treatment resistance. Today's oncologists are at the threshold of realizing a long-sought goal of effective cancer control through the use of targeted therapy that will optimize local-regional control and enhance survival within the context of acceptable toxicity.

73 Melanoma

Julie R. Lange, Leslie A. Fecher, William H. Sharfman, Rhoda M. Alani, Radha Mikkilineni, Suzanne L. Topalian, and Charles M. Balch

SUMMARY OF KEY POINTS

Incidence
- The incidence of melanoma has risen dramatically over the past few decades.
- Approximately 59,940 new cases of invasive melanoma are diagnosed each year in the United States, and it is estimated that 1 in 49 men and 1 in 73 women in the United States will be diagnosed with melanoma in their lifetime.

Etiology and Epidemiology
- Risk of melanoma is strongly related to exposure to ultraviolet irradiation, and to a susceptible host phenotype: fair hair and skin, a tendency to burn, and numerous benign or atypical nevi.
- Family and personal history of skin cancers also are important risk factors.

Pathology
- The most important pathologic features of the primary lesion are thickness (in mm), presence or absence of histologic ulceration, and mitotic rate

Clinical Findings
- Many primary melanomas display typical features of border irregularity and variegated pigmentation.
- Some melanomas may be recognized by a patient's report of a change in the size or color of a pigmented lesion or by a report of itching or bleeding from a skin lesion.
- Other primary melanomas may lack these features and, therefore, may be more difficult to recognize.

Differential Diagnosis and Staging
- Any suspicious lesion or questionable new or changing lesion should have a full-thickness biopsy.
- Staging categorization of the primary lesion relies on accurate determination of the thickness of the lesion and determination of whether histologic ulceration is present.
- The current American Joint Committee on Cancer (AJCC) staging system includes the thickness and presence or absence of ulceration of the primary tumor, the number of positive nodes, whether the nodes are microscopically or macroscopically positive, and whether distant disease is present.

Primary Therapy and Salvage Therapy: Surgical
- All primary melanomas need wide local excision for local control.
- Margins of excision are determined by the thickness of the primary lesion.
- For patients presenting with a new primary melanoma ≥1 mm and a clinically negative regional node basin, sentinel node biopsy is used to determine the node status.
- For patients with known metastatic nodes, regional node dissection is performed.

Complications
- Primary surgical therapy usually can be accomplished with preservation of full function and reasonable cosmesis. Node dissection carries a risk of lymphedema.

Primary Therapy and Salvage Therapy: Systemic
- Adjuvant therapy should be offered to patients with high-risk, resected disease (e.g., nodal metastases or a primary tumor ≥4 mm), either with interferon-alfa or as part of a clinical trial.
- Although interferon has been approved by the U.S. Food and Drug Administration (FDA) for high-risk patients, subsequent clinical trials of interferon have shown a consistent disease-free survival (DFS) benefit, but failed to show a clear overall survival benefit; thus its routine use remains controversial.
- For advanced melanoma, dacarbazine (DTIC) and high-dose interleukin-2 (IL-2) are the only FDA-approved agents.
- Durable complete responses with high-dose IL-2 are possible, and this therapy should be considered for all eligible patients.
- A number of promising new molecular and immunologic agents are under active investigation.

Prognosis
- Prognosis is strongly related to the thickness and ulceration status of the tumor at its original presentation and the nodal status.
- Today, most patients are diagnosed early and usually have an excellent prognosis.
- Once disseminated metastatic disease is recognized, median survival is approximately 6 to 9 months.
- With current therapies, the outcome for patients with advanced disease is poor. Further research is needed to identify therapeutic targets and to improve systemic therapies for melanoma patients.

INTRODUCTION

In the early part of the 20th century, melanoma was considered a rare disease, and often was recognized only at an advanced stage. Today, melanoma is one of the most common malignancies, and it usually is recognized at an early stage, when survival rates are high, often with surgery as the only necessary treatment. Melanoma can occur at all ages, and, therefore, can be associated with potential loss of many years of productive life. For early melanoma, improved understanding of the natural history of melanoma and a number of well-run studies of surgical treatment of melanoma have resulted in standard surgical procedures that are much less radical than those

commonly performed just a few decades ago. Advanced melanoma is difficult to treat and presents opportunities for research to improve treatment strategies. Interest in the biology of melanoma continues to increase; ongoing research in the biology of melanoma and its potential application to the medical treatment of melanoma may lead to improved management strategies. This chapter reviews the current treatment of melanoma.

EPIDEMIOLOGY

According to the American Cancer Society, approximately 59,940 new cases of melanoma and 8110 deaths attributable to melanoma were expected to occur in the United States in 2007. It is the sixth most frequently diagnosed malignancy in both men and women, occurring slightly more commonly in men than in women.[1] The incidence of melanoma has risen dramatically over the last several decades, and it is now estimated that the lifetime risk of melanoma in the United States is approximately 1 in 49 for men and 1 in 73 for women.[1] Melanoma can occur in children and teenagers: the Centers for Disease Control and Prevention estimates that in 2002 there were 475 cases of melanoma in persons younger than 20 years of age.[2] The incidence of melanoma in persons under 20 years of age rose 2.9 % per year from 1973 to 2001.[3] Mortality from melanoma is significant. The overall mortality attributable to melanoma has increased because of the great increase in the incidence of the disease; however, case mortality rates have improved, and today 92% of patients are alive 5 years after their diagnosis.[1] Because melanoma often affects young and middle-aged adults, the potential for years of life lost is great. For most of the 20th century, the incidence of melanoma in populations of European origin rose faster than any other cancer except lung cancer. Current reports indicate that the incidence of melanoma is stabilizing or slightly decreasing, particularly among younger adults.[4]

CLINICAL RISK FACTORS

Most known risk factors for melanoma fall into one of two categories: susceptibility of the host and exposure to ultraviolet irradiation. Persons who are most susceptible to melanoma are fair-skinned, with a tendency to sunburn. They may have more than 20 benign moles, atypical moles, or congenital moles. A family history of melanoma also is associated with increased risk.

Skin Type

Fair-skinned persons with a tendency to burn are at higher risk than darker-skinned persons. Red or blond hair and blue or green eyes are associated with increased risk. Freckling is common.[5]

Common and Atypical Nevi

Common benign nevi, if numerous, are associated with increased risk.[6,7] Atypical nevi are flat macules greater than 5 mm, with variable pigmentation, asymmetrical outlines, and indistinct borders. Atypical nevi are found in 2% to 7% of the white population, but in approximately 40% of patients with melanoma. The presence of atypical nevi implies a greatly increased risk of melanoma, particularly when combined with a family history of melanoma. There is a rare, autosomal dominant syndrome of atypical nevi with variable penetrance. These nevi may occur on non–sun-exposed areas. The lifetime risk of melanoma in some affected families is nearly 100%, with many melanomas occurring de novo and apparently not in pre-existing atypical nevi.[8]

Giant Congenital Nevi

Patients with large nevi present at birth or in early childhood are at increased risk for melanoma. Giant congenital melanocytic nevi often are elevated, and usually are large, prominent, irregular, pigmented lesions. They may follow a dermatome distribution and may cover large areas. They occur in fewer than 1 in 20,000 births. Malignant changes may occur in the deeper areas of the dermis and may, therefore, be difficult to detect.[9] Excision early in life when possible with limited morbidity is advised.

Personal History of Melanoma

Patients with a personal history of melanoma have an approximate 5% lifetime risk of a second melanoma. Persons who have had melanoma need lifelong skin screening.

Exposure

Ultraviolet (UV) radiation exposure, to both UVA and UVB, is strongly associated with subsequent development of melanoma. The exposure history most strongly associated with subsequent melanoma development is intermittent intense exposure, particularly a history of blistering sunburns in childhood. Exposure to UV radiation is of particular interest because it is a modifiable risk factor. However, such exposure is not necessary for the development of melanoma—areas with no sun exposure, such as the soles of the feet and the anal area, can be sites of primary melanoma. The development of melanoma is, like many cancers, a result of a complex interaction between patient susceptibility and carcinogen exposure.

Risk Management

Identification of persons with no prior diagnosis of melanoma who are at increased risk of melanoma can be difficult, and the role of routine screening is poorly defined. A case-control study evaluated the relative risk of melanoma in non-Hispanic whites, using data including common risk factors such as complexion, exposure, and number of moles. The authors developed a statistical tool that can be used to estimate an individual's risk of melanoma. This tool may prove useful in counseling at-risk individuals for reduced UV exposure and regular screening.[10] Further research is needed in risk assessment, risk management and in disease prevention.

CLINICAL PRESENTATION AND BIOPSY

The most important clinical feature of a cutaneous melanoma is change in the color, size, perimeter, or contour of a mole or pigmented skin lesion.[11] Sometimes patients report an itching sensation around a mole or an unusual sensation in a mole. Cutaneous melanoma can arise anywhere on the body. The most common site in women is the lower extremity; the most common site in men is the back. Clinical features typical of melanoma include variegated color, irregular borders, or a history of a change in such a skin lesion. A simple mnemonic to remember concerning features of a pigmented lesion is "ABCDE": **A**symmetry, **B**order irregularity, **C**olor change/variegation, **D**iameter change, and **E**volution (change over time) of the lesion.[12] Some melanomas do not have typical features; some are nonpigmented and may resemble other dermatologic entities such as basal cell carcinoma, squamous cell carcinoma, dermatofibroma, or seborrheic keratosis.

Melanoma appears in five clinical growth patterns: superficial spreading melanoma (SSM); nodular melanoma (NM); lentigo maligna melanoma (LMM); acral lentiginous melanoma (ALM); and desmoplastic melanoma (DM). The clinical features, anatomic distribution, ethnic distribution, and etiology are distinctive. SSM, the most common type of cutaneous melanoma among the white population, is largely responsible for the increased incidence of melanoma over the last few decades and may arise from a pre-existing nevus over a period of months to a few years. The average age at diagnosis is 51 years, which is one to two decades earlier than that for LMM or ALM. SSM has a predominant radial growth phase, both clinically and histologically. These lesions are more common on the trunk in

men and on the legs in women, and typically are larger than common benign moles, with asymmetry, notched or irregular borders, and multiple colors (brown, black, pink, and gray).

NM is the second most common type of melanoma. It is similar to SSM in terms of age at diagnosis and anatomic distribution, but does not have a precursor radial growth phase. The lesions usually are shiny, smooth nodules, often with a single color, usually black, dark brown, or bluish. Nodular melanomas usually are thicker and thus are diagnosed at a more advanced stage than SSM. The survival rates and prognosis for SSM and NM are virtually the same when matched for thickness and ulceration. Both SSM and NM appear to be associated with acute exposure to UVB irradiation in fair-skinned persons who tend to sunburn rather than suntan. SSM is more common in individuals living in areas with greater UVB exposure.
