The FIGO staging system from 1971 is based on findings on clinical examination.[238] In that era, fewer patients were treated with surgery, and primary irradiation was often used. Clinical stage III endometrial cancer was defined as carcinoma extending outside the uterus but not outside of the true pelvis. Stage IV disease included invasion of the bladder or rectum or disease beyond the true pelvis.

Clinical Stage III

Treatment for clinical stage III endometrial cancer has included radiation alone or surgery and radiation. Grigsby and colleagues reported on a series including 27 patients with clinical stage III disease who were treated with total hysterectomy and salpingo-oophorectomy combined with preoperative or postoperative irradiation.[239] The 5-year disease-free survival rate was 33%, with a distant metastatic rate of 48% and pelvic recurrences in 33% of patients. Aalders and colleagues compared outcomes in 108 clinical stage III patients with outcomes of 67 patients with pathologic stage III disease.[240] Radical surgery was possible in 70% of pathologic stage III patents compared to only 13% of those with clinical stage III; thus, 66 patients were treated with radiation alone. Surgical debulking was an important prognostic factor. The 5-year overall survival rate was 16% versus 40% for clinical and pathologic stage III, respectively. In the series by Greven and colleagues, 52 patients had clinical stage III disease, and 20 of these patients had radiation alone after biopsy.[212] The overall survival rate for this stage was 36%, with a median survival of 9 months for patients who were treated with radiation alone compared to 60 months for patients treated with surgery and radiation. The radiation-only group also demonstrated very poor pelvic control, with 89% pelvic failures. In the combined treatment group, the 5-year survival rate was 48%, with 40% pelvic failures. Isolated abdominal failure was much less common at 6%, but 38% of patients overall had a component of abdominal failure, and 16% developed distant metastases alone. Thus, while a combined treatment approach of surgery and adjuvant irradiation results in outcomes that are superior to those of radiation alone for clinical stage III patients, they still experience a high rate of pelvic and abdominal failures.

In some patients with locally advanced disease, surgery might be able to achieve only debulking. Bulky residual disease has been defined as more than 2 cm of residual tumor after primary surgery. This may include pelvic implants, residual nodal disease, or intraperitoneal deposits. There appears to be a benefit with respect to recurrence and survival if tumor is optimally debulked. Surgery is then followed by adjuvant irradiation to the pelvis, para-aortic nodes, or whole abdomen, as indicated by the location of residual disease.

Whole-abdominal radiation for bulky residual disease appears to be inadequate, and patients with greater than 2 cm of residual disease are seldom controlled.[226] This may be related to the lower radiation doses that are achievable in whole-abdominal treatment, owing to limitations of dose tolerance for the small bowel, liver, and kidneys. Limited field boosts to areas of bulky residual disease should be considered, particularly for para-aortic nodes, which can be treated to higher doses without exposing the liver or kidneys to excessive radiation. For patients with bulky disease confined to the pelvis, preoperative radiation may be considered to improve the likelihood of optimal surgical resection.

Clinical Stage IV

Patients with stage IVA disease, presenting with invasion of the bladder or rectum, with or without lymph node metastases, should be treated similarly to patients with stage III disease: with combined surgery and radiation with or without systemic therapy. Preoperative radiation may be considered in patients who are marginally operable or inoperable but with disease confined to the pelvis. Although little data exist for this approach in endometrial cancer, it has been used successfully in a variety of other pelvic malignancies. Patients who present with stage IVB disease are rare and are most often treated palliatively. Residual or progressive pelvic disease can be a major source of symptomatology for these patients. The 5-year survival rate is approximately 0% to 10%.[241,242] Surgical debulking may be of benefit or may be considered for palliation of symptoms. In a study

of surgical cytoreduction in 65 stage IVB patients, optimal debulking to less than 1 cm residual was accomplished in 55%.[243] Those patients had a significantly improved median survival of 34 months versus 11 months for those with bulkier residual disease. Among those with optimal cytoreduction, adjuvant chemotherapy or radiation was associated with improved survival. In another series of patients with stage IV disease, including 24 patients who had optimal debulking to less than 2 cm of residual disease and 31 patients with bulkier residual or unresectable peritoneal carcinomatosis, median survivals were 31, 12, and 3 months, respectively.[244]

For inoperable patients with advanced disease, palliative radiation therapy should be considered. Stage IV patients are also candidates for systemic chemotherapy or hormonal therapy. Bulky disease requires high-dose irradiation even for palliation. Unfortunately, owing to poor tolerance of the bowel to high-dose fractions of radiation, palliative treatment can require several weeks of daily therapy. Conventional doses of 45 to 55 Gy of external irradiation may be followed by LDR or HDR brachytherapy depending on the location and extent of disease. Palliation of bleeding may also be accomplished with brachytherapy alone, which is useful for debilitated patients. In one group of 27 patients with endometrial cancer who were not thought to be surgical candidates, usually because of age or comorbidities, one to three doses of 10-Gy fractions to the pelvis were delivered.[245] Bleeding resolved in 90%, malodorous discharge was reduced in 38%, and 22% had a complete tumor response, with a median survival of 9 months. Only three patients had significant bowel effects. The Radiation Therapy Oncology Group reported a phase II trial in patients with advanced pelvic malignancies who were treated with accelerated split-course irradiation consisting of three courses over 6 days in 12 fractions with 2- or 4-week breaks between courses.[246] Patients who completed all three courses had a 42% response rate, and therapy was well tolerated.

For patients who present with distant metastases or with distant relapses after primary therapy, chemotherapy or hormonal therapy is the mainstay of initial treatment. The most common sites of distant metastases are lung (35%), liver (29%), omentum or peritoneum (25%), gastrointestinal tract (21%), and bone (15%), with rare instances of adrenal (10%) or brain (6%) involvement.[247] Radiation is rarely used for visceral disease; however, palliative irradiation is indicated for specific situations, including painful bony metastases, symptomatic brain metastases, spinal cord compression, and airway obstruction. Short courses of hypofractionated radiation are most commonly employed over 1 to 2 weeks. Therapy is delivered to the whole brain or to the painful portion of involved bone.

SYSTEMIC THERAPY FOR ENDOMETRIAL CANCER

Chemotherapy

The role of chemotherapy in early-stage endometrial cancer is limited. The primary pattern of failure in these patients is locoregional; therefore, the benefit of adding systemic therapy is reserved mainly for patients with more advanced disease. However, for certain high-risk, early-stage tumors, particularly those with clear cell or uterine serous histology, systemic dissemination remains a substantial risk. The use of chemotherapy has been examined in these patients. At M.D. Anderson Cancer Center, 62 patients with high-risk stage I or clinically occult stage II endometrial cancer including grade III tumors, deep myometrial invasion, or high-risk histology (clear cell or uterine serous) were prospectively treated with postoperative cisplatin, doxorubicin, and cyclophosphamide chemotherapy.[248] The addition of chemotherapy did not appear to decrease the rate of distant failure in women who presented with extrauterine disease; however, for patients who presented with uterine-confined disease, the recurrence rate was 24%, with an observed progression-free interval of greater than 36 months. A small prospective study from Sweden treated 31 patients with stage I, grade III or uterine serous histology endometrial cancer patients with hysterectomy, postoperative radiation, and chemotherapy consisting of cisplatin and epirubicin.[249] With a median follow-up of 32 months, none of the patients were found to have recurrent disease. Two recent retrospective studies evaluated the efficacy of chemotherapy in surgical stage I uterine papillary serous cancer.[250,251] In particular, Kelly and colleagues showed improved disease-free and overall survival in stage I patients who received platinum-based chemotherapy.[251] Vaginal brachytherapy should be considered to improve local control.

The GOG attempted to address the issue of chemotherapy following surgery and postoperative radiation therapy in high-risk, early-stage endometrial cancer patients. However, the study included patients with nodal metastases as well as adnexal metastases. There were also a high number of protocol violations and patients who were lost to follow-up, making a more definitive analysis of outcome difficult. Although the results of these small trials are promising, chemotherapy is rarely used in early-stage patients, owing to the risk of increased toxicity with chemotherapy and the lack of definitive data documenting a benefit. As a general practice, chemotherapy remains reserved for patients with more advanced or metastatic endometrial cancer.

Adjuvant chemotherapy for women with recurrent or advanced endometrial cancer has not been shown to prolong survival in comparison to more traditional treatment with radiation. Only one large randomized trial has studied the effect of adjuvant chemotherapy. In 1990, Morrow and colleagues treated 181 patients who had poor prognostic factors with postoperative radiation therapy.[252] Patients were then randomized to either observation or treatment with intravenous doxorubicin to a total dose of 500 mg/m^2. No significant difference in recurrence rates was noted between the two groups.

A variety of different single-agents have been studied in phase II trials for the treatment of metastatic or recurrent disease. Drugs with a reported response rate of over 20% include 5-fluorouracil, cyclophosphamide, ifosfamide, doxorubicin, platinum, and paclitaxel. In particular, paclitaxel has been reported to elicit a response rate of 27% to 38% when used in the first- and second-line setting.[253–255]

Several multiagent combinations have also been tested. The GOG randomized patients to receive doxorubicin or cisplatin plus doxorubicin.[256] A significant improvement was noted in both response rate (45% versus 27%) and progression-free survival (13 months versus 8 months) for the combination. GOG 107 randomized 281 patients to receive doxorubicin or doxorubicin plus cisplatin.[257] The addition of cisplatin improved the overall response rate, with 19% complete responses and 23% partial responses compared to 8% and 17%, respectively, for single-agent doxorubicin. The overall response rate was statistically significant ($P = 0.004$). The progression-free survival rate was also improved, with a median of 5.7% versus 3.8%. However, overall survival was similar in both groups, with increased toxicity seen in the combination group. A smaller study conducted by the EORTC Gynecological Cancer Group showed similar results, though no significant difference in overall survival was noted.[258] The combination of paclitaxel and carboplatin has also been investigated, with reported response rates ranging from 47% to 87%.[259–262] The GOG has completed two additional trials of combination therapy for patients with advanced or recurrent endometrial cancer. A phase III randomized study demonstrated that 24-hour paclitaxel/doxorubicin/granulocyte-colony stimulating factor (G-CSF) was not superior to the combination cisplatin/doxorubicin in response or survival.[263] A second phase III randomized study compared 3-hour paclitaxel/doxorubicin/cisplatin/G-CSF with doxorubicin/paclitaxel.[264] The combination of paclitaxel/doxorubicin/cisplatin/G-CSF significantly improved the response rate, the progression-free survival rate, and overall survival. The GOG is currently evaluating paclitaxel/doxorubicin/cisplatin/G-CSF compared to carboplatin and paclitaxel in advanced or recurrent endometrial cancer.

Hormonal Therapy for Endometrial Cancer

The mainstay of hormonal therapy for endometrial cancer consists of treatment with progestins, either megestrol acetate or medroxyprogesterone acetate. These agents yield overall response rates ranging from 15% to 25%. Dose does not appear to be related to response. Thigpen and colleagues randomized 299 women with advanced or recurrent endometrial cancer to receive either 200 mg or 1000 mg of medroxyprogesterone acetate daily.[265] The overall response rate was 25% in the women on the low-dose regimen, compared to 15% for those on the high-dose regimen. Median progression-free survival for both groups was approximately 2 to 3 months. Lentz and colleagues administered high-dose megestrol acetate at 800 mg daily to women with advanced or recurrent endometrial cancer and noted a 24% overall response rate, similar to lower-dose regimens.[266]

Tamoxifen is the most widely studied nonprogestational hormonal agent for the treatment of endometrial cancer. In a review of eight studies, Moore and colleagues reported a pooled response rate of 22%.[267] Other agents such as goserelin acetate, danazol, and anastrozole have demonstrated very limited activity.[268–270] In phase I and II trials, arzoxifene demonstrated clinical response rates of 25% to 31% in recurrent endometrial cancer.[271,272]

For the highly selected patient, there is a role for conservative primary hormonal therapy.[273] Women with grade I adenocarcinomas who have not completed childbearing and for whom hysterectomy is unacceptable may be managed with progestational agents. The optimal regimen has yet to be determined. These patients must be carefully counseled regarding the risks of this conservative approach.

Systemic Therapy for Uterine Sarcoma

Uterine sarcomas display a high rate of recurrence, even in the setting of stage I disease, and tend to recur at distant sites, making the need for effective systemic chemotherapy a pressing issue. There is currently no proven role for chemotherapy in the adjuvant treatment of completely resected stage I disease. Omura and colleagues randomized 156 patients with stage I and II uterine sarcomas to either observation or adjuvant doxorubicin.[274] No statistical difference was detected in recurrence rate, progression-free interval, or overall survival. For single-agent treatment of patients with advanced or recurrent carcinosarcoma, ifosfamide (30% response rate for chemotherapy-naive patients[275]) and cisplatin (18% to 19% response[276,277]) have demonstrated the most activity. A recent study of paclitaxel has also exhibited moderate activity, with an 18% response rate.[278] Combination therapy with cisplatin and ifosfamide may offer a small improvement over single-agent therapy in progression-free interval, though no improvement in overall survival has been noted.[279] The combination of ifosfamide and paclitaxel was investigated in patients with advanced or recurrent uterine carcinosarcoma. The regimen was tolerable, with a crude overall response rate of 45%.[280] Currently, the GOG is evaluating the combination therapies docetaxel/gemcitibine and paclitaxel/carboplatin in patients with carcinosarcoma.

For patients with leiomyosarcoma, doxorubicin has shown to be the most effective single-agent (25% response rate), though ifosfamide has also demonstrated some antitumor activity.[280,281] The combination of gemcitabine and docetaxel has been shown to be tolerable, with a 53% overall response rate.[283] For leiomyosarcoma, resection of retroperitoneal lymph nodes will rarely provide useful information, given the lower incidence of nodal involvement.[284]

Owing to its rarity, ESS has not been well studied in clinical trials. Low-grade ESS are slow-growing tumors with an indolent course that respond well to hormonal therapy. High-grade ESS behaves more aggressively. The GOG demonstrated a 33% response rate among 22 patients with recurrent or metastatic high-grade ESS who were treated with ifosphamide.[285]

COMPLICATIONS OF TREATMENT

Overall, surgery, including staging of lymph nodes, is well tolerated; however, the addition of lymphadenectomy to TAH-BSO does increase the risk of vascular injuries, hematomas, and lymphocysts.[286] In addition, around 10% to 20% of patients who undergo lymphadenectomy develop lower-extremity lymphedema.[287] The addition of adjuvant radiation to lymphadenectomy has also been show to increase postoperative hospitalization rates and result in a higher rate of severe complications.[288,289] The risk of complications from lymphadenectomy has been shown to be related to the number of lymph nodes that are removed at the time of surgery.[290] Despite these increased risks, the importance of accurate lymph node staging cannot be overstated, and surgical staging of lymph nodes should be performed in appropriately selected patients.

Although pelvic radiation is generally well tolerated, the acute and long-term effects of this treatment have been well documented. Long-term follow-up from the PORTEC trial revealed that the 5-year actuarial rate of late complications of grade I to IV was 26% in the patients who received radiation compared to 4% in those who did not ($P < 0.0001$).[165] Although 63% of the patients experienced some degree of acute toxicity, the majority of these patients had symptoms that resolved without further complications, and only 2% of patients discontinued their treatment because of their symptoms. However, the most important predictor of long-term toxicity was found to be the presence of acute symptoms. These rates of complications are similar to those in other series in which whole-pelvic irradiation has been delivered, either preoperatively or postoperatively.[291] In an attempt to decrease the radiation dose that is received by the surrounding normal tissues, several recent studies have examined the dosimetric advantages of using intensity-modulated radiation therapy in the treatment of endometrial carcinoma. The results of these studies suggest that the volume of normal tissue, namely, the bladder, rectum, and small bowel, that receives high doses of radiation can be significantly reduced while still delivering adequate coverage of the postoperative planning target volume.[292,293] The potential advantages of intensity-modulated radiation therapy in decreasing normal tissue toxicity must be weighed against the potential risk of decreased margin on the target volume and an increased volume of normal tissue receiving low doses of radiation. This increases the need for proper patient positioning and adequate immobilization in order to minimize treatment-to-treatment variations in patient position. Because of its potential to deliver a highly conformal radiation dose, intensity-modulated radiation therapy holds promise in improving the toxicity profile of pelvic irradiation. However, further studies are needed to assess the long-term outcome in patients who are treated with intensity-modulated radiation therapy.

When extended field or whole-abdominal irradiation is given, the treatment technique must minimize the exposure to normal tissues, in particular to the small bowel, liver, and kidneys. The most common acute effects of large abdominopelvic radiation fields are acute gastrointestinal symptoms, including nausea, vomiting, diarrhea, and cramping. Loss of fluid and electrolytes through vomiting and diarrhea can lead to acute dehydration, so antiemetics and antidiarrheals should be prescribed early in therapy, and patients should be monitored closely. Myelosuppression through exposure of the bone marrow may also occur; therefore, blood counts should be monitored, and supportive therapy should be given accordingly. Four field pelvic arrangements including anterior, posterior, and lateral fields often allow for blocking of anterior segments of the small bowel. When the para-aortic nodes or whole abdomen is treated, larger volumes of small bowel are inevitably included, leading to a greater likelihood of acute enteritis. Typically, the whole-abdomen dose is limited to a range of 25 to 30 Gy, keeping the exposure of the kidneys to less than 20 Gy and exposure to the whole liver less than 22 to 25 Gy. Doses beyond 45 to 50 Gy to large volumes of small bowel will significantly increase the risk of late complications. Series using these dose parameters and techniques report late bowel complications, primarily small bowel obstruction, in 3% to 12% of patients for extended field irradiation[230,234] and in 0% to 9% of patients for whole-abdominal irradiation.[218,294–296]

TREATMENT OF RECURRENT DISEASE

Incidence of Pelvic Recurrence

Recurrence in the pelvis after hysterectomy is a common site of relapse in patients with endometrial cancer. Most locoregional recurrences are diagnosed in the first 2 to 3 years after initial treatment. For patients who present with pathologic stage I to II disease, the main risk factors for pelvic recurrence are high-grade histology and myometrial invasion greater than one third to one half of the myometrial width. With no postoperative adjuvant therapy, the pelvic recurrence risk for these patients has been reported to be 10% to 40%. This is reduced to less than 5% with adjuvant pelvic irradiation, with or without a vaginal brachytherapy boost.[164,297,298] The distant metastatic rate and overall survival rate are not altered by the addition of adjuvant pelvic irradiation. Most series have reported failures as total pelvic recurrences, including the vaginal cuff, pelvic lymph nodes, or other limited pelvic sites. High-risk stage I patients, such as those with high-grade or deep invasion, appear to have a 15% risk of vaginal recurrence at 10 years when treated with initial surgery alone.[299] The GOG conducted a randomized study comparing surgery alone to surgery and postoperative pelvic irradiation for "intermediate-risk" patients, including stage IB, stage IC, and occult stage II (GOG Protocol 99).[166] Whole-pelvic radiation reduced the risk of recurrence by 58%. When patterns of recurrence were examined, there were 13 vaginal recurrences among 202 women who were randomized to surgery alone (6%), compared to 2 vaginal recurrences in 190 (1%) women who were randomized to adjuvant irradiation. For vaginal and pelvic recurrences combined, there were 18 in the surgery-alone arm compared with 3 in the adjuvant radiation arm. Patients with extrauterine disease have a higher risk of pelvic recurrence, which depends on the type and number of extrauterine sites.

A group of Dutch institutions conducted the PORTEC randomized trial of surgery alone (without lymphadenectomy) versus surgery and postoperative pelvic radiation for selected patients with stage I disease (grade I and >50% myometrial invasion, grade II and any invasion, grade III and <50% invasion).[165] Cancer-related deaths at 5 years were seen in 6% in the surgery-only arm and in 9% in the adjuvant radiation arm. However, locoregional recurrences were significantly reduced in the adjuvant radiation arm. Locoregional relapses were seen in 14% of patients after surgery alone and in 4% of patients after adjuvant radiation at 5 years, 73% of which were confined to the vagina. At 8-year follow-up, the locoregional relapse rates were similar; however, most of the recurrences in the surgery group were in the vagina, while most of the relapses in the radiation group occurred at distant sites. At 8 years, the rates of death were similar between the two groups: 19.7% in the radiation group versus 15.6% in the control group ($P = 0.35$).[300] Adjuvant pelvic radiation reduced both vaginal vault and pelvic recurrences compared to surgery alone. Vaginal relapse was diagnosed in 39 patients, 35 of whom were candidates for curative intent. A complete remission was obtained in 31 of the 35 patients who had curative treatment. At a median follow-up of 44 months, 77% of the 31 patients who had reached a complete remission after salvage therapy were still disease free. The 3-year actuarial survival rates after vaginal, pelvic, and distant relapse were 73%, 8%, and 14%, respectively. This salvage rate was better in the surgery arm, presumably because high-dose radiation could more readily be delivered for salvage therapy when none was given postoperatively.

Treatment of Pelvic Recurrence

Exenteration

Surgical treatment for pelvic relapse often requires partial or total exenteration. Barakat and colleagues reported on 44 patients who were treated with exenteration for recurrent endometrial cancer in the pelvis (location not otherwise described), 77% of whom had received prior irradiation.[301] The median interval to recurrence in this series was 28 months, and half the patients required a total exenteration. The median survival after salvage surgery was 10 months, with nine patients (20%) alive at more than 5 years. However, 80% had major postoperative complications.

Radical Radiation

Radical irradiation is usually the treatment of choice for patients who are initially treated with surgery alone. High-dose pelvic radiation with intravaginal brachytherapy is effective salvage therapy. Isolated vaginal recurrences are more successfully treated than are pelvic side wall or pelvic lymph node recurrences, but the latter might still require high-dose palliation. Factors that are associated with treatment outcome for recurrence include tumor size, grade, location in the vagina (distal versus apical), and disease-free interval.[302]

Outcomes for Pelvic Recurrence

Prognostic factors and outcomes in patients who experience pelvic recurrences have been examined. Methods of salvage therapy have varied depending on the presentation and extent of recurrent disease and the type of prior therapy. A series of 42 women with recurrent endometrial cancer after surgery alone were treated at Princess Margaret Hospital, all with combined EBRT and intracavitary therapy to a median total dose of 81.5 Gy.[303] The median time to recurrence postoperatively was 1.3 years. The 5-year and 10-year survival rates after salvage treatment were 53% and 41%, respectively. The local control rate was 65%, influenced by vaginal stage and size of the recurrence. The authors also noted that local control rates differed by vaginal location (66% for apex and 100% for distal) compared to central pelvic sites (44%). While the local control rate was better with a total dose greater than 80 Gy (72% versus 54% for <80 Gy), this was not statistically significant. Sears and colleagues reported on 45 patients who had not received postoperative pelvic radiotherapy who then developed vaginal (85%) or pelvic (15%) recurrence of endometrial cancer. Recurrences were analyzed by the corresponding vaginal cancer stage.[304] The median time to recurrence was 12 months, and long-term median follow-up had elapsed. Salvage treatment consisted of EBRT alone in 40%, EBRT and brachytherapy in 56%, and brachytherapy alone in 4%, with a median dose of 50 Gy. The 5-year disease-specific survival rate was 51%, the overall survival rate was 44%, and the locoregional control rate was 54%. Factors that were associated with local control were vaginal stage of recurrent disease, tumor size, radiation boost technique, time to recurrence, and age. The disease-specific survival rate was influenced by local control (74% for local control versus 23% without local control).

An Austrian series of 56 patients with pelvic relapse after hysterectomy included 41% who had received adjuvant irradiation, and 71% of recurrences were vaginal.[305] A reirradiation dose of approximately two thirds of the initial dose was used in previously irradiated patients (30 to 40 Gy) and was increased as the interval from prior radiation increased. Almost half the patients were treated with pelvic radiation and brachytherapy, 25% with brachytherapy alone, and 16% with external irradiation only, while 12% had no radiotherapy. Better 3-year survival rates were seen in patients who had no prior irradiation (59% versus 25%), low-grade disease (48% versus 22%), a relapse-free interval exceeding 2 years (55% versus 35%), and recurrence only in the vagina (54% versus 19%). A series of 26 patients who were treated with external radiotherapy and/or brachytherapy for locoregional recurrence of endometrial cancer reported a 5-year overall survival rate of 44%.[306] These authors also noted that the size of recurrent disease affected the success of salvage therapy. Locoregional control was 100% in patients with recurrent tumors less than 2 cm, 83% in those with tumors 2 to 4 cm, and 67% in those with tumors exceeding 4 cm. Also, the use of combined external irradiation and brachytherapy resulted in 100% locoregional control, while use of either treatment mode alone resulted in second relapse in 4 out of 10 patients.

Other series have had less promising results, possibly related to the extent of pelvic recurrence. Kuten and colleagues reviewed a group of patients with recurrent disease, only 33% of whom had isolated vaginal recurrence, while another third had pelvic and distant recurrence simultaneously.[307] For the entire group, locoregional control was only 35%, and the 5-year survival rate was 18%. The overall vaginal control rate was 82%, and patients with isolated vaginal recurrence had a 5-year progression-free survival rate of 40%. No patients with pelvic recurrence were alive beyond 1.5 years. In a study of 73 women undergoing salvage radiotherapy for pelvic recurrence after surgery alone, 60% received combined external and brachytherapy, 23% received brachytherapy alone, and 17% received external radiation alone, to a mean physical dose of 76 Gy.[308] The majority of patients in this study had vaginal stage II (60%) or stage III (34%) disease. The 5-year survival rate was 25%, and the response rate was 73%, with 67% experiencing progressive disease, just over half of whom had local progression.

Isolated Vaginal Recurrence

Salvage therapy for isolated vaginal recurrence may include treatment with external beam irradiation plus a vaginal brachytherapy boost or intravaginal brachytherapy alone. Several series have examined the prognosis and outcomes for this selected group of patients; these studies are summarized in Table 92-15. Overall survival rates after salvage therapy for vaginal recurrence range from 25% to 75%. In the largest retrospective series from M.D. Anderson, 91 patients with isolated vaginal recurrence received pelvic radiation alone (31%), brachytherapy alone (12%), or a combination of the two modalities (57%).[309] At a median follow-up of 58 months, the 5-year local control rate was 75%, and the overall survival rate was 43%. Predictors of better local control included combined modality irradiation and dose greater than 80 Gy. A multi-institution study by Huh and colleagues identified 69 patients who were initially diagnosed with stage I adenocarcinoma treated with surgery alone, with isolated vaginal recurrences. Of those patients, 62 patients (90%) were treated with a combination of whole-pelvic radiation and brachytherapy, and the remaining 2 were treated with brachytherapy alone. The mean time to initial recurrence was 24 months, and the mean follow-up was 63 months. The authors reported an 81% salvage rate with radiation with a 5-year overall survival rate of 75%.[310] Curran and colleagues reported 55 women with isolated vaginal recurrence posthysterectomy.[311] Nearly half received pelvic radiation and vaginal brachytherapy, 30% had external radiation alone, and 7% had brachytherapy alone, to a median dose of 60 Gy. The 5-year survival rate was 31%, and the 5-year pelvic control rate was 42%. The outcome was highly dependent on the radiation dose, with a 68% pelvic control rate at 5 years if 60 Gy or more was delivered, compared to 10% for those who received less than 60 Gy (including some patients who received no radiation). The 5-year survival rate was also worse for patients who were being reirradiated: 16% at 5 years versus 48% for those who were receiving a first course of radiotherapy. Using the vaginal carcinoma staging criteria as descriptors of the extent of disease, this study found that survival rates diminished as the "stage" of recurrent disease increased. In addition, better pelvic control rates were seen in recurrences that were located in the vaginal

Table 92-15 Results for Treatment of Isolated Vaginal Recurrence

Author	No. of Patients	Treatment	Pelvic Control Rate (%)	Five-Year Survival Rate (%)
Curran et al.[311]	55	Pelvic RT and/or brachytherapy (various)	Stage* I: 100	85

CSS, cause-specific survival; ICRT, intracavitary radiation therapy; HDR, high dose rate; LDR, low dose rate; PFS, progression-free survival; RT, radiation therapy.
*Stage refers to extent of recurrent vaginal disease.

apex than in recurrences that were located in the suburethral area (56% versus 20%). Greven and Olds treated 18 patients with isolated vaginal recurrence with a combination of external pelvis radiation and intravaginal ovoids.[312] They achieved a 44% 3-year local control rate and an overall survival rate of 33% at a follow-up range of 3 to 10 years. Morgan and colleagues used pelvic fields and either intracavitary or interstitial brachytherapy in 34 patients with isolated vaginal recurrence, resulting in an 85% pelvic control rate, a 5-year survival rate of 68%, and a 60% disease-free survival rate.[313] Better control rates were seen in patients with less than 2 cm of disease and in those who were treated with radiation doses greater than 60 Gy. A group of patients from the University of Milan who presented with isolated vaginal recurrence after surgery alone were treated with LDR intravaginal ovoids or cylinders to a dose of 60 to 70 Gy at the vaginal surface.[314] The median time to relapse was 14 months. Vaginal recurrences were located in the upper third of the vagina in 69% of patients, the middle third in 9%, lower third in 11%, and diffusely in 11%. All patients exhibited a complete response to therapy, and 12% subsequently failed, for an overall local control rate of 86%.

LDR brachytherapy, as described in the previous studies, is thought to provide tumor control rates equivalent to those of HDR. Both methods have been widely used in the adjuvant postoperative setting to deliver a vaginal cuff boost, with or without external pelvic irradiation. Pai and colleagues have reported on the use of HDR intracavitary brachytherapy for isolated vaginal recurrence.[315] Thirteen of 20 patients received external pelvic radiation (44 Gy) and an HDR vaginal boost (24 Gy), while the others were treated with HDR intracavitary therapy alone (35 Gy). Complete response was noted in 90% of patients, with second local relapses in 22% within 30 months, for a 10-year local control rate of 74%. The 10-year disease-free survival rate was 46%, and the complication rate was 15% with no grade III or IV late complications. This study suggests that HDR intravaginal therapy is also an effective treatment for vaginal recurrence and is well tolerated.

Interstitial brachytherapy has also been used for treatment of vaginal wall recurrences. Tewari and colleagues reported on 30 patients who presented with isolated vaginal relapse after initial surgery alone (18 patients), who were treated with external irradiation followed by an interstitial implant, or implant alone for previously irradiated patients (12 patients).[316] The method that was used was the Syed-Neblett vaginal template, placed transperineally for a cumulative dose of 86 Gy in the postoperative relapses and 98.5 Gy in the reirradiation group. All of the recurrent tumors were more than 2 cm in size, with a median time to relapse of 29 months from initial diagnosis. Complete clinical responses were noted in 93% of patients, with 18% second local relapses at a median interval of 16 months. The median survival after recurrence was 60 months, with a 5-year survival of 65%. Only five patients experienced major morbidity, including fistula ($N = 2$), stricture ($N = 1$), and proctitis ($N = 2$). Nag and colleagues also used a perineal interstitial template for vaginal recurrences, combining EBRT with a 30-Gy boost for postoperative relapses and 50 to 55 Gy interstitial therapy alone for previously irradiated patients.[317] These authors report an overall local control rate of 66% and a 5-year survival rate of 42%. A French group utilized an intravaginal template with imbedded needles to treat vaginal vault recurrences and achieved a 70% local control rate and an overall survival rate of 56%.[318] Thus, interstitial brachytherapy provides a reasonable chance of local control and may be used to treat more extensive tumors that are not amenable to simple intravaginal brachytherapy.

FUTURE ISSUES

Endometrial cancer largely presents in the early stage, when surgery is possible and often curative. However, a number of high-risk features require select patients to undergo adjuvant radiation therapy postoperatively. Current screening methods are relatively insensitive, and new imaging modalities such as magnetic resonance imaging and ultrasound may be combined with molecular markers to identify patients in even earlier stages. One of the biggest areas of controversy in early-stage endometrial cancer involves which patients benefit from adjuvant therapy and whether this should include pelvic irradiation with or without a vaginal brachytherapy boost. Because bimodality therapy is associated with an increased risk of both acute and long-term sequelae, better criteria for adjuvant therapy in the various subsets of stage I disease might allow fewer patients to be exposed to the risks of combined surgery and radiation. In addition, the use of less invasive and less extensive laparoscopic surgical approaches for both primary surgery and staging procedures may further reduce the risk of side effects. In patients who are destined to be long-term survivors, the focus must now turn to reduction of treatment sequelae and quality of life issues. The outcomes for high-risk histologies remain poor, necessitating the investigation of more effective systemic agents.

In advanced endometrial cancer, both local control and distant metastases are important challenges. Unfortunately, active systemic chemotherapy or hormonal regimens have not been well defined in this disease. Therefore, trials looking at new systemic agents are warranted. The participation of willing patients in collaborative group trials should be strongly encouraged so that these questions and others can be answered.

The GOG is currently evaluating the molecular and surgical-pathologic staging of endometrial cancer. The purpose is to obtain a better understanding of the biology of endometrial cancer, including metastasis and response to therapy. The goal will be to determine specific molecular targets by evaluating genomic, proteomic, and immunoassay data. In the future, such information could be used to individualize the treatment and prevention of uterine cancer by utilizing novel biologic agents.

93 Ovaries and Fallopian Tubes

Deborah Armstrong

SUMMARY OF KEY POINTS

Celomic Epithelial Carcinoma

Basic Characteristics

- Ninety percent of the 23,300 new cases and 13,900 deaths annually in the United States
- Derived from celomic epithelium lining the peritoneal cavity, most commonly from that which invests the ovary
- Most common route of spread: dissemination throughout peritoneal cavity
- Significant prognostic factors: age, histologic type and grade, extent of disease at diagnosis

Screening and Prophylaxis

- High-risk individuals: those with one or more first-order relatives with ovarian carcinoma
- No proven effective screening tests available, although transvaginal sonography and serial CA-125 and proteomic serum patterns under evaluation
- Prophylactic oophorectomy still of no proven value

Initial Evaluation and Management

- Emphasis in initial evaluation placed on the peritoneal cavity, an emphasis requiring exploratory laparotomy in those not clearly stage IV
- Minimum requirements for appropriate laparotomy: surgery through an incision adequate to inspect the entire peritoneal surface, multiple peritoneal biopsies in the absence of gross extrapelvic disease, and a maximal attempt at surgical cytoreduction, including total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy

Management of Advanced (Stage III–IV) Disease

- After surgery, systemic therapy to include at least a platinum compound
- Combination chemotherapy favored by the weight of evidence, preferred combination being paclitaxel-carboplatin: paclitaxel (175 mg/m^2 intravenously over 3 hours) followed by carboplatin (area under the curve, 6 to 7.5 intravenously) repeated every 3 weeks for six cycles
- Controversial issues: the roles of new agents, the role of dose-intense therapy supported by marrow reconstitution, the role of intraperitoneal therapy, and the role of maintenance paclitaxel

Management of Limited (Stage I–II) Disease

- After careful exploratory laparotomy, patients divided into low-risk and high-risk groups on the basis of the presence of one or more high-risk features: poorly differentiated neoplasm, extracystic tumor, positive peritoneal washings, ascites, or extraovarian disease
- Those who are at low risk of recurrence (no high-risk features): total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy followed by observation
- Those who are at high risk of recurrence (one or more high-risk features): the same surgery as in those who are at low risk followed by adjuvant platinum-based chemotherapy (paclitaxel/carboplatin for three cycles)

Salvage Therapy for Recurrent Disease

- Patients divided into platinum-sensitive and platinum-resistant groups
- Platinum-sensitive patients (responded to initial platinum-based therapy and experienced at least a 6-month platinum-free interval before relapse): retreatment with taxane/platinum combination
- Platinum-resistant patients (progressed on platinum-based therapy, best response to platinum-based therapy stable disease, or relapsed during or within 6 months of platinum-based therapy): treatment with drugs that produce responses (weekly paclitaxel, docetaxel, pegylated liposomal doxorubicin, oral etoposide, topotecan, tamoxifen, gemcitabine, navelbine, ifosfamide)
- Offering no proven advantage over intravenous therapy at standard doses to these patients: intraperitoneal therapy, high-dose therapy with marrow reconstitution, radiation therapy, and biologic agents

Germ Cell Cancers

Basic Characteristics

- Germ cell cancers make up 5% of all cancers of the ovary in the United States
- Histologies: dysgerminomas and nondysgerminomas (endodermal sinus tumors, mixed cell tumors, immature teratomas, embryonal carcinomas, and choriocarcinomas)
- Tumor markers are an important means of detecting early recurrence and monitoring the progress of therapy: α-fetoprotein and human chorionic gonadotropin
- For management purposes, two major groups of patients: (1) stages I to III completely resected and (2) incompletely resected stage III to IV disease

Stages I to III Completely Resected

- Initial management: complete resection of disease
- Adjuvant therapy: combination chemotherapy (either bleomycin/etoposide/cisplatin or vincristine/actinomycin/cyclophosphamide)

Stages III to IV Incompletely Resected

- Systemic therapy: bleomycin/etoposide/cisplatin

All
- Close follow-up after chemotherapy, including monthly assessments of tumor markers, physical examination, and chest radiography

Rare Malignant Ovarian Tumors
- Fewer than 5% of ovarian cancer: granulosa cell tumors, thecoma-fibroma tumors, Sertoli-Leydig cell tumors, gynandroblastomas, and steroid cell tumors
- Treatment of choice: surgical resection with little known about the use of radiation or systemic therapy as either adjuvant treatment or management for advanced or recurrent disease

Cancer of the Fallopian Tube
- Rare (300 cases annually in the United States), with more than 90% of all cases papillary serous adenocarcinomas
- Pattern of spread similar to that of celomic epithelial carcinoma of the ovary
- Surgical resection the mainstay for most patients with disease confined to the fallopian tube
- Radiation or chemotherapy reserved for cases with penetration to or beyond the serosa, with evidence favoring management similar to that used for advanced ovarian carcinoma

INTRODUCTION

Cancers of the ovary and fallopian tube together account for most deaths resulting from cancer of the female genital tract. This statistic relates primarily to the fact that, unlike other common malignant gynecologic neoplasms (cancers of the endometrium and cervix), cancers of the ovary and fallopian tube are first seen at relatively advanced stages of disease because of the lack of an effective early diagnostic test. Ovarian cancers are far more common than tubal malignancies and provide most of the data on which the management of both malignancies is based. This chapter first addresses cancers of the ovary extensively, followed by a discussion of cancers of the fallopian tube.

CANCER OF THE OVARY

Cancer of the ovary will be newly diagnosed in more than 23,300 women in the United States each year and will cause the death of more than 13,900 American women annually.[1] The lifetime likelihood that ovarian cancer will develop in a woman is estimated to be between 1 in 60 and 1 in 70, with a higher frequency associated with certain familial syndromes.[2–5] This group of cancers includes three major types: celomic epithelial carcinoma of the ovary, germ cell neoplasms, and stromal tumors. Each of these groups is discussed separately.

Celomic Epithelial Carcinoma

Almost 90% of cancers of the ovary are celomic epithelial carcinoma, which is one of the three most common gynecologic cancers. Management of these lesions evolves from an understanding of certain basic aspects of the disease process.

Basic Characteristics

CLINICALLY RELEVANT DISEASE FEATURES. Celomic epithelial carcinomas may arise in any part of the peritoneal cavity, although most appear to arise from the celomic epithelium that invests the ovary during embryonic development. The reasons for the preference for ovarian celomic epithelium are not entirely clear. It has been speculated that repeated rupture and repair of this portion of the celomic epithelium with the process of ovulation afford a greater opportunity for mutations that lead to malignancy. Such speculation is supported by observations that associate multiple pregnancies and the use of birth control pills, which suppress ovulation, with a decreased risk for ovarian carcinoma.[6]

Furthermore, most of these lesions arise in invaginated epithelium in areas of repair after ovulation, developing as though within a cyst. The process eventually penetrates the capsule of the ovary, forms tumor excrescences on the surface of the ovary, and then disseminates primarily by direct spread throughout the peritoneal cavity. Subsequent spread via lymphatic and hematogenous dissemination also occurs. This pattern of evolution of the disease is reflected in the International Federation of Gynecology and Obstetrics (FIGO) staging system[7] (Table 93-1), in which the most common stage at presentation is stage III, characterized by spread outside the pelvis to involve the peritoneal cavity. Because the process is an intra-abdominal disease that produces few symptoms before intraperitoneal dissemination and is not amenable to early diagnosis by currently available screening techniques, essentially 70% to 75% of patients are first seen with advanced (stage III or IV) rather than limited (stage I or II) disease.

Several characteristics of celomic epithelial carcinomas distinguish their clinical management from that of the other two common gynecologic cancers: endometrial cancer and cervical cancer. First, the primary route of spread, dissemination throughout the peritoneal cavity, opens the possibility for therapy directed toward the peritoneal cavity. Second, unlike the other two common gynecologic cancers, these lesions usually are first seen at a relatively advanced stage (stage III or IV), which necessitates a larger role for systemic

Table 93-1 International Federation of Gynecology and Obstetrics Staging System for Ovarian Carcinoma

Stage	Description
I	Growth limited to the ovaries
IA	One ovary; no ascites; capsule intact; no tumor on external surface
IB	Two ovaries; no ascites; capsule intact; no tumor on external surface
IC	One or both ovaries with either surface tumor; ruptured capsule; or ascites or peritoneal washings with malignant cells
II	Pelvic extension
IIA	Involvement of uterus and/or tubes
IIB	Involvement of other pelvic tissues
IIC	Stage IIA or IIB with factors as in stage IC
III	Peritoneal implants outside pelvis and/or positive retroperitoneal or inguinal nodes
IIIA	Grossly limited to true pelvis; negative nodes; microscopic seeding of abdominal peritoneum
IIIB	Implants of abdominal peritoneum ≤2 cm; nodes negative
IIIC	Abdominal implants >2 cm and/or positive retroperitoneal or inguinal nodes
IV	Distant metastases

Data from the New FIGO stage grouping.[7]

Table 93-2 Impact of Volume of Residual Disease on Pathologic Complete Response to Combination Chemotherapy in Patients with Advanced Ovarian Carcinoma

Regimen	Minimal	Bulky
PAC (GOG)[8,9]	45/137 (33%)	13/107 (12%)
PAC (Ehrlich et al.)[10]	5/17 (30%)	5/39 (13%)
HCAP (Greco et al.)[11]	18/21 (86%)	3/29 (10%)
CHEX-UP (Young et al.)[12]	5/14 (36%)	5/37 (14%)

CHEX-UP, cyclophosphamide + hexamethylmelamine + 5-fluoruracil + cisplatin; HCAP, hexamethylmelamine + cyclophosphamide + doxorubicin + cisplatin; PAC, cisplatin + doxorubicin + cyclophosphamide.

Table 93-4 Prognostic Factors in Ovarian Carcinoma

Factor	Description
Age	Older patients have poorer survival.
Grade	Poorly differentiated lesions are associated with poorer survival.
Histologic type	Clear cell and mucinous histologies are associated with poorer survival. Tumors of low malignant potential imply a much better survival.
Stage	More extensive disease, as reflected in the FIGO staging system, produces poorer survival.
Volume of disease	In patients with stage III disease, larger volume of residual disease leads to poorer survival.

therapy in the management of these cases. Finally, the volume of residual disease at initiation of systemic therapy influences the subsequent response to chemotherapy and survival. The smaller the largest residual nodule, the more likely it is that the disease will regress with drug therapy[8–11] (Table 93-2) and the more likely it is that the patient will live longer[12–14] (Table 93-3).

Other disease characteristics have been observed to influence outcome (Table 93-4). Shortened survival is associated with older age[15] and more poorly differentiated disease. These factors do not, however, affect therapeutic decisions except for the role of histologic grade in limited disease, a role that is discussed later in the chapter. Histologic subtype also affects survival: Patients who have clear cell or mucinous carcinomas have shorter survival, whereas those with tumors of low malignant potential ("borderline carcinomas") have a markedly better survival. These subtypes constitute fewer than 10% of all celomic epithelial tumors. Because no alternative therapeutic choice offers greater benefit for mucinous or clear cell carcinomas, these histologic types do not currently influence therapeutic decisions. Conversely, tumors of low malignant potential do influence therapeutic choices, as will be discussed.

TUMORS OF LOW MALIGNANT POTENTIAL. Celomic epithelial tumors of low malignant potential account for approximately 15% of ovarian carcinomas.[16] Patients with these lesions tend to be younger than those with invasive ovarian carcinoma (average age at onset: 49 years).[17] The sine qua non of the diagnosis is the absence of invasion of the stroma.[18] The vast majority of cases display serous or mucinous histology with bilaterality in roughly one third of serous tumors.

Recognition of these tumors is important because both prognosis and management differ greatly, in comparison to standard management of invasive ovarian carcinomas.[19–21] In general, management should begin with an exploratory laparotomy and resection of as much disease as possible. Pathology should be reviewed carefully to ensure that no areas of invasive carcinoma are present.[22] After surgery, patients should be observed until such time as the disease begins to behave in a more aggressive fashion. At that point, chemotherapy may be used, although its efficacy in this setting is not clear.

Table 93-3 Impact of Volume of Residual Disease on Survival in Patients with Advanced Ovarian Carcinoma

Regimen	Minimal (months)	Bulky (months)
PAC (GOG)[8,9]	42	19
L-PAM (GOG)[13,14]	33	13

L-PAM, melphalan; PAC, cisplatin + doxorubicin + cyclophosphamide.

EXTRAOVARIAN PERITONEAL SEROUS PAPILLARY CARCINOMA. It has long been recognized that celomic epithelial carcinomas can arise in portions of the peritoneal cavity other than the surface of the ovaries. The Gynecologic Oncology Group (GOG) undertook a study of these extraovarian peritoneal papillary serous carcinomas to determine whether they responded in a fashion similar to that of standard treatment for celomic epithelial carcinomas of the ovary.[23] The study of 47 women with these extraovarian celomic epithelial carcinomas showed that when the data are compared with results of treatment of ovarian carcinomas with the same chemotherapy, similar response rates, surgical complete response rates, and survivals are observed. This is the basis on which these lesions are now included in trials of chemotherapy for ovarian carcinoma.

INTERNATIONAL FEDERATION OF GYNECOLOGY AND OBSTETRICS STAGE. The factor that most influences management is the extent of disease at diagnosis (stage). This discussion is organized accordingly: A general approach to initial evaluation and surgical management is followed by a discussion of the role of chemotherapy both in previously untreated patients with advanced disease and in patients with recurrent or persistent disease. The management of patients with limited lesions is then considered.

Initial Evaluation and Management

Patients with celomic epithelial carcinomas generally are first seen with complaints of a full or heavy sensation in the pelvis or with increasing abdominal girth. Unfortunately, these symptoms usually reflect the presence of advanced disease. Efforts directed to earlier diagnosis have largely been unsuccessful, with the possible exception of the application of certain tools to patient populations that are at high risk for the development of ovarian carcinoma.

HIGH-RISK PATIENTS, SCREENING, AND GENETIC TESTING. Within the past decade, interest in using family history to identify patients who are at high risk of developing ovarian carcinoma has escalated.[2,24–26] Data now suggest that women with one first-order relative with ovarian carcinoma have a 3.6-fold higher risk than that of the general population. For those who have two or more relatives with ovarian carcinoma, at least one of whom is a first-order relative, risk is considerably higher, with estimates as great as 50% or better reported but not necessarily substantiated.

Certain hereditary syndromes have been described.[3,25] These include hereditary breast and ovarian cancer syndromes associated with changes at chromosome 17q (BRCA1) and at chromosome 13q (BRCA2) and hereditary nonpolyposis colon cancer syndromes

(Lynch syndrome II with an association with colon and endometrial cancers as well), which exhibit hMLH1, hMSH2, and hPMS2 mutations. These familial ovarian cancers typically appear at a younger age than does sporadic ovarian carcinoma and, despite pathologic factors that should portend a poor survival, predict a significantly better survival than that associated with sporadic ovarian cancer of the same stage.[4,5,25–29] Both hereditary breast/ovarian syndrome and hereditary nonpolyposis colon cancer syndromes appear to be vertically transmitted by an autosomal dominant mode, with incomplete penetrance. Familial ovarian cancer registries have now identified a number of women who either fit one of these syndromes or have at least one first-order relative with ovarian cancer.

These observations raise at least four significant questions with regard to management. First, should prophylactic oophorectomy be recommended to women who are at high risk? The largest experience with prophylactic oophorectomy comes from the Gilda Radner Familial Ovarian Cancer Registry. To date, 324 women with at least one first-order relative with ovarian cancer have undergone prophylactic oophorectomy. The relatively short follow-up evaluation of most of these women shows that in six, celomic epithelial carcinomas of the peritoneal cavity have developed, for an overall rate of 1.8%.[30] Although this rate is low, it exceeds the rate of ovarian carcinoma in the general population. Other reports have documented the occurrence of primary peritoneal neoplasms in women who have previously undergone oophorectomy.[31] This finding raises questions about the value of prophylactic oophorectomy in preventing the development of celomic epithelial carcinomas. No prospective trials have been conducted to examine this question. The weight of evidence suggests that the procedure should not be routinely recommended until further follow-up is available to determine whether a further significant increase in the incidence of peritoneal malignancies will occur. The exception to this might be women who have a true hereditary syndrome with a very high risk of developing ovarian carcinoma, although no clinical trial documents the value of prophylactic oophorectomy even in this population.[32,33]

Second, how should patients who are at high risk be monitored? More simply put, do we have valid screening tests? Family history clearly identifies a high-risk population. Logic dictates that screening leading to early diagnosis would result in a higher cure rate. The problem is the lack of evidence that any monitoring technique yields early diagnosis at a reasonable rate. Both CA-125 and transvaginal sonography have been recommended for screening. Evidence is lacking that CA-125 leads to early diagnosis.[4] By contrast, transvaginal sonography has proved capable of identifying ovarian carcinoma at a limited stage in two series.[5,30] The drawback of the technique is that 15 to 40 laparotomies have to be done to diagnose one case of limited ovarian carcinoma. At least for the present, neither approach can be recommended for routine screening, although selected high-risk patients, with a clear understanding of the attendant difficulties, can be screened with transvaginal sonography.[34,35]

More recently, new technology has offered some hope of an effective approach to screening for ovarian carcinoma. Investigators at the U.S. National Cancer Institute reported the use of proteomic patterns in serum to identify patients with ovarian cancer.[36] In a population of 50 patients with ovarian cancer and 66 patients with nonmalignant disease, the test reportedly had a sensitivity of 100%, a specificity of 95%, and a positive predictive value of 94% for correctly identifying those with or without ovarian cancer. Unfortunately, the calculation of the positive predictive value did not take into account the prevalence of the disease in the target population. When this deficiency is corrected, the true positive predictive value is 1%, not 94%. This is less than the positive predictive value that has been reported for the use of CA-125 alone.[37] Before proteomic patterns can be recommended to screen for ovarian carcinoma, further retrospective and prospective studies are required.

Third, should patients with positive family histories be offered genetic testing? Approximately 10% of ovarian carcinoma is associated with inheritance of an autosomal dominant genetic mutation and a resultant strong family history of ovarian carcinoma and certain other associated cancers, such as breast cancer.[38] These cases fall into two broad categories. The first is commonly called the breast and ovarian cancer syndrome and is associated with mutations at two loci: BRCA1 on chromosome 17q21 (75% to 90% of breast and ovarian cancer syndrome) and BRCA2 on chromosome 13q12 (10% to 25% of breast and ovarian cancer syndrome). In published series, these mutations account for approximately 7% of ovarian carcinoma. The second is commonly called the hereditary nonpolyposis colorectal carcinoma (HNPCC) syndrome and is associated with mutations that include three known genes: hMSH1 (45% to 50% of cases of HNPCC syndrome), hMLH1 (45% to 50% of cases of HNPCC syndrome), and hPMS2 (fewer than 5% of cases of HNPCC syndrome). These lesions account for approximately 3% of ovarian carcinoma.

Although the risk of inheriting a mutation from a parent carrier is 50%, the actual risk of developing a cancer varies from as high as 80% to 85% to as low as 16% for different mutations.[38] This variability of risk and the previously discussed controversy about the efficacy of prophylactic oophorectomy raise questions about the role of genetic testing in individuals with family histories of ovarian carcinoma. The American Society of Clinical Oncology recently issued an updated policy statement about genetic testing and cited three criteria for determining when genetic testing should be offered (Table 93-5).[39] Such testing should be done only if counseling before and after the test is available to discuss such issues as the risks and benefits of genetic testing as well as the efficacy, or lack thereof, of interventions that are prompted by the tests.

Fourth, might interventions other than prophylactic oophorectomy be efficacious in high-risk women? Oral contraceptives have been reported to reduce the risk of ovarian carcinoma by as much as 50% after prolonged (>10 years) use.[40–42] At least some reports suggest that the effects of such oral contraceptive use on cancer incidence differ between women with positive family histories and those with a true hereditary syndrome associated with BRCA1 or BRCA2,[43,44] with an actual increase in breast cancer risk among those BRCA1 or BRCA2 women who take tamoxifen for chemoprevention.[45] Although this implies a need for caution, at least one study reports that prolonged oral contraceptive use reduces the risk of ovarian cancer in women with pathogenic mutations in the BRCA1 or BRCA2 gene,[46] whereas another study shows no impact, negative or positive, of oral contraceptives on ovarian cancer risk.[47] In the absence of clear-cut evidence for a benefit, the role of oral contraceptives to prevent ovarian cancer is not established; hence, they should not be used for such a purpose at present.

Use of other hormones also has been evaluated. At least some reports show a direct correlation between postmenopausal estrogen-replacement therapy and risk for development of ovarian carcinoma with a relative risk ranging from 1.59 to 2.81.[48–50] This correlation

Table 93-5 Criteria for Offering Genetic Testing*

- Individual has personal or family history features suggestive of a genetic cancer susceptibility condition.
- Test can be adequately interpreted.
- Results will aid in diagnosis or influence the medical or surgical management of the patient or family members at hereditary risk of cancer.

*Genetic testing must include pretest and post-test counseling, including a discussion of the risks and benefits of testing and the interventions prompted by the testing.

Data from ASCO Working Group on Genetic Testing for Cancer Susceptibility: American Society of Clinical Oncology policy statement update: genetic testing for cancer susceptibility. J Clin Oncol 2003;21:2397–2406.

appears to hold only for patients who take estrogen only and not for those who take a combined estrogen/progesterone regimen. Other studies have failed to find such a correlation.[51] In women who are survivors of ovarian cancer, no evidence has been found that estrogen use increases the likelihood of relapse or shortens survival.[52]

Finally, one report assessed the relationship between raloxifene and risk for ovarian carcinoma.[53] This study was actually a meta-analysis of seven randomized placebo-controlled trials of raloxifene involving a total of 9837 women. The relative risk associated with the use of raloxifene was 0.50. This suggests that there is no adverse effect, but it does not prove a beneficial effect.

In summary, no scientifically proven screening approach exists for ovarian carcinoma. In addition, no clear role is seen for the use of interventions in the high-risk patient, although the ovarian consensus statement recommends the use of screening with transvaginal sonography and prophylactic oophorectomy in women with true hereditary syndromes. The basis for this recommendation is expert opinion and not appropriate definitive trials.

INITIAL EVALUATION. The initial evaluation of patients with suspected ovarian carcinoma, after the usual history, physical examination, laboratory testing, and CA-125, should be directed toward a detailed assessment of the abdominal cavity. Although a variety of imaging techniques for the abdominal cavity are now available, including sonography, computed tomography (CT), magnetic resonance imaging (MRI), and special isotopic scanning techniques, none provides the level of detailed study necessary for accurate staging of ovarian carcinoma. At the very least, CT scanning of the abdominal cavity, chest radiography, and bone scanning should be done.

Unless this evaluation demonstrates evidence of disease outside the abdominal cavity, exploratory laparotomy is an essential part of the initial evaluation of the patient. The laparotomy should be done through an incision that is adequate to evaluate the entire peritoneal surface, including the undersurface of the diaphragm and the right paracolic gutter, as well as the para-aortic lymph nodes. If no evidence of gross disease is found outside the pelvis, multiple biopsies of the peritoneal surface should be obtained. Many patients in whom the disease is apparently confined to the pelvis will have evidence of microscopic seeding of the abdominal peritoneum in one or more biopsies. At the conclusion of this procedure, accurate staging of the disease will have been accomplished and will serve to direct further management.

Therapeutic Role of Surgery

The volume of residual disease is related both to response to chemotherapy and to survival. As a result, the standard of care of patients with ovarian carcinoma with disease that is confined to the abdominal cavity is to resect as much disease as possible at initial laparotomy. This approach applies to patients with limited disease that can be completely removed as well as to patients with advanced disease that can be only partially resected. Data on which this approach has been based are retrospective analyses showing that patients who initiate chemotherapy with small-volume disease (no nodule larger than 2 cm in diameter remaining in the abdominal cavity) have both a higher frequency of pathologic complete response and a superior survival with chemotherapy[8,10–14,54] (see Tables 93-2 and 93-3).

Several major questions have been raised about the value of cytoreductive surgery in patients with advanced disease that is not amenable to a "curative" resection. First and foremost, detractors have pointed out that approximately one half of the population of patients with small-volume disease consists of patients with stage IIIA or IIIB disease—patients who already have small-volume disease at the time the abdomen was opened without any surgical cytoreduction. According to this line of reasoning, the improved results in small-volume disease relate entirely to this portion of the patients who presumably have biologically less aggressive disease. A retrospective analysis of a GOG database of patients with small-volume disease provided some support for this view.[14] Operative notes on the population in the database were reviewed to separate the patients into two groups: those who had stage IIIA or IIIB disease and those who had stage IIIC disease that was successfully surgically cytoreduced to small-volume residual disease. Patients who required surgical cytoreduction had an inferior survival in comparison with those who already had small-volume disease at the time the abdomen was opened. Although this investigation shows a difference between these two patient groups, it does not prove that surgical cytoreduction has no value, in the absence of a population for comparison in which chemotherapy was started with large-volume disease.

The only way to address the question of the value of cytoreductive surgery is to conduct a randomized trial in which all patients are randomized to surgical cytoreduction or no surgical cytoreduction and are then analyzed by intent to treat. No such study assessing initial surgical cytoreduction has been successfully completed. However, two prospective randomized phase III trials have evaluated the role of interval cytoreduction[55,56] (Table 93-6).

In a European trial by the European Organization for Research and Treatment of Cancer,[55] patients with advanced disease received three courses of cisplatin plus cyclophosphamide and were then randomized to receive either three more courses of the same chemotherapy or interval cytoreductive surgery, followed by three more cycles of cisplatin plus cyclophosphamide. The group that received interval cytoreductive surgery demonstrated a statistically significantly superior progression-free and overall survival.

A GOG study[56] took patients with stage IIIC disease who had undergone an aggressive attempt at initial surgical cytoreduction and still had large-volume disease remaining and randomized them to either six cycles of paclitaxel plus cisplatin or three cycles of paclitaxel plus cisplatin followed by interval surgical cytoreduction and then three more cycles of paclitaxel plus cisplatin. This trial showed no difference between the two study arms.

The most rational interpretation of these two studies rests on an understanding of the differences in study execution. In the European trial, initial surgery was performed by surgeons with varied training backgrounds and, in many instances, probably did not represent true aggressive attempts at surgical cytoreduction. In the GOG study, conversely, virtually every patient underwent an initial attempt at aggressive surgical cytoreduction by a trained gynecologic oncologist. What the two trials show is that patients with a less than optimal initial attempt at surgical cytoreduction benefit from interval bulk reduction, whereas those who undergo an aggressive initial surgery

Table 93-6 Results of Two Studies of Interval Surgical Cytoreduction

Parameter	All	IDS	No IDS
EORTC STUDY[55]			
Patients	408	150	149
Response after three cycles

Progression-free survival		10.5 months	10.8 months
Survival		32 months	33 months

IDS, interval debulking surgery.

and still have large-volume disease do not benefit from interval surgery.

On the basis of the weight of current evidence, patients, except for those with obvious stage IV disease, should undergo an initial laparotomy with intent to carry out maximal surgical cytoreduction. This should improve response to chemotherapy as well as survival. Those who have a less aggressive initial operation should be considered for interval surgical cytoreduction.

Management of Advanced Disease

Patients with stage III or IV disease, on completion of initial surgery, should receive systemic therapy for control of disease. Fortunately, celomic epithelial carcinoma is a chemosensitive disease—hence the significant therapeutic options for patients with advanced disease.

ACTIVE AGENTS. A number of cytotoxic agents as well as biologic and hormonal agents have activity against celomic epithelial neoplasms[6–8,10–15,24–26,54] (Table 93-7). Response rates that have been reported for each of the active agents vary as a result of several factors: (1) volume of residual disease in the patient population at the initiation of therapy, (2) dose and schedule of the agent under study, and (3) whether the patient population has received prior cytotoxic therapy to which the neoplasm has become clinically resistant, as evidenced by clinical progression during therapy. With the reservation that these factors cannot be sorted out in many of the single-agent studies that have been reported, it is possible to point to certain active cytotoxic drugs of major interest: the platinum compounds, the taxanes, the mustard-type alkylating agents, the anthracyclines (including pegylated liposomal encapsulated doxorubicin), the topoisomerase I inhibitors, oral etoposide, gemcitabine, vinorelbine, and hexamethylmelamine. In addition, among hormonal and biologic agents, interferon-α, interferon-γ, and tamoxifen display activity. Among these, the platinum compounds and paclitaxel deserve specific comment because of their current major relevance to front-line therapy for newly diagnosed disease.

Table 93-7 Active Single Agents in Celomic Epithelial Carcinoma of the Ovary*

Drug	Patients

Platinum Analogs. The platinum analogs are the most systematically evaluated and active cytotoxic drugs. Cisplatin demonstrates clear-cut activity in patients with no prior chemotherapy, as well as in those who are refractory to prior alkylating agents.[57–61] Carboplatin produces less neurotoxicity and nephrotoxicity than does cisplatin, in exchange for thrombocytopenia as the dose-limiting adverse effect, and exhibits activity similar to that seen with cisplatin.[61]

Taxanes. Paclitaxel, a diterpenoid extracted from the bark of *Taxus brevifolia* (the Western yew tree), acts to enhance tubulin polymerization and microtubule stability and hence to produce microtubule bundling throughout the cell.[62] This stability leads to inhibition of the dynamic reorganization of the microtubular structure of the cell before cell division. This unique mechanism of action accounts for the apparent lack of cross-resistance between this drug and the platinum analogs.

Paclitaxel demonstrated significant activity in four phase II trials in patients who had received prior platinum-based combination chemotherapy[63–66] (Table 93-8). In two of the four trials, responses were documented in both platinum-sensitive and platinum-resistant patients. Adverse effects, including myelosuppression, hypersensitivity reactions, and significant arrhythmias requiring continuous cardiac monitoring during therapy, were frequent and severe but manageable and resulted in no deaths attributable to toxicity. The occurrence of significant anaphylactic episodes in the initial experience with the drug led to the use of premedication with steroids and H_1 and H_2 blockers in the phase II trials, with the resultant virtual elimination of significant hypersensitivity reactions. The dose-limiting toxicity is myelosuppression, which, with 24-hour infusions, is severe but brief.

The other taxane, docetaxel, has been less extensively evaluated.[67–71] Activity appears to be similar to that of paclitaxel. Whether toxicity differs significantly awaits publication of randomized trials that have evaluated this, but on the basis of data available to date, docetaxel could be less neurotoxic but more myelosuppressive.

In summary, a variety of drugs have activity against ovarian carcinoma. The most important of these are the platinum compounds and the taxanes. Other agents of particular interest exhibit the ability to obtain responses in patients who have progressed on paclitaxel-platinum front-line therapy and include oral etoposide, topotecan, tamoxifen, gemcitabine, navelbine, ifosfamide, and possibly doxil.

COMBINATION CHEMOTHERAPY. An extensive series of questions had to be addressed to evolve effective regimens for the treatment of advanced ovarian carcinoma after surgical cytoreduc-

Table 93-8 Phase II Trials of Taxol as Salvage Therapy in Patients with Ovarian Carcinoma

Investigators	No. of Patients	Response Rate (%)
McGuire et al.[65]	40	30

Kohn et al.[66]	44	48

tion. Over the last two decades, the major themes that have keyed the development of current therapy include the evolution of platinum-based combination chemotherapy, assessment of the value of dose intensity, the defining of the role of paclitaxel, the determination of which platinum compound to use, and the ascertainment of the role, if any, of maintenance or consolidation therapy for those who respond to front-line therapy. Each of these issues is discussed, and a brief look at other significant issues follows.

Evolution of Platinum-based Combination Chemotherapy. A multitude of trials have made a firm case for the value of combination chemotherapy compared with treatment with single agents. The most significant of these studies were three large, randomized trials.[8,9,54] The conclusions from these three GOG studies, supported by other trials of systemic therapy, formed the basis for practice at the end of the 1980s.[72]

The first two GOG trials were successive studies in patients with bulky advanced disease[8,54] (Table 93-9). The first of these (GOG Protocol 22) compared melphalan alone with either melphalan plus hexamethylmelamine or doxorubicin plus cyclophosphamide.[54] The only statistically significant difference that was observed was a greater clinical complete response rate in the patients who were treated with doxorubicin plus cyclophosphamide, as compared with those who received melphalan alone. This was the basis for selection of the two-drug combination as the control arm of the second trial (GOG Protocol 47), which compared doxorubicin plus cyclophosphamide with the same two drugs plus cisplatin.[8] Results showed a statistically significant improvement in clinical complete response rate, overall response rate, progression-free interval, and survival in the patients who were treated with the three-drug cisplatin-based combination.

Table 93-9 Results of Two GOG Studies of Combination Chemotherapy in Large-Volume Advanced Ovarian Carcinoma

	GOG Protocol 22		GOG Protocol 47	
Parameter	**L-PAM**	**AC**	**AC**	**PAC**
Patients	64	72	120	107
CRR	20%	32%	26%	51%
Total response (CRR + PRR)	37%	49%	48%	76%
CRR			4/23	13/39
PCR/total			3%	12%
Duration	8 months	10 months	9 months	15 months
Median survival	12 months	14 months	16 months	20 months

AC, doxorubicin (50 mg/m^2) plus cyclophosphamide (500 mg/m^2), both intravenous, every 3 weeks, for eight courses; CRR, complete response rate; L-PAM, melphalan (0.2 mg/kg/day orally), for 5 days every 4 to 6 weeks, for 10 courses or 18 months; PAC, cisplatin (50 mg/m^2) plus doxorubicin and cyclophosphamide as in AC, all intravenous, every 3 weeks, for eight courses; PCRR, pathologic complete response rate; PRR, partial response rate.

Data from references 8 and 54.

The third critical study (GOG Protocol 52), in patients with minimal residual disease (defined as patients with stage III disease and no nodules larger than 1 cm in diameter), compared the three-drug combination with cisplatin plus cyclophosphamide[9] (Table 93-10). The pathologic complete response rates, as documented at second-look laparotomy, were not significantly different, nor were any differences noted in progression-free interval or survival.

By the late 1980s, these three trials made a strong case for the combination of cisplatin plus cyclophosphamide as the standard chemotherapy for advanced or recurrent ovarian carcinoma. Four other studies focusing on the substitution of carboplatin for cisplatin expanded somewhat the meaning of standard chemotherapy.[73–76] These studies compared the relative efficacy of cisplatin-based versus carboplatin-based regimens (Table 93-11). The trial of the Southwest Oncology Group compared cyclophosphamide (600 mg/m^2) plus either cisplatin (100 mg/m^2) or carboplatin (300 mg/m^2) in patients with bulky stage III or IV disease.[73] The study showed no significant differences between the two regimens with regard to response rate, progression-free interval, or survival. The toxicities of the two regimens was different, the cisplatin regimen producing greater adverse effects. The National Cancer Institute of Canada trial compared essentially the same regimens, except for a slightly lower cisplatin dose of 75 mg/m^2, with similar results.[75]

The study conducted by the Gynaecological Cancer Cooperative Group for the European Organization for Research and Treatment of Cancer compared two four-drug combinations consisting of cyclophosphamide, doxorubicin, and hexamethylmelamine with either cisplatin or carboplatin.[74] No significant differences were noted with regard to response rate, progression-free interval, or survival.

The trial that was conducted by investigators at the Mayo Clinic is flawed by a major design problem.[76] The dose intensity of carboplatin is well below that of cisplatin in the other arm, making it difficult to determine whether the differences in progression-free interval and survival favoring the cisplatin regimen were related to a different platinum compound or to a lower dose intensity of the carboplatin. This study has two other features that distinguish it from the other three trials. The number of patients in the trial is considerably smaller and included 65% with small-volume disease.

Table 93-10 Results of a GOG Study of Minimal Residual Stage III Ovarian Carcinoma

Parameter	PAC	PC
Patients	173	176
Early recurrence	19	30
Refused second look	36	37
Residual disease	73	67
Pathologic complete response (%)	45 (26%)	42 (24%)

PAC, cisplatin (50 mg/m^2) plus doxorubicin (50 mg/m^2) plus cyclophosphamide (500 mg/m^2), all intravenous every 3 weeks, for eight cycles; PC, cisplatin (50 mg/m^2) plus cyclophosphamide (1000 mg/m^2), both intravenous, every 3 weeks, for eight cycles.

Data from reference 9.

Table 93-11 Randomized Trials Comparing Cisplatin-based with Carboplatin-based Combination Chemotherapy in Advanced, Predominantly Large-Volume Ovarian Carcinoma

Study and Regimen	Response Rate (%)	Survival
ALBERTS ET AL[73] (342 PATIENTS)		
Carboplatin (300 mg/m^2), every 4 weeks	CCR, 34	20 months

Doxorubicin (35 mg/m^2 IV), day 1		
Cisplatin (20 mg/m^2 IV), days 1–5		
PATER ET AL[75] (447 PATIENTS)		
Carboplatin (300 mg/m^2), every 4 weeks	PCR, 13	24 months
Cyclophosphamide (600 mg/m^2), every 4 weeks		
Cisplatin (75 mg/m^2), every 4 weeks	PCR, 18	23 months
Cyclophosphamide (600 mg/m^2), every 4 weeks		
EDMONDSON ET AL[76] (103 PATIENTS)		
Carboplatin (150 mg/m^2), every 4 weeks		20 months
Cyclophosphamide (1000 mg/m^2), every 4 weeks		
Cisplatin (60 mg/m^2), every 4 weeks		27 months
Cyclophosphamide (1000 mg/m^2), every 4 weeks		

CCR, clinical complete response; PCR, pathologic complete response.

In summary, these seven randomized trials[8,9,54,73–76] defined four major concepts about standard chemotherapy for advanced ovarian carcinoma as of 1990. First, combination chemotherapy is superior to single-agent therapy. Second, platinum-based combination chemotherapy offers significant advantages over non-platinum-based regimens. Third, carboplatin offers certain advantages over cisplatin in terms of altered and more tolerable toxicity with no diminution in efficacy. Finally, two-drug combinations of a platinum compound and an alkylating agent offer benefits that are equivalent to those that are achieved with more complex regimens. Three major themes dominated clinical research in the 1990s in attempts to improve further on systemic therapy for advanced disease: dose intensity, the development of combinations of a platinum compound and paclitaxel, and the choice of platinum compound.

Dose Intensity. Although debated to some extent, the concept of the importance of dose intensity to the success of chemotherapy in the management of celomic epithelial carcinomas of the ovary has been generally well accepted among oncologists. In vitro data support the efficacy of increasing drug levels in enhancing cell kill in cultures of ovarian cancer cells.[77] In patients who have experienced recurrence after prior platinum-based chemotherapy for ovarian carcinoma, responses to higher doses of the same platinum compound[78] or to greater exposure as a result of intraperitoneal administration[79] have been cited as evidence that enhanced dose can result in response when lower doses have failed. The use of hypertonic saline to permit escalation of cisplatin dose to 200 mg/m^2 per course in combination with cyclophosphamide has been reported to yield high response rates that are superior to those achieved with lower-dose regimens.[80] Finally, meta-analyses have been reported to show a correlation between dose intensity of platinum and response.[81,82] These kinds of evidence have provided strong support for the value of dose intensity in the treatment of ovarian carcinoma.

At first glance, the case for dose intensity would appear to be very solid. However, several significant questions remain. First, with regard to reported responses of "refractory" ovarian carcinoma to higher doses of drug, it is becoming increasingly apparent that such responses occur not in patients whose disease progresses with the lower-dose therapy but rather in patients in whom recurrent disease develops some time after they have completed prior therapy. For example, Ozols and colleagues[83] reported a series of 30 patients with "refractory" ovarian carcinoma who were treated with high-dose carboplatin (800 mg/m^2 per 35 day cycle). Although eight responses were observed, Ozols and colleagues also noted that "no responses were observed from high-dose carboplatin in [9] patients who had progressive disease during prior therapy with a cisplatin-based regimen." Similar observations emerge from second-line phase II studies of intraperitoneal chemotherapy. In other words, patients whose tumors are clinically resistant to platinum-based chemotherapy do not benefit from treatment with higher doses of the same or similar drugs.

Second, the reported improvement in response rate that was seen with high-dose cisplatin regimens has been reappraised in light of the significant neurotoxicity that emerged from these studies.[80] Although this is not a randomized comparison, it is instructive to compare the results of GOG studies with regimens using 50 mg/m^2 of cisplatin in the combination regimen with results of using high-dose cisplatin. In patients with minimal residual stage III disease (no nodule >2 cm remaining), the high-dose regimen (cisplatin 200 mg/m^2 plus cyclophosphamide 1000 mg/m^2 repeated every 4 weeks) yielded a pathologic complete response rate of 38%,[80] whereas the GOG regimen (cisplatin 50 mg/m^2 plus cyclophosphamide 1000 mg/m^2 every 3 weeks) yielded a pathologic complete response rate of 30%.[9] In patients with bulky stage III or stage IV disease, the high-dose regimen (the same as was noted earlier) yielded a pathologic complete response rate of 12%,[80] whereas the GOG regimen (cisplatin 50 mg/m^2 plus doxorubicin 50 mg/m^2 plus cyclophosphamide 500 mg/m^2 repeated every 3 weeks) yielded a pathologic complete response rate of 11%.[8] Thus, no evidence exists that the high-dose cisplatin regimen yielded a superior result, even though the dose intensity of the platinum compound as a function of dose and time was 3 times as high.

Third, although a dose-intensity meta-analysis conducted by Levin and Hryniuk[81] indeed documented a dose-response relation for cisplatin, this relation held only over the range of 0.4 to 0.8. For purposes of this meta-analysis, the "standard" regimen used a cisplatin dose equivalent to 15 mg/m^2 per week. The dose-response relation for cisplatin thus held over a range of 6 mg/m^2 per week to 12 mg/m^2 per week. This equates to a highest dose of 36 mg/m^2 every 3 weeks. This meta-analysis thus supplied no support for the use of

doses higher than those used by the GOG in their relatively low-dose cisplatin regimens.

An extended meta-analysis by the same investigators[82] included more studies in the higher dose range. This study demonstrated the superiority of combination chemotherapy over single agents and also noted a correlation between response and cisplatin dose up to a level of 25 mg/m^2/week (or 75 mg/m^2 every 3 weeks). In this analysis, the investigators also suggested that total dose delivered might be as important as dose intensity. Neither meta-analysis, however, offered any evidence supporting the importance of total dose nor of a correlation between response and dose intensity for any drug other than cisplatin; nor was either meta-analysis able to support the importance of cisplatin dose intensity beyond 25 mg/m^2/week.

These considerations raise serious questions about the value of dose-intense regimens in the treatment of ovarian carcinoma. Addressing these issues appropriately requires randomized prospective trials. Eight such studies have been reported (Table 93-12).[84–91]

Studies Showing No Advantage from Dose Intensity. GOG Protocol 97[84] randomized patients with large-volume disease defined as having nodules larger than 1 cm or stage IV disease to receive either eight cycles of cisplatin (50 mg/m^2) plus cyclophosphamide (500 mg/m^2) every 3 weeks or four cycles of cisplatin (100 mg/m^2) plus cyclophosphamide (1000 mg/m^2) every 3 weeks. A total of 458 eligible patients was randomized, of whom 130 had measurable disease. Prognostic features were evenly distributed between the two treatment arms. If the prescribed low dose is assigned a dose intensity of 1.0, the actual received dose intensity for the low-dose regimen was 0.95, and that for the high-dose regimen was 1.90. A twofold difference in dose intensity was thus achieved. No difference in total dose received was noted between the two arms as planned.

With regard to response, of 60 patients assigned to the high-dose arm, 19 (32%) achieved a clinical complete response, 16 (27%) achieved a partial response, 18 (30%) had stable disease, and 7 (12%) experienced increasing disease. The overall response rate for the high-dose arm was thus 59%. Of 70 patients assigned to the low-dose arm, 27 (39%) achieved a clinical complete response, 18 (26%) achieved a partial response, 24 (34%) had stable disease, and 1 (1%) experienced increasing disease. The overall response rate for the low-dose arm was thus 65%. No statistically significant differences were noted between the two arms with regard to response.

With regard to progression-free interval and survival, all 458 patients were included in the analysis. Median progression-free intervals for the low-dose and high-dose regimens were 12 and 13 months, respectively, whereas median survivals were 24 and 21 months, respectively. No significant differences were observed in either parameter.

The high-dose regimen was associated with more severe or life-threatening (grade III or IV) toxicity, which included more leukopenia (82% versus 40%), more thrombocytopenia (22% versus 1%), more anemia (9% versus 2%), more nausea and vomiting (16% versus 3%), and more nephrotoxicity (5% versus 1%). Very few cases of grade III or IV neurotoxicity were seen.

This GOG study was designed as a pure dose-intensity study only in patients with large-volume disease. No evidence exists that a twofold increase in dose intensity yields any greater patient benefit over the range of doses used in this trial for patients with large-volume disease, but it is clear that the higher-dose regimen was more toxic.

A Gruppo Interregionale Collaborativo in Ginecologia Oncologica trial[86] randomized 306 patients with advanced disease to either cisplatin 75 mg/m^2 every 3 weeks for six cycles or cisplatin 50 mg/m^2 weekly for 9 weeks. The actual received dose intensity of the high-dose regimen was twice that of the low-dose regimen, and no differences existed in the total dose delivered in either arm of the trial. In contrast to the GOG study, 45% of the patients in this study had small-volume advanced disease. No significant differences were observed between the arms with regard to pathologic complete response (24% high-dose versus 28% low-dose), progression-free interval (21 versus 18 months), and survival (36 versus 33 months). Like the GOG study, this was a trial of pure dose intensity, because each regimen delivered the same total dose of drug. Also like the GOG trial, this study provides no support for the importance of dose intensity over the range of cisplatin dose intensity from 25 mg/m^2/week to 50 mg/m^2/week.

A North-West Oncology Group trial[87] randomized 145 patients with large-volume advanced disease to receive cyclophosphamide 600 mg/m^2 plus epirubicin 60 mg/m^2 plus either cisplatin 50 mg/m^2 or cisplatin 100 mg/m^2 every 4 weeks for six cycles. In contrast to the GOG and Gruppo Interregionale Collaborativo in Ginecologia Oncologica trials, this study called for the delivery of twice as much total dose of cisplatin in the high-dose regimen. Actual received dose intensity achieved a 2:1 ratio between the high-dose and low-dose regimens and evaluated the range of cisplatin dose intensity from 12.5 mg/m^2/week to 25 mg/m^2/week. No significant differences were noted with regard to clinical response (57.5% high-dose versus 61.1% low-dose), pathologic complete response (9.6% high-dose versus

Table 93-12 Eight Randomized Trials of Platinum Dose Intensity in Advanced Ovarian Carcinoma

18.1% low-dose), progression-free interval (18 months high-dose versus 13 months low-dose), and survival (29 months high-dose versus 24 months low-dose). The high-dose regimen was clearly more toxic. The trial provides no support for the importance of either dose intensity or total dose over the range of cisplatin dose intensity that was tested (12.5 mg/m^2/week to 25 mg/m^2/week).

A London GOG trial[88] randomized 241 patients with either small-volume or large-volume advanced disease to single-agent carboplatin dosed to an area under the curve (AUC) of either 6 for six courses or 12 for four courses at 4-week intervals. In the high-dose arm, dose intensity was doubled, and total dose increased by 22%. No significant differences were noted with respect to response (63% high-dose versus 57% low-dose), progression-free interval (hazard ratio, 0.98), and survival (hazard ratio: 0.91). This trial also provides no support for the importance of dose intensity or total dose over the range that was tested.

In a Danish Ovarian Cancer Group trial,[89] Danish investigators randomized 222 patients with advanced ovarian carcinoma to carboplatin dosed to an AUC of either 4 or 8 every 4 weeks for six cycles. No differences were observed with respect to pathologic complete response or survival.

An Austrian trial[90] approached the problem of platinum dose intensity by combining cisplatin and carboplatin. A total of 253 patients with stages IC to IV disease were randomized either to cisplatin 100 mg/m^2 plus carboplatin 300 mg/m^2 or to cisplatin 100 mg/m^2 plus cyclophosphamide 600 mg/m^2 monthly for six cycles. Actual received dose intensity for platinum was 1.6-fold greater with the cisplatin/carboplatin regimen. The platinum-intensified regimen produced more myelosuppression, ototoxicity, and gastrointestinal toxicity. The cisplatin/carboplatin regimen produced a response rate of 39%, a complete response rate of 26%, a progression-free median survival of 22 months, and an overall median survival of 42 months. These results were not significantly different from those that were seen with the cisplatin/cyclophosphamide regimen: 42% response rate, 26% complete response rate, 25-month median progression-free survival, and 38-month median overall survival. This trial thus failed to confirm an advantage for a 1.6-fold increase in platinum dose intensity.

These observations contradict the dogma that higher-dose schedules yield better results. Several possible explanations may be found. First, total dose instead of dose intensity could be important. At least four of the six studies, however, used differences in both dose intensity and total dose and showed no advantage. Second, dose intensity may be relatively ineffective in large-volume disease and still yield better results in patients with small-volume disease. All but the GOG trial, however, included patients with small-volume disease, with no advantage noted in the small-volume subset. Third, a twofold increase in dose intensity may be too small to permit observation of differences. Finally, and perhaps most devastatingly, once a certain threshold has been reached, further escalation in dose intensity may yield no further benefit.

Studies Showing an Advantage for Dose Intensity. A study from the Scottish Gynaecology Cancer Trials Group[85] randomized 159 patients with stages IC to IV disease to cyclophosphamide 750 mg/m^2 plus either cisplatin 50 mg/m^2 or cisplatin 100 mg/m^2 every 3 weeks. Actual received dose intensity for the higher-dose regimen versus the lower-dose regimen was 1.8 to 1. The lower-dose regimen produced significantly less neurotoxicity. At 4 years of follow-up, 32% of those receiving the higher-dose regimen were alive compared to 27% of those on the lower-dose regimen. The ratio of deaths among those receiving the higher-dose regimen versus that of those receiving the lower-dose regimen was 0.52 at 2 years and 0.68 at 4.75 years. These results suggest that in contrast to results in the previous five studies, an advantage that diminished with time occurred for the higher-dose regimen. The investigators' conclusion was that the optimal dose of cisplatin would be 75 mg/m^2 every 3 weeks.

This trial has major problems. First, 49 (31%) of the 159 patients had stage IC or II disease. The heterogeneous patient population resulting from the inclusion of these limited-disease patients makes interpretation of results very difficult, especially when one considers the relatively small total number of patients in the study. Second, the actual difference in 4-year survival of less than 6% is not impressive; and the relative death rate of the higher-dose regimen versus the lower-dose regimen after the first 2 years is 1.30. The overall advantage for the higher-dose regimen is significant only at $P = 0.061$. Finally, the choice of 75 mg/m^2 every 3 weeks as the optimal dose of cisplatin does not follow from the results of the study, which did not deal with the recommended dose.

A Hong Kong trial[91] is the smallest of the randomized studies, with only 50 patients entered. The patient population is not well characterized. Cisplatin doses on the two regimens were 60 mg/m^2 and 120 mg/m^2, respectively. The higher-dose regimen yielded a response rate of 55% and a 3-year survival rate of 60% as compared with lower-dose results of a response rate of 30% and a 3-year survival rate of 30%. Even though these results suggest that the higher-dose regimen offered an advantage, the size of the trial and the poor characterization of the patient population make the conclusions less convincing.

Conclusions Regarding Dose Intensity. In conclusion, the case for the use of regimens with greater dose intensity, especially greater dose intensity of the platinum compound, is unclear at best. To understand the apparent contradiction between in vitro data and clinical results, one must look to certain basic principles on which the concept of the value of dose intensity is based. By using a somatic mutation theory for drug resistance, Coldman and Goldie[92] postulated that the failure to cure a patient of malignancy results from either the failure to eradicate all drug-sensitive cells because of insufficient drug dose intensity or the emergence of cells that were resistant to the drug regimen. Enhanced dose intensity functions in two ways to improve the likelihood of cure: (1) eradicating all sensitive cells and (2) eliminating cells that are likely to mutate to resistance before such mutations take place. No evidence exists that drug resistance can be overcome in vivo by enhancement of dose intensity over the range that can be clinically achieved.

If these considerations are translated into simple terms, increasing dose intensity yields increasing clinical response rates up to the point at which all sensitive cells have been eradicated. Further increase in dose intensity cannot be expected to yield further improvement in results over the currently achievable range. The only basis on which an increased cure rate can be expected from dose escalation is that the drugs are started before the emergence of resistant cells, an unlikely circumstance in patients with advanced disease.

Role of Paclitaxel

Paclitaxel, a new agent with a unique mechanism of action, has significant activity in ovarian carcinoma as second-line therapy with a response rate in excess of 20% in patients, regardless of prior response to platinum-based chemotherapy. These results marked paclitaxel as probably non-cross-resistant with the platinum compounds and alkylating agents and suggested a major role for the drug in first-line treatment of ovarian carcinoma. These data prompted four major randomized trials testing paclitaxel in front-line combination chemotherapy.

GOG Protocol 111[93] randomized 386 newly diagnosed patients with large-volume advanced ovarian carcinoma to six cycles of cisplatin 75 mg/m^2 plus either cyclophosphamide 750 mg/m^2 or paclitaxel 135 mg/m^2 over a 24-hour period preceding the cisplatin. The paclitaxel-based regimen proved superior in regard to overall response rate (73% versus 60%, $P = 0.01$), clinical complete response rate (51% versus 31%, $P = 0.01$), percentage grossly disease free at second-look laparotomy (40% versus 24%, $P = 0.001$), progression-free survival (median, 18 versus 13 months, $P < 0.001$), and overall

Table 93-13 Results of GOG Protocol 111 and EORTC/NCIC OV 10: Cisplatin plus Either Cyclophosphamide or Taxol

	GOG 111*		OV 10†	
	TP	**CP**	**TP**	**CP**
Clinical response rate	73%	60%	59%	45%
Clinical complete response rate	51%	31%	41%	27%
Grossly disease-free second look	40%	24%	—	—
Pathologic complete response	26%	20%	—	—
Progression-free survival	18 months	13 months	15.5 months	11.5 months
Overall survival	38 months	24 months	35.6 months	25.8 months

*TP, paclitaxel 135 mg/m^2/24 hours plus cisplatin 75 mg/m^2 every 3 weeks; CP, cyclophosphamide 750 mg/m^2 plus cisplatin 75 mg/m^2 every 3 weeks. Each regimen given for six cycles; all differences statistically significant except pathologic complete response, for which $P = 0.08$.

†TP, paclitaxel 175 mg/m^2/3 hours plus cisplatin 75 mg/m^2 every 3 weeks; CP, cyclophosphamide 750 mg/m^2 plus cisplatin 75 mg/m^2 every 3 weeks. Each regimen given for up to nine cycles; all differences statistically significant.

Data from references 93 and 94.

survival (median, 38 versus 24 months; $P < 0.001$; Table 93-13). Analysis of comparative risk demonstrated a 33% reduction in morbidity and mortality with the addition of paclitaxel to first-line chemotherapy. Although increased myelosuppression, cardiac problems, and alopecia were found with the paclitaxel-based regimen, no major clinical consequences occurred. In particular, the frequency of grade III or IV neurotoxicity was the same with the two regimens. The conclusion of the GOG is that paclitaxel plus cisplatin is the new standard of care for ovarian carcinoma.

In OV-10,[94] a Canadian/European consortium randomized patients with advanced disease to either cyclophosphamide 750 mg/m^2 plus cisplatin 75 mg/m^2 every 3 weeks for six to nine cycles or paclitaxel 175 mg/m^2 over a 3-hour period followed by cisplatin 75 mg/m^2 every 3 weeks for six to nine cycles. This trial shows superiority for the paclitaxel/cisplatin regimen with regard to response rate (59% versus 45%), clinical complete response rate (41% versus 27%), progression-free survival (15.5 months versus 11.5 months), and overall survival (35.6 months versus 25.8 months). This study confirms GOG 111 and conclusively establishes paclitaxel plus a platinum compound as the standard of care.

GOG Protocol 132[95] was completed before availability of the final analysis of GOG Protocol 111. This trial randomized 613 newly diagnosed patients with large-volume advanced disease to six cycles of either cisplatin 100 mg/m^2 every 3 weeks, paclitaxel 200 mg/m^2 over a 24-hour period every 3 weeks, or paclitaxel plus cisplatin, as in GOG Protocol 111 (Table 93-14). No differences were observed among the three arms with respect to survival. The paclitaxel regimen arm was inferior with respect to response and progression-free survival. It is important to note, however, that this trial did not serve as a confirmatory trial for GOG Protocol 111 for a very important reason. At the time of accrual to GOG Protocol 111, paclitaxel was not commercially available in the United States, whereas it was commercially available at the time of accrual to GOG Protocol 132. Very few of the patients on the nonpaclitaxel regimen in GOG Protocol 111 received paclitaxel at the time of first relapse. Conversely, vast majority of patients on the single-agent regimens of GOG Protocol 132 received the other drug before progression of disease. This pattern of second-line therapy blunts differences among the three regimens.

International Collaborative Ovarian Neoplasm (ICON3)[96] (Table 93-15) is the most recently completed of the four trials and the largest (2074 patients). Several features of this trial distinguish it from the other three and dictate how this study should be evaluated. First, the study included patients with all stages of disease, I to IV. Patients with stage I to II disease represent 20% of the patients; hence, the patient population is very heterogeneous. Second, the regimens are not as well defined as those in the other three trials. A choice was made between two regimens for the control arm, and the arms that involved carboplatin allowed a range of AUC doses as long as a minimum was met. That a choice of control regimens was made is perhaps not such a problem as it might have been, because the results of a randomized trial comparing the two has since been reported as showing no differences.[97] Third, the randomization was 2:1 favoring

Table 93-14 Results of GOG Protocol 132: Comparison of Cisplatin versus Paclitaxel versus Cisplatin plus Paclitaxel

	P	**T**	**TP**
Clinical response rate	67%	42%	66%
Clinical complete response rate	42%	21%	43%
Progression-free survival	16.4 months	10.8 months	14.1 months
Overall survival	30.2 months	25.9 months	26.3 months

P, cisplatin 100 mg/m^2 every 3 weeks; T, paclitaxel 200 mg/m^2/24 hours every 3 weeks; TP, paclitaxel 135 mg/m^2/24 hours plus cisplatin 75 mg/m^2 every 3 weeks. Each regimen given for six cycles. Only statistically significant differences are in failure rates: Paclitaxel alone is inferior to the other two.

Data from reference 95.

Table 93-15 Results of ICON3: Comparison of Carboplatin or CAP versus Paclitaxel versus Carboplatin plus Paclitaxel

	Control*	**TP†**
Progression-free survival	16.1 months	17.3 months
Overall survival	36.1 months	35.4 months

*Control regimens included carboplatin or CAP every 3 weeks: carboplatin AUC minimum 5; CAP, cyclophosphamide 500 mg/m^2, doxorubicin 50 mg/m^2, cisplatin 50 mg/m^2.

†TP, paclitaxel 175 mg/m^2/3 hours, carboplatin AUC minimum 5 every 3 weeks. Each regimen given for six cycles.

Data from reference 96.

the control arm, so twice as many patients were assigned to the control regimens as to paclitaxel plus carboplatin. Fourth, quality control was not as tight as in the other three trials. No pathology review is planned. Surgical requirements were nonexistent. No audit of data is planned. These factors detract from the credibility of this trial in comparison with the other three.

The trial shows no significant differences between the control regimens and the experimental regimen in terms of progression-free and overall survival. This contradicts the results of GOG 111 and OV 10. The deficiencies of the study, however, are such that this trial should not detract from the results of the earlier studies.

Conclusions from these four studies should be based not only on the study results, but also on the quality of the study design and execution. Two trials (GOG 111 and OV 10) show a clear advantage for a taxane/platinum combination. One trial (GOG 132) shows no difference, but crossover before progression in all likelihood means that the study actually evaluated concurrent versus sequential use of the two agents. Even in this setting, the concurrent arm was judged to be the treatment of choice because the overall toxicity was less with the concurrent regimen. The last trial (ICON3) has a number of design problems and lack of data audits; hence, its contrary result should be regarded circumspectly. On the basis of these considerations, the current standard of care should be a combination of paclitaxel plus a platinum compound.

Choice of Platinum Compound

Initial studies of paclitaxel in front-line therapy involved regimens with cisplatin. Interest in substitution of carboplatin for cisplatin results from the ease of administration and decreased nonhematologic toxicity associated with carboplatin. Concerns about the use of carboplatin with paclitaxel focused on an interaction between the two agents.[98] This interaction decreases the amount of thrombocytopenia that was observed with carboplatin such that suppression is less severe, and recovery is usually complete by 3 weeks instead of 4, as is seen with carboplatin alone. The mechanism for this interaction is not yet clear; hence, it is not clear whether the same mechanism might also result in tumor protection. This correlation would result in less efficacy than is observed with paclitaxel/cisplatin. This concern led to three phase III trials comparing paclitaxel plus cisplatin with paclitaxel plus carboplatin.[99–101]

The Dutch trial[99] randomized 208 advanced-disease patients to paclitaxel 175 mg/m^2/3 hours plus either cisplatin 75 mg/m^2 or carboplatin AUC 5 every 3 weeks for at least six cycles. No differences in efficacy were observed, and the carboplatin-based regimen had a better toxicity profile. However, the study was too small to permit definite conclusions to be drawn about therapeutic equivalence between the two regimens.

The AGO trial[100] randomized 798 advanced-disease patients to paclitaxel 185 mg/m^2/3 hours plus either cisplatin 75 mg/m^2 or carboplatin AUC 6 every 3 weeks for six cycles. No differences were observed between the two regimens with regard to progression-free or overall survival, though small trends favored the cisplatin regimen. The cisplatin-based regimen was more toxic and produced a significantly inferior quality of life.

GOG Protocol 158[101] randomized 798 patients with small-volume residual advanced disease to either paclitaxel 135 mg/m^2/24 hours plus cisplatin 75 mg/m^2 or paclitaxel 175 mg/m^2/3 hours plus carboplatin AUC 7.5. This study differs from the other two in several important ways. First, the use of the 24-hour infusion of paclitaxel with cisplatin served to decrease the amount of neurotoxicity that was seen with the cisplatin-based regimen. Second, as a result of the 24-hour infusion, the dose of paclitaxel was different in the two regimens. Third, and most important, the dose of carboplatin was substantially higher in this trial. The study showed no difference in progression-free and overall survival between the two regimens, but a strong trend favored the carboplatin-based regimen, with a hazard ratio for survival of 0.86. As a result of the escalated dose of carboplatin, the toxicity of the carboplatin-based regimen was substantially greater than that reported in the other two trials and did not differ greatly from that seen with the cisplatin-based regimen.

Conclusions from these three trials point to no major differences in efficacy between paclitaxel/cisplatin and paclitaxel/carboplatin. The observed trends, however, raise serious questions about the optimal dose of carboplatin in combination with paclitaxel. At the very least, in combining carboplatin with paclitaxel, an AUC of 6 of carboplatin should be used, and serious consideration should be given to the higher AUC of 7.5.

Consolidation or Maintenance Therapy

For patients with advanced ovarian carcinoma, response rates now approach 90%, clinical complete response rates reach 75%, and median survivals range from 26 months for patients with bulky residual disease to more than 60 months for patients with small-volume residual disease. Despite these excellent results, almost 75% of those who achieve a clinical complete response will relapse eventually and die of their disease.

In addition to the continuing effort to improve further the clinical complete response rate, investigators have conducted studies of ways to consolidate or maintain these responses. Over the last 20 years, none of these studies had produced a positive result.[102] The most recent reports focused on consolidation after six initial cycles of paclitaxel plus carboplatin with four cycles of topotecan.[103,104] Neither study showed any advantage for the consolidation therapy. No evidence now supports a role for consolidation therapy.

The one exception to the plethora of negative studies is a recent phase III randomized trial of extended duration paclitaxel as maintenance therapy.[105] This study differs from prior trials in two significant respects. First, only patients who responded to front-line therapy with a clinical complete response were eligible. Second, evidence suggests that extension of the duration of paclitaxel therapy could be beneficial. This includes anecdotal reports of responses to paclitaxel that did not develop until as late as the twelfth cycle of therapy and preclinical observations of an antiangiogenic effect of paclitaxel over a prolonged period of treatment.[106]

Originally designed to accrue 450 patients with clinical complete responses to paclitaxel/platinum and to randomize these patient to either 3 or 12 additional monthly cycles of paclitaxel 175 mg/m^2/3 hours, the study was closed early because of extreme differences in progression-free survival favoring the 12 additional cycles (Table 93-16). Because of patient choice to cross over to the 12-cycle regimen after study closure, survival is not assessable. Toxicity was obviously greater in the 12-cycle regimen, but only 13 patients in the entire study dropped out because of toxicity. Although one study requires confirmation, the trial should certainly prompt discussion of this issue with each patient, and the evidence poses a convincing case for using 12 additional cycles of paclitaxel monthly as maintenance therapy. Whether 12 cycles is enough could be questioned because

Table 93-16 Results of SWOG and GOG Intergroup Study of Maintenance Therapy*

	3 Cycles	12 Cycles
Patients	107	115
Recurrences	34	20
Progression-free survival†	28 months	21 months

*Comparison of 3 versus 12 cycles of monthly paclitaxel in those with clinical complete response to front-line paclitaxel plus cisplatin.[105]

†The difference in progression-free survival was statistically significant ($P = 0.0023$).

of the observation of an increase in recurrence rate after cessation of the paclitaxel on each arm.

Current Standard of Care

On the basis of the series of studies cited over the last two decades, a solid case points to the combination of paclitaxel 175 mg/m^2/3 hours plus carboplatin AUC 6 to 7.5 every 3 weeks for six cycles as the current standard of care. With this approach, an overall response rate of 95%, a clinical complete response rate of 75%, a pathologic complete response rate of 50%, a progression-free survival of 15 to 24 months, and an overall survival of 26 to more than 60 months should result. These results will vary according to the volume of residual disease; patients with small-volume residual disease (no nodule left >2 cm diameter) experienced better outcome.

After this, the issue of maintenance therapy with 12 cycles of paclitaxel should be discussed with the patient. Patient preference will play a large role in determining whether an individual patient will receive maintenance therapy.

Controversies and Issues

Studies of patients with advanced disease address a number of additional issues: optimal paclitaxel schedule, intraperitoneal chemotherapy, high-dose chemotherapy with stem cell support, integration of new agents (both cytotoxic and biologic) into front-line therapy, the role of second-look laparotomy, and the role of CA-125 in assessing response and progression.

Paclitaxel was initially studied in a number of different schedules, from weekly to every-3-week schedules and from 1-hour to 120-hour infusion durations. By 1990, investigators were exclusively using a 24-hour infusion given every 3 weeks because of the higher incidence of hypersensitivity reactions with shorter infusions. Since then, shorter and longer infusions as well as weekly schedules have been studied.

A great deal of interest focused on the potential for shorter infusions because of the inconvenience of 24-hour infusions. A landmark phase III trial of 3-hour versus 24-hour infusions of paclitaxel as a single agent in relapsed ovarian cancer established the feasibility of short infusions preceded by premedication to prevent hypersensitivity reactions.[107] The study dispelled the myth that the 24-hour infusion had superior efficacy by showing no difference in response rate, progression-free survival, and overall survival. In terms of toxicity, the 3-hour infusion produced significantly less myelosuppression in exchange for increased neurotoxicity and other nonhematologic toxicities.

The theoretical advantages of even longer infusions also have been examined. Two studies of 96-hour infusions, prompted by suggestions in breast cancer that this length of infusion produced responses in some patients for whom shorter infusions had failed, defined no role for this approach. Markman and colleagues[108] treated 30 patients, for whom either a 3-hour or a 24-hour infusion had failed, with a 96-hour infusion of a total dose of 140 mg/m^2, to be repeated every 3 weeks. No objective responses were observed, although the regimen was well tolerated. Subsequently the GOG randomized patients with newly diagnosed advanced ovarian carcinoma to either paclitaxel 135 mg/m^2/24 hr plus cisplatin 75 mg/m^2 every 3 weeks for six cycles or paclitaxel 120 mg/m^2/96 hours plus cisplatin 75 mg/m^2 every 3 weeks for six cycles.[109] No differences in efficacy were observed. Therefore, no reason exists to use a 96-hour infusion in the treatment of ovarian carcinoma.

Of potentially greater interest is a weekly schedule of paclitaxel. An initial phase I study of 40 to 100 mg/m^2/1 hour of paclitaxel weekly demonstrated that this approach was feasible and also suggested potential activity (four responses among 13 patients).[110] This study also suggested that these weekly infusions produced fewer adverse effects. Subsequently, a phase II trial treated 53 patients with paclitaxel 80 mg/m^2/1 hour weekly and reported 13 (25%) responses.[111] A randomized phase III trial of weekly versus every-3-week paclitaxel (67 mg/m^2/3 hours weekly versus 200 mg/m^2/3 hours every 3 weeks), however, showed no difference in efficacy and a small advantage for the weekly regimen in terms of toxicity.[112] It should be pointed out that the dose of the every-3-week schedule is higher than is generally used in ovarian carcinoma, and this might account for the greater toxicity seen with that schedule.

In summary, these data on schedule taken together provide the following points that should be considered in the application of paclitaxel to the treatment of ovarian carcinoma. First, efficacy does not appear to be affected by schedule. Second, toxicity does vary with schedule. Longer infusions produce more myelosuppression, whereas shorter infusions produce more nonhematologic toxicity, such as neurotoxicity. With appropriate premedication, hypersensitivity does not appear to be a major problem regardless of infusion duration. Finally, although the weekly schedule is certainly efficacious and feasible, it appears to offer insufficient advantage in general to justify the greater inconvenience of weekly treatments.

Intraperitoneal Chemotherapy

In an effort directed at achieving ever greater dose intensity, three randomized trials involving intraperitoneal therapy have been reported. The first of these studies, an Intergroup study of the Southwest Oncology Group and the GOG, randomized 654 patients with small-volume residual disease to cyclophosphamide 600 mg/m^2 intravenously plus cisplatin 100 mg/m^2 either intravenously or intraperitoneally.[113] Results show a statistically significant small survival advantage and less tinnitus, clinical hearing loss, and neurotoxicity for patients on the intraperitoneal regimen. The study has a flaw in execution (extension of the accrual goal to increase the size of a subset and then an analysis using all patients, an approach that introduces statistical bias) but does suggest an advantage for intraperitoneal chemotherapy. Somewhat counterintuitively, the study shows that the treatment advantage exists only in patients with somewhat larger nodules (0.5 to 2.0 cm) rather than in the expected 0- to 0.5-cm subgroup.

GOG Protocol 114,[114] a second Intergroup trial involving intraperitoneal therapy, randomized small-volume patients to either paclitaxel plus cisplatin as given in GOG Protocol 111 or two cycles of carboplatin dosed to an AUC of 9 at 4-week intervals followed by six cycles of paclitaxel 135 mg/m^2 intravenously over 24 hours followed by intraperitoneal cisplatin 100 mg/m^2 every 3 weeks. The 523 patients with no nodule larger than 1-cm diameter were randomized to study. The intraperitoneal regimen was superior with regard to progression-free survival (median: 27.6 versus 22.5 months, $P = 0.02$), but only a marginal difference in overall survival was observed (median: 52.9 versus 47.6 months, $P = 0.056$).[114] The gain in efficacy, similar to that seen in the prior intraperitoneal study,[113] came at the expense of significantly more toxicity of all types on the intraperitoneal regimen.

The third intraperitoneal study, GOG Protocol 172,[115] randomized 417 small-volume (<1.0-cm nodules) patients to either paclitaxel plus cisplatin, as given in GOG Protocol 111, or six cycles of paclitaxel 135 mg/m^2 intravenously over 24 hours on day 1, intraperitoneal cisplatin 100 mg/m^2 on day 2, and intraperitoneal paclitaxel 60 mg/m^2 on day 8, with the regimen repeated every 3 weeks. Toxicity was dramatically greater on the intraperitoneal regimen, to such an extent that a substantial portion of the patients were unable to complete six cycles of therapy. Analysis of survival awaits sufficient deaths. Progression-free survival, however, is superior on the intraperitoneal regimen, with a hazard ratio of 0.73.

These three trials make the case that intraperitoneal chemotherapy yields a superior survival compared with standard intravenous chemotherapy in patients with small-volume residual advanced ovarian carcinoma. This benefit is bought at the expense of significantly more toxicity, to such an extent that a substantial portion of the patients cannot complete six cycles of therapy. At least at present, the toxicity of the intraperitoneal regimens tested precludes their routine clinical

use. Current efforts are directed at the development of less toxic intraperitoneal regimens that preserve the apparent survival benefit of the approach.

STEM CELL-SUPPORTED HIGH-DOSE CHEMOTHERAPY. The alternative to intraperitoneal chemotherapy for the achievement of higher dose intensity is the use of stem cell-supported high-dose chemotherapy. As with the use of this approach in other cancers, most studies are small and uncontrolled and show high response rates but short response durations and short survivals.[116] The largest study to date reports on the use of stem cell-supported high-dose chemotherapy in 421 patients for whom prior chemotherapy failed.[117] The population had an average age of 48 years, and 59% were platinum sensitive. The reported response rate was 70% (47% complete response and 23% partial response). The 2-year progression-free survival rate was 12%, and the 2-year overall survival rate was 35%. Although these numbers appear promising, patients with similar demographic and disease features fare considerably better with either intraperitoneal chemotherapy or standard intravenous chemotherapy.

To settle the issue of the role of high-dose chemotherapy with stem cell support, a randomized phase III trial should be conducted. Two attempts, one in Europe and one in the United States, have failed to accrue sufficient patients. Until such a trial demonstrates the value of this approach, high-dose therapy should be reserved for clinical trials, preferably phase III clinical trials.

INTEGRATION OF NEW CYTOTOXIC AND BIOLOGIC AGENTS INTO FRONT-LINE THERAPY. The last 10 years saw a veritable explosion of discovery of new agents, both cytotoxic and biologic, with activity in ovarian carcinoma. Many of these agents are active in patients with disease that is still platinum sensitive, but activity in platinum-resistant disease is minimal or nonexistent. Of particular interest for incorporation into front-line therapy are those agents that have activity in patients who have progressed on or shortly after completion of a paclitaxel/platinum front-line regimen. Such agents may be considered at least partially clinically non-cross-resistant with the taxanes and platinum compounds and thus may add additional benefit to front-line regimens.

At least four cytotoxic agents have activity in patients with "paclitaxel/platinum-resistant" disease: oral etoposide,[118] pegylated liposomal doxorubicin,[119,120] topotecan,[121,122] and gemcitabine.[123–125] These four agents have been the focus of efforts by an international consortium to integrate one or more into front-line therapy. Oral etoposide was dropped from further efforts because of the occurrence of three cases of acute myeloid leukemia among 52 patients in the study of paclitaxel plus carboplatin plus escalating duration of prolonged oral etoposide.[126] The other three agents are being evaluated in an ongoing GOG/Gynecologic Cancer Intergroup trial (Table 93-17) that assesses the impact of a third agent added either as a component of a triplet or as part of a sequential doublet.

Biologic agents that are of interest as part of front-line therapy now include tyrosine kinase inhibitors (Iressa); monoclonal antibodies that target either epidermal growth factor receptor (C-225), HER2-neu (trastuzumab), or vascular endothelial growth factor (bevacizumab); agents that reverse resistance (cyclosporine and valspodar); and interferon-γ. Of these, data are available on trastuzumab, cyclosporine, valspodar, and interferon-γ.

The GOG studied trastuzumab in a population of patients with recurrent or refractory ovarian carcinoma.[127] Of a total of 837 patients who were screened, 95 overexpressed HER2-neu ($2^+/3^+$ by immunohistochemistry). Of these 95 patients, 41 were eligible and assessable and agreed to participate in the trial. Among the 41 patients who were treated with trastuzumab, one complete and two partial responses resulted. Investigators concluded that HER2-neu overexpression occurred less frequently than had previously been reported (12% instead of 25%) and that treatment with trastuzumab had at best modest activity (7%).

Table 93-17 Schema for GOG Protocol 182: An International Trial of the Addition of a Third Agent to Front-Line Therapy

Regimen I:	Paclitaxel plus carboplatin × 8 cycles
Regimen II:	Paclitaxel plus carboplatin plus gemcitabine × 8 cycles
Regimen III:	Paclitaxel plus carboplatin plus PLD × 8 cycles (PLD given every other cycle)
Regimen IV:	Gemcitabine plus carboplatin × 4 cycles followed by paclitaxel plus carboplatin × 4 cycles
Regimen V:	Topotecan plus carboplatin × 4 cycles followed by paclitaxel plus carboplatin × 4 cycles

PLD, pegylated liposomal doxorubicin.
Accrual goal: 4000 patients.

The GOG also evaluated cyclosporine (cyclosporin A) for potential ability to reverse resistance to cisplatin.[128] Preclinical data had suggested that cyclosporin A could inhibit P-glycoprotein and reverse MDR-mediated resistance to cisplatin. Among 26 patients with platinum-resistant disease, only three responses to cisplatin plus cyclosporin A occurred. These data were considered insufficient justification for further study. A related compound (cyclosporine D analog), valspodar, subsequently underwent a phase II and a phase III study of its ability to reverse MDR-mediated resistance to paclitaxel. The GOG phase II study[129] administered the combination to 58 patients with clinical resistance to paclitaxel. Five responses resulted and prompted the performance of a phase III trial by an international consortium.[130] This phase III study in patients with newly diagnosed ovarian carcinoma sought to determine whether the concurrent administration of valspodar with paclitaxel/carboplatin produced results that are superior to that of chemotherapy alone. The study report showed no significant differences in efficacy or toxicity. All trends in both efficacy and toxicity favored the chemotherapy-alone regimen. These three trials suggest that these two compounds have no significant role in the management of ovarian carcinoma.

Studies of interferon-γ report significant activity against ovarian carcinoma by either intraperitoneal or intravenous routes.[131] These results prompted a phase III trial of cyclophosphamide/cisplatin with or without interferon-γ administered by the subcutaneous route.[132] Although this study had to be stopped prematurely because of the emergence of paclitaxel/carboplatin as the new standard of care, the trial did show a statistically significant difference in progression-free survival favoring the interferon-γ regimen. As a result, interferon-γ is being evaluated in an ongoing phase III trial of paclitaxel/carboplatin with or without interferon-γ.

Among other biologic agents, agents that are directed against vascular endothelial growth factor attract the greatest interest because of studies suggesting that high levels of vascular endothelial growth factor in tumor specimens are associated with a poorer prognosis.[133] At this point, however, no data define a clear role for any biologic agent.

ROLE OF CA-125. CA-125, a mucin-like glycoprotein, increases in response to disturbances of the celomic epithelium. The marker is most closely associated with the assessment of patients with ovarian carcinoma. As was discussed earlier, the marker has no defined role in the early detection of ovarian carcinoma. The major clinical role is the assessment of disease status in patients receiving treatment for advanced disease.[134] Because of the difficulty in accurately assessing tumor response in a neoplasm often confined to the peritoneal cavity, interest has developed in defining ways to use CA-125 levels to

determine response.[135] Current proposals focus on definitions based on a 50% or 75% decrease of CA-125 levels during the course of therapy and are currently under review by a committee of the Gynecologic Cancer Intergroup.[136]

Until standard definitions are developed, the marker should be confined to allowing a rough idea of whether disease is responding and should not be used as a response criterion. Decreasing CA-125 levels suggest a favorable response of tumor to therapy, whereas increasing levels suggest progression of disease. Certain principles should guide such a use. First, no single CA-125 value should dictate management decisions; a series of increasing or decreasing values (usually three or more) should be required. Second, changes in the CA-125 level should not result in action until the changes are corroborated by other objective evidence.

SECOND-LOOK LAPAROTOMY. Second-look laparotomy is an exploratory laparotomy that is performed at the conclusion of front-line chemotherapy. The purpose of the procedure is to determine disease status accurately so that decisions regarding further management can be made.[137] Patients who are selected as candidates for second-look laparotomy are usually in one of two categories: those with a clinical complete response to front-line therapy and those who are potential candidates for secondary surgical cytoreduction. Among patients who undergo second-look laparotomy, 40% will have no pathologic evidence of disease, yet half of those with a pathologic complete response will relapse.[138,139]

After widespread use in the 1980s, second-look laparotomies are now performed less frequently. Reasons that are cited for decrease in use of the procedure usually focus on the failure of studies to show that patients who undergo second-look laparotomy have improved survival as a result. The most recent and largest study evaluating second-look laparotomy[101,140] came from data that were collected in a study of paclitaxel/carboplatin versus paclitaxel/cisplatin in patients with small-volume residual stage III ovarian carcinoma (GOG Protocol 158). Institutions were required to specify whether women with clinical complete responses on the study would undergo second-look laparotomy at the conclusion of the protocol-assigned therapy. Roughly half of the patients who were entered in the study did undergo the procedure. GOG investigators compared the outcome for patients who did or did not have a second look. No differences were observed; hence, the investigators concluded that second-look laparotomy was of no value.

The problem with the study is the same flaw that has been seen in other reported studies. The potential value of second-look laparotomy lies in the information gleaned from the procedure. What determines whether that value is realized is the value of the management decision that is made on the basis of the information. The proper study should specify the management choice to be made for each finding at second look so that the study evaluates the package of second-look plus a specified management versus no second look. In conclusion, second-look laparotomy is currently not recommended for routine clinical use (Box 93-1).

Summary of Management of Advanced Disease

Patients with advanced ovarian carcinoma should undergo an initial attempt at surgical cytoreduction followed by chemotherapy. The best evidence shows that paclitaxel combined with carboplatin is the regimen of choice. On completion of initial chemotherapy, the use of an additional 12 cycles of paclitaxel monthly as maintenance therapy should be discussed with the patient. Dose-intense regimens, intraperitoneal therapy, and the addition of a third agent to front-line therapy offer no established advantage and hence should be reserved for clinical trials.

Management of Limited Disease

Patients with stage I or II disease compose approximately 25% of all patients with celomic epithelial carcinoma of the ovary. Only a small proportion of these are ever entered into clinical trials, however; hence until recently, it was difficult to provide definitive guidelines for the management of these patients. Recent randomized trials form the basis of current management principles.

Box 93-1. THERAPEUTIC DECISIONS IN NEWLY DIAGNOSED CELOMIC EPITHELIAL CARCINOMA

Newly diagnosed patients with celomic epithelial carcinoma of the ovary must be carefully staged so that appropriate treatment decisions can be made. This necessitates an exploratory laparotomy in all patients but those who have obvious stage IV disease. At laparotomy, as much disease as possible should be resected. Decisions are then governed by the surgical stage of the disease.

For patients with stage I or II disease, total abdominal hysterectomy and bilateral salpingo-oophorectomy should be done. This should be followed by adjuvant therapy if any of the following are present: poorly differentiated disease (grade III), tumor excrescences on the surface of the ovary, ascites, positive peritoneal cytology, or extraovarian disease. The adjuvant therapy of choice at our institution is platinum-based chemotherapy: carboplatin (AUC 7.5 intravenously) after paclitaxel (175 mg/m^2/3 hours intravenously) every 3 weeks for three cycles. At the conclusion of treatment, close observation will suffice.

For patients with stage III or IV disease, an aggressive attempt at surgical cytoreduction should be followed by platinum-based combination chemotherapy for six cycles. The optimal regimen is the combination of paclitaxel 175 mg/m^2 over a 3-hour period plus carboplatin AUC 6 to 7.5 every 3 weeks for six cycles. At the conclusion of initial chemotherapy, the physician should discuss the issue of maintenance paclitaxel 175 mg/m^2 over a 3-hour period monthly for 12 cycles.

GENERAL CONSIDERATIONS. Certain characteristics of the primary lesion are important in determining the prognosis of the patient with limited disease: histologic grade, location of the primary tumor, ascites, peritoneal cytology, and, to a lesser extent, histologic type. These characteristics permit separation of the patient population into those who are at low risk of recurrence and those who are at high risk[141] (Table 93-18). Patients who are at low risk of recurrence exhibit all the following characteristics: one or both ovaries involved, grade I or II (well or moderately differentiated), intracystic (no tumor on the external surface of the ovary), no ascites, negative peritoneal cytology, and no extraovarian disease. Patients who are at high risk have any one of the following characteristics: grade III (poorly differentiated), extracystic (tumor on the surface of the ovary), ascites, positive peritoneal cytology, or extraovarian (stage II) disease. Patients who are at low risk of recurrence have a 5-year survival rate that exceeds 90%, whereas those who are at high risk have a substantially lower survival rate.[142]

The assignment of a patient to a risk category should be based on a careful exploratory laparotomy performed through an incision that permits the exploration of the entire abdominal contents. Ascites should be noted, and samples for cytology should be taken. In the absence of ascites, peritoneal washings for cytology should be obtained. The capsule of the tumor should be inspected for excrescences, dense adherence, or rupture. The peritoneal surface should be carefully examined for implants of tumor. Areas that require particular attention include the undersurface of the diaphragm, the paracolic gutters, and the omentum. Biopsies should be obtained of any suggestive lesion and, in the absence of suggestive areas, of multiple sites. The para-aortic nodes should be examined and sampled. Finally, after inspection of the entire peritoneal surface, a total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy should be carried out.

Table 93-18 Risk Groups for Limited Ovarian Carcinoma

Group	Characteristics
Low risk	Grade I or II disease
	Intact capsule
	No tumor on external surface
	Negative peritoneal cytology
	No ascites
	Growth confined to ovaries
High risk*	Grade III disease
	Ruptured capsule
	Tumor on external surface
	Positive peritoneal cytology
	Ascites
	Growth outside ovaries

*If any high-risk factors are present, the patient is considered high risk.

Data from Young RC, Walton L, Ellenberg SS, et al: Adjuvant therapy in stage I and stage II epithelial ovarian cancer: results of two prospective randomized trials. N Engl J Med 1990;322:1021–1027.

Because selection of therapy will be based on risk category, a detailed staging procedure is mandatory. In a series of 100 patients who were referred after initial laparotomy-based diagnosis of stage I or II ovarian carcinoma and then reexplored, 31 patients were found to have more advanced disease than was noted at initial laparotomy. Such upstaging can have a significant impact on choice of therapy.

MANAGEMENT. The initial approach to patients with limited disease should be surgical resection of disease. This should be combined with a careful staging laparotomy that defines in detail the anatomic extent of disease. However, controversy characterizes recommendations for the use of adjuvant therapy after surgical resection. At least three different approaches have been used in uncontrolled trials: abdominopelvic radiation therapy, intraperitoneal radioactive chromic phosphate (^{32}P), and chemotherapy.

Radiation Therapy. The use of radiation therapy in the management of ovarian carcinoma fell into disfavor because of two flawed approaches to its use: pelvic radiation therapy as an adjuvant to surgical resection of stage I disease[143,144] and abdominopelvic radiation therapy in patients with gross disease. The first approach failed because a significant proportion of the patients who were treated with pelvic fields already had at least microscopic disease outside the pelvis. The second approach attempted the eradication of disease that was too bulky to handle with the doses that were achievable to a whole-abdominal field. Results with abdominopelvic radiation therapy as an adjuvant treatment in patients with stage I through III disease and no gross residual suggest that the potential role of radiation therapy should be reconsidered.

Investigators at the Princess Margaret Hospital in Toronto, Ontario, Canada, randomized patients with stage I, stage II, and minimal residual stage III disease to either abdominopelvic radiation to a total of 22.5 cGy by a moving-strip technique or pelvic radiation with or without chlorambucil. Patients with stage III disease were not randomized to pelvic radiation alone. The study demonstrated clear superiority for abdominopelvic radiation.[145] A follow-up trial that compared abdominopelvic radiation by a moving-strip and open field technique showed no difference.[146]

A subsequent analysis of patients who received abdominopelvic radiation in these two studies looked at the results in patients who were at intermediate or high risk of recurrence on the basis of histologic type, grade, and stage.[147] Of 211 patients who were at intermediate risk, only 60 were assigned to stage I; the 5-year survival rate was 75%. Of 88 patients who were at high risk of recurrence, there were 72 stage III patients and 16 stage II patients; the 5-year survival rate was 32%. Two groups of patients did not benefit from abdominopelvic radiation: those with stage I grade I disease and those with large-volume disease (nodules >2 cm).

An important problem with these studies is the lack of careful surgical staging, as evidenced by the large number (155 of 325) of patients who were assigned to stage II, an uncommon stage in appropriately evaluated patients. This is a major inconsistency in a patient population that purports to serve as the basis for determining prognostic features that can identify low-risk, intermediate-risk, and high-risk patient subsets.

Despite the questionable nature of the surgical staging, the Princess Margaret Hospital experience makes a strong case for a role for abdominopelvic radiation in the management of patients with limited disease who are at significant risk for recurrence. The comparisons with pelvic radiation with or without chlorambucil do not permit conclusions as to the relative merits of abdominopelvic radiation versus chemotherapy because the chemotherapy that was used consisted of suboptimal doses of a single alkylating agent.

Supporting these observations are a number of uncontrolled reports in the literature.[148,149] These experiences confirm that patients with gross disease, particularly those with nodules greater than 2 cm in diameter, do not benefit significantly from radiation.

In contrast to these experiences is one earlier M.D. Anderson Hospital trial of 149 patients with stage I, II, or minimal residual stage III disease who were randomized to either abdominopelvic radiation by the moving-strip technique or oral melphalan. A 10-year follow-up evaluation showed no difference in survival.[150] The study has been criticized for imbalances in prognostic factors favoring the chemotherapy regimen and for problems with the radiation technique used.

On the basis of current evidence, abdominopelvic radiation cannot be recommended as adjuvant therapy in limited disease. Studies suggesting efficacy have critical flaws. However, further study is indicated on the basis of the Princess Margaret Hospital experience.

Radioactive Isotopes. The intraperitoneal administration of radioactive isotopes to treat limited-stage ovarian cancer after surgical resection has been proposed as a promising approach.[151–157] Early studies were characterized by small numbers of patients accrued over many years, lack of control groups, and inadequate surgical staging. Despite these limitations, reported survival rates were sufficiently high to include this modality as one treatment regimen in three major randomized trials described.[142,158,159]

This approach is based on the facts that ovarian carcinoma spreads initially primarily by intraperitoneal seeding and that ^{32}P is an emitter of beta-radiation, which has a maximum tissue penetration of 3 to 4 mm, with an effective penetration of probably no more than 2 mm. Whereas ^{32}P could not be expected to be effective in patients with visible disease, it might well be an effective agent in patients with microscopic or no documentable residual disease after surgical resection. Uncontrolled trials in limited disease as well as reports of efficacy in patients who have achieved a pathologic complete response of more advanced disease with initial chemotherapy supported the possible efficacy of this approach.[149] A subsequent randomized trial (GOG Protocol 95) comparing intraperitoneal ^{32}P with cyclophosphamide/cisplatin showed a superior progression-free survival with chemotherapy and also highlighted distribution problems and bowel toxicities associated with ^{32}P. The GOG investigators concluded that chemotherapy was the preferred treatment for high-risk limited ovarian carcinoma and essentially laid to rest any role for ^{32}P.[160]

SINGLE ALKYLATING AGENTS. Single alkylating agents, most commonly melphalan, appear to offer benefit in uncontrolled trials.[150,160] One series compared melphalan with abdominopelvic radiation and showed similar survival between the two regimens and an advantage for melphalan because of less toxicity.[150] The other study retrospectively evaluated 50 patients with limited disease accrued over a 13-year period and treated with single-agent melphalan.[160] The survival rate at 2 years was 98%, and that at 4 years was 94%. Consistency of surgical staging techniques was not documented in the report. To draw definite conclusions about the efficacy of melphalan from these reports is impossible, but survival figures suggest that melphalan could be an effective adjuvant therapy.

RANDOMIZED TRIALS. Superseding the previously described uncontrolled trials are nine major randomized trials comparing modalities as adjuvant therapy in patients with limited disease: GOG Protocol 1, a National Cancer Institute of Canada Clinical Trials Group study, two critically important trials from the combined efforts of the Ovarian Cancer Study Group and the GOG, two European trials, two additional studies of the GOG, and the combined analysis of two European trials (ICON1/ACTION).

GOG PROTOCOL 1. GOG Protocol 1, conducted during 1970 to 1976, was a phase III trial of patients with stage I ovarian carcinoma.[144] Although all patients underwent exploratory laparotomy, routine exploration of the diaphragm, lymph node sampling, peritoneal cytology, and omentectomy were not required because the importance of these procedures as a part of careful staging was not fully understood. After surgical resection of disease, patients were randomized to either no further therapy, pelvic radiation to 50 cGy, or chemotherapy consisting of melphalan (0.2 mg/kg/day orally) for 5 days every 4 weeks. Of the 168 patients who were entered into the study, only 86 were both eligible and evaluable, a major problem.

An analysis of prognostic factors showed an even distribution of prognostic factors, except that the control arm contained a greater percentage of favorable histology and stage IA. Among 29 patients who were randomized to no further therapy, five (17%) recurrences were found; among 23 patients who were given pelvic radiation, seven (30%) had a recurrence; and among 34 patients who received melphalan, only two (6%) had recurrence. The difference between melphalan and pelvic radiation was significant ($P < 0.05$).

This trial suggests that patients with limited disease benefit from the use of adjuvant melphalan, but flaws in study execution and the relatively small number of evaluable patients prevent definitive conclusions. The results do indict pelvic radiation as an inadequate approach. The analysis of prognostic factors also points to the importance of grade, histologic type, and extracystic tumor in determining patient outcome.

NATIONAL CANCER INSTITUTE OF CANADA CLINICAL TRIALS GROUP STUDY. This investigation of patients with stage I or IIA high-risk (defined by rupture of a malignant ovarian cyst, poorly differentiated disease, extracystic excrescences of tumor, or positive peritoneal cytology), stage IIB, or stage III with disease confined to the pelvis[158] randomized subjects to pelvic radiation to 45 cGy plus either abdominal radiation to 22.5 cGy, radioactive chromic phosphate 15 mCi intraperitoneally, or melphalan (8 mg/m^2/day orally) for 4 days every 4 weeks for 18 months. Of 257 eligible and evaluable patients, 107 were randomized to abdominopelvic radiation, 106 to pelvic radiation plus melphalan, and 44 to pelvic radiation plus intraperitoneal ^{32}P. The arm including intraperitoneal chromic phosphate was closed early because of an unacceptably high incidence of delayed toxicity. No differences in disease-free or overall survival or in recurrence rate were noted among the three arms. The investigators concluded that the survival results of all three arms point to the need for further improvement in adjuvant therapy.

Table 93-19 Results of OCSG and GOG Protocol 7601*

	Observation	Melphalan
Patients	38	43
Recurrences	4	1
Deaths	4	2
Disease-free 5-year survival rate	91%	98%
Overall 5-year survival rate	94%	98%

OVARIAN CANCER STUDY GROUP AND GOG STUDIES. These studies were conducted from 1976 to 1986.[142] The first study, OCSG/GOG Protocol 7601, randomized 81 patients with stage I disease at low risk of recurrence (defined as those patients with well- or moderately well-differentiated intracystic lesions associated with no extraovarian neoplasm, no ascites, and negative peritoneal cytology after a careful and detailed exploratory laparotomy) to either no further therapy (38 patients) or melphalan 0.2 mg/kg/day orally for 5 days every 4 weeks for up to 12 cycles (43 patients). At a median follow-up in excess of 6 years, only six deaths had been observed: four in the control arm and two in the melphalan arm. Five recurrences have been observed: four in the control arm and one in the melphalan arm. No significant differences in recurrence rate, disease-free survival, and survival were noted between the two arms (Table 93-19).

The second trial, OCSG/GOG Protocol 7602, involving 141 patients with stage I high-risk disease (defined as having one or more high-risk feature—that is, poorly differentiated disease, extracystic tumor, ascites, positive peritoneal cytology, or extraovarian lesions—or stage II disease completely resected) randomized subjects to either intraperitoneal radioactive chromic phosphate 15 mCi (73 patients) or melphalan (0.2 mg/kg/day orally) for 5 days every 4 weeks for up to 12 cycles (68 patients). At a median follow-up of more than 6 years, 34 (24%) recurrences were seen, 16 (22%) of 73 in the ^{32}P arm and 18 (26%) of 68 in the melphalan arm. Over the same period, 31 (22%) deaths occurred, 16 (22%) of 73 in the ^{32}P arm and 15 (22%) of 68 in the melphalan arm. The 5-year disease-free survival rate for both arms is 80%. No significant differences between arms are present in regard to recurrence rate, disease-free survival, or overall survival (Table 93-20).

Table 93-20 Results of OCSG and GOG Protocol 7602*

	Intraperitoneal ^{32}P	Melphalan
Patients	73	68
Recurrences	14	13
Deaths	16	15
Disease-free 5-year survival rate	80%	80%
Overall 5-year survival rate	78%	81%

*Randomized trial of patients at high risk of recurrence.

Data from Young RC, Walton L, Ellenberg SS, et al: Adjuvant therapy in stage I and stage II epithelial ovarian cancer: results of two prospective randomized trials. N Engl J Med 1990;322:1021–1027.

Italian Trial. An Italian trial,[161] reported in 1992, grouped patients with limited disease into three categories: a low-risk group including stage IA G1 and stage IB G1 with no extracystic involvement (93 patients), an intermediate-risk group including stage IAG2–3 and stage IBG2–3 with no extracystic involvement (91 patients), and a high-risk group including stage I patients with extracystic involvement (185 patients; Table 93-21). Patients in the low-risk group were followed up on no active treatment after surgical resection and demonstrated a 5-year disease-free survival rate of 90% with five relapses and three disease-related deaths.

Patients in the intermediate-risk group were randomized to either cisplatin 50 mg/m^2 every 4 weeks for six cycles, or no further treatment after surgical resection. The 5-year disease-free survival rate was 76% in the cisplatin arm and 58% in the control arm. Eighteen relapses and nine disease-related deaths were observed. The difference in disease-free survival was significant ($P < 0.05$) in favor of the cisplatin arm.

Patients in the high-risk group were randomized to either cisplatin (50 mg/m^2) every 4 weeks for six cycles or chromic phosphate (15 mCi intraperitoneally). The 5-year disease-free survival rate in the cisplatin arm was 84% versus 61% in the ^{32}P arm, a difference that was statistically significant ($P < 0.01$) in favor of the cisplatin arm. Forty relapses and 25 disease-specific deaths were observed.

Norwegian Study. A Norwegian study[162] that was reported in 1992 randomized 265 patients with stage I limited disease to either cisplatin or intraperitoneal ^{32}P, as in the Italian trial. The trial is difficult to interpret on the basis of the only report to date because of the inclusion of patients with borderline lesions (low malignant potential) and because of a failure to separate patients into low-risk and high-risk groups.

GOG Protocol 95. The GOG randomized 205 patients with high-risk limited disease after complete surgical resection to adjuvant therapy consisting of either intraperitoneal ^{32}P or three cycles of cyclophosphamide 1000 mg/m^2 plus cisplatin 100 mg/m^2.[163] The recurrence-free rate at 5 years was 77% on the chemotherapy regimen versus 66% with ^{32}P. The estimated relative risk is 0.693, favoring the chemotherapy regimen ($P = 0.075$). The 5-year survival rate was 84% for the chemotherapy and 76% for the ^{32}P group. Patients receiving the intraperitoneal ^{32}P experienced problems with distribution of the compound in the abdominal cavity and also with bowel toxicities. The GOG concluded from these data that chemotherapy represented the preferred treatment (Table 93-22).

Table 93-21 Results of a Randomized Trial Involving 369 Patients with Stage I Ovarian Carcinoma

Treatment	Relapses	Deaths	5-Year Disease-Free Survival Rate (%)

ICON1/Action. The combined efforts of the ICON and the European Organization for Research and Treatment of Cancer produced a combined analysis of two randomized studies of adjuvant chemotherapy in patients with limited disease.[164] Both groups required that patients have stage I to IIA disease and that patients be randomized after surgical resection to either no further therapy or adjuvant chemotherapy containing a platinum compound. Of 925 patients who were randomized to the two studies, at a median follow-up of 4 years, 245 patients had either died or experienced recurrence of disease. The recurrence-free survival rate at 5 years was 76% in the chemotherapy arm and 65% in the observation arm (relative risk: 0.64, $P = 0.001$). The overall 5-year survival rate was 82% in the chemotherapy arm and 74% in the observation arm (relative risk: 0.67, $P = 0.008$). This study marks the first report of improved overall survival with chemotherapy and establishes chemotherapy as the standard of care after surgery in patients with high-risk limited disease (Table 93-23).

GOG Protocol 157. The GOG randomized 457 patients with high-risk limited ovarian carcinoma after complete surgical resection to paclitaxel 175 mg/m^2/3 hours plus carboplatin AUC 7.5 every 3 weeks for either three or six cycles.[165] The basis for this trial included the prior studies that showed an advantage for chemotherapy in high-risk limited disease[163,164] and the randomized trials that established paclitaxel/carboplatin as the standard of care for advanced

Data from Vergote I, Trimbos B, Guthrie D, et al: Results of a randomized trial in 923 patients with high-risk early ovarian cancer, comparing adjuvant chemotherapy with no further treatment following surgery [abstract]. Proc ASCO 2001;20:201a.

disease.[93,94,100,101] The chemotherapy regimen that was adopted was the one used in GOG Protocol 158.[101] A large proportion of the patients failed to meet the surgical requirements of the trial (107 of 457, or 23%), so the study was analyzed both with and without these patients. Both analyses showed a reduction in recurrence rate that did not reach statistical significance (relative risk: 0.69 without the surgical exclusions and 0.77 with the exclusions, neither of which was statistically significant). Both also showed no significant difference in survival at 5 years (79% compared to 84% in group without exclusions; Table 93-24).

CONCLUSIONS. The results of the nine randomized trials provide guidelines for the management of patients with limited disease. First, the trials demonstrate the importance of careful surgical staging to establish the patient's risk of recurrence. Second, patients who are at low risk of recurrence have a 5-year survival rate exceeding 90% with or without adjuvant therapy. Additional treatment after surgical resection does not appear to be indicated. Third, patients who are at high risk of recurrence appear to benefit from adjuvant therapy. The weight of evidence supports the use of cisplatin-based chemotherapy as the adjuvant therapy of choice. Although definitive statements about regimen and duration are difficult, it would seem reasonable to use paclitaxel/carboplatin, as in GOG Protocol 157, for at least three cycles of therapy (Box 93-2).

Management of Recurrent, Persistent, or Progressive Disease

Although debate continues about the optimal choice of drugs, dose schedule, and route of administration, platinum-based combination chemotherapy yields the following results in patients with advanced disease:[93,94,100,101] an overall response rate of 95%, a clinical complete response rate of 75%, a pathologic complete response rate of 40% to 50%, a 10-year survival rate of 15% to 40%, and a recurrence rate after clinical complete response of 75% and after pathologic complete response of 40% to 60%. Patients who initiate front-line therapy with small-volume residual disease will fare better than those who start chemotherapy with large-volume residual disease. The fact remains, however, that a majority (60% to 75%) of patients with ovarian carcinoma will require further therapy for recurrent, persistent, or progressive disease. The factors that affect the choice of that therapy and the specific options available are now considered.

RECURRENT DISEASE POPULATION. Long-term follow-up evaluation of 726 women who were treated for ovarian carcinoma on GOG protocols[166,167] identified a number of characteristics associated with increased likelihood of recurrence: clear cell or mucinous histology, non-platinum-based treatment, poor performance status, older age, higher stage, clinically measurable disease, larger residual tumor volume, and ascites. In addition, an analysis of those factors that predict recurrence after pathologic complete response[168] shows that histologic grade is an important determinant of relapse rate, with grade I having a relapse rate of 22%; grade II, 39%; and grade III, 56%.

None of these factors provides guidance in the selection of appropriate subsequent therapy. However, an additional factor that does appear to provide a basis for choosing salvage therapy is the result of immediately preceding therapy. Patients who respond to previous platinum-based therapy and who demonstrate a significant treatment-free interval have a high probability of responding again to platinum-based treatment.[169–174] Patients who progressed during or shortly after completion of platinum-based therapy are unlikely to respond to further treatment with a platinum compound and should be considered for therapy with non-cross-resistant agents.[63–71,118–125,127,175–207] Discussion of salvage therapy is based on this division of patients into "sensitive" and "resistant" populations based on responsiveness to initial platinum-based treatment (Table 93-25).

Box 93-2. THERAPEUTIC CHOICES IN RECURRENT, PERSISTENT, OR PROGRESSIVE CELOMIC EPITHELIAL CARCINOMA

Choices of therapy for progressive, persistent, or recurrent celomic epithelial carcinoma of the ovary hinge on the patient's response to front-line therapy. Patients who respond to initial chemotherapy, who become disease free, and who experience a treatment-free interval of 6 months or longer are highly likely, at recurrence, to be responsive to platinum-based salvage therapy. These platinum-sensitive patients should be retreated with a platinum-based combination regimen. The currently preferred regimen is carboplatin AUC 6 to 7.5 intravenously after paclitaxel 175 mg/m²/3 hours intravenously every 3 weeks. Patients who fail to respond should be deemed platinum resistant and treated accordingly. Those who respond and become disease free with a treatment-free interval of at least 6 months should once again receive platinum-based therapy.

Patients whose disease progresses while they are receiving initial therapy, who have persistent disease at the conclusion of initial treatment, or whose tumor recurs within 6 months of initial therapy should be regarded as platinum resistant. These patients should be treated with regimens that induce responses in platinum-resistant disease. Repeated platinum-based therapy is not indicated. Single agents that achieve responses in resistant patients include weekly paclitaxel, docetaxel, pegylated liposomal doxorubicin, oral etoposide, topotecan, tamoxifen, gemcitabine, navelbine, and ifosfamide. No evidence supports the use of combinations in resistant patients. Therapy should be continued until disease progression or achievement of complete response.

Approaches that should be reserved for clinical trials only include high-dose therapy with autologous bone marrow transplantation or peripheral stem cell support, intraperitoneal therapy, and biologic agents.

MANAGEMENT OF PLATINUM-SENSITIVE PATIENTS

IMPORTANCE OF TREATMENT-FREE INTERVAL. Until recently, most studies of patients who have recurrent, persistent, or progressive disease after initial chemotherapy focused on identification of the activity of new drugs or approaches as a basis for the subsequent testing of these active regimens in phase III studies of front-line therapy. As a result, determination of optimal therapy for this setting was extrapolated from data that had been collected for other purposes. These efforts have led to the conclusion that the most important determinant of the likelihood of a response in the setting of progressive, persistent, or recurrent disease is the treatment-free interval.

Succinctly stated, the duration of the interval from the conclusion of preceding therapy to the need for further therapy influences the likelihood of the patient's responding to the chosen further therapy.

Table 93-25 Definitions of Platinum-Sensitive and Platinum-Resistant Patients for Decision Making in Salvage Treatment

Group	Description
Platinum sensitive	Initial response to platinum
	Platinum-free interval: >6 months
Platinum resistant	Progression on platinum
	Best response stable to prior platinum
	Relapse <6 months after prior platinum

The longer the interval, the greater is the likelihood of a response.[173] To illustrate this principle, four among many studies are examined.

In the first example, intravenous cisplatin-based therapy as salvage treatment was evaluated retrospectively in 72 patients with measurable disease who had received at least two cisplatin- or carboplatin-based regimens and had demonstrated a platinum-free interval of at least 4 months between the completion of the first regimen and initiation of the second.[173] The overall response rate was 43% (31 of 72 with 10 pathologic complete responses). The response rate increased as the platinum-free interval increased. In patients with an interval of 5 to 12 months, the response rate was 27% (5% pathologic complete responses); in those with an interval of 13 to 24 months, it was 33% (11% pathologic complete responses); and in those with an interval of more than 24 months, it was 59% (pathologic complete responses, 22%).

In the second example, a salvage regimen of weekly cisplatin combined with either epirubicin or etoposide[174] yielded a 60% response rate (25% complete response) with a median duration of response of 7 months and a median survival of 13.5 months in 40 patients who had responded to initial platinum-based therapy. The longer the disease-free interval before relapse, the greater was the likelihood of response.

In the third example, the combination of carboplatin (300 mg/m^2) on day 8 preceded by cyclophosphamide (100 mg/m^2/day) on days 1 to 7 in 28 patients produced nine objective responses (five complete and four partial).[171] Six of these responses (46%) occurred among 13 patients who were initial responders and hence platinum sensitive. Only three responses (20%) were observed among the 15 platinum-resistant patients. The relatively high response rate among the platinum-resistant group may be accounted for by the response definitions, because the platinum-resistant group included patients with platinum-free intervals of up to 12 months' duration.

The fourth example evaluated the platinum analog iproplatin at an initial dose of 270 mg/m^2 in patients with recurrent disease after prior cisplatin or carboplatin treatment.[172] Among 78 resistant patients, nine responses (three complete and six partial, 12%) were observed. Among the 19 sensitive patients, five responses (two complete and three partial, 26%) were observed.

These four examples demonstrate that patients who respond to platinum-based therapy initially and relapse after a significant platinum-free interval have a high likelihood of responding again to intravenous platinum-based treatment. The correct definition of a significant platinum-free interval is unclear, although the data suggest that the longer the interval, the more likely is the response. Most studies use the interval of 6 months as the point that defines platinum sensitivity.

Choice of Regimen. The principle of the treatment-free interval appears to apply regardless of the drug or regimen that is chosen.[120] Virtually all active drugs tested to date appear to fare better in the platinum-sensitive group than in the platinum-resistant group. The frequency of response, however, does appear to depend on the drug chosen. For any given point along the plot of treatment-free interval, the frequency of response to platinum-based therapy is 1.5 to 2.0 times greater than that reported with nonplatinum agents or regimens.[122,171–174,185,187] In addition, the duration of response and survival is better with platinum-based regimens than with alternative, nonplatinum-containing regimens.[208]

Debate has focused on whether a platinum compound as a single agent offered a less toxic and equally efficacious alternative to combination chemotherapy in the setting of platinum-sensitive disease. A phase III trial has directly addressed this question. ICON4 randomized patients with platinum-sensitive disease, defined as a treatment-free interval from prior therapy of at least 6 months, to a platinum-containing regimen with or without a taxane.[209] The vast majority of patients received either single-agent carboplatin or a combination of paclitaxel/carboplatin. The analysis showed that the patients receiving the taxane/platinum regimen had a superior response rate (66% versus 54%, $P = 0.06$), a superior progression-free survival (50% progression-free versus 40% at 1 year, hazard ratio = 0.76; $P < 0.001$), and a superior overall survival (57% alive versus 50% at 2 years, hazard ratio = 0.82; $P = 0.023$; Table 93-26). This is the first study in the second-line setting to show a survival advantage for combination chemotherapy over a single agent and establishes a taxane/platinum combination as the preferred treatment for patients with platinum-sensitive disease. (A confirmatory trial will be required to make this the standard of care.)

Dose-Intense Second-Line Chemotherapy. Studies of dose-intense approaches to salvage chemotherapy for ovarian carcinoma[117,210–212] purport to show an advantage for such approaches based on the observation of responses in the recurrent-disease situation. The problem with the interpretation of many of these reports is the lack of information on prior response to platinum-based treatment. Without such data, one cannot determine whether the observed responses occurred only in platinum-sensitive patients at a rate that is expected with standard IV platinum therapy or whether platinum-resistant patients are responding to the higher-dose schedules.

Two reports[169,170] do provide this critical information. The first of these is a study of high-dose carboplatin (800 mg/m^2 intravenously) every 5 weeks in 30 patients who had previously been treated with cisplatin.[169] Eight objective responses (27%) were observed, none in patients with progressive disease during platinum-based therapy.

The second report examined retrospectively two phase II trials of salvage cisplatin-based intraperitoneal therapy.[170] Among 89 patients, 52 were considered platinum sensitive, and 37 were considered platinum resistant. Among the sensitive patients, 29 (56%) developed an objective response; 17 were pathologic complete responses. Among the resistant patients only four responded (11%), all partially.

These two reports suggest that the increase in dose intensity that is achievable by dose escalation or intraperitoneal administration of drug

Table 93-26 Results of ICON and OVAR 2.2*

	Platinum	Taxane/ Platinum	Relative Risk
Patients	410	392	
Response	54%	66%	
Progression free at 1 year	40%	50%	0.76†
Alive at 2 years	50%	57%	0.82‡

*Randomized trial of patients with platinum-sensitive recurrent disease.
†$P < 0.001$.
‡$P = 0.023$.
Data from Schwartz P, Keating G, MacLusky N, et al: Tamoxifen therapy for advanced ovarian cancer. Obstet Gynecol 1982;59:583–588.

cannot overcome true clinical resistance. Although this does not rule out the ability of an even greater dose intensity to overcome resistance, the fact that intraperitoneal drug administration with a fairly significant enhancement of drug exposure to cells did not yield a significant response rate in resistant patients certainly argues against the likelihood that other dose-intense programs will succeed. Conversely, the activity of these approaches in sensitive patients is on the same order as that reported with standard intravenous doses of platinum-based regimens.[116] There is little evidence so far to support the routine clinical use of such dose-intense approaches in the salvage setting.

Conclusions. Evidence supports the use of platinum-based therapy to treat patients with recurrent disease who responded to prior platinum-based therapy and experienced at least a 6-month treatment-free interval before recurrence. In such a setting, platinum-based therapy is far more likely to produce a response than is any alternative. Furthermore, recent evidence supports the use of a taxane/platinum-based combination regimen. The goal of therapy in this setting should be both improvement in survival and palliation. Dose-intense approaches do not appear to offer any advantage over standard intravenous doses.

MANAGEMENT OF PLATINUM-RESISTANT PATIENTS. Successful management of platinum-resistant patients (less than 6-month treatment-free interval after a preceding platinum-based regimen) depends on the identification of agents that are non-cross-resistant with the platinum compounds. Until 1989, essentially no such agents had been identified. Now a number of agents have been shown to produce objective responses in patients who have failed to respond to platinum-based initial therapy. Among these are paclitaxel,[57,63–66] docetaxel,[67–71] pegylated liposomal doxorubicin,[119,120,187–190] oral etoposide,[118,191–194] topotecan,[121,122,183–185] tamoxifen,[204–206] gemcitabine,[123–125] vinorelbine,[195–199] and ifosfamide.[57,213–215] Although each of these agents appears to be more active in platinum-sensitive patients, major interest has been generated primarily by their activity in resistant patients.

In platinum-resistant patients, paclitaxel achieves responses in 24% to 30% of patients in phase II trials.[63–66] This agent is clearly the treatment of choice in patients whose disease has failed to achieve an objective response to initial platinum-based regimens. Because paclitaxel is now a part of standard front-line therapy, current focus is on agents that have activity in patients who have disease that is resistant to both the platinum compounds and paclitaxel. Six agents have demonstrated such activity: docetaxel, weekly paclitaxel, pegylated liposomal doxorubicin, topotecan, oral etoposide, and gemcitabine.

To date, no evidence suggests an advantage for combination chemotherapy over single-agent therapy in the platinum-resistant setting; hence, platinum-resistant patients should be treated with single-agent therapy consisting of one of the six agents that have demonstrated activity against resistant disease. The goal in this setting is palliative because no evidence indicates that therapy in this setting prolongs survival.

Other potential options for treatment of resistant ovarian carcinoma include more dose-intense therapy, biologic agents, and hormones. The lack of evidence supporting the value of more dose-intense approaches has been described. Insufficient data are available to establish the value of biologic agents in resistant disease.

CONCLUSIONS REGARDING SALVAGE THERAPY. The current management of patients with ovarian carcinoma who have recurred after initial platinum-based chemotherapy rests on consideration of the results of the initial chemotherapy. Patients who respond to the initial platinum-based therapy and relapse after a platinum-free interval should be considered clinically sensitive to further platinum-based treatment. Recent evidence suggests that combination chemotherapy with a taxane/platinum combination produces a superior response rate and better progression-free and overall survival. Such therapy will yield response rates as high as 60%, with up to 25% of patients achieving a complete response and also median survivals that exceed 2 years. No evidence indicates that more dose-intense approaches yield better results in these patients than results with standard intravenous schedules.

Patients who fail to respond to initial platinum-based therapy or who relapse shortly after completion of initial therapy should be regarded as clinically resistant to further platinum-based treatment. These patients should be treated with drugs that have been shown to have activity against resistant disease: weekly paclitaxel, docetaxel, pegylated liposomal doxorubicin, oral etoposide, topotecan, tamoxifen, gemcitabine, navelbine, and ifosfamide. No evidence exists that combinations of these drugs are more effective than single-agent therapy.

CONTROVERSIAL ISSUES. Two specific situations in the management of patients with recurrent, persistent, or progressive disease deserve further comment: patients who have a rising CA-125 level as the only evidence of recurrence or progression and potential candidates for secondary surgical cytoreduction.

Patients with Increasing CA-125 Only. With the advent of the widespread use of CA-125 to monitor patients with ovarian carcinoma, an increasingly common situation to confront the physician is that of the patient who develops an increasing CA-125 level but is otherwise free of any evidence, objective or otherwise, of recurrence and is asymptomatic. Because of the high level of awareness of CA-125, patients naturally obsess about their CA-125 values and often demand that the physician intervene with therapy in such a situation. Unanswered as yet is the question as to what is the best choice for these patients: treatment or observation until the development of other objective evidence of disease or of symptoms.

Until recently, all treatment in the second-line setting was regarded as purely palliative. In such circumstances, the rationale for waiting until the patient developed either symptoms or other objective evidence of recurrence, which was almost always followed shortly thereafter by symptoms, was obvious. Except for patients who demanded treatment, the general recommendation was that treatment should await the onset of symptoms or the appearance of other objective evidence of disease.

With the report of the results of ICON4/OVAR 2.2[209] and the demonstration that survival could be improved by treatment in the platinum-sensitive setting, the question of immediate treatment should be revisited. As of this writing, no such study is under way; hence, treatment decisions must be made in the absence of definitive evidence. The best recommendation is to discuss the issue with the patient. In the absence of a preference on the patient's part, a policy of watchful waiting until the development of symptoms would seem to be most prudent.

Potential Candidates for Secondary Surgical Cytoreduction. Secondary surgical cytoreduction is debulking that is performed in the patient with recurrent, persistent, or progressive disease before the use of second-line chemotherapy.[216] Mixed results have been reported with secondary debulking.[217,218] The benefit appears to depend on careful selection of candidates for the procedure. Patients whose disease can be surgically cytoreduced to the point at which no gross disease remains appear to be the patients who benefit from the procedure.[219] The procedure should therefore probably be reserved for those patients in whom the surgeon feels that complete resection of all gross disease can be achieved. To some extent, the benefit that is observed also depends on the availability of chemotherapy that will follow the procedure and to which the patient is likely to be sensitive.

Special Situations

The natural history and spread patterns of celomic epithelial carcinomas of the ovary create at least two special circumstances with

which the clinician must deal: intestinal obstruction and malignant effusions.

INTESTINAL OBSTRUCTION. Up to one half of patients with ovarian carcinoma develop symptoms of gastrointestinal obstruction (nausea, vomiting, abdominal pain, and obstipation), most commonly related to progressive cancer rather than to adhesions.[220,221] Small bowel and, to a lesser extent, colonic and gastric outlet obstruction can occur. Nonoperative management with intravenous hydration, intestinal intubation, and parenteral hyperalimentation is acceptable initial management, but only 10% to 30% of cases of true obstruction will be relieved by such an approach; the majority of patients who are so relieved develop recurrent obstruction within 1 month.[222,223]

Surgical management of intestinal obstruction is the remaining option if no relief is obtained with noninvasive measures. If surgery is used indiscriminantly, median survival after such an approach is uniformly less than 8 months and not dramatically different from that seen in patients who are managed without surgery. The selection of patients to be considered for surgery will depend on several features: performance status, contraindications to general anesthesia, and availability of effective postoperative chemotherapy. Particularly in patients who are still potentially sensitive to chemotherapy, surgical relief of the obstruction is warranted.[224]

MALIGNANT EFFUSIONS. Although malignant effusions associated with ovarian carcinoma can involve any one of three cavities (peritoneal, pleural, or pericardial), only the first two are sufficiently common to warrant detailed consideration. With regard to the first of these, ascites is by far the most common of the effusions. At initial diagnosis, ascites is frequent but seldom severe enough to require specific intervention and usually responds to systemic chemotherapy with resolution after one to two cycles of treatment.[225] For cases that are resistant to systemic chemotherapy and productive of significant problems, paracentesis provides symptomatic relief. Intraperitoneal bleomycin[226,227] and peritoneovenous shunts[228,229] have been used in particularly troublesome cases, but success is temporary and most often related to concomitant chemotherapy the patient received.

Pleural effusions occur in 25% to 30% of patients and are cytologically positive for malignant cells in 75% of cases.[230] When symptomatic, these effusions should be approached with thoracentesis. For patients who are receiving first-line chemotherapy, the pleural effusion usually responds and does not become a recurring problem, whereas patients with recurrent disease and associated pleural effusion, particularly those with platinum-resistant disease, can experience major problems with rapid reaccumulation of fluid after thoracentesis. In such cases, drainage of the fluid with a thoracostomy tube can provide complete resolution of the problem in 36% to 55% of patients.[231,232] Instillation of sclerosing agents such as tetracycline, talc, or bleomycin can significantly improve the rate at which complete resolution is observed.[233] Patients with persistent problems after all these measures can be considered for pleurectomy or thoracopic pleurodesis.[234,235]

Germ Cell Cancers

Approximately 5% of ovarian cancer consists of germ cell carcinomas, which are classified into two broad groups: dysgerminomas and nondysgerminomas[236] (Table 93-27). The same staging system as that used for celomic epithelial carcinomas is used for these tumors. Management begins with exploratory laparotomy to determine extent of disease and to permit surgical resection if possible. Subsequent treatment depends on histology and findings at laparotomy that place patients into one of two groups: those with stage I to III disease that has been completely resected and those with incompletely resected stage III and IV disease. Therapeutic decisions, however, are based on comparisons with historic controls, because these lesions are sufficiently uncommon that randomized trials are not feasible.

Polyembryoma
Mixed cell tumors

Data from Gershenson DM, Malone JM Jr: Chemotherapy for malignant germ cell tumors of the ovary. In Deppe G (ed): Chemotherapy of Gynecologic Cancer, 2nd ed. New York, Wiley-Liss, 1990, pp 217–239.

Tumor Markers

Ovarian germ cell tumors produce markers in most cases. α-Fetoprotein elevations have been noted in patients with endodermal sinus tumors, immature teratomas, mixed germ cell tumors, embryonal carcinomas, and polyembryomas. Elevations of human chorionic gonadotropin have been observed with choriocarcinomas, embryonal carcinomas, polyembryomas, mixed cell tumors, and, less commonly, dysgerminomas. These markers are useful in assessing response to chemotherapy and in monitoring patients who are in complete remission for evidence of recurrence.

Stage I to III Completely Resected

In patients with completely resected stage I, II, or III endodermal sinus tumors, mixed cell tumors, embryonal carcinomas, choriocarcinomas, and immature teratoma, the recurrence rate is high enough to warrant adjuvant therapy. The largest experience with adjuvant chemotherapy is that of the GOG in studies evaluating adjuvant VAC (vincristine, actinomycin D, and cyclophosphamide) and adjuvant BEP (bleomycin, etoposide, and cisplatin).[237–239]

The relative value of these regimens is best established by comparison with historic data on no adjuvant therapy (Table 93-28), which shows a steady increase in the percentage of patients remaining disease free at 16 months of follow-up, as treatment progresses from no adjuvant through VAC to BEP. On the basis of these data, adjuvant BEP is the treatment of choice for patients with completely resected stage I to III disease and specific histologies: immature teratoma grade II and III, endodermal sinus tumor, mixed cell tumor, embryonal carcinoma, and choriocarcinoma. For other histologic types, data are insufficient to permit definitive conclusions (Box 93-3).

Stage III Incompletely Resected and Stage IV Disease

At least two chemotherapy regimens are active in patients with advanced or recurrent disease: VAC and PVB (cisplatin, vinblastine, and bleomycin)[239] (Table 93-29). The cisplatin-based combination yields higher response rates and a greater percentage of patients who remain disease free for extended periods. The current study of the GOG evaluates a combination of bleomycin, etoposide, and cisplatin.

Rare Malignant Ovarian Tumors

Accounting for fewer than 5% of all malignant ovarian tumors are a variety of rare ovarian neoplasms, including granulosa cell tumors,

Table 93-28 GOG Trials of Adjuvant Chemotherapy for Ovarian Germ Cell Carcinoma

Therapy	Endometrial Sinus Tumor and Mixed Cell Tumor	Immature Teratoma
No adjuvant	34/165 (21%)*	36/56 (64%)
VAC†	53/82 (65%)	59/70 (84%)
BEP‡	30/31 (97%)	18/19 (95%)

*Percentage of patients remaining disease free at a median follow-up of 16 months after completion of therapy.

†VAC, vincristine (1.5 mg/m^2 intravenously, maximum 2 mg), every 2 weeks, × 12, actinomycin D (350 µg/m^2/day intravenously) × 5 days every 4 weeks × 6, and cyclophosphamide (150 mg/m^2/day intravenously) × 5 days every 4 weeks × 6.

‡BEP, bleomycin (20 U/m^2 intravenously, maximum 30 units) per week × 9, etoposide (100 mg/m^2/day intravenously) × 5 every 3 weeks × 3, and cisplatin (20 mg/m^2/day intravenously) × 5 every 3 weeks × 3.

Data from Slayton RE, Park RC, Silverberg SG, et al: Vincristine, dactinomycin and cyclophosphamide in the treatment of malignant germ cell tumors of the ovary: a Gynecologic Oncology Group study: a final report. Cancer 1985;56:243–248; Williams S, Blessing J, Liao S, et al: Adjuvant therapy of ovarian germ cell tumors with cisplatin, etoposide, and bleomycin: a trial of the Gynecologic Oncology Group. J Clin Oncol 1994;12:701.

thecoma-fibroma tumors, Sertoli-Leydig cell tumors, gynandroblastomas, and steroid cell tumors. Such lesions are best treated with surgical resection if only limited disease is present. Appropriate management of more advanced disease is unclear. Although both radiation therapy and chemotherapy have been used in the management of advanced disease and as adjuvant therapy for limited disease, evidence is largely anecdotal. It is therefore not possible to make definitive recommendations for the management of more advanced cases.

Box 93-3. THERAPEUTIC DECISION IN NEWLY DIAGNOSED GERM CELL CARCINOMAS

Patients with germ cell carcinomas should be divided into two groups: those with stage I to III disease that has been completely resected and those with incompletely resected stage III and IV disease. After complete resection, patients with endodermal sinus tumor, mixed cell tumor, embryonal carcinoma, choriocarcinoma, or immature teratomas, grade II or III, should receive adjuvant therapy consisting of VP-16 100 mg/m^2/day intravenously plus cisplatin 20 mg/m^2/day intravenously for 5 days every 3 weeks for three cycles and bleomycin 30 units intravenously weekly for the 9 weeks of the three cycles. Second-look laparotomy at the conclusion of therapy is unnecessary if all clinical evidence of disease has disappeared and if both α-fetoprotein and human chorionic gonadotropin levels are normal.

Patients with incompletely resected stage III and IV disease, regardless of histologic type, should be treated with four cycles of the combination described earlier. Those with complete remission, including normalization of α-fetoprotein and human chorionic gonadotropin, can be followed with no further treatment. Those with persistent disease will require further therapy with other active agents, but the precise nature of this therapy has not been defined. Other active drugs include actinomycin D, ifosfamide, and other alkylating agents, anthracyclines, methotrexate, and the vinca alkaloids.

Because most tumors produce either α-fetoprotein or human chorionic gonadotropin or both, therapy should be monitored with the appropriate markers. Subsequent follow-up management of complete responders also should include the marker(s) that were positive.

Table 93-29 GOG Trials of Two Three-Drug Combinations in Incompletely Resected Stage III and IV Germ Cell Carcinomas of the Ovary

Histology and Therapy	Complete Response	Partial Response	Disease Free
Immature teratoma			
VAC*	—	—	4/8 (50%)
PVB†	2/9 (22%)	2/9 (22%)	12/24 (50%)
Endodermal Sinus Tumor and Mixed Cell Tumor			
VAC	—	—	3/14 (21%)
PVB	13/24 (54%)	8/24 (33%)	31/58 (53%)
Dysgerminoma			
PVB	3/4 (75%)	1/4 (25%)	7/8 (88%)
Choriocarcinoma			
PVB	2/3 (67%)	1/3 (33%)	2/3 (67%)

*VAC, vincristine (1.5 mg/m^2 intravenously, maximum 2 mg), every 2 weeks × 12, actinomycin D (350 µg/m^2/day intravenously), × 5 days every 4 weeks × 6, and cyclophosphamide (150 mg/m^2/day intravenously), × 5 days every 4 weeks × 6.

†PVB, vinblastine (12 mg/m^2 intravenously) every 3 weeks × 4, bleomycin (20 U/m^2 intravenously, maximum 30 units) per week, and 12 cisplatin (20 mg/m^2/day intravenously), × 5 every 3 weeks × 3–4.

CANCER OF THE FALLOPIAN TUBE

The fallopian tube is the least common site of origin in the female genital tract for cancer. The most common histologic type of cancer, accounting for 90% of all malignancies of the tube, is papillary serous adenocarcinoma, but even this type is rare, with only 300 cases reported annually in the United States. The pattern of spread is similar to that seen with celomic epithelial lesions of the ovary, dissemination throughout the peritoneal cavity being perhaps the most important route of spread; hence, it is often difficult to distinguish between ovarian and fallopian tube primary tumors. Criteria have been set for lesions that are designated to be of fallopian tube origin:[240,241] The main tumor arises from the endosalpinx and is in the tube; the histologic pattern shows a papillary pattern; a transition zone between benign and malignant epithelium must be demonstrable if the wall is involved; and the ovaries and endometrium must be either normal or less involved than the tube.

As a reflection of the propensity of tubal cancer to spread by intraperitoneal dissemination, 5-year survival rates correlate well with the degree to which the primary lesion penetrates the wall of the tube: 91% for intramucosal lesions, 53% for those with mucosal wall invasion, and 25% or less for lesions that penetrate the tubal serosa.[242] The actual staging system that is used, however, is a modification of the FIGO staging system for ovarian cancer (see Table 93-1).

In contradistinction to ovarian cancer, fallopian tube cancers tend to be first seen at an earlier stage of development: roughly 33% as stage I, 33% as stage II, and 33% as more advanced disease. The mainstay of therapy for patients with limited disease is surgical resection. Whether postoperative radiation therapy is of value as an adjuvant treatment in patients whose tumors have been completely resected is unclear in the absence of a randomized trial. If radiation therapy does have a role, it would seem to be in patients who have no gross disease. Studies of chemotherapy in fallopian tube carcinoma are anecdotal. Agents that have been noted to produce responses are the same that have been noted to be active in celomic epithelial

Box 93-4. THERAPEUTIC DECISIONS IN FALLOPIAN TUBE CARCINOMAS

Firm recommendations on the management of fallopian tube carcinomas are difficult because of the lack of extensive clinical studies. With the best evidence available, four basic groups of patients are found.

Intramucosal Lesions Only
For patients with intramucosal lesions only, cure is excellent with surgical resection. Patients should undergo total abdominal hysterectomy and bilateral salpingo-oophorectomy and should be monitored closely with no further therapy.

Mucosal Wall Invasion
For patients with mucosal wall invasion, the recurrence rate is approximately 50%. These patients are candidates for adjuvant therapy, but no data support the use of such treatment. If adjuvant therapy is to be used, choices similar to those for high-risk ovarian carcinoma seem reasonable. If radiation therapy is to be used, it would seem appropriate to treat the entire abdominal cavity. A preferable approach would be the use of platinum-based chemotherapy, on the assumption that this disease responds similarly to the response of celomic epithelial carcinoma.

Penetration of the Serosa
For patients with penetration of the serosa but no gross spread, the recurrence rate exceeds 75%. An even stronger case for the use of adjuvant therapy can be made. The choices are similar to those noted earlier.

Metastatic Disease
For patients with obvious spread of disease to locoregional and distant sites, platinum-based chemotherapy is a reasonable choice.
The overall strategy should be similar to that used for patients with advanced or recurrent celomic epithelial carcinoma of the ovary.

carcinoma of the ovary. It would seem reasonable to base the choice of systemic therapy in advanced or recurrent disease on extrapolation from data in ovarian carcinoma (Box 93-4).

FUTURE DIRECTIONS

The development of additional information about the nature and management of germ cell cancers and rarer malignant tumors of the ovary as well as fallopian tube cancer will continue to be restricted by the low frequency of these lesions. With regard to celomic epithelial carcinomas of the ovary, however, progress should continue to be rapid. Current and future investigational efforts focus on several distinct areas: biology of ovarian carcinoma, screening and early detection, the proper role of surgery, new agents and their role in systemic therapy, and the role of dose-intense approaches.

First, with regard to the biology of ovarian carcinoma, specific studies are seeking (1) to characterize factors associated with ovarian carcinoma and its outcome, such as specific genetic defects associated with hereditary ovarian carcinoma, various oncogenes, and DNA ploidy; (2) to identify features that are predictive of the likelihood of developing ovarian carcinoma; and (3) to ascertain the biologic reasons for the observation that more aggressive disease is associated with older patients. As these and other investigations expand the understanding of the basic nature of ovarian carcinoma, the development of better and more specific methods for early detection and treatment of the disease should become possible. Where this line of work will ultimately lead is speculative but exciting.

Second, the evolution of effective techniques for screening for and early detection of ovarian carcinoma has a high priority in ovarian carcinoma, the only one of the major gynecologic cancers for which early detection is not the rule. Most interest centers on the potential for transvaginal sonography, especially when enhanced by color-flow Doppler, to permit earlier detection of disease. The recent report of potential value for proteomic patterns in the serum for early detection of ovarian carcinoma has focused on the biologic front as well. Confirmation of the value of such approaches must await larger trials.

Third, although the efficacy of initial surgical cytoreduction in patients with stage III disease has been accepted on the basis of retrospective analyses, prospective trials are needed to address several important questions. Two trials of interval surgical cytoreduction at the midpoint of a series of chemotherapy courses suggest a role for this procedure in patients with a less than optimal initial surgical effort. Prospective randomized trials of initial or secondary surgical cytoreduction have not been performed. Investigations of the relative merits of each of these approaches versus no surgery are needed, as well as trials evaluating which of these points in the therapy represents the optimal time to introduce surgical resection into the management of advanced disease. Such studies are difficult to conduct because of the widespread acceptance of the role of surgical cytoreduction in ovarian carcinoma.

Fourth, efforts continue to investigate the role of new agents in the management of ovarian carcinoma. Current interest continues to center on further delineation of the role of a number of promising new cytotoxic and biologic agents. The plethora of new agents with activity in patients who are clinically resistant to the platinum compounds and paclitaxel opens the possibility for the addition of clinically non-cross-resistant drugs to front-line paclitaxel/platinum therapy. Defining the role of these new agents is of paramount importance.

Finally, dose intensity continues to command significant interest. Three basic ways to enhance the dose intensity have been proffered: escalation of dose within the range that can be achieved without marrow reconstitution, high-dose chemotherapy with support of autologous bone marrow transplant or peripheral stem cell transfusion, and, in the case of ovarian carcinoma, intraperitoneal administration of drug. Eight randomized trials of dose escalation over a standard range of doses have been completed. Six show no advantage to a doubling of dose intensity, and the other two have major design problems. Further exploration of this approach seems unwarranted.

Although uncontrolled studies and anecdotal reports of high-dose chemotherapy with marrow reconstitution appear promising, the highly selected nature of the patients and the expense of the procedures mandate that randomized, comparative trials demonstrate the superiority of this approach over standard therapy before it can be considered a valid part of the therapeutic armamentarium.

Intraperitoneal administration of drug, although it has been under study for more than a decade, still has no defined role in management. In the salvage setting, it appears to have no advantage over intravenous therapy. In the setting of first-line treatment, three large randomized trials in patients with small-volume disease show small advantages at the expense of markedly enhanced toxicity. The final determination of the role, if any, for intraperitoneal therapy awaits the development of less toxic regimens. If a role for intraperitoneal therapy exists, data show that it will be in only those patients with extremely small-volume disease or perhaps no residual disease; hence, its role will be a very narrow one.

In conclusion, the future holds the promise of continuing advances in the management of patients with celomic epithelial carcinoma of the ovary. Although the explosion of knowledge of the basic nature of the disease holds the greatest potential for improvement, the identification of an effective screening technique, the clarification of the role of surgery in advanced disease, and the introduction of exciting new biologic and cytotoxic agents offer the promise of better treatment in the immediate future. The great promise of dose-intense regimens, which are still worthy of further investigation, suffers from a growing body of evidence that no advantage is obtained at least over the clinically achievable range of doses unsupported by marrow reconstitution.

94 Gestational Trophoblastic Disease

Donald Peter Goldstein and Ross Stuart Berkowitz

SUMMARY OF KEY POINTS

Incidence and Epidemiology
- The incidence of complete hydatidiform mole is approximately 1 in 1500 pregnancies in the United States.
- The incidence of partial hydatidiform mole is approximately 1 in 750 pregnancies.
- Repeat moles occur in 1 in 100 pregnancies, and third moles occur in 1 in 25 pregnancies.
- Complete hydatidiform mole is usually due to an androgenetic diploid conception, in which a haploid sperm fertilizes an egg that lacks female chromosomes.
- A partial hydatidiform mole develops when dispermy occurs, and the resulting conceptus is triploidy.

Pathology
- Earlier diagnosis of complete hydatidiform mole due to improved ultrasound and human chorionic gonadotropin (hGC) assays has made the pathologic diagnosis of complete hydatidiform mole more difficult because of its resemblance to partial hydatidiform mole and nonmolar abortions.
- Hydatidiform mole is characterized by hydropic villi with trophoblastic hyperplasia.
- Invasive mole is characterized by invasion of myometrium by hydropic villi surrounded by hyperplastic trophoblasts.
- Choriocarcinoma is characterized by sheets of neoplastic cytotrophoblasts and syncytiotrophoblasts invading tissue and is associated with necrosis and hemorrhage. Hematogenous spread occurs early.
- Placental site trophoblastic tumor is a rare form of choriocarcinoma made up of mononuclear cells from the implantation site that invade myometrium. Placental site trophoblastic tumor metastasizes late and is relatively resistant to chemotherapy.

Clinical Features
- Hydatidiform mole presents in the first trimester with vaginal bleeding.
- Complete hydatidiform mole is usually diagnosed by ultrasound because of the abnormal appearance of the placenta and the absence of a fetus.
- Partial hydatidiform mole can be difficult to diagnose by ultrasound and is usually confirmed pathologically.
- Persistent gestational trophoblastic disease after molar pregnancy is usually nonmetastatic and is characterized by a rising hCG level and persistent bleeding due to residual molar tissue.
- Metastatic gestational trophoblastic neoplasms after hydatidiform mole usually involves the lungs and, rarely, the brain, liver, and other sites.
- The diagnosis of gestational trophoblastic neoplasis after a miscarriage or term pregnancy can be delayed and can present with significant disease.

Staging and Classification
- The 2002 International Federation of Gynecologists and Obstetricians Staging System combines an anatomic description of the disease (i.e., stages I, II, III, and IV) with a prognostic scoring system.

Primary Therapy
- Single-agent therapy is usually curative in patients with stage I, II, and III disease who have low prognostic scores (<7).
- Patients with stage II, III, and IV disease who have high risk scores (≥7) require combination chemotherapy for optimal outcome.
- Survival rates of 100% in patients with stage I, II, and III disease and 80% in patients with stage IV disease should be achieved with proper staging and the use of well-accepted therapy.
- Response to therapy and remission are determined by hCG levels, which should be tested weekly during chemotherapy.
- Patients with high-risk disease should be treated with three or four consolidation courses after the hCG titer normalizes.

Complications
- Toxicity from the chemotherapeutic agents is the most common early complication.
- Other complications relate to the extent of disease and are usually due to internal bleeding.

Prognosis
- Most women survive their disease and are able to achieve subsequent pregnancy.
- The vast majority of patients are cured and are able to return to normal activity soon after attaining a normal hCG titer.

INTRODUCTION

Terminology

Gestational trophoblastic disease (GTD) is a heterogeneous group of interrelated lesions that is biologically unique for several reasons:

- It elaborates a tumor marker, human chorionic gonadotropin (hCG).
- It is exquisitely sensitive to chemotherapy.
- It has a unique immunobiologic relationship with its host, since it arises from fetal rather than maternal tissue.

Several histologically distinct entities make up GTD:

- Hydatidiform mole (partial and complete)
- Persistent or invasive gestational trophoblastic neoplasia
- Choriocarcinoma
- Placental site trophoblastic tumors

Complete and partial moles are abnormal pregnancies and are considered benign. The last three entities are called gestational trophoblastic neoplasms (GTNs) and are considered malignant because of their potential for local invasion and metastases. GTN is one of the rare human malignancies that can be cured even in the presence of widespread metastases. The term GTN is used instead of the more specific morphologic entity because treatment is frequently undertaken without knowledge of the precise histology.

When GTN develops after evacuation of an hydatidiform mole, the resulting tumor morphologically is either an invasive mole, a choriocarcinoma, or, on rare occasion, a placental site trophoblastic tumor. The tumor that develops after a term pregnancy or miscarriage histologically is choriocarcinoma or placental site trophoblastic tumor, as there is no molar disease in these gestations. When GTN develops after an ectopic pregnancy, the tumor morphology can be molar, choriocarcinoma, or placental site trophoblastic tumor.

Relevant Historical Issues

GTD has an ancient and interesting history going back to Hippocrates, who in 400 B.C. described the passage of hydropic villi from the uterus as "uterine dropsy." The first recorded description of molar pregnancy appeared in *Uterus Hydropii* by Aetius of Amida (c. 483–565 A.D.), who observed that "when the menses have been suppressed for some time and the patient has not become pregnant, the uterus becomes filled with tumor and small bladder-like objects are developed in the fluid." In 1565, Von Grafenburg first described the clinical condition of what we now call a "classical mole." In 1827, Velpeau and Boivin correctly observed that hydatids represented cystic dilatation of chorionic villi. In 1895, Marchand reasoned that choriocarcinoma is an epithelial tumor from the trophoblast.

An important milestone in the history of GTD occurred in 1928, when Ascheim and Zondek first described a reliable pregnancy test, which became the basis for the early measurements of hCG. In 1963, MacVicor and Donald first used ultrasound in the diagnosis of molar pregnancy. In 1977, Kajii and Ohama[1] elucidated the androgenetic origin of hydatidiform moles. Finally, in 1978, Szulman and Surti[2] described the genetic basis for partial mole as a triploid gestation.

Prior to the introduction of chemotherapy, survival with GTN remained limited and precarious, as the only form of treatment consisted of hysterectomy or local excision of metastatic sites where possible. In 1959, Brewer[3] reviewed survival with choriocarcinoma at the Albert Mathieu Chorioepithelioma Registry at Northwestern University. Only 6 of 103 patients with metastatic choriocarcinoma (CCA) were free of disease at 5 years after their diagnosis. Brewer's group also analyzed the 5-year survival rates in patients with nonmetastatic CCA treated by hysterectomy. Only 29 of 70 patients (41%) with presumably localized tumor survived, despite prompt hysterectomy. The remaining patients developed metastases after the operative procedure and died from widely disseminated disease.

A new era in the management of GTN was inaugurated in 1956, when Li and colleagues[4] reported the complete regression of metastatic CCA in three women who were treated with methotrexate. In 1961, Hertz and coworkers[5] reported the initial 5-year experience with chemotherapy for metastatic GTN from the National Cancer Institute. Complete remission was achieved with methotrexate in 28 of 63 patients (47%) who had metastatic disease. After obtaining dramatic results with chemotherapy in disseminated disease, Hertz and associates[6] successfully employed chemotherapy for nonmetastatic tumors. During the 1960s, it became apparent that certain patients with metastatic GTN were relatively resistant to single-agent chemotherapy and experienced a high mortality rate. In 1965, Ross and colleagues[7] reported that patients with prolonged delay in diagnosis, high hCG levels, and liver and/or brain metastases were resistant to treatment with single-agent therapy. The use of intensive combination chemotherapy for so-called high-risk metastatic disease has resulted in substantial improvement in survival.

During the past three decades, the management of GTN has been guided by the results from various regional centers. Virtually all patients with nonmetastatic and low-risk metastatic GTN can now expect to achieve cure with chemotherapy, with preservation of reproductive function in the vast majority of cases. Patients with widespread disease also can anticipate an 80% survival rate. Treatment of GTN represents one of the most dramatic successes of chemotherapy in the treatment of human malignancy.

INCIDENCE AND EPIDEMIOLOGY

The reported incidence of GTD varies significantly in different regions of the world. For example, the frequency of molar pregnancy in Asian countries historically has been seven to ten times greater than the reported incidence in Europe or North America.[8] Japan has a reported incidence of 2 in 1000 pregnancies, which is twofold to threefold higher than the incidence in Europe or North America. The incidence of hydatidiform mole in Taiwan is reported to be one in 125 pregnancies. In Ireland, the incidence of complete and partial moles has been determined to 1 in 1945 and 1 in 695 pregnancies, respectively.[9] In the United States, hydatidiform moles are encountered in 1 in 600 therapeutic abortions and in 1 in 1000 pregnancies.

Although much of the geographic variation in the incidence of molar disease could be due to differences in reporting rather than to true differences in incidence, the high incidence of molar pregnancy in some populations has been attributed to nutritional and socioeconomic factors. Acosta-Sisson and Espaniola[10] carefully studied cases of molar pregnancy that were managed at the Philippine General Hospital. Hydatidiform mole was detected infrequently among wealthy Filipino patients. Although molar pregnancy was diagnosed in 1 in 200 pregnancies in indigent patients, molar gestation occurred in only 1 in 2000 pregnancies in the affluent population. In Korea, the incidence of molar pregnancy has shown a considerable and continuing decrease over the past four decades, presumably owing in part to changing social conditions, including completion of childbearing at an earlier age and improved nutrition.[11] Marked differences in the incidence of molar pregnancy and GTN also occur among various socioeconomic groups in this country. The risk of molar pregnancy or GTN has been reported to two to three times greater in American Indians than in Caucasians, but the incidence in American Indians is declining.[12,13]

Low levels of carotene (vitamin A precursor) and animal fat intake might explain some of the global differences in the incidence of complete mole. We have observed in a case-controlled study that the risk of complete molar pregnancy is associated with low levels of consumption of these nutrients.[14] Parazzini and colleagues[15] also reported from Italy that low carotene consumption was associated with molar pregnancy. Geographic areas with a high incidence of vitamin A deficiency correspond to regions with a high incidence of molar pregnancy.

The risk of having a complete molar pregnancy also increases with increasing maternal age.[8] Women older than age 40 have a 5- to 10-fold greater risk of having a complete molar gestation. Ova from older women could be more susceptible to faulty fertilization and abnormal embryonic development. There does not appear to be any significant association with gravidity or the age of the male consort. The risk for both complete and partial molar pregnancy is increased in women with histories of prior spontaneous abortion and infertility.[16] Women with a history of one molar pregnancy have an approximately 1% chance of a repeat mole in subsequent pregnancies. The risk after two molar pregnancies increases to 16% to 28%.[17]

Certain epidemiologic features of complete and partial mole differ markedly. Parazzini and coworkers[16] reported that the risk for partial mole was not associated with maternal age. Additionally, the risk for partial mole has been reported to be associated with the use of oral contraceptives and a history of irregular menstruation but not with dietary factors.[18] Therefore, the risk of partial mole appears to be associated with reproductive history rather than dietary factors.

The overall incidence of invasive mole has been estimated at 1 in 15,000 pregnancies. Approximately 15% to 29% of hydatidiform moles will result in invasive mole. Choriocarcinoma is reported to occur in 1 in 40,000 pregnancies. Approximately 3% to 5% of hydatidiform moles progress to CCA, which accounts for almost 50% of cases. Twenty-five percent of CCA cases follow abortion or tubal pregnancy (1 : 15,000), and 25% are associated with term pregnancies (1 : 150,000).

ETIOLOGY AND PATHOGENESIS

Our perspectives on the etiology and pathogenesis of hydatidiform mole and GTN have become focused significantly over the past few years. The etiology of hydatidiform mole appears to be due to abnormal gametogenesis and fertilization. Recent studies have defined two different forms of hydatidiform mole: partial and complete. They are distinct cytogenetic processes with characteristic clinical and histopathologic findings and do not represent a transition from normal to molar gestation.

Partial hydatidiform moles (PHMs) usually have a triploid karyotype (69 chromosomes) derived from two paternal and one maternal haploid sets of chromosomes. Most have a 69,XXX or 69,XXY genotype derived from a haploid ovum with dispermic fertilization. Lawler and coworkers[19] and Lage and associates[20] reported that 93% and 90%, respectively, of partial moles were triploid. More recent data from our institution present convincing evidence that all partial moles are triploid. Genest and colleagues[21] reviewed 19 presumed nontriploid partial moles using standardized histologic diagnostic criteria and repeat flow cytometry; on reevaluation, none of these cases was convincingly a nontriploid partial mole. This finding suggests that nontriploid partial moles might not exist. When a fetus is present in conjunction with a partial mole, it generally exhibits the stigmata of triploidy, including growth retardation and multiple congenital anomalies such as syndactyly, hydrocephaly, omphalocele, and hare lip.

Complete hydatidiform moles (CHMs), in contrast, usually have a chromosomal complement that is totally derived from the paternal genome, while the maternal chromosomes are either inactivated or absent. The 46,XX genotype is most common, representing in most cases reduplication of the haploid genome of one sperm. A smaller portion of complete moles have 46,XY karyotype, consistent with dispermic fertilization. It appears that molar disease, both partial and complete, is associated with excess male genetic composition due to an abnormality of the egg, which is either devoid of maternal chromosomal material or allows for dispermy.

Several growth factors and oncogenes have been studied in molar tissues and CCA.[22] Increased expression of p53 and c-fms has been observed in CHM, and increased ras and c-myc RNAS have been measured in CCA.[23,24] Fulop and associates[25] have investigated the expression of various growth factors and oncogenes in normal placenta, complete and partial mole, and CCA. CHM and CCA were characterized by overexpression of c-myc, c-erbB-2, and bcl-2, and these oncoproteins could be important in the pathogenesis of GTN. Expression of c-fms protein did not differ between normal placenta and GTN. CHM and CCA were also characterized by increased expression of p53, p21, Rb, and MdM2. The p53 gene was studied to detect any mutation in 22 complete moles and 11 CCAs that had increased expression of p53. Because only one nonsense mutation in p53 was detected by polymerase chain reaction analysis, it is likely that the overexpressed p53 protein was the wild type. Although studies have identified increased expression of several growth factors in GTN, the precise molecular pathogenesis has not been determined. It was observed that the level of expression of epidermal growth factor receptor (EGFR) in CCA and the syncytiotrophoblast and cytotrophoblast of complete mole was significantly greater than the expression of EGFR in syncytiotrophoblast and cytotrophoblast of placenta and partial mole.[26] This observation was consistent in both immunohistochemical and in situ hybridization studies. In complete mole, strong expression of EGFR and c-erbB-3 in the extravillous trophoblasts was significantly associated with the development of postmolar tumor. The EGFR-related family of oncogenes might be important in the pathogenesis of GTN.

Extracellular proteinases such as matrix metalloproteinases (MMPs) are thought to be important in modulating both cell-matrix interactions and the degradation of the basement membrane necessary for invasion and metastases. CCA exhibits significantly stronger expression of MMP-1 and MMP-2 and decreased expression of tissue inhibitor of MMP-1 (TIMP-1) than are seen in the syncytiotrophoblast of complete and partial mole and normal placenta.[27] The increased expression of MMP-1 and MMP-2 and decreased expression of TIMP-1 in CCA could contribute to the invasiveness of CCA cells.

Certain genes are expressed normally on either the maternal or paternal allele, and this occurrence is described as parental imprinting. Modification of parental imprinting has been associated with tumor formation; both complete moles and CCA have relaxation of parental imprinting.[28] Relaxation of parental imprinting could be important in the pathogenesis of GTN.

PATHOLOGY

Hydatidiform moles can be categorized as either complete or partial on the basis of gross morphology, histopathology, and karyotype (Table 94-1).

Complete Hydatidiform Mole

CHM is a pregnancy that is characterized by vesicular swelling of placental villi and the absence of an intact fetus. Microscopically, there is proliferation of the trophoblast (both cytotrophoblast and syncytiotrophoblast) with varying degrees of hyperplasia and dysplasia (Fig. 94-1). The chorionic villi are fluid-filled and distended, and blood vessels are absent or scant. Complete mole undergoes early and total hydatidiform enlargement of the villi in the absence of a fetus or embryo, and the trophoblastic cells are hyperplastic.

The pathologic features of complete molar pregnancy have changed significantly over the past two decades owing to earlier diagnosis and uterine evacuation.[29] Whereas cavitation and circumferential trophoblastic proliferation were present in three quarters of complete moles in the past, these findings are now present in fewer than half the cases. Mosher and coworkers[30] compared pathologic findings of 23 current complete moles (1994–1997; mean gestational

Table 94-1 Features of Complete and Partial Hydatidiform Moles

Feature	Complete Mole	Partial Mole
Fetal or embryonic tissue	Absent	Present
Hydropic villi	Diffuse	Focal
Trophoblast hyperplasia	Diffuse	Focal
Scalloping of chorionic villi	Absent	Present
Trophoblastic stromal inclusions	Absent	Present
Karyotype	46,XX; 46,XY	69,XXY; 69,XYY

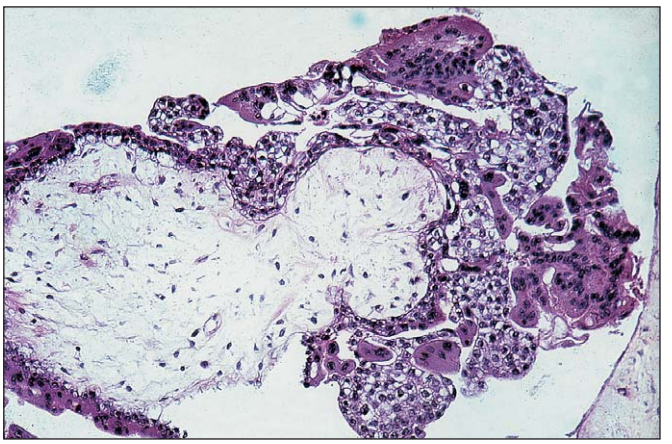

Figure 94-1 • Photomicrograph of complete hydatidiform mole showing diffusely hydropic chorionic villi and diffuse trophoblastic hyperplasia. Embryonic tissue is not present.

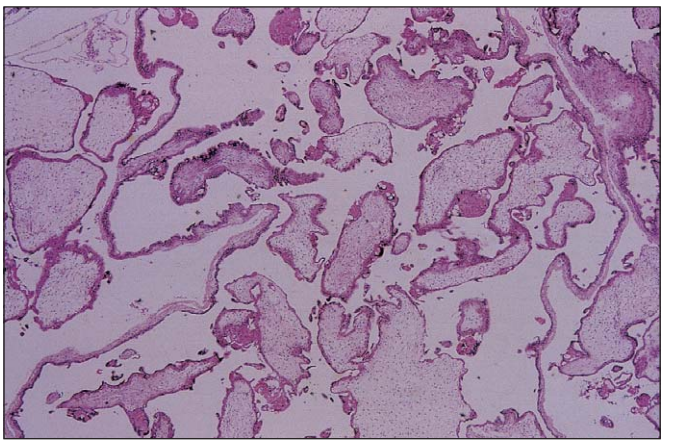

Figure 94-2 • Photomicrograph of partial hydatidiform mole showing varying-sized chorionic villi with focal trophoblastic hyperplasia, stromal trophoblastic inclusions, and villous scalloping. Fetal tissue is present.

age: 8.5 weeks) with 20 past complete moles (1969–1975; mean gestational age: 17 weeks). Histologically, complete moles that are now encountered have smaller mean maximal villous diameter (5.7 mm versus 8.2 mm), less circumferential trophoblastic hyperplasia (39% versus 75%), more primitive villous stroma (70% versus 10%), and less global necrosis (22% versus 54%). Keep and coworkers[31] observed that early complete moles were characterized by focal trophoblastic hyperplasia, minimal villous cavitation, and hypercellular primitive stroma. Complete moles are now often characterized by subtle morphologic alterations that could result in their misclassification as partial moles or nonmolar hydropic abortions. DNA ploidy studies or karyotyping are useful adjuncts in these circumstances.[21] Immunohistochemical tests for maternally expressed genes can also differentiate complete mole from partial mole and hydropic abortion.[32,33]

Partial Hydatidiform Mole

PHM is characterized by the following pathologic features:

- Varying-sized chorionic villi with focal swelling and focal trophoblastic hyperplasia.
- Focal, mild atypia of implantation-site trophoblast
- Marked villous scalloping and prominent stromal trophoblastic inclusions
- Identifiable fetal or embryonic tissues (Fig. 94-2)

Invasive Mole

Invasive mole is a tumor arising from a hydatidiform mole that invades the myometrium by direct extension or by venous channels. It also metastasizes to distant sites in about 15% of cases, most commonly to the lungs and vagina. The tumor is characterized by swollen placental villi and accompanying hyperplastic trophoblast, which is usually dysplastic when located in sites outside the uterine cavity (Fig. 94-3).

Choriocarcinoma

CCA is a highly malignant tumor that is characterized by abnormal trophoblastic hyperplasia and anaplasia, absence of chorionic villi, hemorrhage, and necrosis (Fig. 94-4). It can invade the uterine wall directly or metastasize by vascular channels to the myometrium and distant sites, most commonly to the lungs, vagina, brain, liver, spleen, kidneys, and intestines. The tumor is composed of both cytotrophoblasts and syncytiotrophoblasts.

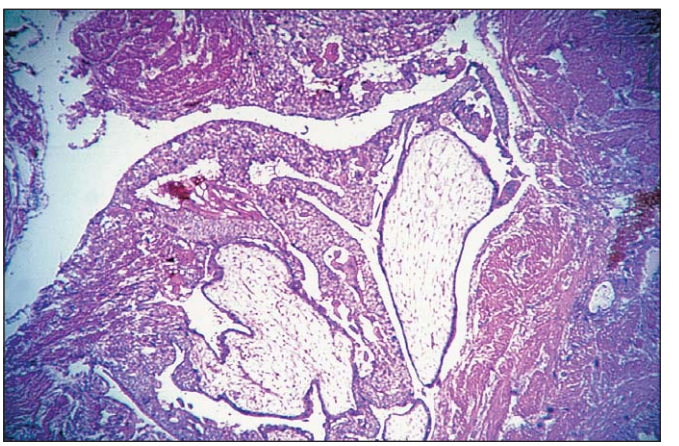

Figure 94-3 • Invasive mole with hydropic villous and hyperplastic trophoblast invading myometrium.

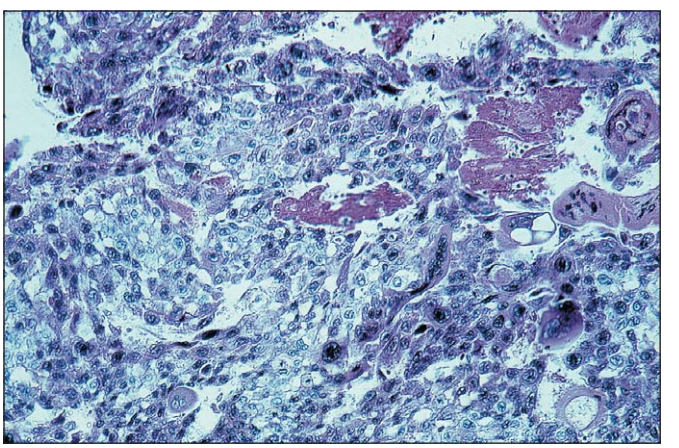

Figure 94-4 • Photomicrograph of choriocarcinoma showing sheets of anaplastic cytotrophoblasts and syncytiotrophoblasts.

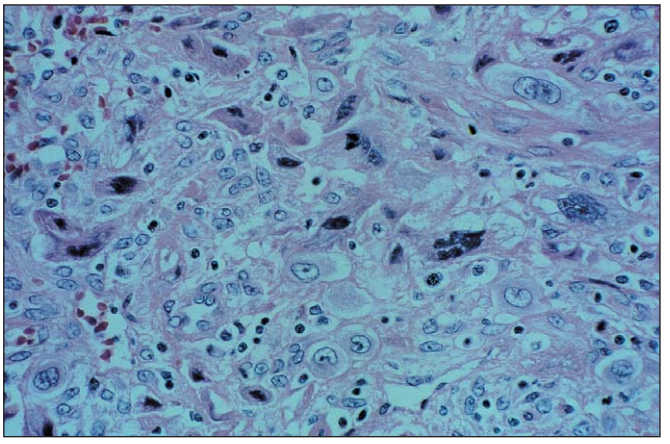

Figure 94-5 • Photomicrograph of placental site trophoblastic tumor composed almost entirely of mononuclear cells of the intermediate trophoblast.

Placental Site Trophoblastic Tumor

Placental site trophoblastic tumor (PSTT) is an extremely rare tumor that arises from the placental implantation site and, in contrast to CCA, is monocellular. Tumor cells infiltrate the myometrium and grow between smooth muscle cells with vascular invasion (Fig. 94-5). PSTT differs from CCA primarily in the absence of an alternating pattern of cytotrophoblast and syncytiotrophoblast, in that the cells are morphologically of one population (intermediate trophoblast) and hemorrhage and necrosis are less evident. There are no placental villi. Human placental lactogen is present in the tumor cells, whereas immunoperoxidase staining for hCG is positive in only scattered cells. Serum hCG levels are relatively low in comparison with those seen in CCA. A relatively high level of free beta subunit of hCG is detectable in patients with PSTT as compared to other forms of GTN.[34] There appears to be a direct correlation between the mitotic activity of the tumor and the prognosis.[35]

IMMUNOBIOLOGY

The remarkable curability of GTN might be attributable partly to a host immunologic response to paternal antigens expressed on trophoblastic cells.[36] The prognosis of patients with gestational CCA has been related to the intensity of lymphocytic and monocytic infiltration at the tumor-host interface.[37] Because the lymphocytes and macrophages that infiltrate gestational CCA are probably exposed to paternal antigens and oncoproteins, the immune cells could become activated. Immunologically active cells might promote the regression of GTN through their release of cytokines. Cytokines have been reported to inhibit the proliferation of CCA cells in vitro and to increase the HLA expression of CCA cells in vitro, thereby increasing immunogenicity.[38]

It has been theorized that the development and progression of GTN could be favored by histocompatibility between the patient and her partner. If the patient and her partner are histocompatible, the trophoblastic tumor that bears paternal antigens might not be immunogenic in the maternal host. The intensity of the host's immunologic response might depend on the immunogenicity of the trophoblastic tumor. On the other hand, histocompatibility between the patient and her partner does not appear to be a prerequisite for the development of persistent GTN.[39] HLA systems could, however, influence the clinical course of rapidly progressive and fatal GTN. Tomoda and colleagues[40] reported that drug-resistant CCA was associated with increased histocompatibility between the patient and her partner. Similarly, Morgenson and coworkers[41] observed that histocompatibility between patients and partners was associated with a greater risk of metastatic disease. Because all chromosomes in a CHM are paternal in origin, a CHM is a complete allograft and could stimulate a vigorous immune response by the maternal host. There is evidence for both a cellular and a humoral response to CHM. When compared with normal placentas, molar implantation sites have fivefold increased infiltration by helper T cells.[40] Circulating immune complexes have also been measured in patients with CHM and have been noted to increase as the patient entered remission.[42,43]

Circulating immune complexes in patients with CHM have been demonstrated to contain paternal HLA antigens.[44] The maternal host with a CHM is therefore sensitized to paternal HLA antigens. The distribution of HLA antigens in molar chorionic villi has been determined by immunofluorescent assays.[45] HLA A, B, and C antigens were detected on the stromal cells of molar chorionic villi but not on the villous trophoblast; however, the molar villous fluid that bathes the stromal cells does not contain soluble HLA antigen.[38] The maternal host could therefore be sensitized to paternal HLA antigen when the villous trophoblastic layer is disrupted and HLA-positive villous stromal cells are released into the circulation.

CLINICAL PRESENTATION

Complete Molar Pregnancy

The clinical presentation of CHM has changed dramatically over the past two decades in the wake of the widespread use of ultrasound and the availability of improved methods for hCG testing. Whereas CHM was usually diagnosed in the second trimester prior to 1980, the diagnosis of CHM is now usually made in the first trimester, before the classic clinical signs and symptoms appear.[29] Table 94-2 summarizes the signs and symptoms of classical CHM and PHM. When patients with CHM present with these classical signs and symptoms, they are at high risk for developing GTN. Soto-Wright and associates compared the clinical presentation and outcome of patients with CHM at the New England Trophoblastic Disease Center (NETDC) between 1988 and 1993 with those of patients between 1965 and 1975. Soto-Wright noted that despite the change in presentation, there was no change in the incidence of GTN disease requiring treatment. Patients now less frequently present with excessive size, anemia, theca lutein cysts, and hyperemesis.

Partial Molar Pregnancy

Patients with partial molar pregnancy typically present with symptoms that are indistinguishable from those of a threatened or

Table 94-2 Presenting Signs and Symptoms of Classical Complete and Partial Hydatidiform Moles

Sign or Symptom	Complete Mole (%) (*N* = 306)	Partial Mole (%) (*N* = 81)
Vaginal bleeding	97	73
Excessive uterine size	51	4
Theca lutein cysts >6 cm	50	0
Preeclampsia	27	3
Hyperemesis	26	0
Hyperthyroidism	7	0
Trophoblastic emboli	2	0

spontaneous miscarriage (rather than with the classical symptoms of CHM) unless diagnosis is delayed until the second trimester. Eighty-one patients with PHM were studied at the NETDC between 1979 and 1984. The diagnosis of PHM is usually suggested by ultrasonography and confirmed by pathologic review of curettage material. The hCG levels in patients with PHM are usually not as elevated as in patients with CHM. When PHM progresses into the second trimester, the ultrasound diagnosis becomes more accurate because of the obvious fetal malformations associated with triploidy and the extent of vesicular change of the placenta. Patients with PHM whose diagnosis is delayed until the second trimester will, in many instances, recapitulate the classical signs and symptoms associated with CHM with regard to the incidence of preeclampsia, hyperthyroidism, trophoblastic embolization, and other complications.[46–48] While patients with complete mole are now diagnosed earlier and their clinical presentation has changed, patients with partial mole have not been diagnosed substantially earlier and their clinical symptoms have not changed.[17]

Gestational Trophoblastic Neoplasia

Gestational trophoblastic neoplasia (GTN) is the term that is used when there is clinical, radiologic, pathologic, and/or hormonal evidence of persistent GTD, which can follow any type of antecedent pregnancy. Rarely, the antecedent pregnancy cannot be determined. GTN that follows a molar pregnancy is diagnosed by a plateau in the level of hCG over more than 3 consecutive weeks, a 10% or greater rise in hCG for three or more values over at least 2 weeks, persistence of hCG 6 months after molar evacuation, or histologic evidence of invasive mole, CCA, or PSTT. GTN comprises two distinct disease entities—nonmetastatic or metastatic—based on whether there is evidence of disease beyond the uterus.

Nonmetastatic Gestational Trophoblastic Neoplasia

Nonmetastatic or locally invasive GTN develops in about 15% of patients after evacuation of a complete mole and infrequently following other pregnancies. Locally invasive GTN occurs after partial mole in 1% to 6% of patients.[17,49] These patients usually present with irregular vaginal bleeding, theca lutein cystic changes in the ovaries (depending on the level of hCG), uterine subinvolution or asymmetrical enlargement, and elevated hCG levels. The invasive tumor can erode through the uterine vessels, causing vaginal bleeding, or can perforate through the myometrium, leading to intraperitoneal hemorrhage. The presence of bulky necrotic tumor, characteristic of CCA, can serve as a nidus for sepsis, particularly *Clostridium welchii*. The presence of deep myometrial invasion can be confirmed by curettage, laparoscopy, or imaging studies, including ultrasound, magnetic resonance imaging (MRI), or angiography.

Metastatic Gestational Trophoblastic Neoplasia

Metastatic GTN occurs in approximately 5% of patients after molar evacuation and infrequently after other gestations. Although invasive mole can metastasize to distant sites, most metastatic GTN is generally associated with CCA, which has the propensity for early vascular invasion and widespread dissemination. Because trophoblastic tumors are highly vascular, metastatic lesions often present with signs and symptoms of spontaneous bleeding. The most common metastatic sites are the lung (80%), vagina (30%), brain (10%), and liver (10%). As a general rule, cerebral and hepatic metastases are uncommon unless there is concurrent involvement of the lungs and/or vagina.

PULMONARY METASTASIS. The pulmonary parenchyma is the most common site of metastasis. Eighty percent of patients with metastatic disease have lung involvement. Patients with pulmonary involvement can present with cough, chest pain, hemoptysis, and/or dyspnea or an asymptomatic lesion on chest x-ray. Respiratory symptoms can have an acute onset or be chronic. Pulmonary involvement produces four principle radiologic patterns:

1. Discrete rounded densities
2. "Snowstorm" or alveolar pattern
3. Embolic pattern resulting from pulmonary artery occlusion
4. Pleural effusion

Patients can develop pulmonary hypertension in the absence of substantial parenchymal involvement. Because the respiratory symptoms and radiographic findings can be striking, the patients might be thought to have a primary pulmonary disease. Unfortunately, the diagnosis of GTN might be made only after thoracotomy is performed. Therefore, it is important to obtain an hCG level in all women of reproductive age who have unexplained respiratory symptoms or a lesion on chest x-ray. Gynecologic symptoms could be minimal or absent in patients with extensive pulmonary involvement. In fact, the reproductive organs could be free of trophoblastic tumor in patients with widespread metastases. Early respiratory failure requiring mechanical ventilation can develop in patients with extensive pulmonary involvement and can cause death before effective chemotherapy can be started.[50–52] Risk factors for early respiratory failure within 1 month of presentation include greater than 50% lung opacification, dyspnea, anemia, cyanosis, and pulmonary hypertension. With chemotherapy, patients could develop bleeding into metastatic sites and potentially worsen pulmonary symptoms and radiologic findings. Kelly and associates[50] observed that reducing the initial dose of chemotherapy did not protect against early respiratory failure and recommended administering intensive chemotherapy at the outset.

VAGINAL METASTASES. Thirty percent of patients with metastatic disease have vaginal involvement. Vaginal metastases occur most commonly suburethrally or in the fornices and cause purulent discharge or irregular bleeding (Fig. 94-6). Vaginal lesions are highly vascular and can bleed vigorously if biopsied. Surgical excision of a vaginal metastasis should be avoided except in unusual circumstances, owing to the risk of hemorrhage that could be difficult to control. We have observed that after instituting chemotherapy when some tumor shrinkage has occurred, the vaginal lesion can be excised with less risk.

HEPATIC METASTASES. Choriocarcinoma involves the liver in 10% of patients who develop disseminated disease. Hepatic metastases are encountered almost exclusively in patients who have extensive tumor burdens and prolonged delays in diagnosis. Hepatic lesions can cause liver rupture with exsanguinating intraperitoneal hemor-

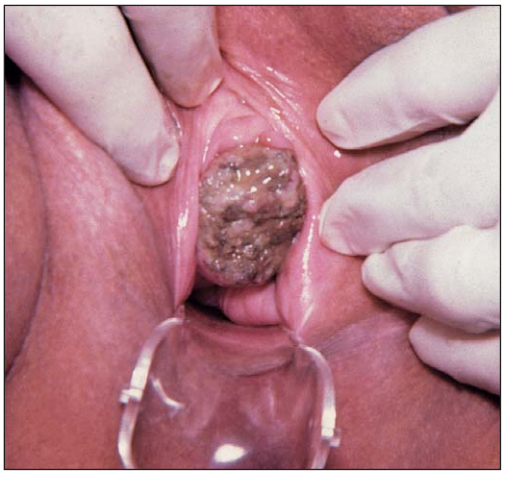

Figure 94-6 • Vaginal metastasis of choriocarcinoma.

rhage; however, patients with liver metastases usually do not present with symptoms that are related to hepatic involvement.[53]

BRAIN METASTASES. Cerebral lesions also occur in approximately 10% of patients with metastatic GTN. Cerebral involvement is usually seen in patients with advanced disease and histologically is almost always related to CCA. The main presenting symptoms of brain metastases are headache, vomiting, seizures, and focal neurologic signs such as slurred speech, hemiparesis, or visual disturbances. Neurologic symptoms usually result from increased intracranial pressure or intracerebral bleeding.[54–56]

Cerebral lesions are associated with elevated levels of hCG in the cerebrospinal fluid (CSF). Bagshawe and Harland[57] reported that the plasma-to-CSF hCG ratio was less than 60 in patients with cerebral involvement. However, a single plasma-to-CSF hCG ratio can be misleading because rapid changes in the hCG levels in the serum might not be reflected promptly in the CSF.[58] With earlier diagnosis of GTN and the advent of improved imaging techniques (particularly MRI), occult brain metastases are now frequently being detected before patients present with neurologic symptoms.

OTHER METASTATIC SITES. Gastrointestinal, renal, and splenic metastases are seen only in patients with advanced disease, most commonly in patients with post-term CCA, where there has been a delay in diagnosis. Abdominal computed tomography (CT) scanning is useful for the early detection of metastases to these sites. Testing for hematochezia should also be part of the workup in any patient who presents with metastatic GTN.

PLACENTAL SITE TROPHOBLASTIC TUMORS. PSTTs are rare tumors that are derived from intermediate cytotrophoblast cells. They can arise from any antecedent pregnancy but most commonly arise from a term pregnancy or miscarriage. They generally present months to years after the antecedent pregnancy with irregular vaginal bleeding or amenorrhea, enlarged uterus, and, rarely, nephrotic syndrome. The serum hCG level is relatively low in relation to tumor volume in comparison to other types of GTNs. Over 30% of patients already have metastases at diagnosis.[59]

LABORATORY AND IMAGING STUDIES

The optimal management of GTN requires a thorough evaluation of the extent of the disease prior to treatment. All patients with persistent disease should undergo a thorough pretreatment evaluation, including a complete history and physical examination; baseline levels of peripheral blood and platelet counts; hCG titer; hepatic, thyroid, and renal function tests; and stool guiac tests. A pelvic sonogram is helpful in detecting adnexal involvement, the presence of residual tissue in the uterine cavity, or the presence of deep myometrial invasion. A baseline chest x-ray should be performed in all patients at the time of molar evacuation to identify pre-existing pulmonary disease that might be misinterpreted if the patient were to develop postmolar GTN. Patients with persistent GTN should undergo CT scans of the chest and abdomen and MRI scanning of the brain as part of the staging workup.

Human Chorionic Gonadotropin Measurement

A reliable assay for total hCG is central to the management of patients with trophoblastic disease. The assay must measure all portions of the hCG molecule, particularly free beta subunit, nicked hCG, and hyperglycosylated hCG.[60] Several commercial assays do not measure free beta subunit or nicked hCG and do not differentially recognize hyperglycosylated hCG. Practically speaking, however, the available clinical assays for β-hCG are adequate in the vast majority of patients for diagnosis, monitoring therapy, and follow-up to ensure that the patient remains in complete gonadotropin remission. Physicians treating patients with GTN, however, must recognize the limitations of the assay they are using and base clinical decisions on the clinical, morphologic, and radiologic findings as well as on hormonal results.

Patients with CHM commonly have markedly elevated pre-evacuation hCG levels. Genest and coworkers[61] noted that 46% of 153 patients with CHM who were managed at the NETDC between 1980 and 1990 had pre-evacuation hCG levels above 100,000 mIU/mL. Patients with PHM less commonly present with markedly elevated hCG values. Czernobilsky and associates reported that only 1 of 17 patients with PHM presented with urinary hCG levels above 300,000 mIU/mL. Review of our own data at the NETDC noted that only 2 of 30 patients with PHM presented with levels greater than 100,000 mIU/mL.[48] Complete and partial moles also differ in their levels of free beta and alpha subunits of hCG. Whereas complete moles have higher percentages of free β-hCG, partial moles have higher levels of free α-hCG.[62]

False-Positive Human Chorionic Gonadotropin Tests

False-positive hCG test results can occur because of a substance in the blood that interferes with the hCG assay. Although this is a rare occurrence (estimated at 1 in 10,000 to 1 in 100,000 tests), false-positive tests can be confusing to clinicians when they are attempting to diagnose disorders of pregnancy, including GTN. The misinterpretation of a false-positive test has led to inappropriate treatment with extirpative surgery and chemotherapy based only on persistently elevated serum β-hCG levels. False-positive hCG tests should be suspected if the clinical picture and the laboratory results are discordant, if there is no identifiable antecedent pregnancy, or if patients under treatment with low levels of hCG do not respond to treatment appropriately. Heterophile antibodies are thought to be responsible for this problem by interfering in the immunoassay systems utilized. These patients are also at risk of other false-positive test results. To avoid the pitfalls of a false-positive hCG test, it is important for the clinician to remember that the patient's clinical presentation should correlate with the laboratory results. If there is a discrepancy, then a repeat hCG assay using a different immunoassay and a sensitive urine hCG test should be performed.[63]

Quiescent Gestational Trophoblastic Neoplasia

Quiescent GTN is another rare entity that is associated with persistent low levels of hCG, which can lead to inappropriate treatment. This entity is thought to be due to the presence of highly differentiated, noninvasive syncytiotrophoblastic cells. Characteristically, foci of disease are not otherwise demonstrable clinically, nor do hCG levels fall with therapy, presumably because the growth cycle of these cells is long and comparable to that of normal cells. Close observation of these patients is indicated because 6% to 10% will eventually develop overt GTN requiring therapy. The hCG of patients with quiescent GTN is not hyperglycosylated, which is useful in correctly identifying these patients.[64,65]

Ultrasonography

Sonographic examination of the first-trimester uterus, particularly when combined with transvaginal color Doppler flow, has made possible the detection of abnormalities of early pregnancy. The diagnosis of molar pregnancy is nearly always made by sonography except in very early pregnancy. The indications for ultrasound in pregnant patients when molar disease or GTN is suspected include the following:

- First-trimester bleeding
- The appearance of signs and symptoms of molar pregnancy
- Unusually high hCG levels

The ultrasonographic appearance of CHM does not vary considerably between the first and second trimesters. At either stage,

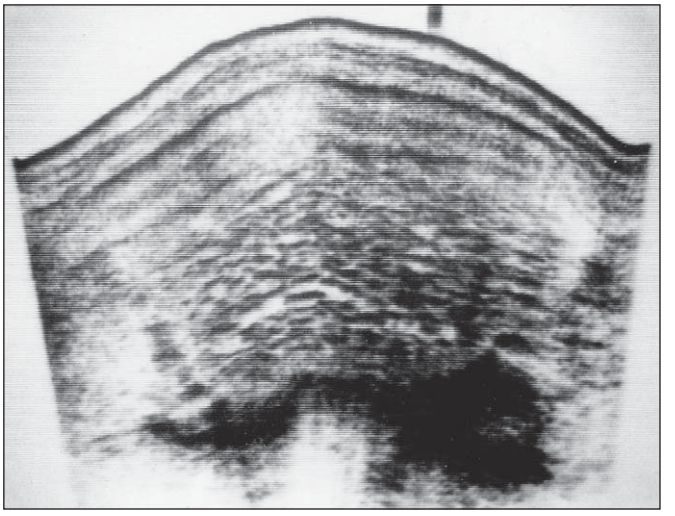

Figure 94-7 • Ultrasound of complete hydatidiform mole characterized by absence of fetus and amniotic sac and the presence of a "Swiss cheese" pattern representing hydropic villi surrounded by blood and hyperplastic trophoblast.

complex, echogenic masses with multiple small cystic spaces are visible within the uterus, and no fetus is identifiable (Fig. 94-7).

Two sonographic features have been described that are significantly associated with PHM: focal cystic changes in the placenta and a ratio of the transverse-to-anteroposterior dimension of the gestational sac greater than 1.5.[66] Changes in the shape of the gestational sac could be part of the embryopathy of triploidy. On rare occasions, particularly when PHM has progressed into the late first or early second trimester, the sonogram will show the presence of a fetus with multiple congenital abnormalities associated with a focally hydropic placenta, oligohydramnios, and abnormal placental Doppler flow pattern. These changes might not be visible in the first trimester.

Ultrasound is also useful after molar evacuation when there is abnormal bleeding or a rising hCG level to determine whether there is sufficient residual tissue in the uterine cavity to justify another evacuation or whether there is evidence of invasive disease or adnexal involvement. Ultrasonography can help the clinician to select patients who will benefit from hysterectomy because it can detect accurately the presence of extensive uterine trophoblastic tumor. Ultrasonography is also useful in monitoring the progress of theca lutein cyst regression and aids in decompression when the cysts cause symptoms such as pain and difficult respiration.

Computed Tomography and Magnetic Resonance Imaging

When a patient develops persistent GTN, the current standard of care is to obtain a CT scan of the chest rather than a plain radiographic film to look for metastatic lesions, particularly for patients who are thought to have nonmetastatic disease and who are likely candidates for primary surgical treatment. The findings of occult metastatic disease on chest CT scan would mandate that chemotherapy be included in the treatment protocol. Because it is unusual for metastatic sites other than the vagina or pelvis to be involved in the absence of pulmonary metastases, a full metastatic workup is usually not indicated unless lung involvement is observed. When a chest CT is positive, metastatic workup should consist of an abdominal CT scan to detect liver, renal, splenic, and gastrointestinal involvement and an MRI scan of the head. These new radiologic techniques for brain imaging have greatly enhanced our ability to diagnose asymptomatic cerebral lesions, which allows for earlier intervention before irreversible neurologic changes occur. However, an initial positive chest CT in the nonmetastatic patient does not affect clinical management, since most of these patients are low risk and do well with single-agent protocols.[67]

Positron Emission Tomography

Positron emission tomography (PET) with [^{18}F]fluorodeoxyglucose (FDG-PET) scanning can aid in identifying residual disease sites in women who relapse from previously treated GTN. Dhillon and colleagues have reported that PET scanning appropriately identified the presence of pulmonary lesions that were successfully resected, when they were equivocal on CT scanning. It is important to realize that a false-positive PET scan can occur in nonmalignant conditions such as sarcoid. Therefore, careful evaluation in combination with other imaging modalities is required to reduce the risk of false-positive results.[68,69]

STAGING AND PROGNOSTIC SCORING SYSTEM

The staging/prognostic scoring system was developed to provide a basis for comparison of treatment outcomes among multiple treatment centers and as a guide for clinicians to estimate prognosis and select optimal therapy.

National Institutes of Health Clinical Classification

The National Institutes of Health Clinical Classification (Table 94-3) separates patients with nonmetastatic disease from those with metastases because virtually all patients with nonmetastatic disease can be cured with single-agent chemotherapy or hysterectomy.[70] Patients with metastatic disease are further subdivided into low-risk and high-risk disease categories based on five risk factors. "Risk" in this context refers to the likelihood that the patient will develop drug resistance and ultimately die of her disease. Patients are classified as being at high risk on the basis of the presence of one or more of the following:

- Pretreatment serum hCG level in excess of 40,000 mIU/mL
- Duration of disease longer than 4 months from the antecedent pregnancy event or from onset of symptoms to treatment if the antecedent pregnancy is not known
- Metastases to sites other than the lungs or vagina
- Antecedent term pregnancy
- Prior unsuccessful chemotherapy

International Federation of Gynecologists and Obstetricians Staging

An anatomic staging system for GTN, adopted by the Cancer Committee of the International Federation of Gynecologists and Obstetricians (FIGO) in 1982 and modified in 1992, was based on material presented by Dr. H. C. Sung at a meeting of the International Society for the Study of Trophoblastic Disease in Beijing in 1979. The FIGO system delineates stages as follows:

- Stage I includes all patients with persistently elevated hCG levels and tumor confined to the uterus.
- Stage II includes all patients with disease outside the uterus but localized to the vagina and/or pelvic structures.
- Stage III encompasses all patients with pulmonary metastases with or without uterine, vaginal, or pelvic lesions. Precise histologic diagnosis is not easily obtained in this group of patients without biopsy or available tissue from another source. Nonetheless, we do not advocate performing thoracotomy or other invasive procedures merely to obtain information about the histologic pattern of the metastatic site, as treatment is based on staging rather than pathology.

Table 94-3 National Institutes of Health Clinical Classification of Gestational Trophoblastic Neoplasm

NONMETASTATIC
METASTATIC
Good prognosis
Duration of disease <4 months from antecedent pregnancy or onset of symptoms
Pretreatment serum hCG level <40,000 mIU/mL
No prior chemotherapy
No evidence of brain and/or liver metastases
Antecedent pregnancy not term
Poor prognosis
Duration of disease >4 months from antecedent pregnancy or onset of symptoms
Pretreatment serum hCG level >40,000 mIU/mL
Prior chemotherapeutic failure
Evidence of brain and/or liver metastases
Antecedent pregnancy term

- Stage IV comprises patients with far advanced disease with involvement of one or more of the following organs: brain, liver, kidney, spleen, and gastrointestinal tract. Patients with stage IV disease are more likely to become drug resistant and are therefore in the highest risk category. Patients with stage IV disease invariably have histologic evidence of CCA, which is more likely to follow a nonmolar pregnancy.

World Health Organization Prognostic Score

In addition to anatomic staging, other variables are needed to predict the likelihood that a patient will develop drug resistance and to serve as a guide to the selection of an appropriate chemotherapy regimen. In 1983, the World Health Organization (WHO) adopted a modification of the Bagshawe prognostic scoring system, which was based on a number of clinical, radiologic, hormonal, and demographic factors, each of which was considered an independent variable and assumed to be additive.[71] Patients with prognostic scores of 7 or lower are considered to be at low risk of developing drug resistance and are ideal candidates for single-agent chemotherapy. When the prognostic score is greater than 7, the patient is considered to be at high risk for developing drug resistance and requires combination therapy to obtain optimal treatment outcomes. In general, patients with stage I tumors have low risk scores, and patients with stage IV tumors have high risk scores. Therefore, the prognostic scoring system is most useful when it applies to stages II and III in that it helps to identify patients who require more intensive therapy for best results.

The variables that are included in the prognostic score include tumor volume (hCG measurement, size, and number of metastases), site of involvement, prior chemotherapy exposure, and duration of disease.

CCA after term pregnancy has been noted to be a poor prognostic factor and to have distinctive clinical features. We reviewed the experience with post-term CCA at the NETDC from 1964 to 1996.[72] Seven of 44 patients (16%) presented with clinical evidence of maternal-fetal bleeding that resulted in severe fetal anemia and nonimmune hydrops or third trimester bleeding. Although none of the infants had evidence of metastatic CCA, rare cases of fetal involvement by CCA have been reported and are usually associated with either fetal or neonatal death. The time interval from delivery to diagnosis, sites of metastases, and pretreatment hCG level were all significant risk factors in predicting outcome. All 31 of our patients with a WHO score less than or equal to 8 survived, whereas 6 of 13 patients (46%) with a WHO score greater than 8 succumbed to their disease.

During the past 5 years, the International Society for the Study of Trophoblastic Disease, the International Gynecologic Cancer Society, and FIGO have moved to modify the staging systems for trophoblastic disease by combining the basic FIGO stages with the WHO Prognostic Score (Table 94-4). Therefore, a patient's stage and total risk score are described by Roman and Arabic numerals, respectively, separated by a colon (e.g., III:8).

TREATMENT

Molar Pregnancy

The primary management of molar pregnancy is surgical evacuation. Before proceeding with surgery, however, the patient should be thoroughly evaluated to identify the presence of medical complications, such as preeclampsia, electrolyte imbalance due to hyperemesis, hyperthyroidism, and anemia, which might complicate the surgical procedure. After evacuation, the clinician must be committed to conscientious hCG follow-up screening for persistent GTN and to counseling regarding the management of future pregnancies.

Surgical Management

Once the patient's medical condition has stabilized, a decision must be made regarding the most appropriate surgical treatment. If the patient no longer desires to preserve fertility, hysterectomy should be considered. At the time of hysterectomy, prominent theca lutein cysts can be decompressed. The advantage of removing the uterus is that it eliminates the possibility that the patient will develop nonmetastatic disease. Although hysterectomy eliminates the risk of local invasion, however, it does not obviate the need for chemotherapy if metastases pre-exist or subsequently appear.

Suction curettage is the preferred method of evacuation, regardless of uterine size, in patients who desire to preserve fertility. At the time of evacuation, if the uterus is larger than 12 weeks' size, it is advisable to administer oxytocin at the onset of cervical dilatation to facilitate uterine involution. In larger uteri, as the cervix is being dilated, the surgeon might encounter brisk bleeding due to the release of retained blood. Shortly after commencement of suction evacuation, uterine bleeding is generally well controlled, and the uterus involutes rapidly. If the uterus is larger than 14 weeks' size, it is helpful for the surgeon to massage the uterine fundus to stimulate uterine contraction. When suction evacuation is thought to be complete, a gentle sharp curettage should be performed to remove any residual chorionic tissue. It is important to avoid too vigorous curettement because of the risk of inducing uterine synechiae (Asherman's syndrome). Patients who are Rh negative should receive Rh immune globulin at the time of evacuation because Rh D factor is expressed on trophoblast.

Some authors have proposed using cervical ripening agents to facilitate cervical dilatation and prevent trauma. In general, we have not found this to be necessary. The size of the curette to be used is determined by the uterine size. Generally, a 10-mm or 12-mm suction curette suffices, and greater dilatation of the cervix is not necessary. Patients with large-for-dates uteri and high hCG levels should be observed for signs and symptoms of acute respiratory insufficiency postoperatively, which could indicate that massive trophoblastic embolization has occurred, as well as for thyroid storm.

Role of Prophylactic Chemotherapy

Patients with complete mole with high pre-evacuation hCG levels (>100,000 mIU/mL) and signs of marked trophoblastic growth (excessive uterine size) are at increased risk (40%) of developing persistent GTN (Table 94-5).[73] In these patients, the use of

Table 94-4 Combined FIGO Staging and WHO Prognostic Scoring System for Gestational Trophoblastic Neoplasm

FIGO STAGES

FORMAT FOR DETERMINING FIGO STAGE AND WHO PROGNOSTIC SCORE

To stage and allot a risk factor score, a patient's diagnosis is allocated to a stage as represented by a Roman numeral I, II, III, or IV. This is then separated by a colon for the sum of all the actual risk factor scores expressed in Arabic numerals (e.g., stage II:4, stage IV:9).

chemotherapy prophylactically at the time of evacuation has been shown to reduce the incidence of persistent GTN.[74,75] The administration of methotrexate or actinomycin D reduced the incidence of postmolar tumor from 47% to 14% and from 50% to 14%, respectively. None of the patients in either series developed metastatic disease. Prophylaxis should also be considered in situations in which hCG follow-up is either unavailable or unreliable.

Persistent Gestational Trophoblastic Neoplasia

Persistent GTN can occur after any antecedent pregnancy. The clinical presentation is more important in determining prognosis than is the precise histologic diagnosis, which might not be available. Infrequently, the diagnosis is made solely on the basis of a rising or plateaued hCG level in the absence of a documented pregnancy or of any clinical, radiologic, or pathologic evidence of trophoblastic tissue.

Table 94-5 Sequelae of Low- and High-Risk Complete Hydatidiform Mole*

	Number of Patients (%)	
Outcome	**Low-Risk**	**High-Risk**
Normal involution	486/506 (96)	212/352 (60)
Persistent GTN		
Nonmetastatic	17/506 (3.4)	109/352 (31)
Metastatic	3/506 (0.6)	31/352 (8.8)
Totals	506/858 (59)	352/858 (41)

*All patients were managed by evacuation without prophylactic chemotherapy.

When this occurs, it is important to make certain that the hCG that is being measured by the assay is true rather than a false-positive test (the so-called phantom hCG).[76] Postmolar GTN is diagnosed on the basis of a rising (increase of 10%) or plateauing (<10% for at least 3 weeks) level. Abnormal vaginal bleeding, subinvolution of the uterus, and cystic ovaries can be present. Women with GTN after nonmolar pregnancies can present with subtle signs and symptoms, making diagnosis difficult. Abnormal bleeding after any pregnancy should be evaluated promptly with an hCG test. Because metastases from CCA have been reported in virtually every anatomic site, a diagnosis of persistent GTN should be considered in any woman of reproductive age who presents with metastatic disease from an unknown primary site.

Chemotherapy

SINGLE-AGENT CHEMOTHERAPY. Single-agent chemotherapy with either methotrexate or actinomycin D has induced comparable and excellent remission rates in both nonmetastatic and metastatic GTN.[77] An optimal regimen should maximize the cure rate while minimizing toxicity. Table 94-6 summarizes the various protocols that are in use for the primary treatment of both nonmetastatic and low-risk metastatic GTN. Several regimens of methotrexate and actinomycin D have induced complete remission in 70% to 100% of patients with nonmetastatic GTN and in 50% to 70% of patients with low-risk metastatic GTN. Fortunately, if a patient develops resistance to the single agent that is utilized initially, she usually can achieve remission with the alternative drug.

Methotrexate with Folinic Acid Rescue. Bagshawe and Wilde[78] in 1964 described administering methotrexate with folinic acid to reduce chemotherapeutic toxicity. Methotrexate plus folinic acid has remained the primary treatment of nonmetastatic and low-

Table 94-6 Single-Agent Regimens for Low-Risk Gestational Trophoblastic Neoplasm

Methotrexate Regimens	Remissions (%)
METHOTREXATE	
Methotrexate 0.5 mg/kg IV or IM daily for 5 days	93.0
Pulse methotrexate	81.0
Methotrexate 50 mg/m^2 IM weekly	
METHOTREXATE/FOLINIC ACID	90.2
Methotrexate 1 mg/kg IM or IV on days 1, 3, 5, 7	
Folinic acid 0.1 mg/kg PO on days 2, 4, 6, 8	
HIGH-DOSE METHOTREXATE/ FOLINIC ACID	61
Methotrexate 100 mg/m^2 IV bolus	
Methotrexate 200 mg/m^2 12-hour infusion	
Folinic acid 15 mg every 12 hours × 4 doses IM or PO beginning 24 hours after starting methotrexate	
Actinomycin D Regimens	
5-day actinomycin D	94.0
Actinomycin D 12 µg/kg IV push daily for 5 days	
Pulse actinomycin D	94.0
Actinomycin D 1.25 mg/m^2 IV push every 2 weeks	

risk metastatic GTN at the Charing Cross Hospital. Although methotrexate plus folinic acid is highly effective, a 20% rate of resistance and 6% incidence of toxicity were observed. Methotrexate plus folinic acid has also been the preferred single-agent regimen at the NETDC for the treatment of GTN since 1974.[79] Complete gonadotropin remission was achieved in 147 of 163 patients (90%) with stage I GTN and in 15 of 22 patients (68%) with low-risk stage II and III GTN. Among the 23 patients who were resistant to methotrexate/folinic acid, 14 (61%) subsequently achieved remission with actinomycin D, and 9 required combination chemotherapy. Thrombocytopenia, granulocytopenia, and hepatotoxicity occurred in only 11 (6%), 3 (2%), and 26 (14%) patients, respectively. One patient required platelet transfusion and developed sepsis due to myelosuppression. No patient developed alopecia. The effectiveness of this methotrexate/folinic acid protocol could be due partly to the prolonged exposure to methotrexate. When methotrexate is administered at a higher dose (300 mg/m^2 over 12 hours and 30 minutes), the remission rate declines to 69% in patients with nonmetastatic GTN.[80]

5-Fluorouracil. Although methotrexate and actinomycin D are the two most commonly used single agents in GTN in the United States and Europe, 5-fluorouracil has been the preferred single-agent chemotherapy in China. Sung and associates[81] reported that 5-fluorouracil induced complete remission in 93% of patients with stage I GTN and in 86% of patients with stage II disease.

Dactinomycin. Single-agent dactinomycin is as effective as methotrexate when used for initial therapy in patients with low-risk GTN. Two protocols have been extensively used: the 5-day and biweekly pulsed regimens. Over time, the 5-day regimen has evolved to the pulsed regimen, which is associated with less toxicity and greater ease of administration. The main side effects, regardless of the regimen that is used, are nausea and vomiting, skin rash, mucositis, and alopecia. The 5-day regimen administered at a dose of 10 to 12 µg/kg/day is associated with a 94% response rate in nonmetastatic disease. A similar complete remission rate has been achieved with a biweekly dose of 1.25 mg/m^2. When actinomycin is used for the treatment of methotrexate-resistant nonmetastatic GTN, the 5-day regimen should be used because the biweekly pulse regimen is associated with significantly lower remission rates.

Etoposide. Etoposide administered orally has also been shown to be highly effective in the treatment of nonmetastatic and metastatic GTN by the Hong Kong group, who reported complete sustained remission in 56 of 60 patients (93%).[82] Etoposide can also be used as salvage therapy when resistance to methotrexate is encountered in place of actinomycin.

COMBINATION THERAPY. The use of combination therapy is indicated as primary therapy in patients with high risk scores or as salvage therapy in women who experience single-agent treatment failures.

MAC. Triple chemotherapy with methotrexate/folinic acid, actinomycin D, and cyclophosphamide (MAC) had been the preferred combination drug regimen at the NETDC in patients with high-risk GTN (Table 94-7). This regimen, however, has been shown to be associated with a low success rate in patients with high risk scores and therefore is used almost exclusively as salvage therapy in patients with low-risk disease who are resistant to single-agent therapy.

EMACO. Bagshawe[83] reported an 83% remission rate in patients with metastatic GTN and high risk scores using a regimen that included etoposide, methotrexate/folinic acid, actinomycin D, cyclophosphamide, and vincristine (EMACO). Similarly, Lurain and colleagues reported that 67% of patients with high-risk metastatic GTN achieved remission with EMACO.[84] This has become the preferred treatment for patients with metastatic GTN, particularly those who have high risk scores (Table 94-8). If patients prove resistant to EMACO, remission can still be achieved by treating with a modification of this

Table 94-7 Protocol for MAC Regimen

Day	Drug	Dose
1	Methotrexate	1.0 mg/kg IM or IV
	Actinomycin D	12 µg/kg IV push
	Cyclophosphamide	3 mg/kg IV bolus
2	Folinic acid	0.1 mg/kg IM or PO

	Cyclophosphamide	3 mg/kg IV bolus
6	Folinic acid	0.1 mg/kg IM or PO
7	Methotrexate	1.0 mg/kg IM or IV
8	Folinic acid	0.1 mg/kg IM or IV

Table 94-8 Protocol for EMACO Regimen

Day	Drug	Dose
1	Etoposide	100 mg/m^2 by infusion in 200 mL saline over 30 minutes
	Actinomycin D	0.5 mg IV push
	Methotrexate	100 mg/m^2 IV push
		200 mg/m^2 by infusion over 12 hours
2	Etoposide	100 mg/m^2 by infusion in 200 mL saline over 30 minutes
	Actinomycin D	0.5 mg IV push
	Folinic acid	15 mg every12 hours ∞ 4 doses IM or PO beginning 24 hours after starting methotrexate
8	Cyclophosphamide	600 mg/m^2 by infusion in saline over 30 minutes
	Oncovin (vincristine)	1.0 mg/m^2 IV push

regimen by substituting etoposide and cisplatin on day 8 (EMACE; Table 94-9). Bower and colleagues[85] reported that EMACE induced remission either alone or in conjunction with surgery in 16 of 21 patients (76%) who were resistant to EMACO. Unfortunately, the use of etoposide in GTN has been reported to increase the risk of later secondary tumors, including myeloid leukemia, melanoma, colon cancer, and breast cancer.[86] The increased risk for breast cancer did not become apparent until after 25 years. Among all patients who were treated with etoposide, 1.5% subsequently developed leukemia. Therefore, toposide should be used only in patients who require it to achieve remission, most commonly patients with metastatic disease and high risk scores. When patients with nonmetastatic and low-risk metastatic disease prove resistant to single-agent therapy, we now administer triple therapy (MAC) at our center before using regimens that contain etoposide.[87]

VBP. Second-line therapy with cisplatin, vinblastine, and bleomycin (VBP) could also be effective in patients with drug-resistant GTN. This regimen has been shown to induce complete remission in 18%, 57%, and 63% of patients with drug-resistant GTN.[87]

5-Fluorouracil and Floxuridine. Matsui and colleagues employed 5-fluorouracil and actinomycin D in 11 patients with drug-resistant high-risk GTN, and 9 patients (81.8%) achieved remission.[88] Two of these patients later relapsed but attained remission with other combination chemotherapy. Similarly, Wan and colleagues administered an FUDR-containing regimen to13 patients with drug-resistant GTN, and all achieved complete remission.[89]

Table 94-9 Protocol for EMACE Regimen

Day	Drug	Dose
1	Etoposide	100 mg/m^2 by infusion in 200 mL saline over 30 minutes
	Actinomycin D	0.5 mg IV push
	Methotrexate	100 mg/m^2 IV push
		1000 mg/m^2 by infusion over 12 hours
2	Etoposide	100 mg/m^2 by infusion in 200 mL saline over 30 minutes
	Antinomycin D	0.5 mg IV push
8	Cisplatin	60 mg/m^2 with prehydration
	Etoposide	100 mg/m^2 by infusion in 200 mL saline over 30 minutes

OTHER MODALITIES. The role of autologous bone marrow transplantation or stem cell rescue in GTN has yet to be defined. Individual cases have been reported in which high-dose chemotherapy with autologous bone marrow techniques have been successful in inducing remission in patients who were refractory to the usual regimens. Efforts continue to identify new agents that are effective in treating patients with GTN. Although ifosfamide and taxol are both active, further studies are needed to better define their roles as primary and second-line therapy in the treatment of this disease.

METHOD OF ADMINISTRATION. At the NETDC, β-hCG levels are measured weekly after each course of chemotherapy and serve as the primary basis for determining the need for additional treatment in patients with stage I GTN. After the first treatment, further chemotherapy is withheld as long as the hCG level falls progressively. A second course of the same agent is administered under the following conditions:

- β-hCG level plateaus for more than 2 consecutive weeks or re-elevates, or
- β-hCG levels do not decline by one log (tenfold) within 18 days after completing the first treatment.

If a second course of methotrexate/folinic acid is necessary, the dosage of methotrexate remains unaltered if the patient's response to the first treatment has been adequate. An adequate response is defined as a fall in the β-hCG level by one log (tenfold) after a course of chemotherapy. When the response to the first treatment is inadequate, the dose of methotrexate is increased by 50%. If the response to two consecutive courses of methotrexate/folinic acid is inadequate, the patient is considered to be resistant to methotrexate, and actinomycin D is instituted promptly. If a patient fails to respond to sequential methotrexate/actinomycin D, then combination chemotherapy using MAC is administered at 3-week intervals or as frequently as toxicity permits until the patient's β-hCG level becomes undetectable. Patients who require combination chemotherapy should be treated intensively to attain remission. To prevent relapse, at least two additional courses of chemotherapy should be administered after the patient achieves undetectable hCG levels.

Patients who require combination chemotherapy must be treated intensively to attain remission. We administer combination chemotherapy as frequently as toxicity permits (usually at 2- to 3-week intervals) until the patient attains three consecutive undetectable hCG values. After the patient achieves normal β-hCG levels, three or four additional courses of chemotherapy are administered to reduce the risk of relapse. Relapse can be attributed to the fact that residual disease is present, producing hCG below the threshold of assay systems that are currently in use.

Stage I (Nonmetastatic Disease)

The protocols for the management of stage I disease at the NETDC are shown in Table 94-10. The treatment of stage I GTN is either surgical or medical, depending on the patient's desire to preserve fertility. Hysterectomy is advisable as initial treatment in patients with stage I nonmetastatic GTN who no longer wish to preserve fertility. The use of hysterectomy to treat nonmetastatic disease results in a reduced number of courses of chemotherapy and a shorter duration and lower dose of chemotherapy required to achieve remission.[90] Adjuvant chemotherapy administered at the time of surgery is indicated to eradicate any occult metastases and to reduce the likelihood of tumor dissemination at the time of surgery. Adjuvant chemotherapy administrated at the time of surgery has not been associated with increased postoperative morbidity. Nonmetastatic PSTT should be treated with hysterectomy because of this tumor's poor response to chemotherapy. Once PSTT metastasizes, the sur-

Contraception	12 consecutive months of normal hCG tests

vival rate is lower than that of other GTNs despite multimodal therapy.[91] Thirty-one patients who were treated by primary hysterectomy and adjuvant chemotherapy all achieved complete remission with no additional therapy.

Between July 1965 and June 2006, 543 patients with stage I disease were treated at the NETDC (Table 94-11). Complete sustained remission was achieved in 460 patients (92%) with single-agent therapy. The remaining 83 patients who were resistant to single-agent chemotherapy subsequently attained remission with either further chemotherapy or surgical intervention. If a patient no longer wishes to preserve fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as the primary treatment.

Stages II and III

The protocol for the management of stage II and stage III GTN is reviewed in Table 94-12. Tables 94-13 and 94-14 summarize the results of treatment of stages II and III, respectively. Between July 1965 and June 2006, all 29 patients with stage II disease achieved remission. Single-agent chemotherapy induced complete remission in 16 of 20 (80%) low-risk patients. In contrast, only 2 of 9 high-risk patients achieved remission with single-agent treatment. Between July 1965 and June 2006, 160 of 161 patients (99%) with stage III GTN attained complete remission. Single-agent chemotherapy induced complete remission in 85 of 104 patients (82%) with low-risk disease and in 13 of 49 patients (27%) with high-risk disease. All patients who were resistant to single-agent treatment later achieved remission with combination chemotherapy. Although low-risk patients (prognostic score ≤7) are treated with primary single-agent chemotherapy with methotrexate or actinomycin, patients with high-risk scores (prognostic score >7) require primary combination chemotherapy to achieve optimal outcomes. Patients who are resistant to single-agent chemotherapy receive salvage therapy with combination chemotherapy, either MAC or EMACO. Patients who are resistant to MAC should then receive EMACO, and those who are resistant to EMACO may be treated with a modification of that regimen by substituting cisplatin and etoposide on day 8 and escalating the dose of methotrexate infusion to 1 g/m^2 (EMACE).

MANAGEMENT OF VAGINAL AND ADNEXAL METASTASES. Because trophoblastic tissue is highly vascular, vaginal metastases can bleed profusely. When bleeding is a problem, it could be necessary to pack the lesion or to perform a wide local excision. The administration of one or two courses of chemotherapy could result in the development of avascular planes around the vaginal tumor, making excision less bloody. Angiographic embolization of the hypogastric artery or of the specific vessels feeding the tumor could be required to control hemorrhage from a vaginal metastasis. Extension of tumor to the adnexa should be monitored by ultrasound when asymptomatic. These tumor deposits usually resolve once chemotherapy is administered; however, surgical intervention could be required if signs of intra-abdominal bleeding appear.

MANAGEMENT OF LUNG METASTASES. Thoracotomy has a limited role in the management of stage III GTN. Thoracotomy should be performed initially if there is the possibility that the lesion

is an hCG-producing primary lung tumor. Pulmonary resection is also indicated if a patient has a persistent viable nodule despite intensive chemotherapy. Before undertaking thoracotomy, however, a metastatic workup should be carried out to exclude the presence of other metastatic sites. Excision of persistent nodules in the face of complete gonadotropin remission is not indicated, because treated pulmonary nodules can undergo fibrosis and remain indefinitely on chest x-ray. If there is any question regarding the viability of a pulmonary lesion, a scan with radioisotope-labeled antibody to hCG or a PET scan could be helpful. These scans might also be useful in identifying occult sites of viable tumor.

Tomoda and colleagues[92] reviewed their experience with pulmonary resection in 19 patients with chemotherapy-resistant GTN and proposed the following criteria for successful resection:

- Good surgical candidate
- Primary malignancy is controlled
- No evidence of other metastatic sites
- Pulmonary metastasis localized to one lung
- hCG level below 1000 mIU/mL

In Tomoda's series, complete remission was achieved in 14 of 15 patients who met all five criteria but in none of the 4 patients who had one or more unfavorable clinical features. Similarly, Lurain and coworkers[93] reported that four of five carefully selected patients with drug-resistant pulmonary GTN attained complete remission after lung resection. Several investigators have reported that the achievement of nondetectable hCG levels within 1 to 2 weeks after resection of a solitary pulmonary nodule is highly predictive of a favorable outcome. Survival after salvage surgery is also influenced by other factors, such as the number of preoperative chemotherapy regimens, the number of disease sites, and the patient's WHO score.

Stage IV

The protocol for the management of patients with stage IV GTN at the NETDC is summarized in Table 94-15. All patients are managed with primary combination chemotherapy with EMA-CO. In the presence of cerebral metastases, the methotrexate dosage in the infusion is increased to 1 g/m^2 (in divided doses). Whole-head or focused irradiation is administered immediately. Patients with disease that is resistant to EMACO may then be treated with EMACE. Brain irradiation is both hemostatic and tumoricidal. The concurrent use of combination chemotherapy and brain irradiation appears to reduce the risk of spontaneous bleeding in cerebral metastases. Yordan and associates[94] reported that deaths due to central nervous system involvement occurred in 11 of 25 patients (44%) who were treated with chemotherapy alone but in none of 18 patients who were treated with both brain irradiation and chemotherapy. Evans and colleagues, on the other hand, have reported excellent remission rates in patients with cerebral metastases who were treated with chemotherapy alone.[95] Thirty of 35 patients (86%) with cerebral lesions achieved sustained remission with intensive combination chemotherapy that included high-dose intravenous and intrathecal methotrexate.

Table 94-15 Treatment Protocol for Stage IV Gestational Trophoblastic Neoplasm

INITIAL
EMACO
With brain metastases: Radiation, craniotomy as indicated
With liver metastases: Embolization, resection to manage complications
RESISTANT
Salvage chemotherapy (EMA-EC, VBP)
Local resection as indicated
Hepatic artery infusion as indicated
FOLLOW-UP HCG
Weekly until normal for 3 weeks, then monthly for 24 consecutive months
CONTRACEPTION
24 consecutive months of normal hCG values

SURGICAL MANAGEMENT OF CEREBRAL METASTASES. Craniotomy should be reserved for patients who develop progressive neurologic deterioration, indicating the need for acute decompression or for control of bleeding. In rare instances, cerebral metastases that are resistant to chemotherapy could be amenable to local resection, particularly if they are localized in the periphery. Evans and coworkers[95] reported complete remission in three of four patients who underwent craniotomy to relieve intracranial pressure and in two of three patients undergoing craniotomy for resection of chemotherapy-resistant tumor. Most patients with cerebral metastases who achieve remission have little or no residual neurologic deficits unless there has been an acute hemorrhagic episode.

MANAGEMENT OF HEPATIC METASTASES. The management of liver metastases is particularly difficult and problematic. If a patient is resistant to chemotherapy, hepatic arterial infusion might induce remission in selected cases. Hepatic resection might also be necessary to control acute hepatic bleeding or to remove localized areas of resistant tumor. Grumbine and associates[96] reported the use of selective occlusion of the hepatic arteries and concurrent combination chemotherapy in a patient with bleeding liver metastases who ultimately attained remission. Wong and colleagues[97] also noted that nine out of ten patients with hepatic involvement achieved complete remission with primary intensive combination chemotherapy without hepatic irradiation. Bakri and colleagues[53] similarly reported that five of eight patients (63%) with liver metastases who were treated with combination chemotherapy alone attained remission.

RESULTS OF TREATMENT. Table 94-16 summarizes the results obtained at the NETDC since 1965. Prior to 1975, only 6 of 20 patients (30%) with stage IV disease achieved remission. After 1975, 16 (84%) of 19 patients attained remission. This dramatic improvement in survival resulted both from the introduction of multimodal therapy early in the course of treatment and from the availability of supportive treatments that help to control life-threatening drug-induced toxicity.

Management of Primary Treatment Failure

When a patient becomes resistant to or relapses after treatment with primary and secondary chemotherapy as manifested either by a plateau in or a reelevation of the β-hCG level, it is necessary to reevaluate her status, looking for occult metastases that might be protected from the effects of drug therapy. Mutch and colleagues[98] reported recurrences after initial remission in 2% of patients with nonmetastatic GTN, in 4% of patients with good-prognosis metastatic disease, and in 13% of patients with poor-prognosis disease. Relapses developed within 3 and 18 months in 50% and 85% of patients, respectively. We have observed relapses after initial remis-

Table 94-16 Results of Treatment of Stage IV Gestational Trophoblastic Neoplasm: Number of Remissions

Time Period	Total No. of Patients (%)
1965–1975	6/20 (30)
After 1975	16/19 (84)

sion in 3% of patients with stage I, 8% with stage II, 4% with stage III, and 9% with stage IV disease.[99] The mean time to recurrence from the last undetectable hCG level was 6 months, and this rate did not differ among the four FIGO stages. All patients with stage I, II, and III GTN who relapsed were subsequently cured, whereas both of the stage IV patients with recurrent disease succumbed. Patients with uncomplicated molar pregnancy who spontaneously resolve their β-hCG levels rarely recur after 3 weeks of undetectable tests.

ROLE OF SURGERY. In contrast to its limited role in primary therapy, surgery can play an important role in the treatment of patients who prove resistant to first- and second-line therapy. Surgical removal of resistant disease of the uterus, lung, brain, liver, spleen, and gastrointestinal tract should be undertaken to reduce tumor burden and prevent bleeding when it is apparent that these metastatic sites no longer respond to either primary or salvage therapy.

SALVAGE CHEMOTHERAPY. Resistance to primary and secondary chemotherapy regimens requires the use of salvage regimens in addition to surgery and radiation therapy. A number of well-recognized protocols have been used with some success in this situation, including VBP and EMACE.

FOLLOW-UP

After Evacuation of a Molar Pregnancy

After evacuation, patients with either a complete or partial mole should be followed with weekly quantitative β-hCG tests until the β-hCG levels are undetectable for 3 consecutive weeks. Until recently, the standard follow-up after three successive weekly undetectable hCG titers has been monthly testing for 6 to 12 months before pregnancy is advised. Recent studies at our center have shown that the risk of relapse after achievement of undetectable hCG levels is negligible.[100,101] We have therefore modified our follow-up protocols and now discontinue testing and allow for pregnancy after 3 consecutive weeks and 3 months of undetectable hCG tests.

Patients should be counseled to use effective contraception during the entire interval of β-hCG follow-up. We do not encourage the insertion of intrauterine devices until the patient achieves undetectable β-hCG levels because of the risk of infection or perforation if residual tumor is present. If the patient does not desire surgical sterilization, her options are therefore either hormonal or barrier methods. The incidence of postmolar tumor has been reported to be increased in patients who start oral contraceptives before the β-hCG level becomes undetectable.[102] Data from the NETDC, the Gynecologic Oncology Group, and the Brewer Center, however, indicate that oral contraceptives do not appear to increase the risk of postmolar GTN.[103,104]

After completion of the prescribed follow-up period, pregnancy may be undertaken. Patients should be counseled that they are at increased risk of another molar pregnancy in any subsequent gestation. For that reason, we highly recommend that a pelvic ultrasound be performed at 10 weeks of gestation. There is also evidence that patients who have been treated for GTN have a higher incidence of another trophoblastic event after any subsequent pregnancy. Therefore, all patients with a history of molar pregnancy or GTN should undergo β-hCG testing at the 6-week postpartum or postabortal visit.

After Treatment for Gestational Trophoblastic Neoplasia

Stages I–III

All patients with stage I, II, or III GTN should be followed with weekly β-hCG tests until the level is undetectable for 3 consecutive weeks. Testing should then continue monthly for 12 months. During the entire period of hCG monitoring, patients must be encouraged to use effective contraception. When patients have completed the prescribed period of follow-up, they are free to try for pregnancy. As can be seen in the subsequent pregnancy data, which is summarized in the following sections, patients can be reassured that subsequent pregnancies are not associated with an increase in the risk of congenital malformations, prematurity, or other obstetric problems.

Stage IV

Patients with stage IV disease should be followed with weekly β-hCG tests until the level is undetectable for 3 consecutive weeks. They should then be followed monthly for 24 months. A more prolonged follow-up is required for patients with stage IV disease because of the increased risk of late recurrence.

Subsequent Pregnancy

Pregnancy after Complete Hydatidiform Mole

Patients with molar pregnancies can anticipate normal reproduction in the future. Patients with CHM who were treated at the NETDC had 1278 later pregnancies between June 1965 and November 2001 (Table 94-17). These pregnancies resulted in 877 (69%) normal, full-term live births; 95 (7%) premature deliveries; 11 ectopic pregnancies; and 7 stillbirths. First-trimester spontaneous abortions occurred in 221 pregnancies (17%). Major and minor congenital malformations were detected in only 40 infants. The primary cesarean section rate of 19% was consistent with that of the normal population.

Pregnancy after Partial Hydatidiform Mole

Between June 1965 and November 2001, patients with PHM at the NETDC had 251 subsequent gestations, which resulted in 189 (75%) full-term live births, 1 stillbirth, 1 ectopic pregnancy, and 4 premature deliveries (Table 94-18). First-trimester spontaneous abortions occurred in 39 (15%) pregnancies, and major and minor congenital anomalies were detected in only 3 infants.

After a patient has had a molar pregnancy, she has an increased risk of developing another molar pregnancy at a later conception.[105] Thirty-four (1 in 150) of our patients had at least two molar gestations between June 1965 and November 2001. Patients can have an initial CHM or PHM and then, in a later pregnancy, can develop the other type of molar disease. Following two molar pregnancies, 34 patients had 35 later conceptions resulting in 20 (57%) full-term normal deliveries, 7 (20%) molar pregnancies (6 complete, 1 partial), 3 spontaneous abortions, 1 ectopic pregnancy, 1 intrauterine death, and 3 therapeutic abortions. Bagshawe and colleagues also reported that the risk of a third molar disease after two episodes of molar pregnancy was 15%. In six of our cases, we have documented that

Congenital anomalies	40/979 (4.1)
C/S (1979–2001)	70/373 (18.8)
Spontaneous abortions	229 (17.9)
Therapeutic abortions	41 (3.2)
Ectopic pregnancy	11 (0.9)
Repeat molar pregnancy	18 (1.4)

Table 94-18 Subsequent Pregnancy Outcome in Partial Molar Pregnancy (1975–2001)

Outcome	Number (%)
Total pregnancies	251
Total deliveries	194
Term live	189 (75.3)
Preterm	4 (1.6)
Stillbirth	1 (0.4)
Congenital anomalies	3/194 (1.5)
C/S (1979–2000)	23/194 (14.9)
Spontaneous abortions	39 (15.5)
Therapeutic abortions	11 (4.4)
Ectopic pregnancy	1 (0.4)
Repeat molar pregnancy	6 (2.4)

Table 94-19 Subsequent Pregnancy Outcome in Patients Treated for Gestational Trophoblastic Neoplasms

Outcome	Number (%)
Total pregnancies	581
Total deliveries	437
Term live	393 (67.6)
Preterm	35 (6.0)
Stillbirth	9 (1.5)
Congenital anomalies	10/437 (2.3)
C/S (1979–2000)	68/335 (20.3)
Spontaneous abortions	99 (17)
Therapeutic abortions	28 (4.8)
Ectopic pregnancy	7 (1.2)
Repeat molar pregnancy	8 (1.4)

the patient had different partners at the time of conception of different molar pregnancies.

Pregnancy after Gestational Trophoblastic Neoplasia

Patients who are treated successfully with chemotherapy can also generally experience normal reproductive function. Table 94-19 summarizes the experience at the NETDC in 581 pregnancies that occurred between June 1965 and November 2001. These later pregnancies resulted in 393 (68%) full-term live births, 35 premature deliveries, 7 ectopic pregnancies, and 9 stillbirths. First-trimester spontaneous abortions occurred in 17% of patients, and major and minor abnormalities were detected in only 10 infants. It is reassuring that the frequency of congenital anomalies is not increased despite the use of chemotherapeutic agents, which are both teratogenic and mutagenic.

Our experience is in general agreement with that of other centers regarding the pregnancy outcome after chemotherapy for GTN. A total of 2657 subsequent pregnancies have been reported, which resulted in 77% full-term live births, 5% premature deliveries, 1% stillbirths, and 14% spontaneous miscarriages.[106] Although the frequency of still births appears somewhat increased, congenital anomalies were noted in only 1.8% of patients, which is consistent with the general population. Woolas and associates[107] noted that there were no differences in either conception rate or pregnancy outcome between women treated with single agents and those treated with combination chemotherapy. Furthermore, only 7% of women who wished to become pregnant after GTN failed to conceive.

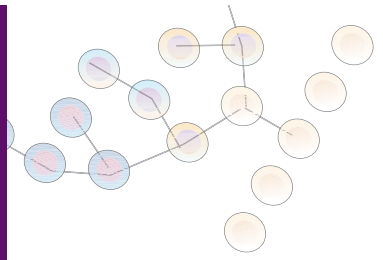
Psychosocial Consequences of Gestational Trophoblastic Neoplasia

Women who develop GTN can experience significant mood disturbance, marital and sexual problems, and concerns over future fertility.[108] Because GTN is a consequence of pregnancy, patients and their partners must confront the loss of a pregnancy at the same time that they face concerns regarding malignancy. Patients can experience clinically significant levels of anxiety, fatigue, anger, confusion, sexual problems, and concern for future pregnancy that last for protracted periods of time. Patients with metastatic disease and active disease are particularly at risk of serious psychological disturbances.

Psychosocial assessments and interventions should be provided to patients with GTN and their partners; these assessments should be targeted particularly to patients in the metastatic and active disease groups. The psychological and social stresses related to persistent GTN can last for many years beyond achieving remission.

ISSUES FOR THE FUTURE

Survival in GTN has improved dramatically over the past three decades because of the introduction of sensitive and specific hCG assays for diagnosis, treatment, and follow-up and because of the introduction of effective chemotherapy regimens based on patients' risk profiles. Further advances in the treatment of GTN can be achieved through earlier detection and intervention and through the introduction of effective chemotherapeutic protocols for resistant disease.



It is well recognized that the treatment of patients, particularly those with high-risk GTN, by physicians who are experienced in the management of this disease achieves optimal results. Therefore, prompt referral to or consultation with treatment centers is always in the best interest of the patient.

95 Cancer of the Breast

Martin D. Abeloff, Barbara L. Weber, Antonio C. Wolff, Beryl McCormick, Tal Z. Zaks, and Vergilio Sacchini

SUMMARY OF KEY POINTS

Incidence and Epidemiology

- Breast cancer is the most frequently diagnosed cancer in women in the United States, accounting for an estimated 274,900 new cases (212,920 invasive cancers and 61,980 in situ carcinomas) and 40,970 deaths in 2006.
- In the United States, the age-specific incidence of breast cancer increases with age, to a lifetime risk of breast cancer of 1 in 8 (to 110 years of age); by age 40, approximately 1 in 250 women will have been diagnosed with breast cancer annually; at 60 years of age, the figure is 1 in 35 women.
- Incidence rates rose 21% from 1973 to 1990, but then began to decline; mortality rates have stayed relatively constant until recently, when annual decreases have been seen.
- A sharp decline in the incidence of breast cancer in the early 2000s followed a decrease in the use of postmenopausal hormone replacement therapy.
- Age, family history, and both endogenous and exogenous ovarian hormone exposure have an important effect on risk and have been incorporated into models that predict individual risk of breast cancer; diet, alcohol use, and other factors play a smaller role.
- Inherited mutations in BRCA1, BRCA2, and CHEK2 play a role in the development of breast cancer and can be directly tested in individuals.

Biology and Estimation of Risk

- The expression of nuclear estrogen and progesterone receptors plays an important role in the differentiation and growth of normal breast epithelium and the response of breast cancer cells to hormonal therapeutics.
- ERBB2 (HER2) is a growth-signaling molecule on the surface of normal breast cells that is overexpressed in approximately 20% of breast cancer tumors, contributing to growth autonomy and genomic instability.
- TP53 is a tumor-suppressor gene that is mutated in 30% to 50% of breast cancers; loss of normal TP53 function is associated with a poor prognosis and reduced likelihood of treatment response, possibly because of decreased response to apoptotic signaling, increased genome instability, and angiogenesis.
- DNA microarray studies identified an "intrinsic gene list" of 534 genes that defines five biological subtypes of breast cancer including the basal type (HER2-positive, cytokeratins 5 and 17 positive), the "triple negative" type (HER2-, ER-, and PR-negative), two luminal types (so-called luminal-A and luminal-B), and the normal breast-like type.
- BRCA1 and BRCA2 are tumor-suppressor genes that play a critical role in the cellular response to DNA damage; inherited mutations in these genes are associated with an increased risk of breast cancer.
- Regardless of the criteria used by an individual physician and patient to define high risk, four possible actions may be taken, some of which can be used simultaneously: (1) enhanced surveillance, (2) behavioral modification, (3) chemopreventive strategies, and (4) prophylactic mastectomy or oophorectomy.

Screening and Diagnosis

- Despite recent challenges to the benefits of mammographic screening, the United States Preventive Service Task Force and many other organizations recommend screening mammography, with or without clinical breast examination, every 1 to 2 years for women 40 years of age and older.
- Microcalcification and soft tissue density are the major indications for biopsy in mammographic screening; the mammographic abnormality with the highest rate of malignancy is a mass density with associated calcification.
- Computer-assisted digitized mammographic imaging, magnetic resonance imaging, positron emission tomography, and radionuclide scanning are under intense investigation as emerging techniques for breast imaging.
- For patients with breast symptoms or palpable abnormalities, mammography characterizes the suspicious area, evaluates the remainder of the breast for occult lesions, and assesses the contralateral breast.
- Malignant breast masses classically are nontender and firm, with irregular borders.
- Diagnostic methods include fine-needle aspiration cytology, needle core biopsy with ultrasound or stereotactic guidance, and excisional biopsy, with or without wire or tack localization.

Management of Noninvasive Disease

- Lobular carcinoma in situ (LCIS) is a nonpalpable lesion that usually is discovered with another indicator for biopsy; it is more common in premenopausal women and accounts for 30% to 50% of cases of carcinoma in situ.
- LCIS has a propensity for multicentricity and bilaterality; it is an indicator of risk of subsequent invasive breast cancer.
- Management of LCIS had shifted toward observation after biopsy rather than mastectomy; increasing evidence shows that tamoxifen should be considered as a preventive approach.
- The multifocal nature of LCIS makes margin clearance an unrealistic and unnecessary goal.
- Unlike LCIS, ductal carcinoma in situ (DCIS), almost always is first identified by mammography; the peak incidence is

between 51 and 59 years of age, and it accounts for most of the increasing number of carcinoma in situ lesions diagnosed.
- DCIS is more likely to be localized to one area of the breast; thus, most patients are candidates for breast conservation; tamoxifen should also be considered following lumpectomy and radiation to reduce the risk of another ipsilateral or a new contralateral event, invasive or noninvasive.

Management of Early Stage Breast Cancer

- Patients should undergo a complete history and physical examination.
- Hemogram and renal and hepatic function tests as well as serum alkaline phosphatase evaluation should be performed in all patients.
- Bilateral mammography is indicated for all patients, and other breast imaging (ultrasound and MRI) should be used as needed for each individual patient; other imaging studies are recommended only to evaluate specific signs or symptoms or in patients with locally advanced disease.
- Prognostic factors include pathologic tumor size, hormone receptors, axillary nodal status, histologic subtype, tumor grade, and perhaps age.
- HER2 is a strong predictive marker, and accurate determination of HER2 status identifies patients with T1cN0 tumors and above who should be considered candidates for adjuvant therapy with a trastuzumab-based regimen.
- Promising results have been shown with microarray-based expression profiling as a potential means of gauging prognosis or predicting response to therapy.
- Specific gene expression profiling assays also have prognostic value, and two of them are undergoing prospective testing as a predictive marker for therapy selection.
- The revised American Joint Committee on Cancer TNM staging system takes into account the increasing use of novel imaging and pathology techniques, such as sentinel node biopsy and immunochemistry; it also considers the number of involved nodes a strong prognostic factor.
- Axillary dissection of level I and II nodes remains a valuable staging procedure; however, sentinel lymph node mapping is becoming the standard of care for accuracy and less morbidity.
- For patients with stage I and II disease, breast conservation and modified radical mastectomy are the therapeutic options; for most patients, breast conservation is an acceptable approach.
- Factors that affect local control in breast conservation include pathologic margin evaluation, extensive intraductal component, age, and the presence of multiple tumors.
- Adjuvant therapy with cytotoxic drugs or endocrine treatment, or both, is recommended for patients with node-positive disease.
- Pathologic tumor size, hormone-receptor status, histologic subtype, and nuclear grade are used to select patients with node-negative disease for adjuvant therapy.
- The results of the meta-analysis performed by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) show that the survival benefits of adjuvant chemotherapy and endocrine therapy persist after 15 years of follow-up.
- Challenges that require resolution include identification of biologic parameters that more precisely predict the natural history of disease and the response to systemic therapy; more effective treatments are clearly needed.

Management of Locally Advanced Disease

- Patients with locally advanced disease are a heterogeneous group, including those with T3N1, T0–3N2–3, and T4N0–3 disease.
- Multimodality therapy is recommended for virtually all patients with locally advanced disease; the sequence of chemotherapy, surgery, and radiation depends largely on the operability of the primary disease.
- For women with inoperable or inflammatory breast cancer (or both), preoperative. chemotherapy is recommended, followed by surgery, radiation, and endocrine therapy, if appropriate. Preoperative endocrine therapy for patients with receptor-positive disease is also a reasonable option.

Management of Locally Recurrent Disease

- Local recurrence is an indicator of systemic relapse in most cases; an exception may be local relapse in a breast that has undergone conservation therapy.
- Selection of the treatment modality depends largely on the extent of local and regional failure and the presence of distant metastases.
- Surgical removal alone may be sufficient in some cases, but it often is combined with locoregional radiation and/or systemic therapy.

Management of Metastatic Disease

- Although a small percentage of patients with metastatic breast cancer achieve long-term disease-free survival, this stage of disease essentially is not curable, and therapy is largely palliative.
- A wide range of systemic, local, and supportive therapies are available for the palliation of metastatic breast cancer.
- The selection of endocrine, cytotoxic, or biologic therapy usually is based on disease-free interval, receptor status, HER2 status, site of metastasis, performance status, age, and previous exposure to systemic therapy.
- Trastuzumab has changed the natural history of patients with HER2-positive metastatic breast cancer. Bevacizumab has been shown to improve progression-free survival, but not overall survival, when added to paclitaxel as first-line therapy for metastatic disease. Adjuvant trials began in late 2007.

EPIDEMIOLOGY

Incidence

Worldwide, breast cancer is the most common type of cancer and the most common cause of cancer-related mortality among women.[1] In the United States, approximately 212,920 new cases of invasive breast cancer, 61,980 in situ cases, and 40,970 deaths were expected to have occurred in 2006.[2] In women, breast cancer accounts for 26% of new cases of cancer and 15% of cancer deaths, second only to lung cancer as a cause of cancer-specific death.[3] Approximately 1% of breast cancers occur in males and 90% are estrogen receptor (ER)-positive.[4] Incidence rates continued to increase until 2002, likely reflecting increase use of mamographic screening, but recently have

Table 95-1 Risk of Breast Cancer in U.S. Women

Age Range (yr)	Breast Cancer Risk
30–40	1:252
40–50	1:68
50–60	1:35
60–70	1:27
Lifetime (to age 110 yr)	1:8

Data from www.cancer.gov/cancertopics/factsheet/Detection/probability-breast-cancer. Accessed 2/11/2008.

been reported to be declining. Part of that decline may be due to a decrease in the use of postmenopausal hormone replacement therapy.[5] Although incidence rates (all races combined) are substantially higher for women age 50 and older (375.0 per 100,000) compared with women younger than 50 years (42.5 per 100,000), approximately 23% of breast cancers are diagnosed in women younger than 50 years, because those women represent 73% of the female population (Table 95-1).

Although breast cancer is a major disease for women in the United States, survival analysis performed by the Surveillance Epidemiology and End Results (SEER) program shows that, for women diagnosed between 1988 and 2001, survival rates are better than those observed for many other tumors.[6] Around the world, there are large variations in incidence, mortality, and survival, and these may be due to several underlying complex factors including age, ethnicity, diet, and lifestyles.[1] Most of our knowledge regarding specific risk factors has been derived from large observational studies in developed countries, such as the Nurses' Health Studies (NHS)[7] in the United States and the "Million Women Study" in the UK (www.millionwomenstudy.org). Some of these risk factors are briefly summarized in the following sections.

Diet

Alcohol consumption is the best-established dietary factor associated with increased risk for breast cancer, and folate intake is inversely related to breast cancer, especially among women who consume alcohol.[8] Initial studies correlated fat intake with an increased risk of developing breast cancer, but more recent prospective studies have failed to confirm those observations.[9–11] However, there appears to be an association between body mass index (BMI) and breast cancer, which may be accounted for by increased estrogen levels in women with a higher BMI.[12,13] Dietary phytoestrogens such as those found in soybeans have a chemical structure that is similar to that of 17β-estradiol and can bind to the estrogen receptor to compete with estrogen[14]; their consumption may have a weak protective effect against breast cancer.[15] Interestingly, a recent study of French women correlated consumption of phytoestrogens derived from lignans with a reduced risk[16]; whether these association are causal remains to be proven in prospective intervention studies.

Ionizing Radiation

The accumulated knowledge about radiation-related breast cancer risk in women derives mainly from epidemiologic studies of patients exposed to diagnostic or therapeutic radiation and of the Japanese atomic bomb survivors. Low-dose radiation exposure to the breast is carcinogenic, and risk increases as a linear function of increasing dose. The risk is particularly high in the developing breast (i.e., before the age of 20), and is minimal for women exposed after menopause.[17] Given that germline mutations in DNA repair genes are rare, their influence on radiation-associated risk of breast cancer has been difficult to study. One group that theoretically could be at increased risk are flight attendants exposed to cosmic radiation, although it has been difficult to determine whether such an association exists. The excess estimated lifetime risk of dying from radiation-associated cancers (of all histologies) is about 1% following an exposure of 100 mSievert, which is 10 to more than 100 times the estimated annual exposure of flight attendants.[18]

Exogenous Hormones

The NHS originally was set up to determine whether oral contraceptive usage was associated with an increase in breast cancer. An analysis of data from that study and over 50 additional studies has confirmed that current users of exogenous hormones have a slightly increased risk of developing breast cancer.[19] However, the mortality associated with this risk appears to be offset by a decreased risk of developing colon and ovarian cancer, such that there is no increase in overall cancer mortality associated with their use.[7] Estrogen-only hormone replacement therapy (HRT) for postmenopausal women is associated with a small but significant risk of all types of invasive breast cancer (RR of ~1.6). This relative risk is even higher for estrogen-progestagen combinations (RR of ~2.5); however, the risk drops back to baseline by 5 years after cessation of therapy.[11] Recently, age-adjusted incidences of invasive breast cancer decreased in the United States between 2002 and 2003 by 7%, reflecting an absolute decrease of ~14,000 breast cancer cases (Fig. 95-1). This decrease was limited to women 50 years of age or older, occurred primarily in ER-positive tumors, and coincided closely with a dramatic decrease in the use of HRT following the publication of the Women's Health Initiative results that correlated HRT with an elevated risk of coronary heart disease.[5]

Reproductive Factors and Endogenous Hormones

Breast cancer risk consistently has been correlated with an earlier age of menarche, later age of menopause, nulliparity, and late age of first birth, all of which determine the cumulative number of ovarian cycles. This finding is consistent with the correlation between estrogen levels and breast cancer risk.[13] In addition to sex hormones, insulin-like growth factor 1 (IGF1) is a mitogenic growth factor that had been implicated by in vitro and animal data in breast cancer carcinogenesis, as discussed later in this chapter. IGF-1 plasma levels consistently have been correlated with an increased risk of developing breast cancer in premenopausal women.[20] Finally, prolactin levels also have been associated with an elevated risk in both pre- and postmenopausal women.[21]

Familial History and Predictive Models of Breast Cancer Risk

Breast cancer is approximately twice as common among first-degree relatives of breast cancer patients as in those women with no family history of the disease. The two most important breast cancer susceptibility genes, BRCA1 and BRCA2, were identified by linkage analyses in the mid-1990s.[22] Since then, rare germline mutations in several other genes, such as TP53, PTEN, and ATM, have been shown to confer an increased risk of breast cancer. BRCA1 and BRCA2 account for less than 20% of familial clustering of breast cancer. Given that linkage analyses have failed to yield additional susceptibility loci, it is likely that most of the genetic susceptibility is a result of multiple low-penetrance alleles that co-exist in highly penetrant combinations in a polygenic model.[23]

An increasing understanding of relevant risk factors has led to integrated efforts at evaluating a women's individual risk,[24] and several individualized risk-assessment tools are available, such as the Gail and Claus models.[25] One such tool is available on the NCI website at http://www.cancer.gov/bcrisktool/. These tools are being used for clinical counseling for both breast cancer patients and healthy women perceived to be at risk. Given that for women living in the Western hemisphere the lifetime risk of breast cancer is approximately 11%, even a small relative risk reduction will translate into many thousands of lives saved.

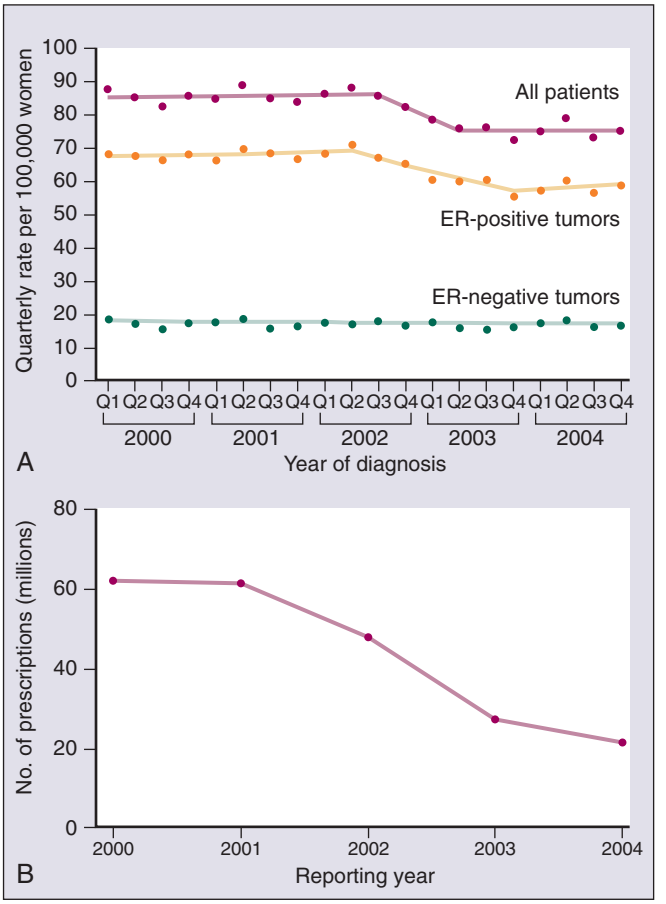

Figure 95-1 • Quarterly incidence of breast cancer in women between the ages of 50 and 69 years, according to estrogen-receptor (ER) status, and the number of prescriptions for hormone-replacement therapy, 2000–2004. **A,** Data are from nine of the NCI's SEER registries, with trends modeled with regression-analysis statistical software (Joinpoint). Trends were age-adjusted to the standard population in the year 2000 and were adjusted for reporting delays. **B,** The number of prescriptions reported in the United States for the combined estrogen-progestin preparation Prempro and the conjugated equine estrogen Premarin, according to year. BIOLOGY

Modern diagnosis, prevention, and therapy of breast cancer has benefited from a conceptual understanding of cancer as a genetic disease and an ongoing elucidation of molecular lesions that underlie breast cancer. Traditional anti-mitotic chemotherapy has been used empirically in the treatment of breast cancer as in other epithelial cancers; more recently the discovery of breast cancer-specific therapeutic targets such as ER and ERBB2 (human epidermal growth factor receptor 2 [HER2]) has led to the successful development of therapies that are effective only in patients whose tumors harbor these targets. This paradigm, which has been remarkably successful in other cancers where the underlying genetic aberration can be targeted (e.g., imatinib mesylate in CML and GIST, gefitinib in lung cancer with EGFR mutations), has provided the impetus for large-scale sequencing efforts of cancer genomes to identify additional targets. In addition, microarray technologies that enable the simultaneous quantitation of all RNA species and genome-wide DNA copy number changes have begun to provide diagnostic classifications that may be superior to traditional histologic critera for determining prognosis and therapy. Finally, the recent identification of both normal mammary gland and breast cancer stem cells will allow novel therapeutic approaches that may revolutionize therapy for metastatic disease. These advances and their implications for therapy are summarized in the following sections.

Estrogen and Progesterone Receptors

Estrogen plays a key role in the development of both normal breast epithelium and breast cancer, and the modulation of estrogen levels is a key therapeutic modality for breast cancer. Estrogens interact with mammary epithelial cells via specific estrogen receptors that function as nuclear transcription factors.[26] The two known receptors, ERα and ERβ, are encoded by different genes and share an overall sequence homology of about 30%, although the homology is higher in the DNA- and hormone-binding regions. ERα was the first estrogen receptor to be isolated and is the one most closely associated with breast cancer; it is expressed mainly in the breast, uterus, ovary, and endometrium. ERβ is more widely expressed and its relationship to breast cancer is less clear.[27] Most of the literature referring to ER (e.g., the staining of breast cancer cells as "ER-positive") refers to ERα unless otherwise specified. The major ligand-dependent transcriptional activation activity (so called "AF-2") function of ER dislodges from a complex with heat-shock proteins upon binding specific ligands, undergoes a conformational change, and homodimerizes. This homodimer then binds to the estrogen responsive elements (ERE) of the target genes, and recruits various co-activators (or co-repressors) that further influence transcription.[28] The participation in a multimeric signaling process likely contributes to the differential biologic effects that estrogen and estrogen-related compounds (e.g., tamoxifen) can have in different target organs. ER also has a minor ligand-independent transcriptional activating function, which is modified by phosphorylation and can facilitate "cross-talk" between ER activity and receptor tyrosine kinase signal transduction pathways. Approximately 70% of breast cancers express ER (i.e., they are ER-positive); these tumors tend to grow more slowly and appear better differentiated that ER-negative tumors. Moreover, anti-estrogen therapy is effective both in preventing recurrence in the adjuvant setting and in prolonging survival once metastases have developed. However, the relation between the ER expression and cancer initiation is not clear, because ER-positive cells are nonproliferating in the normal breast epithelium that is found adjacent to proliferating cells, suggesting a paracrine effect. The paracrine effect hypothesis is further supported by evidence that even in most ER-positive tumors only a minority of cells express ER by IHC, and breast cancer stem cells do not express ER.

The progesterone receptor (PR), itself an estrogen-regulated gene, gives rise to two distinct isoforms, PRA and PRB, by alternative splicing. PRB appears to be more specific to breast cancer, whereas PRA is more widely expressed. Interestingly, a polymorphism in the PR promoter (+331 G/A) that increases transcription of PRB has been associated with an elevated risk of endometrial and breast cancer.[29] PR is variably expressed in ER-positive tumors, and this variability has prognostic relevance. ER-positive/PR-negative tumors occur more commonly in women over 50, tend to be more aneuploid, and present as larger tumors with more frequent nodal involvement than ER/PR-positive tumors. Furthermore, ER/PR-positive tumors are more likely to respond to anti-estrogen therapy than ER-positive/PR-negative tumors.[30] Historically, ER-positive/PR-negative tumors were thought to have a nonfunctional ER pathway (as PR is downstream of ER). However, recent preclinical and clinical data suggest that these tumors may have a different biology, in that receptor tyrosine kinase pathways are more active and may directly down-regulate PR.[31] This is consistent with the finding that HER2 amplification is inversely correlated to PR expression.[32] While the aromatase inhibitor anastrozole is more active than tamoxifen in all ER-positive patients and the relative activity at first appeared greatest

in patients whose tumors are PR-negative,[33] this theory subsequently was not confirmed.[34] Regardless, the clinical combination of an aromatase inhibitor (e.g., letrozole) with HER2 blockade by trastuzamab may be synergistic.[35]

BRCA1, BRCA2, and Hereditary Susceptibility to Breast Cancer

It is estimated that 5% to 10% of all breast and ovarian cancer cases occur in the setting of inherited susceptibility due to a high-penetrance gene mutation, and the breast cancer susceptibility genes *BRCA1* and *BRCA2* have been identified as responsible for most these cases.[36] Women who carry a germline mutation in *BRCA1* have a cumulative lifetime incidence of 50% to 85% of developing breast cancer and 40% to 60% of developing ovarian cancer.[22] BRCA1 function is implicated in a variety of cellular processes including DNA damage repair, cell-cycle regulation, transcriptional regulation, and chromatin remodeling, whereas BRCA2 is involved primarily in DNA recombination and repair,[37] although it also may be involved in cytokinesis.[38] Tumors that arise in heterozygote carriers of germline mutations usually have an inactivated wild-type allele and do not express a functional protein. Cells that lack BRCA1 or BRCA2 protein have a specific deficiency in the repair of DNA double-strand breaks by the conservative and relatively error-free mechanism of homologous recombination by gene conversion.[38,39] Evidence for this defect is further supported by the finding that BRCA2 functions as part of the Fanconi anemia complex and actually is the long-sought-after FANCD1. Fanconi anemia complementation group FA-N results from biallelic mutations in *PALB2* ("partner and localizer of BRCA2"),[40,41] whereas monoallelic mutations in the same gene are associated with an increase susceptibility to familial breast cancer.[42] Moreover, several additional genes function in the same DNA repair pathway where germline mutations carriers are at increased risk of developing breast cancer—*CHEK2, ATM, NBS1, RAD50,* and *BRIP1*.[43] Why these genes predispose primarily to breast and ovarian cancers remains unknown, and somatic mutations in them are not commonly found in sporadic breast or ovarian cancers.[44] BRCA1-associated tumors usually are of the basal type (so-called "triple negative": HER2-, ER-, and PR-negative). Conversely, sporadic triple-negative breast cancers may share phenotypic similarities with cancers arising in BRCA carriers.[45] The identification of these genes and their function has important implications for prevention, diagnosis, and therapy of breast cancer in carriers.

Clinical management of carriers with *BRCA1* or *BRCA2* mutations is geared primarily toward preventing both ovarian and breast cancer.[46] Prophylactic mastectomy, albeit an invasive procedure with cosmetic consequences, is the most effective strategy available; it is associated with a 90% reduction in the risk of breast cancer. Oopherctomy, in addition to reducing ovarian cancer risk by 95%, reduces the risk of breast cancer by 50%. Finally, chemoprevention with tamoxifen has been associated with a 50% risk reduction in the contralateral breast in patients wth breast cancer, with a concomitant improvement in survival. Additionally, tamoxifen has been shown to reduce the risk of contralateral breast cancer by about 50% in both *BRCA1* and *BRCA2* carriers.

Once cancer is diagnosed, therapy remains dictated by standard prognostic features, with no specific regimens indicated on the basis of genetic predisposition. The involvement of BRCA proteins in DNA repair by homologous recombination suggests that these tumors would be particularly sensitive to chemotherapies that induce DNA inter-strand cross-links such as platinum salts. This hypothesis is supported by in vitro observations in both *BRCA*-null and FA cell lines. An ongoing clinical trial is testing this hypothesis.[47] In addition, *BRCA1*-related breast cancers commonly express EGFR (as is true of sporadic triple-negative cancers).[48] EGFR inhibitors, both antibodies and small-molecule tyrosine kinase inhibitors (TKI), are commercially available, but their specific efficacy in *BRCA*-related tumors remains to be defined. Similarly, it has been shown recently that a tyrosine kinase inhibitor of SRC, dasatinib, is particularly effective against triple-negative breast cancer cells, suggesting utility in *BRCA*-null tumors.[49] Finally, poly (ADP-ribose) polymerase 1 (PARP1) is critical for the base excision repair pathway; when this repair pathway is inhibited, double-strand breaks form at replication forks, and these are lethal to cells that cannot repair those breaks. Accordingly, BRCA-null cells are exquisitely sensitive to PARP inhibitors.[50,51] PARP inhibitors are still in early-phase clinical development, but the near future should enable more efficacious treatment to be tailored to tumors that lack functional BRCA proteins.

TP53

TP53 (*p53*), also termed the "guardian of the genome," is the most frequently mutated gene in human cancer. It plays a central role in sensing genotoxic and nongenotoxic stresses and transducing an antiproliferative effect (cell cycle arrest or apoptosis) in response. It is activated and regulated by post-translational modifications to the N-terminal region, (e.g., phosphorylation and ubiquitination) and, binding as a tetramer to specific DNA sequences via a central DNA-binding core region, exerts its primary biologic function by modulating the transcription of dozens of genes.[52] In transgenic mice, loss of *p53* is associated with multiple spontaneous tumors, although not of the mammary glands.[53] However, *p53* loss accelerates the appearance of mammary tumors in murine mammary tissue that also overexpresses MYC, HER2, IGF1, and/or WNT1. These genetic studies are consistent with a role for *p53* loss late in tumor development.[54] Indeed, the transgenic restoration of *p53* function leads to tumor regressions.[55]

Inheritance of a *p53* mutant allele causes the rare familial Li-Fraumeni syndrome, characterized by multiple early-onset cancers, including breast cancer in women who survive childhood cancers. Germline mutations in *ATM* and *CHEK2*, which are involved in *p53* activation, also cause an increased susceptibility to breast cancer.[56] Thirty to 50% of sporadic cases of breast cancers harbor somatic mutations in *p53* based primarily on sequencing of exons 5 through 8 (the DNA-binding core), where approximately 90% of mutations are found.[57] Currently, 2274 mutations that have been observed in breast cancers are listed in the *p53* database maintained by the International Agency for Research on Cancer (IARC; version R11, October 2006).[58]

p53, when mutated, accumulates in the nucleus of neoplastic cells. Thus, initial studies that described only a weak association between aberrant *p53* and adverse prognosis in breast cancer relied on IHC detection; more recent analyses based on mutation detection have confirmed a strong association.[59] More recently, *p53* mutations from 1794 European patients with at least 10 years of follow-up have been analyzed. Mutations in exons 5 through 8 were more common in ductal and medullary tumors, tumors with an aggressive phenotype (high grade, large size, node-positive cases, and low hormone receptor content), and in women less than 60 years old. Furthermore, the presences of a mutation conferred an overall 2.27-fold increased relative risk of breast cancer-specific mortality, independently of other known prognostic markers (e.g., tumor size, node status, and estrogen and progesterone receptor expression).[60] Finally, although not all mutations confer the same biologic properties (e.g., missense vs. nonmissense), all had similar prognostic utility.

Initial attempts at correlating p53 expression (by IHC) with resistance to chemotherapy have been supplanted with studies directly evaluating mutations. Some of these studies have shown breast cancers with *p53* mutations to be associated with less benefit from both anti-estrogens[61,62] and anthracylines,[63–65] although conflicting results also have been reported.[66] An overall analysis is complicated by different p53 assay methods, different disease settings (adjuvant, preoperative, and metastatic), and different combinations of drugs. In contrast, it appears that no clear relation between aberrant p53 and sensitivity to paclitaxel exists.[67–69]

p53 is an obvious target for cancer therapy, despite the apparent intractability of a loss-of-function genotype. Two approaches are being taken to overcome this limitation—small molecules to restore *p53* function[70] or inhibit its interaction with *MDM2*,[71] or adenoviral-mediated gene delivery. While the latter approach is approved for therapy of head and neck tumors in China, no clear activity in breast cancer has been demonstrated to date.[72]

ERBB2 (HER2)

The proto-oncogene *ERBB2* (*HER2*) encodes a transmembrane tyrosine kinase receptor, one member of a family of related growth factor receptors that include *EGFR* (*ERBB1*), *ERBB3* (*HER3*), and *ERBB4* (*HER4*). The ligands for these receptors, termed *heregulins,* are a family of growth factors known to bind to ERBB3 and ERBB4, inducing heterodimerization with ERBB2 and subsequent transduction of downstream signals. As HER2 does not bind ligand directly,[73] the ability to heterodimerize with other family members that do bind ligand is crucial for its activity. Of these, HER3 appears to be the most important heterodimerization partner.[74]

The amplification and/or protein overexpression of *HER2* is found in 20% of newly diagnosed breast cancers, and is associated with a more aggressive clinical course and decreased survival time compared to tumors with normal levels of HER2.[75] Amplification leads to very high levels of protein expression and constitutive activation of the receptor tyrosine kinase signal transduction pathway, namely RAS-MEK and AKT,[76] although the downstream effects may be more plietrophic than originally believed.[77] In contrast to EGFR, where amplifications in lung cancers frequently harbor activating mutations in the kinase domain, such mutations have not been found in breast cancer (see the Sanger Centre's COSMIC database, http://www.sanger.ac.uk/genetics/CGP/cosmic/). The identification of *HER2* as an oncogene in breast cancer facilitated the development of therapies directed against it. Trastuzumab, a humanized monoclonal antibody that binds to the extracellular domain of HER2, induces clinical responses as a single agent, prolongs survival in combination with chemotherapy, and decreases recurrence rates by about 50% in the adjuvant setting when given to women whose cancers overexpress HER2.[78,79] More recently, lapatinib, an oral small molecule tyrosine kinase receptor inhibitor active against HER2, also has been shown to be of benefit in metastatic, HER2-positive breast cancer. However, not all women with HER2-positive breast cancer respond to trastuzamab or lapatinib, and studies aimed at elucidating mechanisms of resistance are providing further insight into the pathophysiology of HER2-positive breast cancer. For example, increased levels of IGF1R may bypass HER2 blockade by trastuzamab and allow growth factor activation of AKT,[80] and a similar outcome may result from PTEN loss, as discussed earlier. In addition, a truncated form of HER2 that lacks the extracellular domain but retains the kinase activity has been described to correlate with trastuzumab resistance.[81]

The amplicon containing *HER2* frequently contains additional genes that influence therapeutic efficacy. Although initially it was thought that HER2-positive disease is more sensitive to anthracylines, recent data suggest that this sensitivity is conferred by the topoisomerase II gene (*TOP2A*) when it is present in the amplicon.[82] Modern genome-wide analysis methods currently are being applied both to panels of cell lines[83] as well as tissues from patients treated with anti-HER2 agents[84] to better understand mechanisms of resistance. The insights gained, in turn, are being exploited for further drug discovery: both antibody and small molecule inhibitors of IGF1R as well as PI3K and AKT kinase inhibitors currently are in clinical development for breast cancer, and synergy with anti-HER2 therapy has been demonstrated in vitro.[85]

PI3K and PTEN

Phosphatidylinositol-3,4,5-triphosphate (PIP_3) is a lipid second messenger formed by PIP_3 kinase (PI3K) in response to receptor tyrosine kinase signaling. PIP_3 activates AKT and other related pathways to induce proliferation and inhibit apoptosis. Approximately 25% of human breast cancers harbor oncogenic activating mutations in the p110 α catalytic subunits of PI3K (*PIK3CA*).[86] This signal is inactivated by the opposing phosphatase action of the tumor suppressor gene *PTEN*.

Germline *PTEN* mutations cause a hereditary cancer predisposition syndrome known as Cowden's syndrome, characterized by a high incidence of breast, uterine, thyroid, and skin neoplasms.[87] PTEN is inactivated in a wide variety of human tumors as a result of either mutation or, more commonly, epigenetic silencing through methylation, including in breast cancer.[88] PTEN loss is associated with genetic instability, and primary breast tumors that lack PTEN have increased aneuploidy.[89] In addition, PTEN loss has been associated with a decreased likelihood of response to the anti-HER2 therapy with trastuzumab.[90] Recent data elucidating the relationship between presence of *PIK3CA* mutations and PTEN status show that they are inversely correlated. Furthermore, PIK3CA mutations are twice as common in HER2-positive or ER-positive tumors, suggesting that more than one aberration upstream of AKT may be necessary to overcome the effect of an intact PTEN.[91] The relevance of *PIK3CA* mutations to the clinical activity of anti-HER2 directed therapy by trastuzumab and lapatinib is under active investigation.[92]

Breast Cancer Genome

The elucidation of genetic aberrations in cancer genomes (mutations, deletions, and amplifications) has led to a better understanding of cancer pathophysiology and is providing targets for rational drug development. With the determination of the DNA sequence of the normal human genome, efforts have shifted toward a more comprehensive analysis of cancer genomes. This effort began with a focus on tyrosine kinases but recently has been extended to an analysis of whole genomes. Recently, the first report of a comprehensive sequence analysis of 21,000 of the best studied and annotated human genes was published, including data from 11 breast and 11 colon cancer samples.[93] This screen rediscovered cancer genes known to be associated with breast cancer (e.g., *p53* and *BRCA1*) as well as genes not previously characterized as associated with cancer. This impressive effort suggests that an individual breast cancer harbors an average of about 90 mutant genes, of which a small minority (~12) are expected to contribute to the neoplastic process. Unfortunately for ease of therapeutic development, the functionally important mutations often differ among tumors (i.e., no tumor had more than six mutated cancer genes in common with any other tumor). However, when the genes were analyzed by functional groups, mutations in signal transduction pathway and transcription factor genes were found in nearly all breast tumor samples. These preliminary results have begun to allow a more complete genetic characterization of tumors, which will undoubtedly yield novel biologic and therapeutic insights in the near future.

Molecular Profiling in Breast Cancer

Simultaneous genome-wide determination of the relative abundance of RNA species (i.e., *transcriptional profiling*) combined with novel bioinformatic approaches has led to the development of molecular classifications based on continuous expression ranges of thousands of genes (as opposed to a binary determination of discrete factors, i.e., ER/PR and HER2). Tumors can be classified either according to transcripts that tend to segregate together according to underlying biologic differences (*unsupervised clustering*) or sorted by a given endpoint such as prognosis or response to therapy (*supervised clustering*). The first of these studies identified an "intrinsic gene list" of 534 genes that defined five biologic subtypes of breast cancer including the basal type (HER2-positive, cytokeratins 5 and 17 positive), the "triple negative" type (HER2-, ER-, and PR-negative), two luminal types (so-called luminal-A and luminal-B), and the normal-like type (Fig. 95-2).[94] Studies by others have confirmed large-scale gene

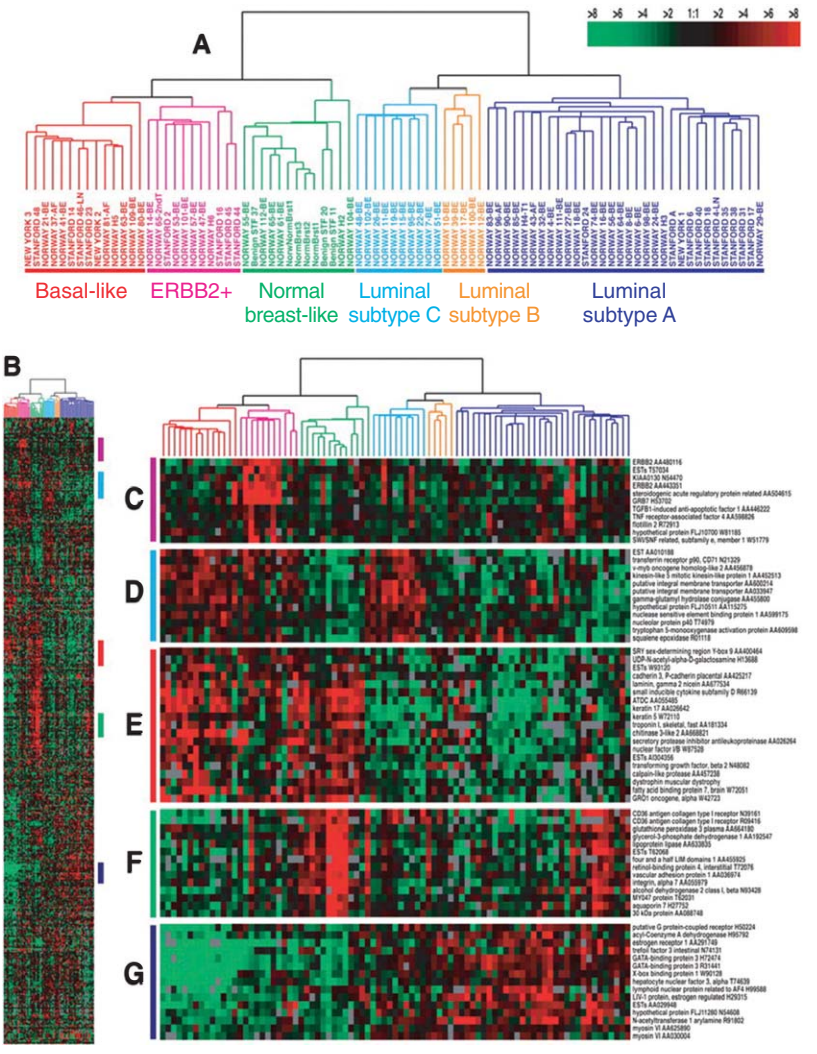

Figure 95-2 • Hierarchical clustering of 115 tumor tissues and 7 nonmalignant tissues using the "intrinsic" gene set. **A,** Scaled-down representation of the entire cluster of 534 genes and 122 tissue samples based on similarities in gene expression. **B,** Experimental dendrogram showing the clustering of the tumors into five subgroups. Branches corresponding to tumors with low correlation to any subtype are shown in gray. **C,** Gene cluster showing the ERBB2 oncogene and other coexpressed genes. **D,** Gene cluster associated with luminal subtype B. **E,** Gene cluster associated with the basal subtype. **F,** A gene cluster relevant for the normal breast-like group. **G,** Cluster of genes including the estrogen receptor (ESR1) highly expressed in luminal subtype A tumors. Scale bar represents fold change for any given gene relative to the median level of expression across all samples. (From Sorlie TR, Tibshirani R, Parker J, et al: Repeated observation of breast tumor subtypes in independent gene expression data sets. Proc Natl Acad Sci USA 2003;100: 8418–8423.)

expression differences between ER-positive and ER-negative tumors and have shown additional molecular subsets within these categories.[95] This molecular classification of breast cancer is robust in that it is observed regardless of microarray platform type, and the various subtypes correlate with overall prognosis. Luminal-type cancers have the most favorable long-term survival, whereas HER2-positive and basal-like cancers may be more sensitive to chemotherapy but have the worst overall prognosis.[96,97] Thus, breast cancer is not a single disease with heterogeneous ER and HER2 expression but appears to be comprised of three to five molecularly and clinically distinct subtypes.

A similar approach can be taken by assaying DNA amplifications and deletions across the genome.[98] Such data recently have been mapped against both the "intrinsic gene set" and clinical outcome data, and have the potential to identify high-level DNA amplification that, similar to HER2, may be useful as therapeutic targets.[99] However, it should be noted that while these classifications are robust across a population, there is no standardized assay of measurement for assigning a molecular class to a new individual case. Furthermore, much of the molecular heterogeneity overlaps with conventional histopathology and is captured by determination of ER, PR, HER2 status, and tumor grade.[95]

In addition, while the intrinsic gene set and its derivations correlate with prognosis, this correlation does not easily translate into the specificity and sensitivity required for clinical decision making. One of the greatest clinical challenges has been determining the value of adjuvant chemotherapy for individual women with early-stage breast cancer, where many patients are treated but only a few benefit directly.

Several multigene prediction scores that correlate with outcome and provide more accuracy than traditional histopathologic markers have been retrospectively derived from microarray data, and, in some cases, prospectively validated on additional datasets. The best known examples are a 70-gene predictor set (Fig. 95-3)[100,101] and a 21-gene predictor set.[102,103] Both of these assays measure RNA levels by qPCR technology (which provides a less expensive and more robust method than microarrays as well as a larger dynamic range) and both have been submitted to the U.S. Food and Drug Administration (FDA) for approval. The 21-gene test is commercially available (Oncotype Dx, Genomic Health). It consists of only 16 target transcripts (and 5 reference transcripts), three of which are ER, PR, and HER2. However, there is an additional "proliferation" group of 5 genes (which includes Ki67 and cyclin B1) and a carefully constructed weighted formula to determine the overall "recurrence score."[102] Although this recurrence score provides a continuous risk variable, for clinical use it is pared down to three categories of low, intermediate, and high (of note, given the weighting schema, it is unlikely that a HER2-positive tumor would be classified as "low risk"). It is interesting that these two gene sets as well as the "intrinsic gene set" described earlier and yet another "wound healing" signature all seem to perform similarly when tested against the same clinical data set, even though they share few to none of the same genes.[104] The ability

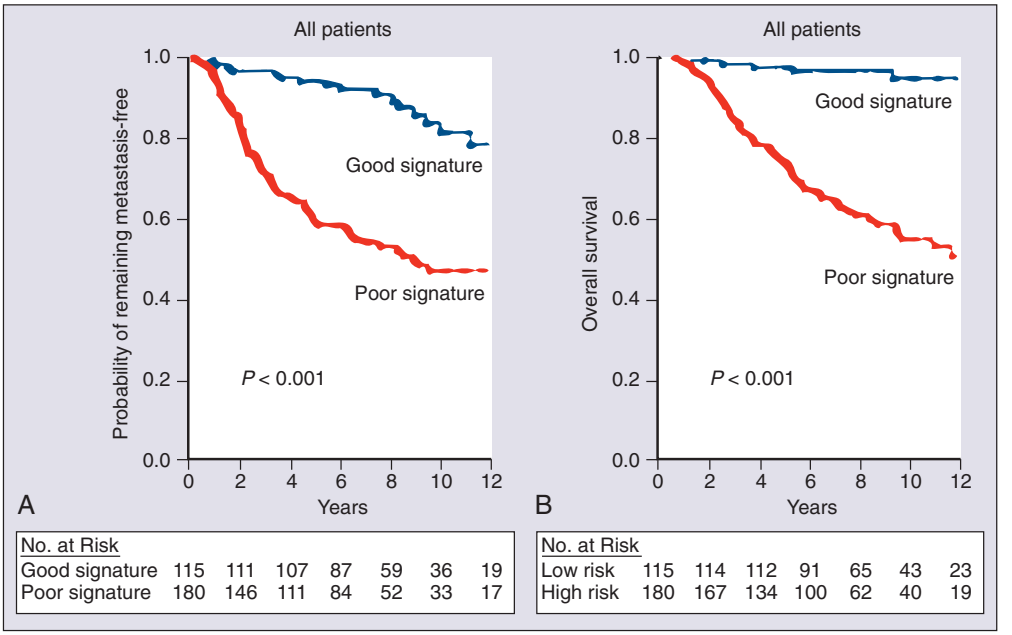

Figure 95-3 • Performance of a microarray-derived 70-gene multigene signature. Kaplan-Meier analysis of the probability that patients would remain free of distant metastases (**A**) and the probability of overall survival among all patients (**B**) according to whether they had a good-prognosis or a poor-prognosis signature. The performance of the signature also was determined separately for patients with lymph node-negative and lymph node-positive disease. The *P* values were calculated with use of the log-rank test. (Reproduced with permission from van de Vijver MJ, He YD, van't Veer LJ, et al: A gene expression signature as a predictor of survival in breast cancer. N Engl J Med 2002;347: 1999–2009.)

of the 70-gene assay to determine which ER-positive node-negative patients are most likely to benefit from adjuvant therapy will be prospectively tested in the Microarray in Node-Negative Disease May Avoid Chemotherapy (MINDACT) trial. Similarly, the Trial Assigning Individualized Options for Treatment (Rx) (TAILORx) study will prospectively test the utility of adjuvant chemotherapy in patients who have an "intermediate risk" according to the test; low-risk patients will not receive therapy, whereas all high-risk patients will be treated. These assays have the potential to revolutionize the way therapy is individualized in the adjuvant setting. However, by providing a continuous variable risk assessment (as in the case of the Oncotype recurrence score) they add complexity to the clinical decision-making process, which hitherto was binary in nature (i.e., ER positivity determines anti-estrogen therapy, HER2 positivity determines anti-HER2 therapy).

Disseminated and Circulating Tumor Cells

From 20% to 45% of patients with primary operable breast cancer and 70% of patients with metastatic disease have disseminated tumor cells (DTCs) that can be detected in bone marrow[105] or in lymph nodes.[106] Historically, DTCs usually have been evaluated by IHC staining for various cytokeratin markers. While their existence has been associated with a worse prognosis,[105] the need for a relatively invasive procedure (a bone marrow biopsy) and the lack of sufficient specificity and sensitivity as well as method standardization has prevented the routing use of such information in clinical decision making.[107] However, it is now possible to measure circulating tumor cells (CTCs) accurately using an automated immunobead enrichment followed by pan-cytokeratin staining. Using this approach, patients with metastatic breast cancer and five or more CTCs per 7.5 mL of blood are predicted to have a significantly worse disease-free survival (2.1 vs. 7 months) and overall survival (8.2 vs. 18 months) than patients with fewer CTCs.[108] This measurement may enable routine minimally invasive assessment of disease progression and response to therapy. Furthermore, the ability to isolate CTCs allows the study of molecular markers such has HER2 amplification and their relationship to the primary tumor[109] in real time. This approach has the potential not just to monitor patients but also to select specific therapy based on a molecular diagnosis obtained at the time of therapy (as opposed to relying on the original diagnostic biopsy.[110] The clinical utility of CTCs is now being prospectively tested in a trial randomizing patients with 5 or more CTCs per 7.5 mL after 1 month of therapy to continue the same course or change systemic therapy.

Breast Cancer Stem Cells

Cancer cells have two somewhat contradictory traits. Although they originate from a single clone, they often display marked genetic, biologic, and morphologic heterogeneity. Historically, the prevailing hypothesis was that genomic instability contributed to continuing evolution and emergence of different and ultimately more virulent subclones. This theory has been invoked to explain both progression (in terms of metastatic spread) and emerging resistance to therapy. Recently, an alternative explanation was provided by ground-breaking work elucidating the "cancer stem cell" model[111] (Fig. 95-4). Initially demonstrated in hematologic reconstitution and malignancies, cancer stem cells, while constituting a small minority of the cancer cell mass, retain the capacity for asymmetric division where they both self-renew and give rise to more differentiated daughter cells. The latter, while forming the bulk of the tumor, are themselves incapable of endless replication. Given that stem cells are long-lived and slow to replicate, this would explain both the accumulation of genetic lesions over time as well as resistance to therapy targeting dividing cells. It would also explain the frequently observed concordance between primary and metastatic cells. For a long time this model for epithelial cancers has been theoretical, as it was technically difficult to identify these cells. However, recently such cells have been isolated from both normal mammary glands and breast cancers, based on the presence and absence of specific surface markers. Thus, in mice, a single $^{Lin+D29}$(hi)CD24^{-} cell can reconstitute a complete functional mammary gland in vivo, contributing to both luminal and myoepithelial lineages.[112] Similarly, the ability to reconstitute human breast cancers in immunocompromised mice seems to reside within a minority CD44^{+}, CD24(−/low) subclone. Notably, tumors formed by these cells gave rise to mixed populations of epithelial cells, recapitulating the morphology of the parent tumor.[113] These findings have several important implications for breast cancer therapy. As a first step, the molecular and biochemical pathways that control CSC division (such as Wnt and Notch pathways) provide novel targets for therapy.[114]

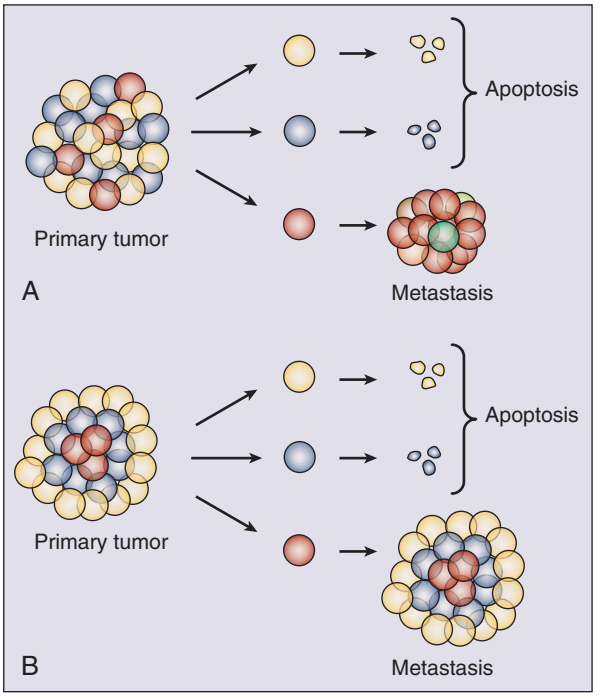

Figure 95-4 • Impact of the cancer stem cell (CSC) model on the origin and biology of metastases. **A,** According to standard cancer models, tumors are composed of heterogeneous mixtures of independent subclones, originated by divergent genetic mutations; different subclones are endowed with different functional properties, and only selected clones (*orange cells*) can migrate and form metastases. The metastasis is predicted to be a homogeneous monoclonal expansion of an individual subclone, which in turn can accumulate further mutations (*blue and yellow cells*) and diverge even further from the primary tumor. Overall, the model predicts that primary tumors and corresponding metastases are substantially different. **B,** The CSC model assumes that intratumor heterogeneity is caused mainly by cell differentiation, and that only CSCs (*orange cells*) can migrate and form overt metastases, while differentiated cells (*yellow cells*) undergo apoptosis. In the CSC model, metastatic cancer tissues undergo differentiation programs that closely resemble those observed in the corresponding primary tissues. Recent experimental evidence based on gene-expression microarrays tends to support the CSC model for human epithelial tumors, such as breast and colon cancer. The two hypotheses are not mutually exclusive, and elements of both are probably true. (Reproduced with permission from Dalerba P, Cho RW, Clarke MF: Cancer stem cells: models and concepts. Annu Rev Med 2007;58:267–284.)

MANAGEMENT OF PATIENTS AT HIGH RISK FOR BREAST CANCER

Once an individual patient's risk has been estimated, it is a matter of personal opinion as to what constitutes high risk. For many women, a relative risk of 1, with a lifetime probability of 1 in 8 of being diagnosed with breast cancer, is already high. For others, a relative risk of 2 or more would be considered high risk. Whatever criteria an individual physician and patient use to define high risk, four possible actions may be taken, some of which can be used simultaneously: (1) enhanced surveillance; (2) behavioral modification; (3) chemopreventive strategies; and (4) prophylactic mastectomy or oophorectomy.

Increased Surveillance

As discussed in the section on mammographic screening, the United States Preventive Task Force recommends screening mammography, with or without clinical breast examination, every 1 to 2 years for women 40 years of age and older. Although this task force recommended mammographic screening only as a category B intervention on the grounds that the quality of evidence was fair and the net gain moderate, and although controversy remains about the utility of routine screening before 50 years of age, ample evidence supports increased surveillance in women at high risk for breast cancer. A number of prediction models for breast cancer risk are available, and surveillance strategies are developing rapidly, particularly for women who are BRCA1 and BRCA2 mutation carriers.[115]

There is general agreement that women at high risk for breast cancer are candidates for mammographic surveillance in their 40s, and in some cases, earlier initiation of mammographic screening may be appropriate. Shorter screening intervals may be necessary because of the accumulating evidence of unacceptably high rates of interval breast cancers, even with annual screening, in BRCA1 and BRCA2 mutation carriers. Additionally, other imaging modalities, such as magnetic resonance imaging (MRI), must be considered in these high-risk groups. Finally, although controversy remains about the role of breast self-examination in the general population, experts in the surveillance of high-risk women still recommend monthly breast self-examination for women with BRCA1 and BRCA2 mutations.[116]

Behavior Modification

Multidisciplinary centers that provide counseling for women who are at substantial risk for breast cancer are well established throughout the United States. These multidisciplinary consultations provide recommendations for a range of surveillance and interventional approaches. In addition to the available surgical and medical preventive strategies, modification of lifestyle factors, such as obesity, high-fat diet, alcohol consumption, and lack of exercise, should be discussed. It probably will be many years before it is possible to say conclusively whether lifestyle modification changes a woman's risk. In the meantime, patients and their physicians must choose whether and how to modify lifestyle factors.

Chemoprevention

Tamoxifen was studied as a chemopreventive agent for breast cancer in four randomized prospective clinical trials. A significant reduction in breast cancer risk with tamoxifen was seen in the National Surgical Adjuvant Breast and Bowel Project (NSABP) P-1 study[117] and the International Breast Cancer Intervention Study (IBIS-I).[118] Futher analysis of the patients in the NSABP P-1 study showed that tamoxifen reduced the incidence of breast cancer among BRCA2 carriers by 62%, but not among BRCA1 carriers.[119] However, two European chemoprevention studies performed at the Royal Marsden Hospital[120] and by the Italian Tamoxifen Prevention Study Group, respectively, did not show a decrease in the incidence of breast cancer in women using tamoxifen.

Based in large part on compelling evidence from the NSABP study, which showed a 49% reduction in overall risk of invasive breast cancer with the use of tamoxifen, a number of review groups, including the American Society of Clinical Oncology Technology Assessment Working Group, recommended that tamoxifen should at least be considered to reduce the risk of breast cancer in women with a defined 5-year projected risk of 1.66 or greater. However, this group of studies had considerable methodologic differences, and further studies are needed to better define the role of chemoprevention in high-risk women. Furthermore, the NSABP study was not designed to show a difference in death rate from breast cancer as a primary endpoint.

Two selective estrogen-receptor modulators (SERMs), tamoxifen and raloxifene, were compared in the NSABP STAR trial and showed similar outcomes regarding invasive but not in situ disease.[121] The International Breast Cancer Intervention Study (IBIS-II) is randomizing high-risk postmenopausal women to receive the aromatase inhibitor anastrozole or placebo. It is not known whether SERMs

reduce the incidence of breast cancer by preventing the formation of cancer or by a treatment effect on small, clinically occult cancers. The use of these agents outside of a clinical trial requires an in-depth assessment of the risks and benefits of using the specific drug in an individual patient.

Prophylactic Mastectomy or Oophorectomy

Prophylactic mastectomy and oophorectomy are controversial preventive approaches to breast cancer. In recent years, considerable new data have been obtained on the use of these prophylactic surgical procedures in patients with hereditary breast or ovarian cancer syndrome. Current data show that prophylactic mastectomy is effective in preventing breast cancer in patients with either a strong family history of breast and/or ovarian cancer[122] or a genetic predisposition to breast cancer.[123] Additional data show that prophylactic contralateral mastectomy can reduce the risk of breast cancer in patients with a previous diagnosis of unilateral disease.[124] A high prevalence of premalignant lesions is seen in prophylactically removed breasts from women who are at hereditary risk for breast cancer.[125]

The total and incremental life expectancy with prophylactic mastectomy is difficult to demonstrate. Statistical analysis has shown that depending on the assumed penetrance of the BRCA mutation, compared with surveillance alone, 30-year-old patients with early-stage breast cancer who have BRCA mutations may gain 2.9 to 5.3 years from prophylactic bilateral mastectomy and 0.6 to 2.1 years from prophylactic contralateral mastectomy.[126] Still controversial is the gain in quality of life in these high-risk women who chose to have prophylactic mastectomy.[127]

Oophorectomy was first performed as a therapeutic procedure for advanced breast cancer over 110 years ago and as hormonal adjuvant treatment of primary breast cancer over 50 years ago. Uncertainty remains about the appropriate use of oophorectomy in adjuvant treatment, so it is not surprising that preventive oophorectomy in high-risk women remains controversial. Again, the identification of women with BRCA1 or BRCA2 mutations has provided an opportunity to study this prophylactic procedure. Initial results show that bilateral prophylactic oophorectomy reduces the risk of breast cancer and epithelial ovarian cancer in this population.[128]

DETECTION OF BREAST CANCER

Despite a lifetime probability currently estimated as 1 in 8 (in women who live to be 110 years of age) for breast cancer, only 30% of all women have one or more identifiable risk factors. Although these risk factors affect the parameters for breast cancer screening, current screening and education programs must include all women. The goal of breast cancer screening is early detection that will lead to a reduction in mortality. For breast cancer, the ideal screening program is sensitive enough to detect occult cancer with a minimum of false-positive findings. In addition, a screening program for breast cancer should be safe, relatively easy to provide to the public, acceptable to both patients and physicians, and cost-effective. A lower stage at diagnosis is associated with improved 5-year survival (Tables 95-2 and 95-3).[6]

During the last 40 years, an intense effort has been mounted to evaluate the efficacy of mammography, clinical breast examination, and patient self-examination as tools for breast cancer screening. These efforts have included a number of case-control and cohort clinical trials as well as eight major randomized, prospectively controlled studies. More than 650,000 women have participated in the randomized trials alone.[129]

Film screen mammography was the "gold standard" for many years. However, a randomized comparison with the new generation of digital mammography images concluded that both provide an equivalent level of detection overall, although digital images were superior in pre- and perimenopausal women with dense breasts and women under the age of 50.[130] Digital imaging offers a lower average dose of radiation, improvement in storage and retrieval, and easier access to images and computer-assisted diagnosis, which must be weighed against the higher cost of digital imaging equipment.

Computer-aided diagnosis enables a digital reading of the mammogram to identify areas that meet a computer pattern of discrimination. Newer applications "learn" from the radiologist's over-read of their identification points and are being evaluated.[131,132] The goal for optimizing breast cancer screening must be a higher rate of false-positive findings so that the risk of false-negative findings may be virtually eliminated. In breast cancer screening, the discovery of smaller tumors has the added benefit of increasing the number of patients who can be treated by breast-conserving approaches. Although mammography is the best screening tool, it detects only 85% to 90% of biopsy-proven cancers. Mammography is not a substitute for tissue sampling and histologic evaluation of any palpable abnormality, nor is it a substitute for careful physical examination. Other imaging tools are also under evaluation for early detection of breast cancers in young women with dense breasts. These are discussed in the following section.

Screening

The efficacy of screening for occult cancer depends heavily on the following factors: (1) tumor growth rate; (2) the sensitivity of the test related to tumor volume; and (3) the interval between screens. Growth rates of breast cancer vary, and some younger women have more rapidly growing tumors. In determining the efficacy of screening, four biases must be considered: lead-time bias, length bias, selection bias, and overdiagnosis bias. Lead-time bias is the interval that the diagnosis has been advanced by screening. Length bias concerns the timing of detection. When screening is infrequent, fast-growing tumors are not detected as early in their natural history as more slowly growing tumors. Thus, the outcome of cancers detected by screening is better than that for interval cancers. Selection bias is an obvious factor. For example, women who participate in breast cancer screening may have been shown to be more health conscious; they also are more likely to obtain Pap smears, use seat belts, and not smoke.[133] Thus it is likely that their outcomes would be better, even in the absence of screening. Overdiagnosis has always been a concern in screening for cancer. Detection of breast lesions of questionable malignancy affects mortality data, because these lesions would not be diagnosed without screening. It is not known how many of these very early in situ cancers would progress to become invasive malignancies.

These biases complicate the design and evaluation of screening trials. In evaluating the results of screening trials, several points must be remembered. First, the survival and case fatality rates of patients with breast cancer are not adequate endpoints for determining results. Second, the closest endpoint for studying the mortality rate in a population is an observed reduction in the incidence of advanced disease. Finally, if screening detected an excessive number of cancers that were not destined to be lethal, then the death rate among the screened women would not be altered and no benefit would be observed.

Before 1977, no formal guidelines existed for screening women for occult breast cancer. The publication of the Health Insurance Plan (HIP) of Greater New York Screening Project, conducted in the 1960s, led the NCI and the American Cancer Society to support a nationwide breast cancer screening project to evaluate further the efficacy of screening by mammography and physical examination. The Breast Cancer Detection Demonstration Project (BCDDP) took place in 29 centers, and 280,222 women were screened over a period of 5 years.[134]

Although the study is well documented, it is important to review the design and findings of the HIP landmark clinical trial. The HIP study invited women 40 to 69 years of age who were enrolled in the

HIP of Greater New York to be screened for breast cancer. The HIP project was the first randomized controlled trial and included annual clinical examinations and mammography for 4 years. Using pairwise allocation, 62,000 women were randomized to the study group or the control group. Of the total population, 45% were 40 to 49 years of age at study entry. Of the 31,000 women in the study group, 65% attended one or more screening sessions. Because it was not possible to identify within the control group women who would decline screening, the outcome of the control group was evaluated in relation to the total study group.

A surprising aspect of the initial evaluation of the results was the striking difference in the effectiveness of screening at different ages. At 5 years, the HIP study found a 50% decrease in mortality rate in women older than 50 years of age, but only a 5% decrease in mortality rate in women younger than 50 years of age. However, after further follow-up, this difference in effectiveness began to change. With follow-up, the mortality rate in women younger than 50 years of age showed a 23.5% decrease, and it became statistically significant at year 18 of follow-up. In women older than 50 years of age, the reduction in mortality became evident at approximately the fourth year of follow-up. Significantly, a reduction in mortality rate in younger women took longer than a decade to manifest. Women who refused screening or who had interval cancers had no reduction in mortality rate.

For the first time, the results of the HIP study provided strong evidence that early detection of breast cancer increased the duration of survival. Since the HIP trial was published, seven additional randomized trials of mammography and two of breast self-examination have been reported. The results of these trials have been included in a meta-analysis commissioned by the The United States Preventive Service Task Force (USPSTF)[129] (Table 95-4). Between the ages of 39 and 74 years, the summary relative risk for death from breast cancer was 0.84% for the use of screening mammography. Much like the findings of some of the individual studies included in this analysis, greater reduction in risk was seen in women over the age of 50 years. The summary relative risk for women 40 to 49 years old was 0.85, compared to 0.78 for those 50 years of age and older. Of interest, this same meta-analysis noted "direct evidence of effectiveness among older women, limited to two trials that included women over 65 years of age."

The controversy about the efficacy of screening for women 40 to 49 years of age is ongoing because breast cancer is less frequent in this age group, and there is a greater likelihood that mammographic abnormalities will prove benign on biopsy. To further address this controversy, the Cancer Screening Evaluation Unit in Sutton, in the United Kingdom, conducted a trial called Age, directed at women ages 39 to 41, comparing annual screening mammogram with routine medical care. In selecting this age group, the trial targeted women who would still be younger than 50 years through 10 years of follow-up screening. This trial did demonstrate "a reduction in breast cancer mortality in the intervention group, in relative and absolute terms, which did not reach statistical significance.[135] Table 95-5 lists the screening guidelines for mammography for the American College of Radiology (ACR), the National Comprehensive Cancer Network (NCCN), and the NCI.

Patient Compliance

Over the last decade, aggressive public education programs conducted by the American Cancer Society, the NCI, and public interest groups have led to a dramatic increase in mammographic screening in the United States. A particular concern was its marked underuse by minority women, although the use of mammography has increased dramatically and the racial gap has virtually disappeared. A recent study concluded that ethnicity was "not associated with seeking and obtaining a screening mammogram, once socioeconomic factors are considered."[133] Interventions associated with an increased use of screening included providing women with information, especially if by a health care provider urging compliance, and vouchers for free mammography. Media intervention has little effect on compliance and limited long-range benefit, but educational interventions targeting primary care physicians should become a priority.

Sensitivity of Mammography

Mammography is more effective in detecting occult malignancy as patients begin to age and breast tissue is replaced with fat. Breast

Table 95-5 National Organizations' Screening Guidelines for Mammography

ACS

For women for normal risk, yearly mammograms are recommended starting at age 40. CBE suggested about every three years for women in the (?) 30's and every year for women age 40 and above. BSE is suggested for women starting in their 20s.

NCCN

Women at normal risk are recommended to have CBE every 1–3 years; periodic SBE is encouraged. Beginning at age 40, annual CBE and mammograms are recommended, and periodic SBE is encouraged.

NCI

Women who are age 40 and above should be screened with mammograms every 1–2 years.

ACS, American Cancer Society; BSE, breast self-examination; CBE, clinical breast examination; NCCN, National Comprehensive Cancer Network; NCI, National Cancer Institute; SBE, self breast examination.

density most directly affects the risk of false-negative and false-positive interpretations; it is affected by several factors. Age is the most significant factor, because premenopausal women are more likely to have breasts that are more glandular and thus more dense. Mammographic sensitivity may be increased by scheduling evaluation during the first 2 weeks of the menstrual cycle, corresponding with the follicular phase. HRT in postmenopausal women may increase breast density.

The sensitivity, or accuracy, of mammography also is affected by the experience of the radiologist. Features with the highest positive predictive value for carcinoma were spiculated margins, irregular shape, linear calcification, and segmented or linear calcification distribution. In general, the positive predictive value of a Breast Imaging Reporting and Data System (BI-RADS) category 5 lesion is over 80%, while that of a category 4 lesion aproaches 30% to 40%. The last decade has seen the development of full-field digital mammography. A recent multicentric trial comparing conventional to digital mammography showed an improvement over conventional film mammography in the detection of breast cancer in young, premenopausal, and perimenopausal women, and in women who have dense breasts. However, there was no significant difference in diagnostic accuracy between digital and film mammography in the population as a whole or in the other predefined subgroups.[130]

Other Methods of Screening

To overcome some of the variables that affect the predictive value of mammography, a number of new technologies are being explored. Emerging techniques for breast screening, such as MRI, scintimammography, and ultrasound are under study in selected women who present difficulties in screening with mammography. Data increasingly suggest that women with very dense breasts and those with BRCA1 and BRCA2 mutations are more likely to have clinically occult carcinomas detected by other screening than by mammograms.[136] Women who meet the criteria for hereditary breast cancer, as defined by a careful, three-generation family history, should be considered for additional screening as well. Options include the following: (1) initiation of screening 10 years before the onset of a first-degree relative's breast cancer, or at 30 years of age; (2) the addition of MRI screening; (3) shorter screening intervals (e.g., every 6 months); and (4) the addition of ultrasound screening. A woman with BRCA1 or BRCA2 mutations may have a risk as high as 20% with certain mutations by 40 years of age, and MRI appears to be the most sensitive technique for screening these very young women.[137,138] The role of clinical examination and breast self-examination in high-risk women seems particularly limited.[116,139] Shorter screening intervals have been based on modeling data, and no prospective data have validated this recommendation. Although MRI shows improved sensitivity, it has lower specificity than mammography and may lead to additional fine-needle aspiration (FNA) or core biopsy in these young women at high risk.

Ductal lavage is promoted as a screening technique in asymptomatic women who are considered at increased risk. The goal of this technique was to stratify women at increased risk in terms of intervention (e.g., tamoxifen). Although numerous research studies are underway, no data recommend the use of ductal lavage, alone or in combination with other screening techniques, and the technique remains investigational. The sensitivity of ductal lavage to detect breast cancer in women with a known diagnosis treated with mastectomy has been shown to be low,[140] although molecular techniques may improve its yield.[141] The role of FDG-PET scanning for screening of the breast and axilla is limited.[142]

Screening in the Elderly Patient

The life expectancy for women (all races) in the United States increased from 77.4 years in 1980 to 80.4 years in 2002 (see http://www.cdc.gov/nchs/fastats/lifexpec.htm). Biologic parameters suggest a higher prevalence of higher-risk tumors in younger women, with lower-risk tumors (better differentiated and hormone receptor-rich) occurring in older women. Tabar and colleagues[143] showed that for a given tumor size, the likelihood of nodal involvement is lower in older women than in younger women, and these data in aggregate have led some to suggest that it may be appropriate to increase the screening interval to 2 years in older women. However, there are insufficient data to suggest an age when routine screening can be abandoned. At 75 years of age, the average additional life expectancy for a white or a black woman in the United States is 12 years or more. Even so, fewer elderly women are being screened annually, even those with a history of breast cancer. While the benefits from screening appear to be seen in all age groups, and even in patients with comorbid disease, the magnitude of the benefit appears to diminish with age and with the severity of comorbid illnesses. In fact, data from the U.S. National Health Interview Survey show an overall drop in the overall rate of mammography screening, from 70% in 2000 to 66% in 2005.[144]

MAMMOGRAPHIC ABNORMALITIES

The value of mammography relies heavily on the technical expertise available in obtaining the study as well as on the experience of the radiologist interpreting the study. Vigorous compression is essential to even out the breast tissue over the film to provide more uniform exposure. Compression decreases the possibility that glandular areas will obscure masses or calcification. It also avoids motion, which causes loss of fine resolution. Additional views may be required to image all of the breast tissue, especially tissue adjacent to the chest wall. Magnification films are valuable for evaluating areas of architectural distortion and fine calcification. Evidence supports the importance of significant experience in administering mammograms (radiographs) and interpreting the results. Distinct advantages for the patient occur when mammography is provided by a dedicated mammography unit with a full-time technical team and an experienced radiologist. When more than one radiologist specializing in breast radiology reviews films, the accuracy of interpretation is further increased, and evidence also suggests that that having mammography technologists review screening mammograms in addition to radiologist review may increase the rate of breast cancer detection.[145]

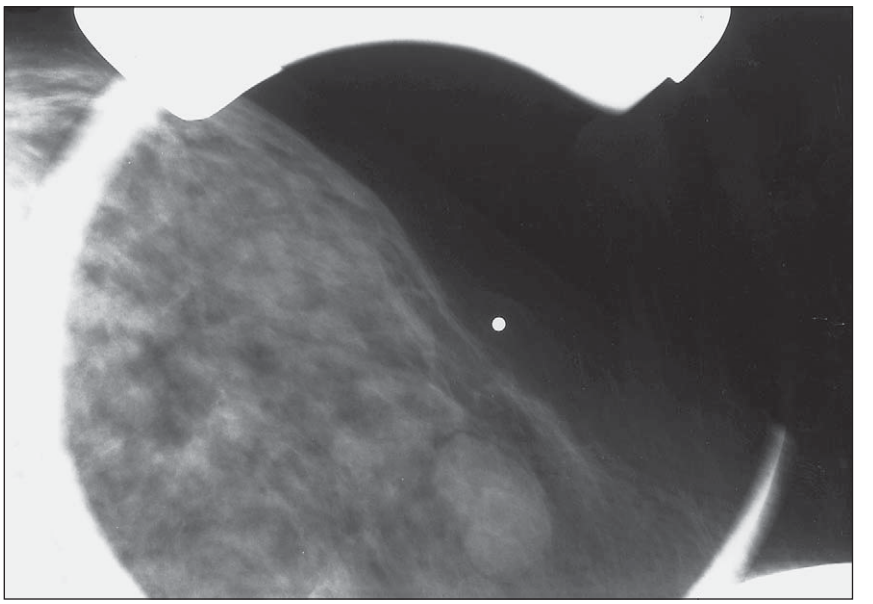

Figure 95-5 • Magnified view showing that a palpable lump is uniform in density, lacks microcalcifications, and has sharp, clear borders. Biopsy established the lump to be fibroadenoma.

Masses

Benign masses typically are well defined, with sharp margins, and have little effect on the surrounding breast architecture. Fibroadenomas, papillomas, intramammary lymph nodes, and cysts are the most common causes of benign mammographic density (Fig. 95-5). Malignant breast densities classically have irregular borders that blend into the surrounding tissue and often appear to infiltrate the breast background tissue with a stellate appearance. Usually, there is some distortion of adjacent breast stroma. The mammographic abnormality that has the highest rate of malignancy is a mass density with associated calcification (Figs. 95-6 through 96-8). Examples of questions that should be asked include the following:

- Is this really a mass? (it must be identified in more than one view, and special views may be required)
- Where is it located?
- Are there associated calcifications?
- Is the mass solid or cystic? (this usually requires ultrasonography)
- Is the mass new?

Calcifications

Malignant calcifications typically are linear, or small (<1 mm) in diameter, nonuniform in size, and clustered. Between 20% and 25% of clustered microcalcifications are positive for cancer on biopsy. Benign calcifications usually are larger and coarser, and are often round, with smooth margins. Table 95-6 lists various types and distributions of calcifications. Benign causes of microcalcification include involuting fibroadenoma, arteriosclerosis, sclerosing adenosis, fat necrosis, and previous mastitis with ductal calcium deposits.

Ultrasonography

Ultrasound is of greatest use when the mammographic findings are equivocal and when examination shows multiple areas of abnormal-

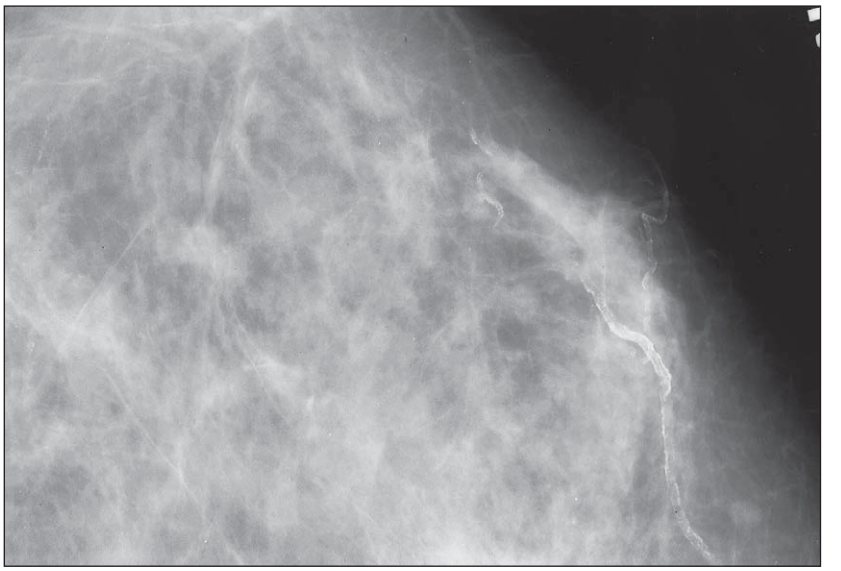

Figure 95-6 • Mammogram showing arterial calcifications in an otherwise normal examination.

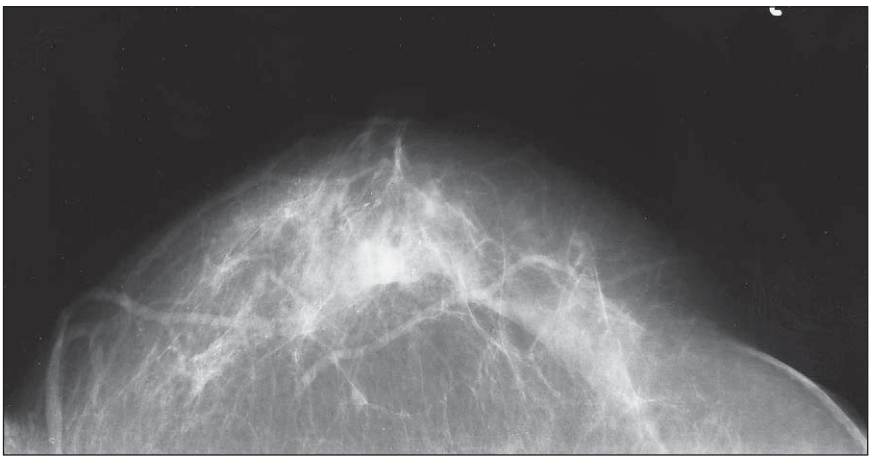

Figure 95-7 • Pleomorphic calcifications in an area of extensive ductal carcinoma in situ.

ity (Fig. 95-9). Ultrasonography is very accurate (>95%) in diagnosing breast cysts. Cysts have well-demarcated, smooth margins and an echo-free center (Fig. 95-10) and usually are rounded and thin-walled and produce distal shadowing. Clear cysts require no further evaluation. Complex cysts that contain evidence of tissue or debris may be aspirated to clarify whether they are simply cysts or represent cystic degeneration of a tumor.

Ultrasonic image texture analysis is an effective way to distinguish benign from malignant breast lesions. This technique is a simple way to reduce the number of biopsies performed on benign lesions without missing additional cancers. Doppler flow analysis may provide additional information about solid lesions. Malignant tumors show increased blood flow compared with benign tumors, resulting in a characteristic blood flow signal.

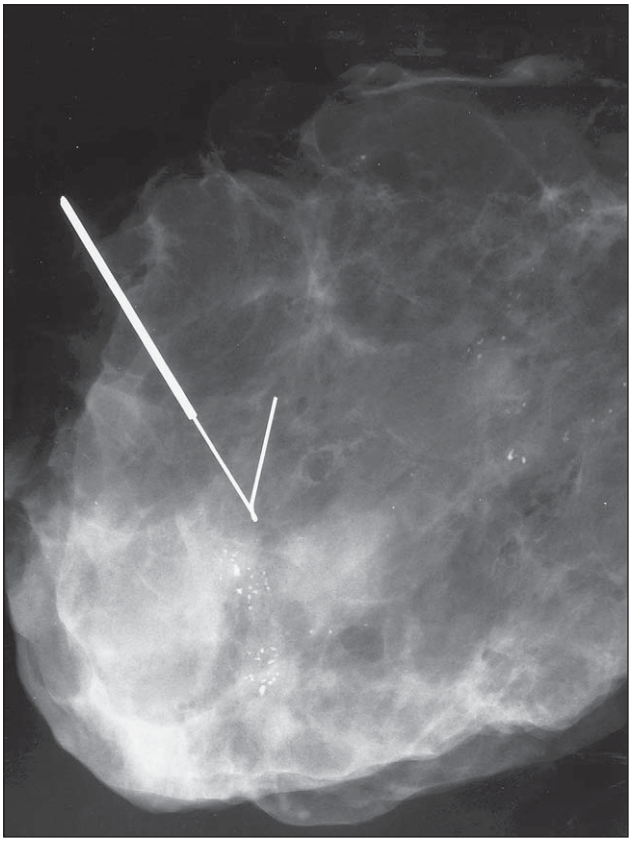

Figure 95-8 • Specimen radiograph confirming removal of the clustered microcalcifications. Histopathologic examination showed ductal carcinoma in situ.

APPROACH TO THE PATIENT

Management of the Palpable Mass

Finding a breast mass by accident or regular self-examination is not uncommon. One study found that 57% of all women presenting to an urban breast clinic in the year 1999 complained of a mass.[146] The determination of whether a palpable abnormality is malignant can be difficult, especially in premenopausal women. In general, if a palpable mass is determined to be solid, histologic diagnosis is required. An area of abnormal thickening in the breast that is not dominant and discrete (asymmetrical thickening compared with the same area in the opposite breast) usually suggests a benign change. Such areas of thickening may be safely observed for one or two menstrual cycles.

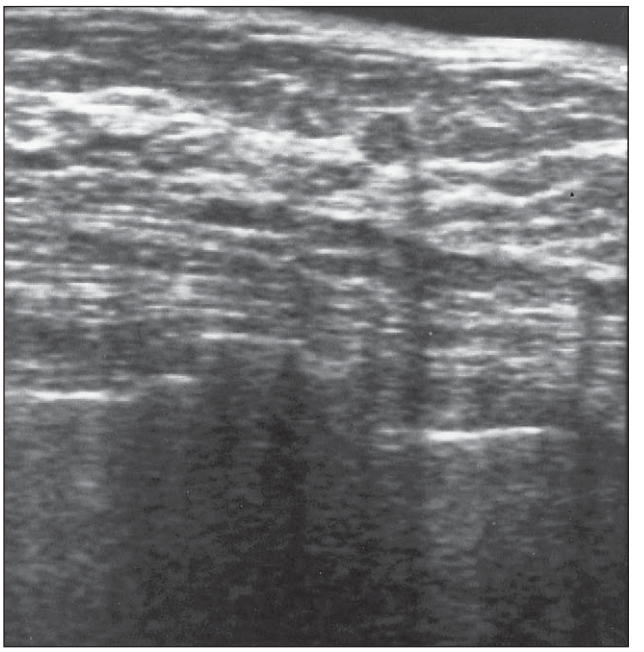

Figure 95-9 • Ultrasonography confirms the presence of a solid mass.

Table 95-6 Types and Distributions of Calcifications

Type of Calcification	Description
TYPICAL BENIGN	
Skin (dermal)	Typical lucent-centered deposits that are pathognomonic. Atypical forms may be confirmed by tangential views to be in the skin.
Vascular	Paralled track or linear tubular calcifications that are clearly associated with blood vessels.
Coarse or popcorn-like	The classic calcifications produced by an involuting fibroadenoma
Large rod-like	Benign calcifications forming continuous rods that occasionally may be branching. They usually are >1 mm in diameter, and may have lucent centers, if calcium surrounds rather than fills an ectatic duct. These are the kinds of calcifications found in secretory disease, "plasma cell mastitis," and duct ectasia.
Round	When multiple, they may vary in size. They usually are considered benign, and when small (<1 mm), they often are formed in the acini of lobules. When <0.5 mm, the term "punctate" can be used.
Lucent-centered	Benign calcifications ranging from <1 mm to ≥1 cm. These deposits have a smooth surface, are round or oval, and have a lucent center. The "wall" that is created is thicker than the "rim" or "eggshell" type of calcifications. Included are areas of fat necrosis, calcified debris in ducts, and occasional fibroadenomas.
Eggshell or rim	Very thin, benign calcifications that appear as calcium deposited on the surface of a sphere. These deposits usually are <1 mm thick when viewed on edge. Although fat necrosis can produce these thin deposits, calcifications in the walls of cysts are the most common "rim" calcifications.
Milk of calcium	Consistent with sedimented calcifications in cysts. On the craniocaudal image, they often are less evident and appear as fuzzy, round, amorphous deposits; on the 90-degree lateral view, they are sharply defined, similunar, crescent-shaped, curvilinear, or linear, defining the dependent portions of cysts.
Suture	Calcium deposited on suture material. They are relatively common in the postirradiated breast. They typically are linear or tubular in appearance, and knots often are visible.
Dystrophic	Calcifications that usually form in the irradiated breast or in the breast after trauma. Although irregular in shape, they usually are >0.5 mm in size. They often have lucent centers.
Punctate	Round or oval, >0.5 mm, with well-defined margins.
INTERMEDIATE CONCERN	
Amophous or indistinct	Often round or flake-shaped calcifications that are so small or hazy that a more specific morphologic classification cannot be determined
HIGHER PROBABILITY OF MALIGNANCY	
Pleomorphic or heterogeneous (granular)	Usually more conspicuous than the amorphic forms. They are neither typically benign nor typically malignant irregular calcifications. They vary in size and shape and are usually <0.5 mm in diameter.
Fine linear, or fine linear branching (casting)	Thin, irregular calcifications that appear linear, but are discontinuous and <0.5 mm wide. Their appearance suggests filling of the lumen of a duct involved irregularly by breast cancer.
DISTRIBUTION MODIFIERS	Used as modifiers of the basic morphologic description. These terms describe the arrangement of the calcification. Multiple similar groups may be indicated when there is more than one group of calcifications that are similar in morphology and distribution.
Grouped or clustered	Although historically the term "clustered" has connoted suspicion, the term is now used as a neutral distribution modifier and may reflect benign or malignant processes. It is used when multiple calcifications occupy a small volume (<2 mL) of tissue.
Linear	Calcifications are arrayed in a line that may have branch points.
Segmental	Worrisome in that their distribution suggests deposits in a duct and its branches, raising the possibility of multifocal breast cancer in a lobe or segment of the breast. Although benign causes of segmental calcifications exist (e.g., secretory disease), this distribution is of greater concern when the morphology of the calcifications is not specifically benign.
Regional	Calcifications scattered in a large volume of breast tissue and not necessarily conforming to a duct distribution. They are likely benign, but are not everywhere in the breast, and do not fit the other, more suspicious categories.
Diffuse/scattered	Calcifications that are distributed randomly throughout the breast.

Adapted from Breast Imaging Reporting and Data System: American College of Radiology, 1998, p 27.

Patients with a palpable mass or a new breast symptom should have mammography and often an ultrasound as well (Fig. 95-11). The goals of diagnostic mammography for patients with breast symptoms or positive findings on examination are different from the goals of screening. For the patient with a breast lump, the goals are to characterize the area of palpable abnormality, to evaluate the remaining breast for signs of additional occult lesions, and to evaluate the contralateral breast.

Whether a mammogram is obtained in women younger than 35 years of age depends on the character of the palpable abnormality (e.g., the level of concern about potential malignancy on examination). Ultrasonography is simple to perform and may distinguish a

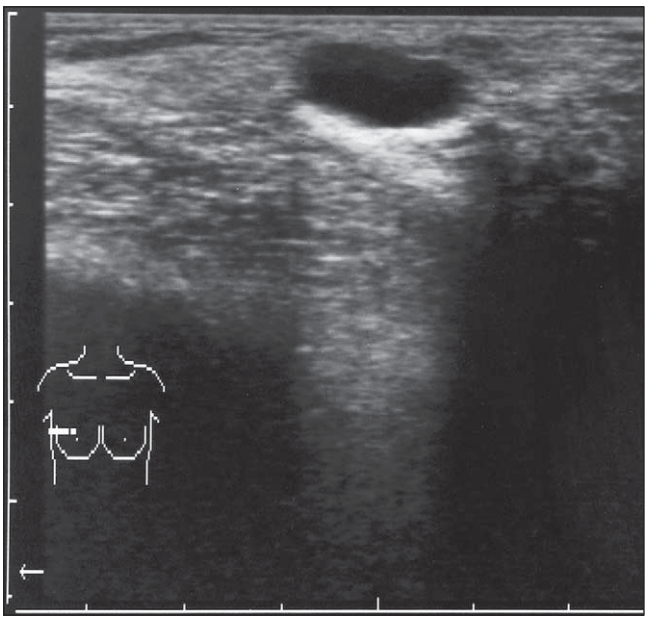

Figure 95-10 • Ultrasonography of the breast showing the palpable lump to be cystic. Cystic lesions have a characteristic hypoechoic pattern, with prominent acoustic shadowing.

solid from a cystic mass; a cyst usually can be aspirated. Cytologic examination of aspirated fluid is not indicated, because cysts rarely are positive for carcinoma. Follow-up of these patients in 3 to 4 months usually is indicated, and most breast surgeons excise a chronically recurring cyst or a cyst with bloody fluid.

A solid mass, as confirmed by mammography, ultrasonography, or needle aspiration, requires histologic confirmation of its character. If the cytologic findings indicate cancer, then definitive therapy is planned. If they do not, then cytologic or core biopsy diagnosis must be consistent with the findings that led to the biopsy. If the lesion is highly suspicious, negative findings on FNA or core biopsy will not completely remove suspicion unless they show a histologic explanation of the findings. When cytologic findings are nondiagnostic, excision of the lesion offers both patient and surgeon peace of mind. The finding of proliferative epithelium, or atypia, affects the risk of subsequent breast cancer. Atypical hyperplasia is found in 4% to 10% of benign biopsy specimens. Associated risk relates strongly to family history. Table 95-7 shows the relative associated risks for patients with benign histologic findings.

Core biopsy has some advantages with respect to FNA in evaluating a solid breast mass. The overall predictive value of a core biopsy is higher than FNA. The tissue sampling optained with core biopsy can diagnose the invasive component of the cancer, allowing final surgery with sentinel lymph node biopsy (SLNB) or axillary dissection to be scheduled. Both false-negative and false-positive rates of FNA and core biopsy depend on the expertise of the operator and

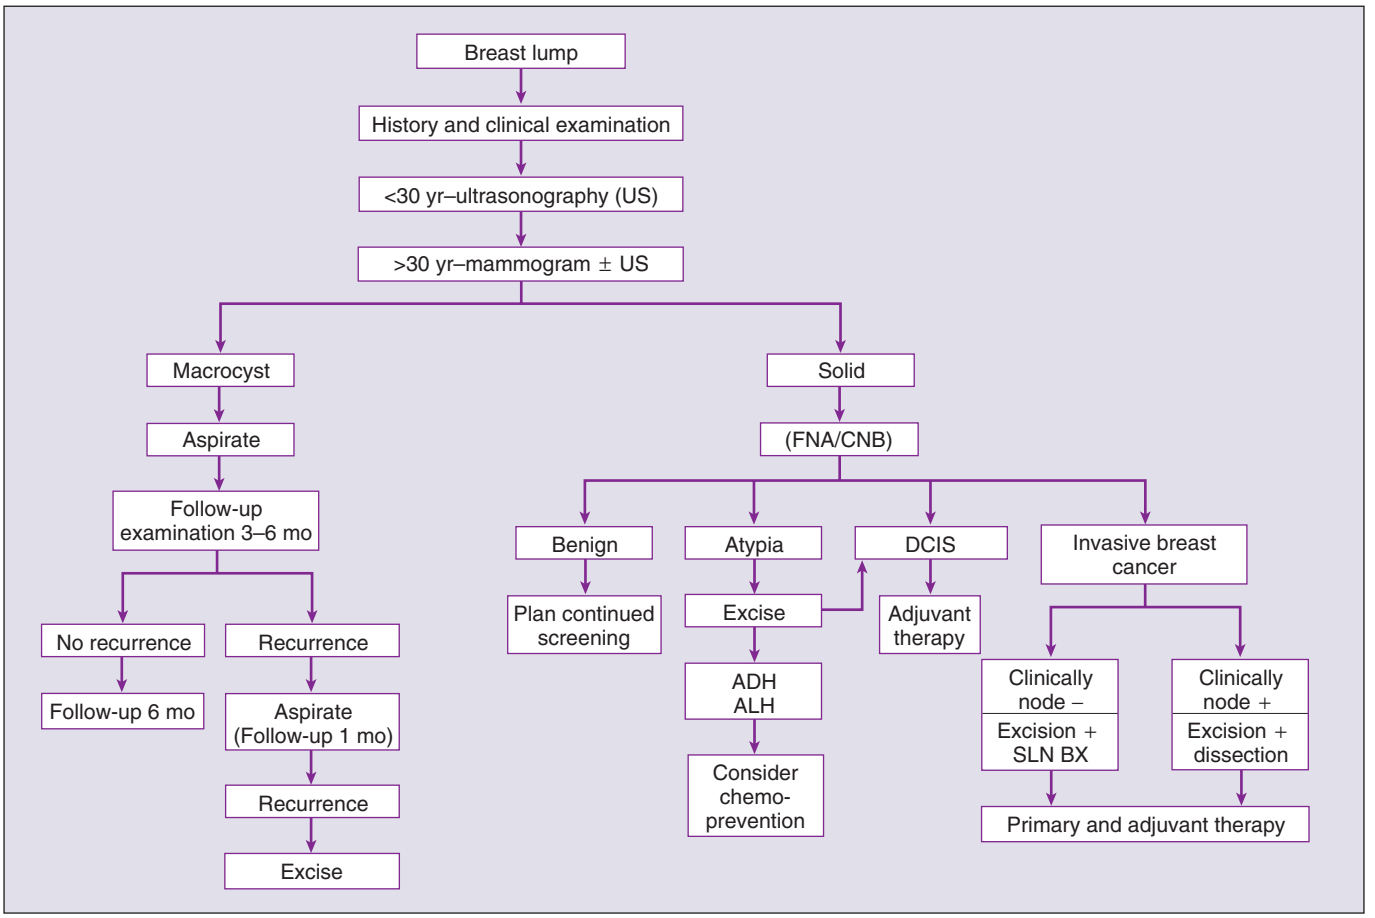

Figure 95-11 • Algorithm for breast lump management. ADH, atypical ductal hyperplasia; ALH, atypical lobular hyperplasia; CNB, core needle biopsy; DCIS, ductal carcinoma in situ; FNA, fine needle aspiration.

Table 95-7 American Board of Pathology Histologic Classification of Benign Disease

Histopathology	Approximate Relative Risk
Nonproliferative	No added risk
Cysts	
Duct ectasia	
Calcification	
Fibroadenoma	
Milk ductal epithelial hyperplasia	
Sclerosing adenosis	No added risk
Papillomatosis	Slight added risk
Radial scars	
Complex sclerosing lesions	?
Moderate florid hyperplasia	1.5:1 to 2:1
Atypical hyperplasia (ductal and lobular)	4:1
Extensive ductal involvement of atypical hyperplasia	7:1
Lobular carcinoma in situ	10:1
Ductal carcinoma in situ	10:1

pathologist. If physical examination and mammograms both suggest a benign lesion and FNA cytology or core biopsy findings are consistent, the likelihood of a missed breast cancer is extremely low. If the findings of any of the three tests are suspicious, a more aggressive biopsy to prevent progression of breast cancer is strongly recommended.

Management of the Nonpalpable Mammogram Abnormality

The health care provider often is faced with a patient who is asymptomatic and has a normal breast examination, but has an abnormal mammogram. The mammographic criteria for biopsy are fairly well accepted and include the following:

- A localized soft tissue density that was not previously seen on mammography
- A localized soft tissue density that has changed on successive studies
- A localized soft tissue density with ill-defined borders or stellate distortion of the stroma (or both)
- A focus of suspicious microcalcification, with or without soft tissue density (see Table 95-6)

If these findings are seen on screening mammograms, diagnostic mammograms—including magnification views—are required to confirm the abnormality. Often mammographic changes are not as clear as those listed in Table 95-6. The mammography report may state "cannot exclude an early breast cancer," or "clinical correlation is recommended." In these situations, all previous mammograms must be obtained for comparison. If the mammographic abnormality is believed to warrant histologic evaluation, several options exist: needle core biopsy (NCB) under ultrasound guidance if the abnormality is easily visualized by ultrasound; NCB using a dedicated stereotactic mammography unit; and wire localization and guided excisional biopsy with specimen radiography. Clearly, the expense of tissue sampling is considerably less if stereotactic NCB is used and proves reliable. Candidates for NCB include patients with highly suspicious mammographic findings, those with multiple suspicious lesions in the same breast, and those with lesions of low suspicion.

The procedure requires the patient to lie prone and to remain immobile for 30 to 45 minutes. NCB is not suitable for lesions that are close to the skin or for patients with very small or thin breasts (compressed to < 3 cm). NCB is not optimal in the evaluation of radial scars or areas of diffuse microcalcification. Studies evaluating the efficacy of NCB indicate that a biopsy needle larger than 14 gauge is preferred, because it significantly increases the rate of concordance with surgical biopsy. Approximately half to two thirds of patients diagnosed by stereotactic cores as having DCIS ultimately may be found to have invasive cancer. Similarly, when core biopsy shows atypical ductal hyperplasia, open surgical biopsy shows DCIS in 30% to 50% of cases. Thus, excisional biopsy is indicated in the following situations: (1) for a nondiagnostic core biopsy, (2) when atypical ductal hyperplasia is found, (3) when DCIS is present, (4) when the patient has a radial scar, and (5) when calcifications cannot be sampled. All patients with benign histologic features should have a 6-month follow-up two-view mammogram, and a system should be in place to ensure compliance.

When LCIS is found in a NCB, in situ or invasive cancer can be found in about 25% of cases at surgery.[147] On biopsy, approximately two benign tumors are found for each cancer that is discovered, but some authors argue that biopsy should be performed when the chance of finding cancer reaches 10%. Driving the rate of positive biopsy findings even lower, with the goal of decreasing the incidence of interval cancers, would significantly increase the overall cost of screening. The refinement in technology for the use of NCB suggests that this may be a way to reduce cost and provide an alternative to short-interval follow-up mammography. As with wire-localized biopsy, however, careful evaluation of the criteria for the use of NCB is required. Performing NCB biopsy on all patients would clearly defeat the goal of reducing cost. It is estimated that about 10% of women who undergo screening require either diagnostic biopsy or short-interval (4- to 6-month) follow-up. False-negative rates for NCB are reported to be as low as 2%, a rate similar to that for wire-localized guided excisional biopsies. No cost savings will occur if every negative stereotactically guided NCB is followed by excisional biopsy.

The techniques used for wire-localized excisional biopsy are shown in Figures 95-12 through 95–15. Wire-localized excisional breast biopsy is highly accurate and results in good to excellent cosmetic outcome. The key to success is the accuracy of the needle or wire placement, which should go directly into the area to be removed. Other techniques of preoperative localization using radioisotopes, radioactive seeds, and cryo-assistance, have been described with possible surgical advantages in obtaining more of the lesion in the surgical specimen and higher rate of negative margins.[148] The surgical specimen is sent to the radiology department, where it is filmed and compared with the mammogram to ensure that the suspicious lesion or microcalcifications are contained within the specimen. For patients with a benign biopsy finding, repeat mammogram is obtained 4 to 6 months later to re-establish a baseline and confirm clearing of the suspicious abnormality.

Management of the Magnetic Resonance Imaging Abnormality

With the increasing use of MRI in high-risk women for breast cancer, radiologists and breast surgeons often are faced with an MRI lesion not visible with mammography and ultrasound. A focal ultrasound in an MRI suspicious lesion fails to reveal a sonographic correlate in up to 77% of cases,[149] and MRI-guided percutaneous, vacuum-assisted biopsy should be performed. MRI percutaneous biopsy is not easily available, is expensive, and requires expertise.[150] Open surgical biopsy with MRI needle localization is the other option to diagnose a suspicious MRI lesion. Because the nonmagnetic wire used for the

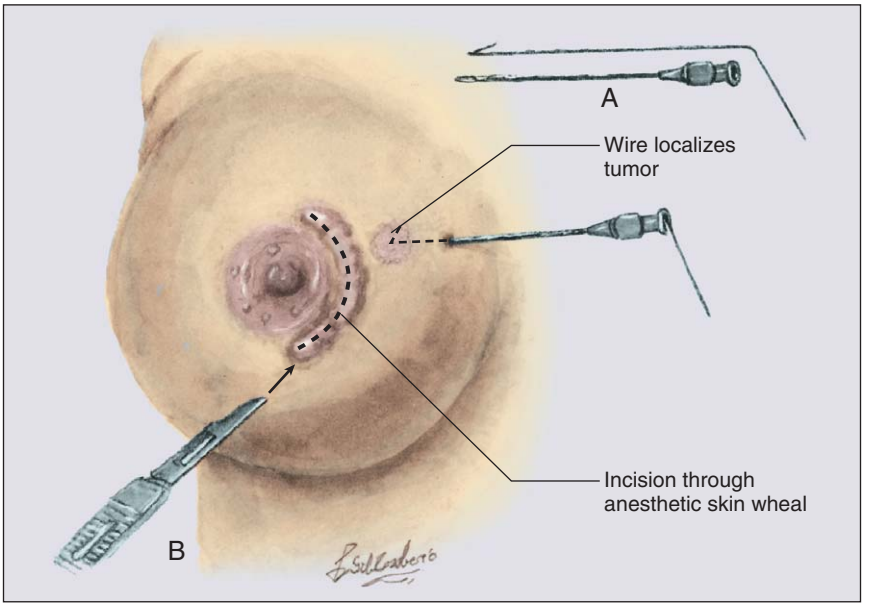

Figure 95-12 • Excision of nonpalpable mammographic abnormalities. **A,** Kopans hook wire and localizing needle. **B,** The incision is placed near or directly over the spot where the tip of the wire and the radiographic lesion are located. In this case, a circumareolar incision was ideal. The skin welt that is seen is the result of infiltration with local anesthetic (1% lidocaine with 1:200,000 epinephrine). (From Baker RR, Niederhuber J: The Operative Management of Breast Disease. Philadelphia, WB Saunders, 1994.)

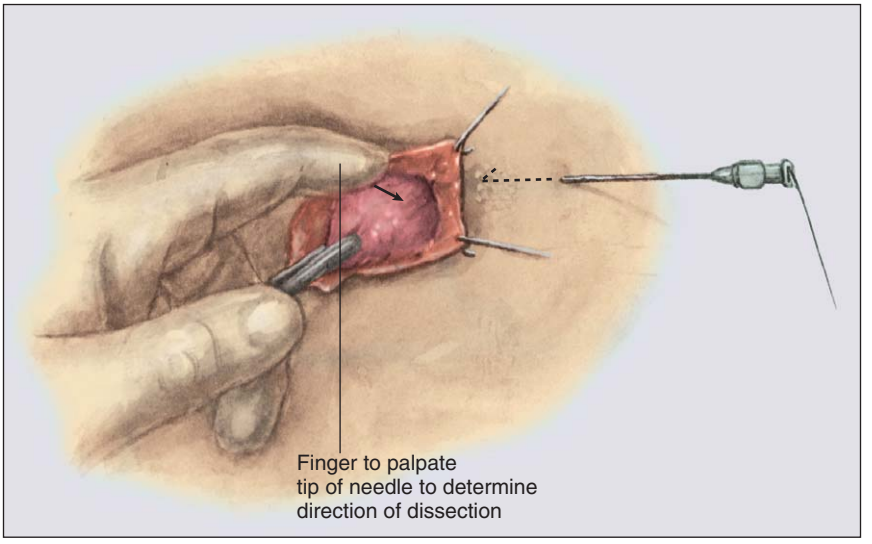

Figure 95-13 • Skin hooks are retracted as the surgeon raises a flap toward the point of entrance of the localizing needle. An Allis clamp is used to grasp the breast tissue as the area surrounding the end of the hook wire is dissected. (From Baker RR, Niederhuber J: The Operative Management of Breast Disease. Philadelphia, WB Saunders, 1994.)

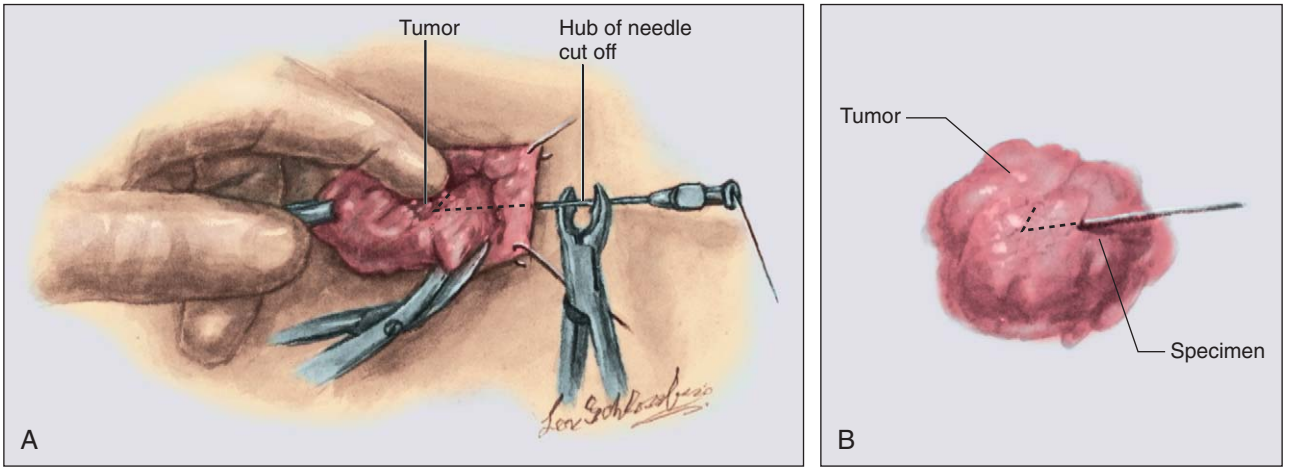

Figure 95-14 • **A,** The hub of the needle is cut off with a wire cutter, allowing the needle and wire to be passed through the skin flap. The surgeon can sharply excise the breast tissue that surrounds the tip of the hook wire, including the mammographic abnormality. **B,** After a specimen radiograph is taken to confirm the radiographic abnormality, the specimen containing the hook wire is oriented and marked for histopathologic assessment. (From Baker RR, Neiderhuber J: The Operative Management of Breast Disease. Philadelphia, WB Saunders, 1994.)

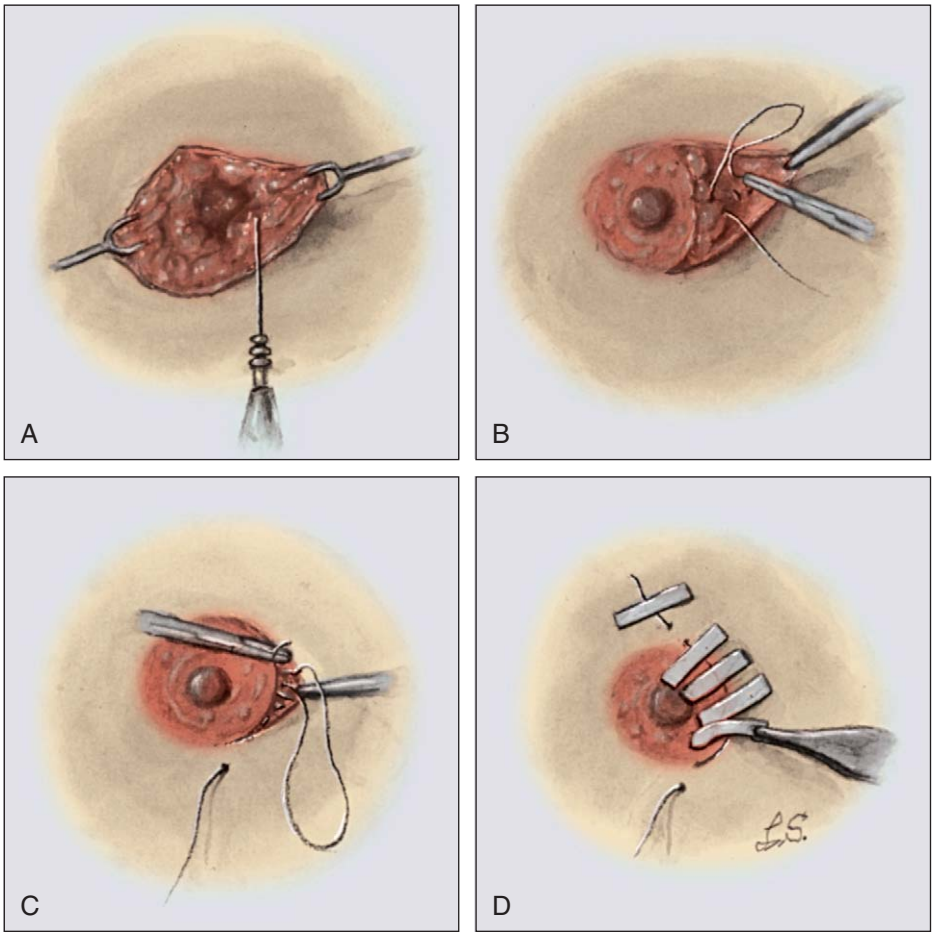

Figure 95-15 • A, After the specimen is removed, careful hemostasis is obtained with electrocautery. **B,** The deep tissues are never reapproximated, to avoid distortion of the breast and poor cosmetic result if subsequent irradiation is required. **C,** The deep dermis is closed with 3–0 absorbable sutures. The skin is closed with a subcuticular pull-out suture of 5–0 Prolene. **D,** Steristrips and dressings are applied. (From Baker RR, Neiderhuber J: The Operative Management of Breast Disease. Philadelphia, WB Saunders, 1994.)

MRI localization is thinner then the wire used for ultrasound or stereotactic localizations, possible transection of the wire during surgery may make removal of the area more challenging. Because the presence of the lesion in the specimen cannot be confirmed by x-ray, postexcisional MRI should be performed 1 month after the procedure to confirm removal of the lesion.

STAGING AND PROGNOSTIC EVALUATION

Once the pathologic diagnosis of breast cancer is established, the clinician should promptly obtain the staging information necessary to make therapeutic recommendations and decisions, which are important for medical, psychological, and economic reasons. The primary goal of staging evaluation is to assess whether the patient is has operable disease and is potentially curable by one or more therapy modalities, which most frequently include surgery plus radiation therapy (if breast conservation and if higher risk factors) plus systemic therapy (before or after surgery and according to predictive and prognostic factors).

2003 Update of the TNM Staging System

In January 2003, the American Joint Committee on Cancer released the sixth edition of the Cancer Staging Manual with a revision of the TNM staging system for breast cancer (Table 95-8).[151–153] This revision considers the increasing use of novel imaging and pathology techniques, such as SLNB and immunohistochemistry. It also considers the number of involved lymph nodes (a strong prognostic factor) in staging allocation. The main changes in the TNM staging system include the following: (1) the distinction between micrometastases and isolated tumor cells on the basis of size and histologic evidence of malignant activity; (2) identifiers to indicate the use of SLNB and immunohistochemical or molecular pathology techniques; (3) indication of the number of malignant lymph nodes as shown by routine hematoxylin and eosin (H&E) staining (preferred method) or by immunohistochemistry staining (i.e., pN1 for 1 to 3 involved lymph nodes, pN2 for 4 to 9 involved lymph nodes, and pN3 for 10 or more lymph nodes); (4) reassignment of metastasis to the infraclavicular nodes as N3 disease and downstaging of ipsilateral supraclavicular node involvement from M1 to N3; and (5) staging of internal mammary lymph nodes based on detection by SLNB (N1 disease), radiologic or clinical examination (N2 disease), or concomitant axillary nodal involvement (N3 disease).

Undoubtedly, the TNM staging system for breast cancer has become more complex, although the allocation of specific TNM combinations to different stage groupings remains the same. A major exception is the creation of a new stage IIIc to include patients with exclusively TanyN3M0 disease. This revised staging system acknowledges the limitations of the previous TNM system, and will help facilitate the collection of uniform data from international databases and allow researchers to better assess the long-term outcome of specific patient subgroups and the effect of novel imaging and pathologic techniques. However, the TNM staging system does not yet account for the biologic diversity of breast cancer and its various phenotypes, and the seventh edition of the AJCC manual is scheduled for release in 2009.

Table 95-8 American Joint Committee on Cancer TNM Staging System for Breast Cancer

TNM STAGING

Primary tumor (T)

Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by the physical examination, the examiner uses the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1-cm increment.

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget's)	Paget's disease of the nipple with no tumor

Note: Paget's disease associated with a tumor is classified according to the size of the tumor.

T1	Tumor 2 cm or less in greatest dimension
T1mic	Microinvasion 0.1 cm or less in greatest dimension
T1a	Tumor more than 0.1 cm but not more than 0.5 cm in greatest dimension
T1b	Tumor more than 0.5 cm but not more than 1 cm in greatest dimension
T1c	Tumor more than 1 cm but not more 2 cm in greatest dimension
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size with direct extension to (a) chest wall or (b) skin, only as described below
T4a	Extension to chest wall, not including pectoralis muscle
T4b	Edema (including peau d'orange) or ulceration of the skin of the breast or satellite skin nodules confined to the same breast
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma

Regional lymph nodes (N)

Clinical

NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral axillary lymph node(s)
N2	Metastases in ipsilateral axillary lymph nodes fixed to one another (matted) or in clinically apparent* ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
N2a	Metastases in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastases only in clinically apparent ipsilateral internal mammary nodes and in the absence of clinically evident axillary lymph node metastasis
N3	Metastasis in ipsilateral infraclavicular lymph node(s), with or without axillary lymph node involvement, or in clinically apparent ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s), with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)

Pathologic (pN)†

PNX	Regional lymph nodes cannot be assessed (e.g., previously removed or not removed for pathologic study)
PN0	No regional lymph node metastasis histologically and no additional examination for isolated tumor cells (ITCs)

Note: ITCs are defined as single tumor cells or small cell clusters not greater than 0.2 mm that usually are detected only by immunohistochemical (IHC) or molecular methods, but may be verified on hematoxylin and eosin stains. ITCs do not usually show evidence of malignant activity (e.g., proliferation or stromal reaction).

pN0(i–)	No regional lymph node metastasis histologically, negative IHC
pN0(i+)	No regional lymph node metastasis histologically, positive IHC, no IHC cluster greater than 0.2 mm
pN0(mol–)	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR)
pN0(mol+)	No regional lymph node metastasis histologically, positive molecular findings (RT-PCR)

Table 95-8 American Joint Committee on Cancer TNM Staging System for Breast Cancer—cont'd

pN1	Metastasis in 1 to 3 axillary lymph nodes, or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection, but not clinically apparent‡
pN1mi	Micrometastasis (greater than 0.2 mm, none greater than 2.0 mm)
pN1a	Metastasis in 1 to 3 axillary lymph nodes
pN1b	Metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection, but not clinically apparent
pN1c	Metastasis in 1 to 3 axillary lymph nodes and in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection, but not clinically apparent
	(If associated with greater than 3 positive axillary lymph nodes, the internal mammary nodes are classified as pN3b to reflect increased tumor burden)
pN2	Metastasis in 4 to 9 axillary lymph nodes or in clinically apparent internal mammary lymph nodes in the absence of of axillary lymph node metastasis
pN2a	Metastasis in 4 to 9 axillary lymph nodes (at least one tumor deposit greater than 2.0 mm)
pN2b	Metastasis in clinically apparent internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN3	Metastasis in 10 or more axillary lymph nodes, in infraclavicular lymph nodes, or in clinically apparent ipsilateral internal mammary lymph nodes in the presence of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes
pN3a	Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit greater than 2.0 mm), or metastasis to the infraclavicular lymph nodes
pN3b	Metastasis in clinically apparent ipsilateral internal mammary lymph nodes in the presence of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection, but not clinically apparent
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes

Distant metastasis (M)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

STAGE GROUPING

Stage 0	Tis	N0	M0
Stage I	T1§	N0	M0
Stage IIA	T0	N1	M0
	T1§	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
Stage IIIA	T0	N2	M0
	T1§	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

Note: Stage designation may be changed if postsurgical imaging studies show distant metastases, provided that the studies are carried out within 4 months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy.

HISTOPATHOLOGIC TYPE

The histopathologic types are the following

In situ carcinomas

NOS (not otherwise specified)

Intraductal

Paget's disease and intraductal

Continued

Adenoid cystic

Secretory

HISTOPATHOLOGIC GRADE (G)

All invasive breast carcinomas except medullary carcinoma should be graded. The Nottingham combined histologic grade (Elston-Ellis modification of the Scarff-Bloom-Richardson grading system) is recommended.[1,2] The tumor grade is determined by assessing the morphologic features (tubule formation, nuclear pleomorphism, and mitotic count), assigning a value of 1 (favorable) to 3 (unfavorable) to each feature, and adding the scores for the three categories. A combined score of 3 to 5 points is grade 1, a combined score of 6 to 7 points is grade 2, and a combined score of 8 to 9 points is grade 3.

1. Elston CW, Ellis IO: Pathological prognostic factors in breast cancer. I. The value of histologic grade in breast cancer experience from a large study with long-term follow-up. Histopathology 1991;19:403–410.

2. Fitzgibbons PL, Page DL, Weaver D, et al: Prognostic factors in breast cancer. College of American Pathologists consensus statement 1999. Arch Pathol Lab Med 2000;124:966–978.

Histologic grade (Nottingham combined histologic grade is recommended)

GX Grade cannot be assessed

G1 Low combined histologic grade (favorable)

G2 Intermediate combined histologic grade (moderately favorable)

G3 High combined histologic grade (unfavorable)

NOS, not otherwise specified; RT-PCR, reverse transcriptase polymerase chain reaction.

*Clinically apparent is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically.

†Classification is based on axillary lymph node dissection with or without sentinel lymph node dissection. Classification based solely on sentinel lymph node dissection without subsequent axillary node dissection is designated (sn) for "sentinel node" (e.g., pN0[i+] [sn]).

‡Not clinically apparent is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

§TI includes TImic.

Pathologic Factors for Invasive Carcinoma

For many decades, the most important prognostic characteristic of a breast cancer was the number of axillary lymph nodes involved with the disease (Table 95-9). In addition, increasing pathologic size of the primary tumor is inversely related to disease-free survival and overall survival rates (see Table 95-3). Especially in women with lymph node-negative disease, tumor size is a powerful predictor of recurrence. However, the role that these traditional pathologic characteristics play in assessing the prognosis of the patient is rapidly changing. Specific existing markers, such as ER, PR and HER2, gene expression signatures, and newer predictive and prognostic tests under development not only will aid traditional pathologic assessment but in many cases will serve as the sole determinant of therapy selection. The clinical utility of predictive and prognostic markers is discussed later in this chapter.

Histologic status of the axillary lymph nodes remains the single most important prognostic factor for operable breast cancer as of press time for this book. Axillary staging is an essential procedure because of the strength of axillary lymph node status as a prognostic factor, and SLNB in experienced hands now is accepted as the preferred staging procedure for early-stage tumors.[154] Many pathologic factors of the primary tumor, including histologic subtype, nuclear and histologic grade, and lymphatic or vascular invasion, have been evaluated as additional prognosticators of clinical course. Although each of these parameters can be useful in expert hands, histologic subclassification has the greatest applicability. Most invasive breast cancers are epithelial neoplasms. The rarer sarcomas, lymphomas,

and nonepithelial tumors are discussed elsewhere. Infiltrating breast cancers are histologically heterogeneous, but most of them are adenocarcinomas arising from the terminal ducts. Invasive ductal carcinoma, which accounts for approximately 85% of breast cancers, has no specific histologic features (Fig. 95-16), and it often is accompanied by ductal carsinoma in situ (see the Radiation Treatment section for additional discussion regarding the presence of extensive intraductal component [EIC]). Invasive lobular carcinoma accounts for 5% to 15% of breast cancers. Its overall prognosis is thought to be similar to that of the invasive ductal subtype. One recent report suggests that women with invasive lobular cancers have better long-term outcomes, as compared with those with invasive ductal histology, when treated with neoadjuvant chemotherapy.[155] Microscopically, lobular carcinoma is characterized by single-filing ("Indian file") of small, regular epithelial cells that tend to grow around ducts and lobules (Fig. 95-17).

Many special types of breast carcinoma are less common than the invasive ductal and lobular variants and usually have a more favorable prognosis. These include mucinous, papillary, tubular, and adenoid cystic carcinoma. The better prognoses associated with these special histologic subtypes have been most clearly defined in node-negative patients, and patients with lymph node-negative disease with special tumor types up to 3 cm in diameter have, on average, a prognosis equivalent to that of patients with infiltrating ductal or lobular carcinoma up to 1 cm. The clinical and biologic features of 444 patients with tubular carcinoma and 1221 patients with mucinous carcinoma were compared with those of 43,587 patients with infiltrating ductal carcinoma, not otherwise specified.[156] The actual need and benefit offered by adjuvant systemic therapy in these subsets have not been adequately studied, but it is accepted that therapy is not required in most cases. Mucinous (colloid) carcinoma is characterized microscopically by abundant accumulation of extracellular mucin around tumor cells (Fig. 95-18). A frond-forming growth pattern characterizes papillary carcinoma (Fig. 95-19). Tubular carcinoma is distinguished by the proliferation of small glands that resemble normal mammary ducts (Fig. 95-20).

The histopathologic features that define medullary carcinoma include a well-circumscribed border, intense reaction with lymphocytes and plasma cells, poorly differentiated nuclei, a syncytial growth pattern, and little or no intraductal carcinoma (Fig. 95-21). The more favorable prognosis requires the presence of all of these characteristics. Thus, atypical medullary tumors do not have the same excellent outcome. Furthermore, the risk of incorrectly labeling an aggressive, poorly differentiated carcinoma as medullary carcinoma led some to exclude the latter from the special types of breast cancer with favorable prognoses.

Studies of the prognostic value of other pathologic factors, such as histologic and nuclear grade, vascular-lymphatic invasion,

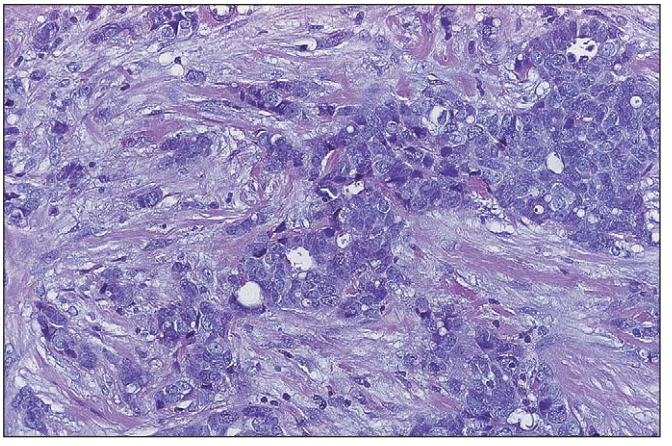

Figure 95-16 • Typical infiltrating ductal carcinoma. Irregularly dispersed glands and cords of tumor cells are set in a desmoplastic stroma.

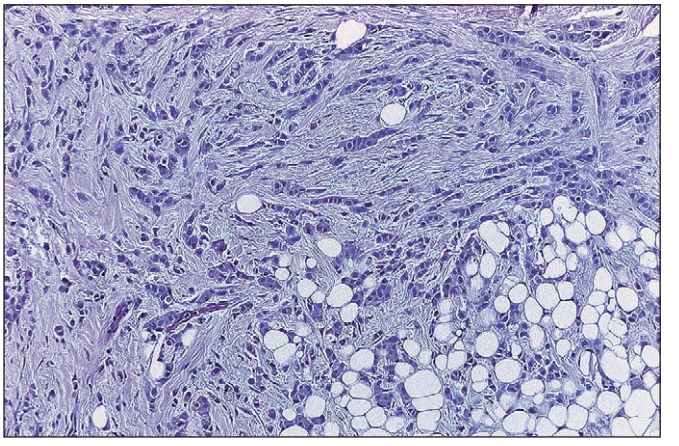

Figure 95-17 • Invasive lobular carcinoma. The tumor cells are small, and form linear, single files.

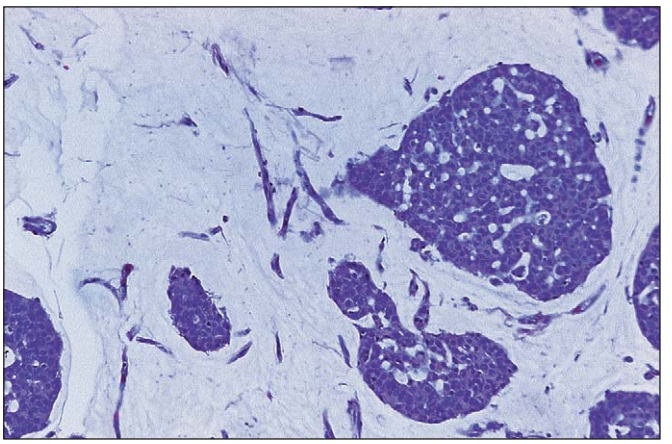

Figure 95-18 • Invasive mucinous (colloid) carcinoma. Bland nests of tumor cells float in abundant extracellular mucin.

inflammatory response, and tumor necrosis, have shown considerable variation. The major criticism of nuclear grade is the lack of observer consistency in making this subjective classification. Various prognostic indices incorporating several parameters have been intensively studied. The Nottingham Prognostic Index,[157] derived from tumor size, nodal status, and tumor grade, was validated by the German Breast Cancer Study Group[158] in a series of 600 patients with node-negative breast cancer.

MANAGEMENT OF NONINVASIVE BREAST CANCER

Much evidence supports the view that the development of malignancy is a multistep process and that invasive breast cancer has a preinvasive phase. During the carcinoma in situ (CIS) phase, normal epithelial cells undergo enough genetic alterations to result in malignant transformation. Transformed epithelial cells proliferate and pile up within lobules or ducts, but lack the additional required genetic alteration that enables cells to penetrate the investing basement membrane. Because of the increasing acceptance of breast cancer screening in the United States, CIS accounts for an increasing proportion of all new breast cancers. Between 1975 and 1978, surveys suggested an incidence of pure in situ lesions of 1.4% to 5.1%. By 2001, nearly 20% of all new breast cancers in the United States were DCIS, and this denominator does not include cases of lobular carcinoma in situ (Fig. 95-22).[159] An important research question attempts to address which CIS is preinvasive cancer, which indicates an unstable epithelium that represents an increased risk of subsequent invasive cancer, and how to intervene optimally (surgery or other preventive measures). Until better predictive markers are identified, traditional methods of estimating risk are still in use.

Lobular Carcinoma in Situ

Although breast CIS was first reported in 1932 by Broders, Foote and Steward in 1941 first described a noninvasive malignancy confined to the lobules and terminal ducts, and referred to this entity as LCIS. Foote and Steward described this lesion as rare and reported it as the sole finding in 2 of the 300 mastectomy specimens reviewed.

Anatomy and Pathology

The original description of LCIS characterized the lesion as a lobular unit with a cluster of ductules or acini-filled, distorted, and distended by proliferating epithelial cells (Fig. 95-23). LCIS cells have a fairly uniform pattern of clear cytoplasm containing rounded, bland nuclei. Intercellular spaces are preserved, and clear vacuoles within the cytoplasm may displace the nucleus. This often is referred to as *classic LCIS*, and while lesser forms of lobular unit involvement are known as lobular hyperplasia, a consensus definition of these two pathologic entities has not been reached. Some investigators argue that the word *carcinoma* should not be included in the term and that it is better to refer to atypical lobular hyperplasia and LCIS as *lobular neoplasia.* However, LCIS is a well-established entity and should be retained as the descriptive label, because it is recognized as a risk factor for the development of invasive breast cancer. Recently, a more pleomorphic type of LCIS has been described, and there is indirect evidence to suggest that this pleomorphic variant may progress to invasive cancer.[160] LCIS is a microscopic diagnosis, usually not associated with a mammographic abnormality. When LCIS is found after needle-localization biopsy of suspicious microcalcifications, the calcifications usually are outside the LCIS. The only exception is the rare fibroadenoma that contains a focus of LCIS within the mass.

Incidence, Multicentricity, Bilaterality, and Invasive Disease

LCIS had been thought of as a disease of younger women. However, SEER data from 1980 through 2001 show an increase in LCIS rates

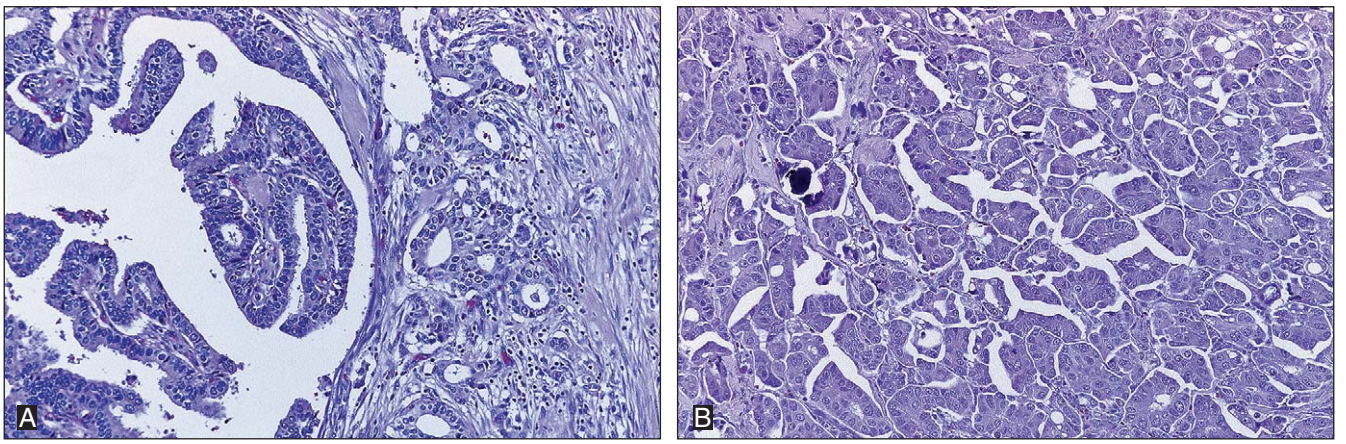

Figure 95-19 • **A,** Invasive carcinoma arising in papillary ductal carcinoma in situ (invasive papillary carcinoma). The in situ component seen on the right has a frond-like appearance, and the invasive carcinoma component on the left consists of irregularly shaped small glands. **B,** Invasive micropapillary carcinoma of the breast. The tumor resembles ovarian serous carcinoma, and small clusters of invasive tumor cells are separated from the stroma by spaces. A psammoma body is seen.

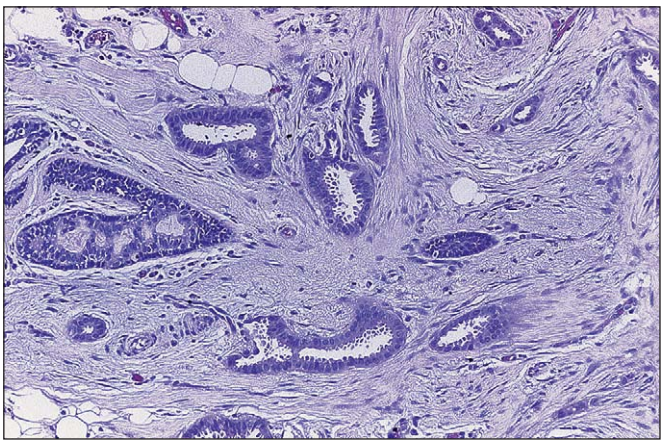

Figure 95-20 • Infiltrating tubular carcinoma. The invasive glands are irregularly dispersed, lack a second myoepithelial cell layer, and are set in a desmoplastic stroma. Tubular carcinoma resembles normal breast ducts. Two normal ducts, seen in the center, appear darker than the tubular carcinoma and have two cell layers.

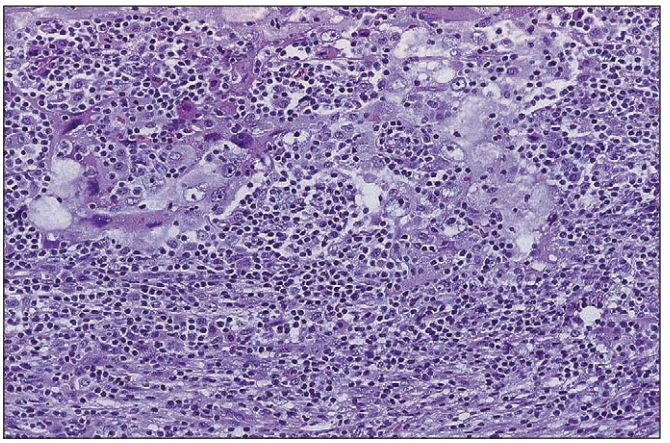

Figure 95-21 • Medullary carcinoma characterized by a well-defined border, an intense lymphoplasmacytic reaction, and pleomorphic tumor cells with vesicular chromatin.

among women over age 50 (Fig. 95-24).[159] A greater use of mammography and a tendency to perform a more thorough histologic evaluation of biopsy tissue appear to have contributed to this increase. LCIS often is multicentric and has an increased incidence of bilaterality. Several series described women who had a diagnosis of breast cancer on one side, and a mirror-image biopsy of the contralateral breast. Such series are likely to have a higher incidence of bilateral findings then those series reporting on sporadic contralateral biopsies. This topic was reviewed by Schnitt and colleagues, who reported multicentricity in 60% to 80% of cases and a correlation of this finding with an increased risk of subsequent invasive cancer in both breasts.[161] Various historical series suggested a 9-fold increased risk of subsequent development of invasive breast cancer after more than 20 years of follow-up. However, a recent SEER database study of about 4000 women with LCIS that was treated with biopsy or breast conservation surgery demonstrated a higher risk for ipsilateral invasive cancer occurrence than for contralateral cases, with the invasive histology being lobular in about half of those cases.[162]

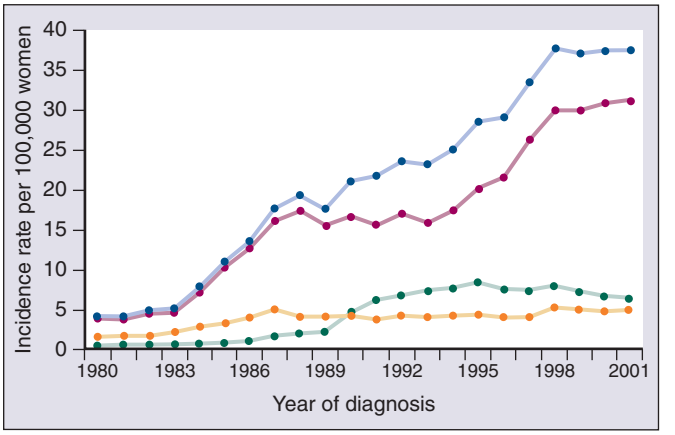

Figure 95-22 • Age-adjusted incidence rates of different histologic types of in situ breat carcinoma among women 30 years of age and older, 1980–2001. Ductal carcinoma in situ (DCIS) overall, *blue curve*; noncomedo DCIS, *magenta curve*; comedo DCIS, *green curve*; lobular carcinoma in situ (LCIS), *yellow curve*. Treatment

LCIS does not require treatment. History of a previous breast biopsy with a diagnosis of LCIS is part of the risk assessment of developing a breast cancer.[163] Evaluation for risk-reducing surgery in LCIS must take into account other risk factors, such as family history, BRCA1 or -2 mutations, and the patient's desires and worry or anxiety level. The NSABP P-1 tamoxifen prevention study showed that tamoxifen at the dose of 20 mg/day for 5 years can reduce the risk of developing a DCIS or invasive cancer by 49% with acceptable side effects.[164] Preliminary results from the NSABP STAR trial evaluating tamoxifen versus raloxifene in high-risk women suggest that raloxifene is as effective as tamoxifen in reducing the risk of invasive breast cancer in postmenopausal women at high risk for breast cancer, including those with a previous diagnosis of LCIS, and has a lower risk of thromboembolic events, cataracts, and endometrial cancer.[121]

Ductal Carcinoma in Situ

Noninvasive ductal carcinoma, or DCIS, is defined as "a proliferation of malignant cells confined within the basement membrane of the ducts of the breast." Before the widespread use of mammography, DCIS was not commonly diagnosed and usually presented as a palpable mass or bloody nipple discharge. The increasing use of screening mammography has resulted in a significant increase in the number of patients diagnosed with DCIS. Most of these cases are clinically occult. The evaluation and treatment of DCIS identified by imaging is summarized in Table 95-10.

Anatomic Histology

The terminal ductal lobular unit has been proposed as the site of origin of most breast cancer, including DCIS (Fig. 95-25). In contrast to LCIS, which tends to be multicentric, DCIS is likely to be

Table 95-10 Gudielines for Evaluation and Treatment of Nonpalpable Ductal Carcinoma in Situ

1. Careful multiview mammography with or without ultrasonography and including magnification views
   - Document extent of disease
   - Identify other areas of microcalcification
2. Suspicious microcalcifications and densities cleared with needle localization biopsy
3. Specimen radiography with magnification techniques
4. Radiograph-directed histopathologic evaluation with:
   - Orientation of specimen by surgeon
   - Multicolored inked margins
5. Complete pathologic description to include:
   - Type of DCIS and size of tumor
   - Relation to microcalcifications
   - Distance of lesion from inked margins
   - Presence of multifocality
   - Presence or risk of microinvasion
6. Repeat mammography with magnification to confirm successful clearing of suspicious areas
7. Repeat breast excision if:
   - Residual microcalcifications are found
   - Margins are unacceptable

DCIS, ductal carcinoma in situ.

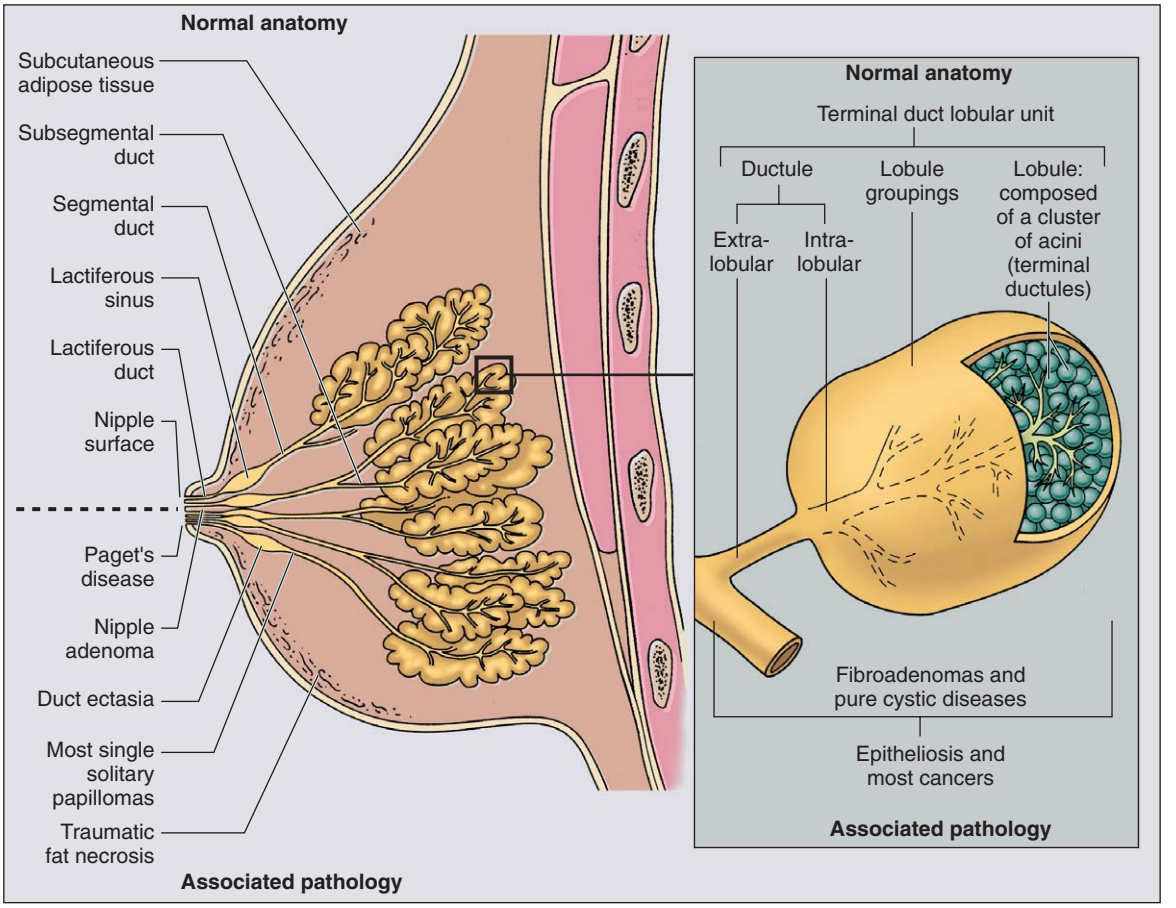

Figure 95-25 • Anatomy of the breast, showing the organization of the elements of the terminal duct lobular unit and their relationship to specific pathologic abnormalities. (From Hayes D: Breast cancer. In Skarin AT [ed]: Atlas of Diagnostic Oncology. Philadelphia, JB Lippincott, 1991, p 64.)

confined to one branching ductal system in the breast. In the past, the pathologic classification of DCIS was based on the architectural patterns of DCIS as seen microscopically. These patterns included a solid pattern of growth filling the duct, a cribriform pattern characterized by well-defined holes seen within the growth pattern in the duct (Fig. 95-26), a comedo pattern with necrosis seen in the center of the duct (Fig. 95-27), and both micropapillary (Fig. 95-28) and papillary (Fig. 96-29) variants, characterized by frond-like projections of tumor cells into the lumen of the duct. Pathology reports commonly describe two or even three subtypes of DCIS in the same specimen when using this system. To clarify these pathology classification schemas and, more importantly, to identify subtypes of DCIS that may predict patient prognosis or response of the DCIS to various clinical interventions, a 1997 consensus conference agreed on issues such as pathologic classification, methods of determining the size and extent of the DCIS, methods of determining margin width, and, most importantly, the procedure for processing the specimen in the pathology laboratory to ensure that all pertinent information can be obtained from the tissue.

Significant recommendations of the report on the classification of DCIS included noting the nuclear grade of the cancer cells, the proportion of involved ducts showing necrosis, the polarization of cells around the intercellular spaces, and the architectural pattern. Nuclear grade was determined to be the most important feature, and low- and high-grade lesions were described. Low-grade lesions had monotonous nuclei, measuring 1.5 to 2 times the size of a normal red blood cell, with finely dispersed chromatin and only

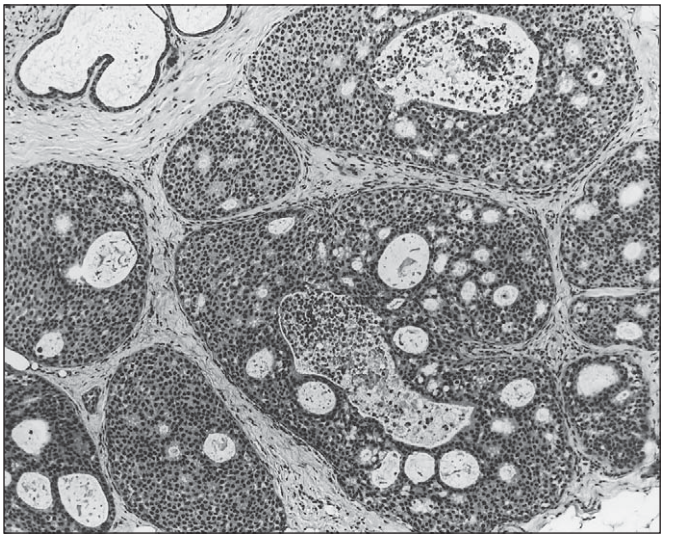

Figure 95-26 • Cribriform ductal carcinoma in situ, which accounts for most of the ductal carcinoma in situ detected. It is characterized by interconnecting strands of hyperchromatic cells. Few necrotic cells are seen, and arches of connecting strands appear rigid.

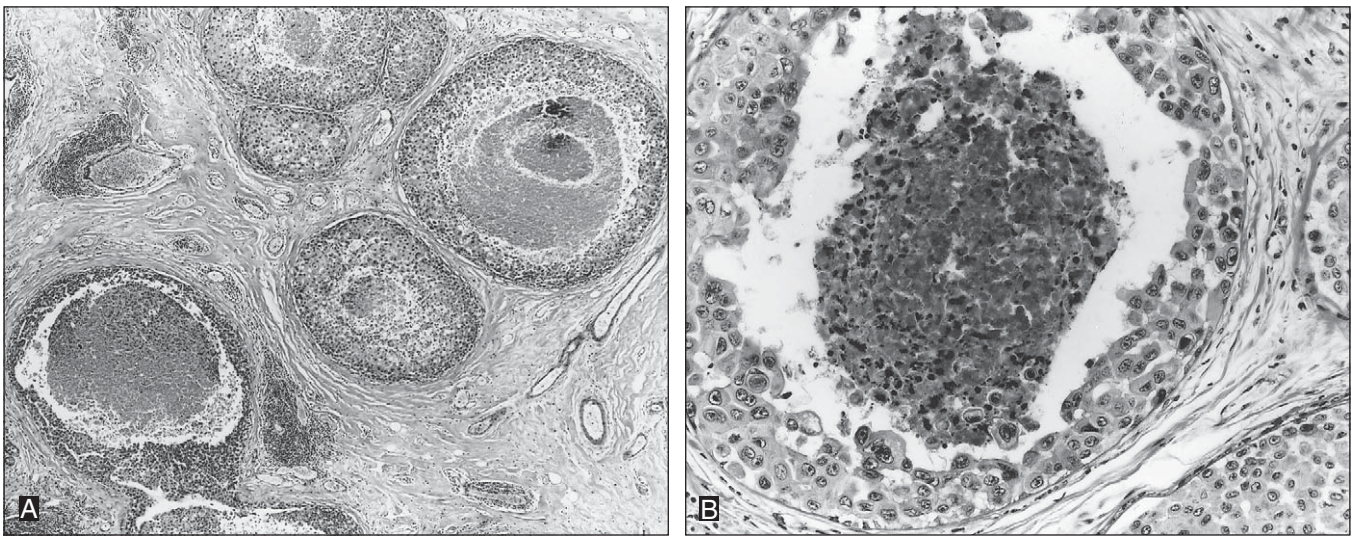

Figure 95-27 • **A,** Comedo ductal carcinoma in situ (DCIS). The ducts are expanded by sheets of proliferating cells with areas of central necrosis. The sheets of cells show more pleomorphism than is common with other histologic types of DCIS. A higher incidence of microinvasion also is seen with comedo DCIS. **B,** The same specimen seen at a higher magnification.

occasional nucleoli and mitotic figures. High-grade lesions had markedly pleomorphic nuclei, measuring more than 2.5 times the size of a normal red blood cell, with irregular chromatin distribution and prominent nucleoli with conspicuous mitoses. Intermediate-grade nuclei were defined as those not meeting the criteria for high- or low-grade lesions. Necrosis also was defined as the presence of ghost cells and karyorrhectic debris. It was further quantified as "comedo," with central-zone necrosis, or "punctate," with nonzonal necrosis and without a linear pattern within the ducts. The traditional architectural patterns also were noted as appropriate to mention in the pathology report independently of the other pathologic features. Tissue processing in the pathology laboratory also was described, because it is key in determining such information as lesion size and margin width. Important steps to follow included orientation of the specimen by the surgeon; radiograph of the specimen when feasible; inking of the surface of the specimen for margin information, unless the surgeon sends separate margin specimens; and, most importantly, processing the specimen in sequence in separate cassettes.

The extent of DCIS involvement can be determined in several ways. If DCIS is closely associated with linear or branching-type calcifications, the mammogram size can provide minimum size information. If seen microscopically on only one slide, measurement across this slide also is a meaningful estimate of size. If present on multiple slides, the pathologist should note the number of sequential slides or segments that show DCIS. Margin information is usually described in terms of the width of the closest margin, using the distance from the inked margin to the nearest involved duct. Like size, this measurement is an estimate, because the pathologist can view only a finite number of representative sections. In the unsampled tissue, the margin may actually be closer than the distance recorded in the sampled slides.

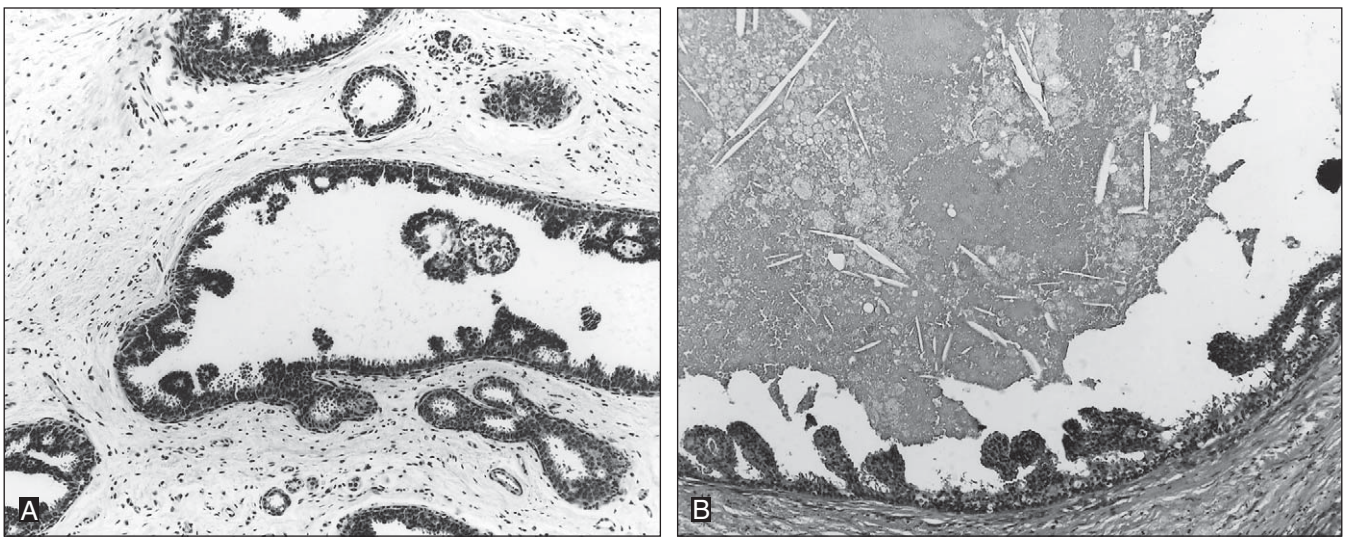

Figure 95-28 • **A,** Micropapillary ductal carcinoma in situ is characterized by small papillary projections of neoplastic cells. The papillary projections are frond-like, with a narrow base, and arise from the intersurface of ductal spaces. They are several cells thick. **B,** The same example seen at a higher magnification.

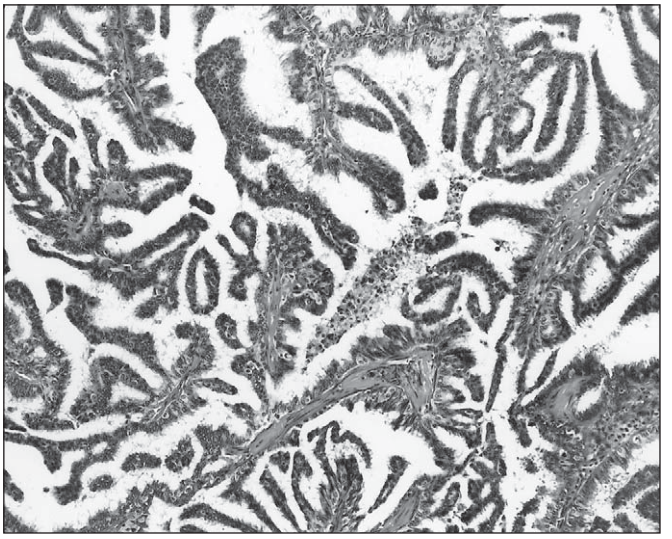

Figure 95-29 • Papillary ductal carcinoma in situ. In contrast to the micropapillary form, fibrovascular fronds are seen, similar to a duct papilloma. The fibrovascular fronds are covered by multiple layers of neoplastic cells with hyperchromatic nuclei.

Incidence and Multicentricity

Autopsy series suggest that as many as 16% of asymptomatic women have occult DCIS lesions. Reports on the multicentricity of DCIS often present data that are less than convincing. Multicentric DCIS has been described as two or more separate foci of carcinoma within the breast that are believed to have developed independently from the same carcinogenic stimulus. Some researchers suggest that the second separate focus of DCIS should be at least 5 cm distant from the primary site. Multifocality and residual DCIS within the same breast duct segment, which does not always correspond to the index "quadrant," should not be confused with true multicentricity. When several foci of calcifications are seen on the mammogram, they often are found to be "connected" at the light microscopy level.

Clinical Diagnosis

Unlike LCIS, DCIS almost always is diagnosed by mammography. Even when palpable DCIS is present, the mammographic findings are quite characteristic, with a diffuse, often linear, and extensive pattern of pleomorphic calcifications. However, the screening mammogram usually is the first indication of DCIS. Several patterns of calcifications raise the suspicion of the diagnostic radiologist. These include linear or casting-type calcifications, fine or "powdery" calcifications, and irregularly shaped calcifications often described as "crushed stone." Although any pathologic grade of DCIS can be diagnosed with any type of calcification, the most common associations are high-nuclear-grade lesions with the linear pattern and low- to intermediate-nuclear-grade lesions with a fine or powdery pattern. Less likely mammographic findings include architectural distortion or a mass.

Bloody nipple discharge also can be a symptom of DCIS. Paget's disease of the breast, another form of DCIS, commonly causes a crusty, eczema-like change in the skin of the nipple, and bleeding may be noted. Approximately half of these women have a palpable mass as well. In those who do not, a recent series found a negative mammogram in 63% of women with nipple changes only.

Clinical research on MRI for DCIS is ongoing in many centers equipped with a dedicated breast coil. Although some technical problems must be overcome in imaging DCIS with MRI, it has proven useful in evaluating the extent of residual disease in women requiring re-excision after initial biopsy and providing a better definition of extent of disease when DCIS is not associated with calcium. FNA is not ideal for evaluating DCIS because the pathologist cannot discriminate between invasive or in situ cancers.[165] For years, when mammographic abnormalities suggested DCIS, needle-localization-directed open biopsy with specimen radiography was the standard approach. Recently, with the availability of large-gauge, image-guided automated core biopsy devices, this technique has become widely accepted in appropriate cases.[166]

Biology

DCIS, by definition, has intact basement membrane on light microscopy. Unlike pure DCIS, when microinvasion is present, type IV collagen and lamina are lost from the basement membrane in association with loss of membrane continuity. Such observations lend weight to the argument that DCIS is a precursor of invasive ductal cancer. Not all cases of DCIS progress to invasive cancer. Identifying the predictors of this process is a major challenge in understanding the biology of this disease. Traditional ways of classifying pathology subtypes of DCIS have not provided these data.

A recent subset analysis by histologic type (well vs. intermediate vs. poorly differentiated) of the 1010 women in the European Organization for Research on the Treatment of Cancer (EORTC) 10853 trial concluded that histologic type was not related to the risk of invasive recurrence.[167] However, patients with well-differentiated DCIS had a lower overall risk of local failure, when the DCIS-only recurrences were included. Table 95-11 demonstrates the risk factors for any local recurrence in this EORTC study. An understanding of

From Bijker N, Meijnen P, Peterse JL, et al: Breast-conserving treatment with or without radiotherapy in ductal carcinoma-in-situ: ten-year results of European Organisation for Research and Teatment of Cancer randomized phase III trial 10853—a study by the EORTC Breast Cancer Cooperative Group and EORTC Radiotherapy Group. J Clin Oncol 2006;24:3381–3387.

DCIS at the genetic level is the goal of many ongoing studies. However, little is known about this biology.

Treatment

Most cases of DCIS are diagnosed by mammography. Approximately 72% of cases are detected by calcification alone, 12% by calcification and a soft tissue density, and 10% by a soft tissue abnormality. The surgeon, when offering the patient a breast-conserving approach, must be confident that the remaining breast is free of suspicious mammographic abnormalities. Other clusters of microcalcification within the breast take on greater significance after a diagnosis of DCIS is established, and biopsy of these may be appropriate. Coordination between the pathologist and the breast-imager is very important in documenting the relationship between calcium observed on film and that observed in the specimen. When a patient has extensive areas of suspicious calcification, the entire area must be cleared surgically to ensure the success of breast conservation. When this is not possible, simple mastectomy with reconstruction, if the patient desires, is appropriate local treatment. Recent experiences with combined breast excision and plastic restoration (oncoplastic tecniques) showed the possiblity of complete removal of relatively large areas of microcalcifications with acceptable cosmetic results.[168]

Guidelines for DCIS therapy have been influenced significantly by a number of retrospective reports on follow-up of patients treated with excision only or with excision plus irradiation. More importantly, these retrospective study results have been used to design large, prospective phase III trials.

The need for radiation after wide excision first was tested prospectively by the NSABP group in a randomized trial.[169] This study randomized 818 women with DCIS to receive lumpectomy, with or without radiation. Patients were stratified by method of detection (i.e., mammogram only or palpable mass) as well as by age. Negative tumor margins were required, and were defined as no DCIS seen at the inked margin. After a median of 12 years of follow-up, the local failure rate in the index breast was 17% in women randomized to receive radiation, compared with 39.7% in the observed group. However, this significant difference in local control did not translate to any difference in survival for the women in this trial.[170]

A similar large phase III trial comparing radiation with observation after wide local excision for women with DCIS was undertaken by the EORTC group (see Biology of DCIS). This study randomized 1010 women to lumpectomy and radiation versus lumpectomy only, showing a rate of local control similar to that of the NSABP B-17 study. With a median follow-up of 10 years, the local control rate was 74% in the excision-only group, compared with 85% in women randomized to radiation. The risk of DCIS and invasive LR was reduced by 48% ($P = 0.0011$) and 42% ($P = 0.0065$), respectively. Both groups had similar low risks of metastases and death. At multivariate analysis, factors significantly associated with an increased LR risk are shown in Table 95-11, and the effect of the radiation was seen across all risk factors.[167]

A randomized trial of 1046 women, all undergoing mammographic screening in Sweden, comparing whole breast radiation to observation, showed similar results as well.[171] With a median follow-up time of 5.2 years, the cumulative incidence of local recurrences was 7% in the RT group compared with 22% in the observed group. As with both the NSABP and the EORTC trials, no differences were seen in the SweDCIS study in terms of disease-specific survival.

Several breast surgeons published individual series of patients with DCIS treated with wide excision only. Patient selection clearly plays a role in this kind of reporting. Nonetheless, local control rates in these retrospective studies are quite good, and the results generated another series of cooperative group trials. Silverstein's series from Van Nuys, using an index of the same name, related outcome to the following factors: size, pathology grade, patient age, and surgical margin width.[172,173] Several U.S. trials testing these hypotheses recently were closed. This included the Eastern Cooperative Oncology Group (ECOG) 5194 observation-only registry trial, which showed that carefully selected patients with low- or intermediate-grade DCIS treated with lumpectomy without irradiation have an acceptably low risk of ipsilateral events at 5 years.[174] The Radiation Therapy Oncology Group (RTOG) recently closed the accrual of a phase III trial that randomized selected low-risk patients with DCIS to wide excision, with or without radiation. Final sample size trial was less than initially planned due to low accrual rate (600 women enrolled compared to the target of 1800). In a Danish nationwide prospective study of in situ carcinoma of the breast, a total of 275 women treated with excision alone were registered from 1982 to 1989. Within a median follow-up of 120 months, a crude recurrence rate of 28% was found, of which 53% recurred as invasive carcinomas and 47% as in situ cancers.[175] Thus, this issue of identifying a "good risk" group of women with DCIS who can be observed without the addition of radiation remains controversial.

In general, a woman's risk of local failure in the index breast after wide excision appears to be reduced by a factor of approximately one half by the addition of whole-breast radiation. Because survival remains excellent, whatever local treatment is selected, involving the patient in a decision, based on her assessed risk and the relative benefits and risks of radiation, appears appropriate for women in lower-risk groups. These groups are defined by older age, tumor grade, size, and margin width, and likely by other factors yet to be described. Several trials comparing lumpectomy plus radiation versus mastectomy are summarized in Table 95-12.

The NSABP B-24 study tested the role of tamoxifen, in addition to lumpectomy and radiation therapy, in a prospective trial of 1804 women. With a median follow-up of 74 months, with the addition of tamoxifen to 50 Gy radiation, the risk of ipsilateral invasive recurrence was further reduced by approximately 50%. However, the absolute risk reduction was only 3%, and no significant reduction in noninvasive recurrence was seen. Predictably, the addition of tamoxifen decreased the risk of a contralateral breast event by approximately 1.5%.[176] A 2 × 2 factorial design randomized trial in the United Kingdom, Australia, and New Zealand randomized 1701 patients to receive, after lumpectomy, either tamoxifen alone, tamoxifen plus radiation therapy, radiation therapy alone, or nothing. At a median of 52.6 months, ipsilateral invasive disease was not reduced by tamoxifen, but recurrence of overall ductal carcinoma in situ was decreased (hazard ratio 0.68 [0.49–0.96]. Radiotherapy reduced the incidence of ipsilateral invasive disease (0.45 [0.24–0.85]) and ipsilateral ductal carcinoma in situ (0.36 [0.19–0.66]).[177] The NASBP and the International Breast Cancer Intervention Study (IBIS) groups are independently evaluating the aromatase inhibitors in preventing local recurrences after lumpectomy and RT for DCIS. In these trials the patients are randomized to take anastrazole or tamoxifen for 5 years.

Male breast cancer accounts for only approximately 1% of all cases of breast cancer. Men with DCIS are estimated to be only 7% of that already small group, so aside from case reports, little information exists on the management of this unusual entity.[178] Total mastectomy or wide excision with free margin may be considered a reasonable treatment.

Sentinel Lymph Node Biopsy in Ductal Carcinoma in Situ

Investigators are now questioning whether the SLNB technique, well established for the staging of invasive breast cancer, may have a role in the staging of DCIS. Several studies have documented a high incidence of lymph node micrometastases detected by SLN biopsy in patients with high-risk DCIS and DCISM (DCIS with microinvasion). Although the biologic significance of breast cancer micrometastases remains unclear at this time, these findings suggest that SLNB should be considered in patients with high-risk DCIS and DCISM. One reason for the high rate of detection of positive SLNs in DCIS is that DCIS of the breast is defined as stage 0 disease, without invasion, but its diagnosis is subject to sampling errors. A positive SLN

SENTINEL LYMPH NODE MAPPING

Radioisotope

Europe: ^{99m}Tc colloidal albumin (unfiltered) [ideal particle size 10–200 nm] 0.1–0.6 mCi/4 mL normal saline injected subdermally or into the breast.

United States: ^{99m}Tc sulfur colloid 0.3–1.0 mCi in 4 mL normal saline is injected subdermally or into the breast 1 to 4 hours before surgery; a handheld gamma probe is used.

Between 4 and 5 mL isosulfan blue dye is injected subdermally beneath the areola or into the breast parenchyma on the axillary side or at the tumor site. Breast is massaged for 5 minutes before the low axilla is explored.

EORTC, European Organization for Research on the Treatment of Cancer; NCI, National Cancer Institute; NSABP, National Surgical Adjuvant Breast and Bowel Project.

may raise the question of whether invasion was missed at the breast pathology examination, and thereby reduce the sampling error. Another point in favor of SLNB in DCIS is the fact that the diagnosis of pure DCIS often is made subsequent to surgical excision of the lesion. Some patients with lesions considered to be at high risk for invasion based on clinical, pathological, or mammographic criteria may benefit from a SLNB if final pathology shows invasion.

Some criteria for predicting invasion can help decide whether to perform a SLNB. On mammography, DCIS is generally evident as calcifications, whereas a mass often is seen in the setting of an invasive carcinoma. In patients with DCIS, the presence of extensive calcification or an associated mass/lesion at mammography suggests a greater likelihood of an invasive component. High-grade DCIS with comedo necrosis on core biopsy frequently shows invasion at the final pathology of the surgical excision. Consideration should be given to SLNB in patients who are at high risk for invasion or who are undergoing a mastectomy. This would include patients with pathology that is either suspicious or diagnostic for microinvasion and cases that involve the presence of lymphovascular invasion, or the presence of a palpable or mammographic mass. In women who undergo mastectomy, a SLNB can be justified due to its associated lower morbidity, additional pathology attention to the lower number of lymph nodes submitted, and the potential avoidance of a formal ALND if the SLNB procedure shows no nodal involvement should a focus of invasion be identified in the breast specimen.[179]

MANAGEMENT OF EARLY-STAGE BREAST CANCER

The management of early invasive breast cancer is multidisciplinary and must involve specialists in breast imaging, pathology, surgical oncology, radiation oncology, medical oncology, and reconstructive surgery. More than half of all women in the United States (including African-American women) who are diagnosed with breast cancer present with early-stage breast cancer,[3] often 2 cm or less, and most are potential candidates for breast conservation (lumpectomy and radiation) assuming adequate surgical margins and cosmetic outcome.[180] Preoperative systemic therapy (PST) is a reasonable option to consider for women with operable breast cancer who are not candidates for breast conservation due to large tumor size and/or small breast size at presentation. However, the absolute increase in the number of women ultimately treated with breast conservation after PST is less than 10%. Available data show no clear survival benefit for preoperative systemic therapy.[181] Not all breast cancers have systemic involvement at presentation,[182] and maximization of local control with radiation therapy also may reduce the subsequent risk of distant relapse and improve survival.[183] Decisions about adjuvant systemic therapy first must take into account the accurate determination of the expression of any predictive markers that identify potential candidates for therapy centered around anti-estrogens (if ER- and/or PR-positive disease),[184] trastuzumab (if HER2-positive disease),[75] or chemotherapy (if triple negative disease). Estimates of risk based on more traditional prognostic markers (e.g., tumor size and degree of lymph node involvement) are then added to help estimate the absolute improvement offered by the specific systemic therapies in question. Some measures of gene expression profiling appear to offer predictive utility to help with therapy selection.[103]

Breast-Conservation Therapy with Surgery and Radiation

Fortunately for most patients, the appropriateness of breast conservation is one of the most studied treatment decisions in modern medicine. Pioneering investigators in the 1920s and 1930s began to treat groups of women with breast-conserving partial mastectomy, followed by irradiation to the intact breast, challenging the need for total mastectomy. Results from these early studies were promising. Many single institutions initiated programs, including excision plus radiation therapy, for their patients with breast cancer, first in European and Canadian centers and later in the United States. In the early 1970s, several European reports created worldwide interest in nonmastectomy treatment based on individual series that suggested local recurrence rates of 5% to 10% and similar survival.

These single-institution studies caused considerable controversy between breast surgeons who believed in the mastectomy as a local treatment and those that embraced breast conservation. This, in turn, led to six randomized prospective trials using megavoltage radiation techniques comparing lumpectomy plus radiation with mastectomy, which were carried out with cooperative groups in both Europe and the United States. A meta-analysis of these trials noted that survival at the 10-year mark in the conserved group was similar to the mastectomy group with a survival trend among lymph node-positive

patients.[185] Both the NSABP-B 06 Trial[180] and the Milan Cancer Institute Trial[186] have reported 20-year results showing equivalent outcomes. The NSABP B-06 Trial was unique, in that it randomized women to three treatment arms—the mastectomy arm, the breast conservation arm with radiation, and a breast conservation arm without radiation. The in-breast local failure rate without the additon of radiation approached 40% in that trial. Although initial analyses did not demonstrate a relationship between local in-breast failure and distant metastases, a recent report from the NSABP, focusing on node-positive women receiving breast conservation therapy including radiation, treated on a series of five trials, now shows a significant hazard ratio for mortality associated with local in-breast failure.[187] Thus, maximization of the chance of local control in this group of women is now associated with survival as well as in-breast failure. The BCT data were so convincing that in 1990, the NCI held a consensus development conference on the treatment of early breast cancer and declared that breast-sparing therapy not only was equivalent to mastectomy but actually was the "preferable" treatment, because it preserved the breast, with all of the attendant psychological and body image advantages associated with a lesser surgical procedure.

Resection of the Primary Lesion

Resection of the primary cancer for therapeutic purposes has different definitions accordingly to different authors. *Lumpectomy, wide excision, tumorectomy, segmentectomy,* and *quadrantectomy* are different terms to indicate excision of the cancer with "healthy " surrounding parenchyma. The European segmentectomy and quadrantectomy were characterized by a larger amount of breast parenchyma removal compared with surgical procedures in the United States, at least in the past.[188] The concept of large excisions has been progressively replaced by the concept of free margins. An excision that achieves negative margins for invasive cancer usually is considered sufficient. Numerous reports demonstrate that the margin status appears to influence the risk of recurrence, but still controversial is a definition of the free margin distance, defined as the safe distance of the cancer from the margins. Some authors have correlated the microscopic margin distance to the risk of local recurrences, showing that the distance is proportional to the risk of local recurrence.[189] The concept of free margins has been extended to the intraductal component when associated with the invasive cancer. Although the risk of local recurrence decreases in direct proportion to the extent of resection, as expected, the cosmetic result also declines with more aggressive resection. When margins are positive or close (many authors define close margins as < 2 mm), the ideal approach is reexcision of the previous biopsy site or reexcision of the involved/close margin, when specified. For reexcision, sharp dissection is preferred. Electrocautery should be avoided until the specimen is removed to avoid cautery artifacts that might obscure margin information.

Patients must be thoroughly informed about the indications for reexcision and the possibility that the histologic features of the specimen will dictate a change in therapy. For example, a reexcision specimen sometimes contains extensive or multifocal intraductal cancer. Some of these patients have intraductal cancer that is not marked by calcification extending into unknown areas of the breast. If all apparent intraductal cancer cannot be removed surgically, the risk of local failure can become unacceptably high and dictates planning for mastectomy and reconstruction.

Once the tumor has been removed, sutures or numbered tags are placed on the specimen so that it can be oriented, and the entire specimen has its surface inked in some fashion to allow evaluation of the histologic margins. Different colored inks may be used to represent different surfaces. The specimen is then cut and histologic sections prepared. Extra attention is paid to areas near the surgical margin wherever tumor is seen to encroach grossly. A thorough histopathologic evaluation can be done in a reproducible fashion, and a template for reporting surgical pathology in patients who undergo lumpectomy can be used to ensure that no important details are neglected.

As mentioned before, surgical excision is a balance between complete removal af the cancer with surrounding foci and an accetable cosmetic result. When this goal cannot be achieved, mastectomy and reconstruction may be a better option unless the patient strongly desires conservation of the breast, accepting a possible unsatisfactory cosmetic outcome.

Small titanium surgical clips may be placed in the tumorectomy wall to guide the radiation oncologist for precise placement of a radiation boost when indicated. Reapproximation of breast tissue may be used when it does not distort the breast shape. Closure of the parenchyma of the lumpectomy cavity may prevent seroma formation. Although most women today can have breast-conserving surgery, there are some contraindications, which are based on the premise that all invasive or preinvasive cancer should be removed surgically and that radiation therapy is an essential component of breast conservation, thereby reducing the risk of local failures. The contraindications are as follows:

- Scleroderma, cutaneous lupus erythematosus, and other active collagen disease of these tissues.
- Diffuse calcifications indicating an extensive intraductal component: biopsy of two separate areas of microcalcifications should be performed to confirm the diagnosis of multicentricity.
- Multicentric invasive cancers or DCIS may preclude breast conservation. Biopsy of two separate lesions should be performed to confirm the multicentricity pathologically.
- Large residual disease after induction chemotherapy may make it difficult to achieve acceptable cosmesis with breast conservation. This is a highly personal decision that the patient must make in conjunction with her physician.

Patients with previous chest wall radiation require evaluation by a radiation oncologist to determine the feasibility of breast conservation.

Axillary Staging

The second aspect of breast-conservation therapy involves staging the axilla (Fig. 95-30). Although many studies have suggested that a panel of prognostic indicators and molecular markers of the primary tumor might eventually be a better predictor of outcome than the number of involved lymph nodes, no combination of such parameters has been validated.

When suspicious axillary lymph nodes are present, axillary dissection should take place. Originally, axillary lymph nodes, including level III nodes medial to the medial border of the pectoralis minor muscle, were carefully removed. These dissections were associated with a higher incidence of lymphedema of the arm than limiting dissection to levels I and II. Level I and II dissection is now the standard for axillary clearance. This type of axillary dissection is associated with the lowest risk of regional failure. When bulky lymph nodes at level I and II are present, or suspicious level III nodes are detected, the removal of the level III nodes, bordered medially by Halsted's ligament, laterally by the medial edge of the pectoralis minor muscle, superiorly by the anterior aspect of the axillary vein, and posteriorly/inferiorly by the anterior chest wall, should be performed to avoid possible axillary recurrences, which are difficult to treat with chemotherapy and radiation and sometimes are associated with axillary vein thrombosis and invasion of the axillary plexus.

During the axillary dissection, care is taken to preserve the lateral and medial pectoral nerves, the long thoracic nerve (to avoid a "winged scapula" appearance), and the thoracodorsal nerve. When possible, preserving the upper branches of the inner costobrachial sensory nerve can avoid paresthesia and numbness in the inner posterior arm. Careful sparing of the brachial lymphatics that lie anterior

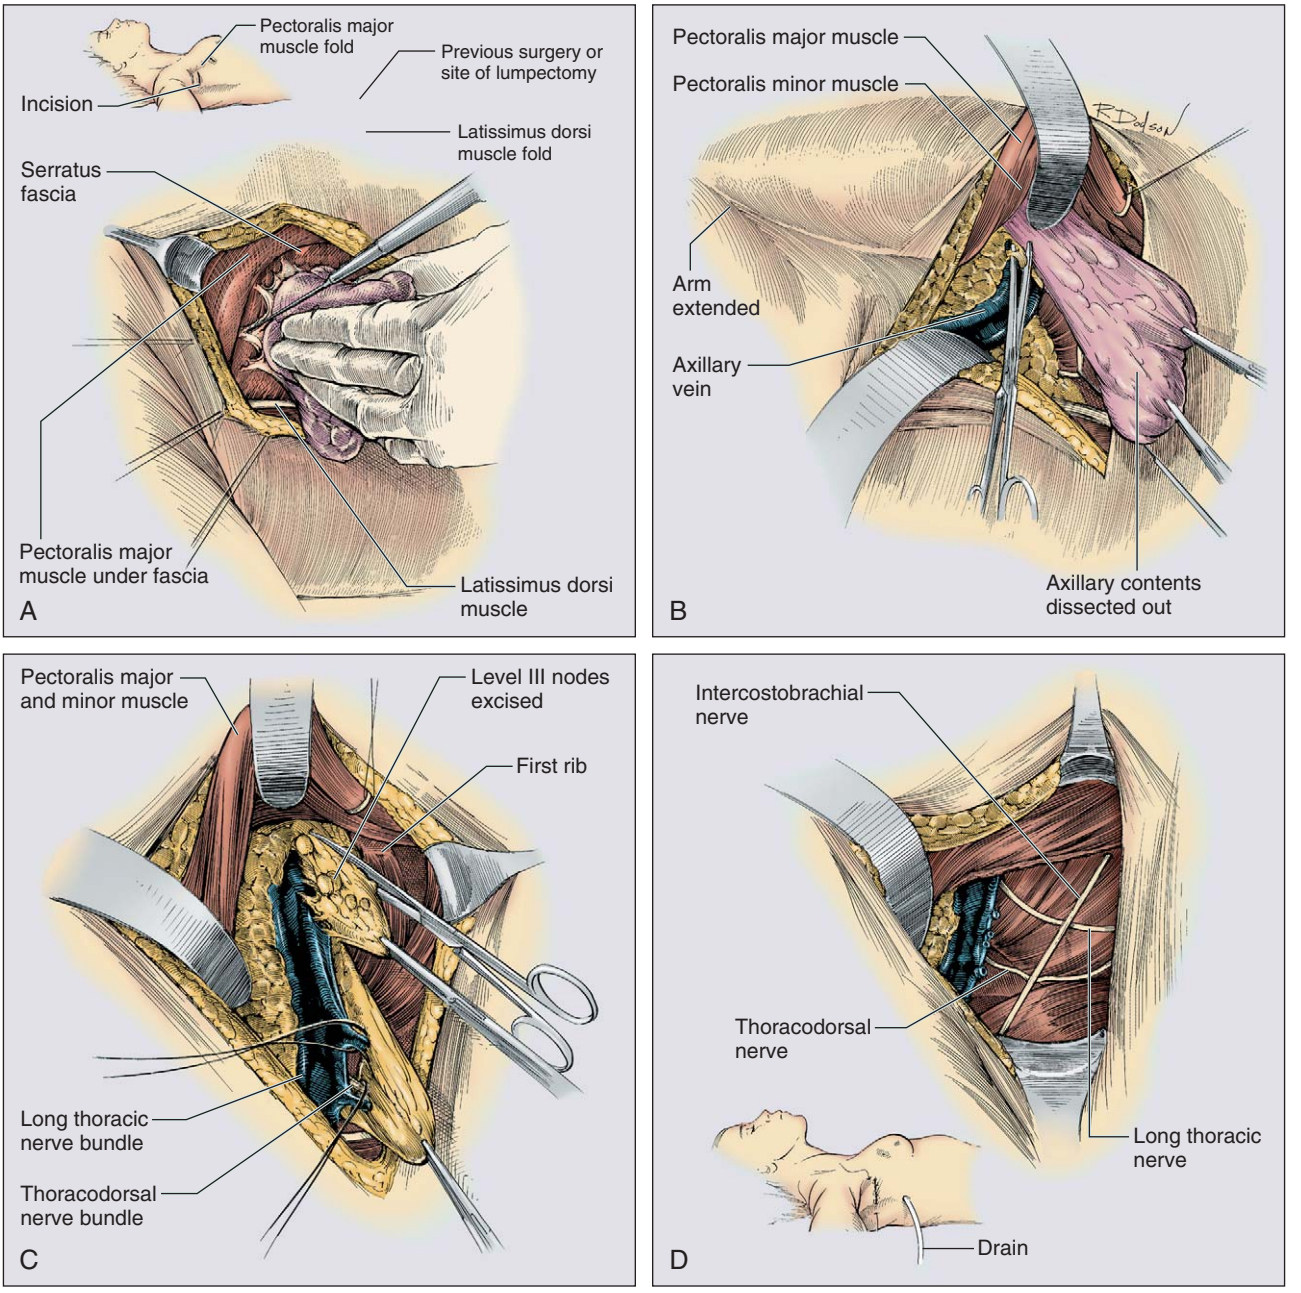

Figure 95-30 • **A,** The incision for axillary node dissection is placed at the inferior aspect of the axillary hairline, and extends from the lateral border of the pectoralis major muscle to the anterior border of the latissimus dorsi muscle. Nylon traction sutures are placed in the dermis. Flaps are raised superiorly and inferiorly. **B,** The pectoralis major and minor muscles are retracted to facilitate dissection of the lymph node-bearing fatty tissue from beneath the muscles and away from the axillary vein and chest wall. **C,** Excision of level III lymph nodes (highest level near the entrance of the axillary vein into the chest) is easily accomplished, even through the small axillary incision, with the arm rotated upward. **D,** The completed dissection, showing the isolated nerves to the serratus muscles, the latissimus dorsi muscle, the pectoral muscles, and the sensory nerve to the inner aspect of the upper arm.

to the axillary vein and brachial plexus minimizes the risk of lymphedema. Lymphedema is associated with body habitus, and people with obesity are at higher risk, despite optimal surgical technique.

Sentinel Lymph Node Biopsy in Invasive Disease

SLN biopsy has largely replaced axillary dissection for patients with clinically negative axillae and is becoming the standard surgery for staging breast cancer.The concept of the sentinel lymph node (SLN) originated with a 1977 description of mapping of the first draining lymph node in penile carcinoma. Detection of a sentinel "blue" node was described in melanoma in 1992 and in breast cancer the year after using blue dye and radioisotope localization. Published reports validated the sentinel lymph nodes by concurrent axillary dissection, and the use of isotope and blue dye simultaneously appear to shorten the learning curve and result in slightly better identification of sentinel lymph nodes. However, some surgeons prefer using the blue dye alone.

Axillary lymph node biopsy (ALND) and SLN biopsy in breast cancer are done for staging/prognosis, local control of disease, and the possibility of a survival benefit from removing involved nodes. The premise of SLNB is equivalent to ALND in all three aspects, with the added advantage of sparing node-negative patients the morbidity of a larger operation from which they could not benefit. The debate over SLN biopsy is whether current data, largely observational, are sufficient to adopt SLN biopsy as standard of care in the absence of level I evidence from the two ongoing U.S. trials (ACOSOG Z0011, a randomized trial of axillary node dissection in women with clinical T1 or T2 N0 M0 breast cancer who have a positive SLN; and *NSABP* B-32: a randomized phase III clinical trial designed to compare SLN resection to conventional axillary dissection in clinically nodenegative breast cancer patients) *and* six European clinical trials (a Milan Trial,[190] the ALMANAC trial,[191] the EORTC 10981–22023 AMAROS trial, the German clinical interdisciplinary sentinel study-KiSS protocol, the French randomised SLN study (Fransenod) trial, and the International Breast Cancer Study Group randomized 23–01 trial.

For lymph node staging, SLNB is best regarded as a diagnostic test for the detection of nodal metastases and, as such, should not require validation by randomized trials. More than 60 observational studies (in over 6000 patients) of SLN biopsy validated by a "backup" ALND have established a 95% success rate for SLN identification and a 95% sensitivity for detecting nodal metastases (i.e., SLNB is "falsely negative" in 5% of node-positive patients, or 2% to 3% of all cases). While this observation suggests a loss of prognostic information for those few false-negative patients, it must be balanced against studies showing that following ALND, 9% to 20% of patients initially deemed node-negative by conventional pathology (a single H&E-stained section) are found on further sectioning and/or immunohistochemical (IHC) staining to have nodal metastases, and that these missed nodal metastases are prognostically significant.[192]

Such exhaustive pathologic analysis is not logistically feasible for an entire ALND specimen. One study alone required the examination of 1600 slides to identify each additional node-positive patient, but it is feasible for the two or three nodes obtained at SLN biopsy. Enhanced pathologic analysis of SLN finds nodal metastases in an additional 10% of cases and is associated with a lower false-negative rate compared with SLN examination by the conventional single-section method. Viewed in this way, SLN biopsy with enhanced pathology generates fewer false-negative results than ALND with conventional pathology, and so it may turn out to have similar accuracy rates when compared to ALND.

If SLN biopsy is falsely negative in a small proportion of node-positive cases, this would seem to pose an increased risk for the development of axillary local recurrence (LR) among patients staged by SLNB alone. In fact, data from several observational studies[193–199] and one randomized trial[190] demonstrate that LR following a negative SLN biopsy is a rare event, occurring in 0.2% of cases, results which compare favorably to those of axillary sampling and of ALND (Table 95-13).[200]

Of particular interest is the observation from the single randomized trial[199] of a 9% false-negative rate in the control arm (SLN biopsy plus ALND) but no axillary LR in either study arm, including the 167 patients staged by SLN biopsy alone. Possible explanations for this consistently low rate of axillary LR across all 10 studies includes selection for early-stage disease, a local effect of systemic therapy, and most importantly the use of breast radiotherapy, which inevitably treats the axillary nodes closest to the breast. While all reports of LR following SLN biopsy are limited by relatively short follow-up, a significant future increase in LR is unlikely, as evidenced by an earlier study of mastectomy without ALND (NSABP B-04[201]) in which 75% of axillary LR appeared within the first 2 years. In preventing axillary LR, SLN biopsy is at least equivalent both to ALND and to axillary sampling.

There is considerable controversy about the staging of patients whose SLNs appear negative by standard H&E examination, but who have isolated tumor cells found by immunohistochemistry or reverse transcriptase polymerase chain reaction evidence of a few cancer cells. The latest TNM staging manual suggests classifying these patients as node-negative, with a subscript to indicate these additional findings. Of note, some European centers consider these patients node-positive. Also controversial is the surgical management of patients with positive SLN biopsy: is completion of the axillary dissection necessary? Some of the clinical trials just described will, we hope, answer this question. A nomogram to predict the likehood of additional positive nodes after positive SLNs has been developed.[202]

Initial contraindications for SLN biopsy, including clinically suspicious axillary lymph nodes, tumor arising from the axillary tail of the breast, multicentricity, large cancers, large biopsy cavity, previous axillary sampling, previous breast and/or axilla radiation therapy, and pregnancy, have been progressively cleared by evidence specific to these patient subsets.[203] Still controversial is the use for SLN biopsy after PST, but data from the NSABP B-27 study shows that SLN biopsy appears to be a reliable procedure following preoperative chemotherapy.[204]

Irradiation of the Intact Breast

No subsets of women have been identified who do as well following conservation surgery without radiation therapy as with it, although such subsets of patients have been aggressively sought.[205] Current recommendations are to irradiate the breast after lumpectomy to achieve the lowest possible recurrence rate. The only possible exception is elderly women with comorbid conditions, as discussed later in this chapter. When radiation therapy is elected, the whole breast is treated through a pair of tangentially directed fields to a dose of 4500 to 5000 cGy over 5 to 6 weeks. Traditionally, the patient is

Table 95-13 Axillary Local Recurrence after Axillary Sampling, Axillary Lymph Node Dissection, and Sentinel Lymph Node Biopsy

	No. of Patients	Median Months Follow-up (range)	Axillary Local Recurrence No. (%)

10 series (2000–2004)			

ALND, axillary lymph node dissection; SLN, sentinel lymph node.

Data from Naik AM, Fey J, Gemignani M, et al: The risk of axillary relapse after sentinel lymph node biopsy for breast cancer is comparable with that of axillary lymph node dissection: a follow-up study of 4008 procedures. Ann Surg 2004;240:462–468.

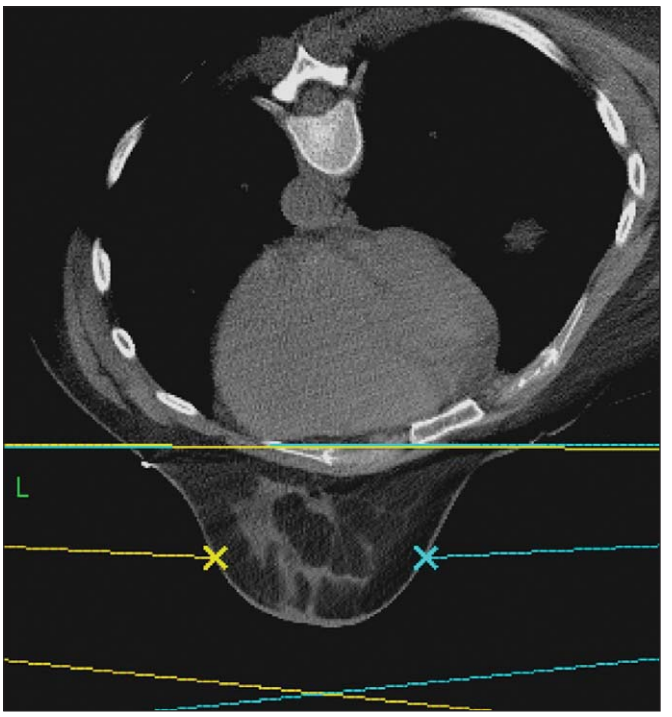

Figure 95-31 • Left breast irradiation using prone breast technique can spare lung, left ventricle, and coronary arteries.

treated supine, with fields designed to skim along the lung/chest wall interface, and irradiate the smallest volume of underlying lung. In left-sided primary lesions, the fields should result in the lowest possible exposure of the heart. Alternatively, the patient may be treated in the decubitus or prone position (Fig. 95-31).[206]

Following the completion of whole breast treatment, an additional series of radiation treatments (or "boost") usually is directed to the lumpectomy cavity only. A striking exception to the use of the boost has been the series of NSABP trials, starting with the B-06 trial; no boost was used until the opening of the B-39 Trial. A randomized prospective EORTC trial evaluated the need for a boost in patients undergoing lumpectomy.[207] In this trial, 5318 women were randomly assigned to a boost of 1600 cGy or no boost, after completing 5000 cGy whole-breast radiation. The results demonstrated that the boost reduced the local failure rate by a factor of 2; looking at age, this translated to a reduction from 19% to 9.5% for those women under age 40, but an absolute difference in those over 60 years of only 1.9%. Most institutions currently recommend a boost for all patients, although based on the EORTC study, considering omitting the boost for women with negative margins over the age of 60 is reasonable. This set of data also confirms the favorable prognosis in the elderly patient. The boost is accomplished quickly and easily on a linear accelerator equipped with electron-beam capability, and requires five to eight additional treatments. Localizing the target within the breast for boost purposes can be accomplished by CT, by ultrasound, or by clips left in the tumor bed. Morbidity associated with a boost is limited to temporary skin tanning.

With either a complete axillary dissection or a successful SLNB and negative results, the axilla is considered treated by the surgeon. Much clinical experience indicates that the axilla is the site of first breast cancer failure in fewer than 1% of patients who have had an axillary dissection. Axillary recurrences occur in approximately 2% of patients with negative nodes or one to three positive nodes and in patients with axillary dissection who received irradiation to the breast only after lumpectomy. Widespread extracapsular extension and gross tumor left behind in the axilla are the only indications for specifically irradiating the dissected axilla. Microscopic extracapsular nodal extension appears to have little effect on the local control rate in the axilla after surgery alone, and can safely be ignored. A clinically negative axilla that is undissected is well controlled by axillary irradiation of 4500 to 5000 cGy. In patients with positive axillary nodes found on axillary dissection, most investigators use a field that irradiates the supraclavicular nodes and the apex of the axilla (level III nodes).

Some institutions prefer to use this field only in patients with four or more positive nodes, whereas other institutions apply it to all axillary-positive patients, and the recent meta-analysis from the Oxford Overview would support the later practice.[183] The Early Breast Cancer Trialists Collaborative Group (EBCTCG; www.ctsu.ox.ac.uk/~ebctcg) compared radiation therapy to none in two patient groups: those with breast conservation therapy (approximately 8,300 women) and those treated with mastectomy (approximately 10,000 women). For all node-positive women, the addition of radiation therapy not only reduced the risk of a local failure, but also reduced mortality at 15 years follow up, by about 5%. Figure 95-32 demonstrates the positive effect of breast or breast and nodal radiation for women on breast cancer study trials.

Elderly Patients

A North American intergroup trial focused on women 70 years of age or older with stage I ER-positive disease, all of whom underwent lumpectomy followed by 5 years of tamoxifen and were randomized to receive radiation therapy or not. Two thirds did not undergo an axillary dissection, and half were 75 years of age or older. With a median follow-up of 0.82 years,there was a statistical difference in local failure rates: 1% of the radiated women versus 69% of the tamoxifen-only women had a recurrence in the ipsilateral breast. However, no differences were found in the rates of mastectomy, distant recurrence, and overall survival.[208]

Partial Breast Irradiation

Despite the excellent results of breast-conserving surgery with whole-breast radiation, a study from the American Colleges of Radiology and Surgeons noted only 42.6% of women in the United States. with stage I and II breast cancer were treated in this manner.[209] The study also demonstrated that 11% of women with breast-conservation surgery never received radiation. Thus, considering ways of making this treatment more available to women who may not live near a center equipped with radiation facilities was addressed in the early 1990s, especially as data from Milan showed that almost all local failures in women treated with "standard" BCT were located in the original quadrant of diagnosis.[210] The concept of "partial accelerated breast irradition" (PBI) was thus proposed and tested. The goals were two-fold: to increase the proportion of women who had access to both the surgery and the radiation, by dramatically shortening the time course of the radiation; and to limit the radiation to the lumpectomy cavity with a small margin of normal tissue. In the United States, two centers, the Ochsner Clinic and William Beaumont Hospital, independently initialized pilot PBI studies using catheter-based brachytherapy and low-dose rate sources. After reports of initial success, the RTOG Cooperative Group opened a phase II trial, allowing either high- or low-dose-rate sources and the catheter technique. The dose used was 3400 cGy, given over 5 days using twice-per-day treatments for the 33 high-dose patients. Results in the 99 patients in the trial, with a median follow-up time of 6.1 years, showed an in-breast failure of 3% for the high-dose-rate group, and 6% for the 33 women in the low-dose-rate group.[211]

Catheter-based PBI is technically demanding. Although most radiation oncologists are not trained to use it, in 2002 the FDA approved a new catheter for deliver of brachytherapy, the MammoSite Radiation Therapy System (Cytyc Surgical Products)

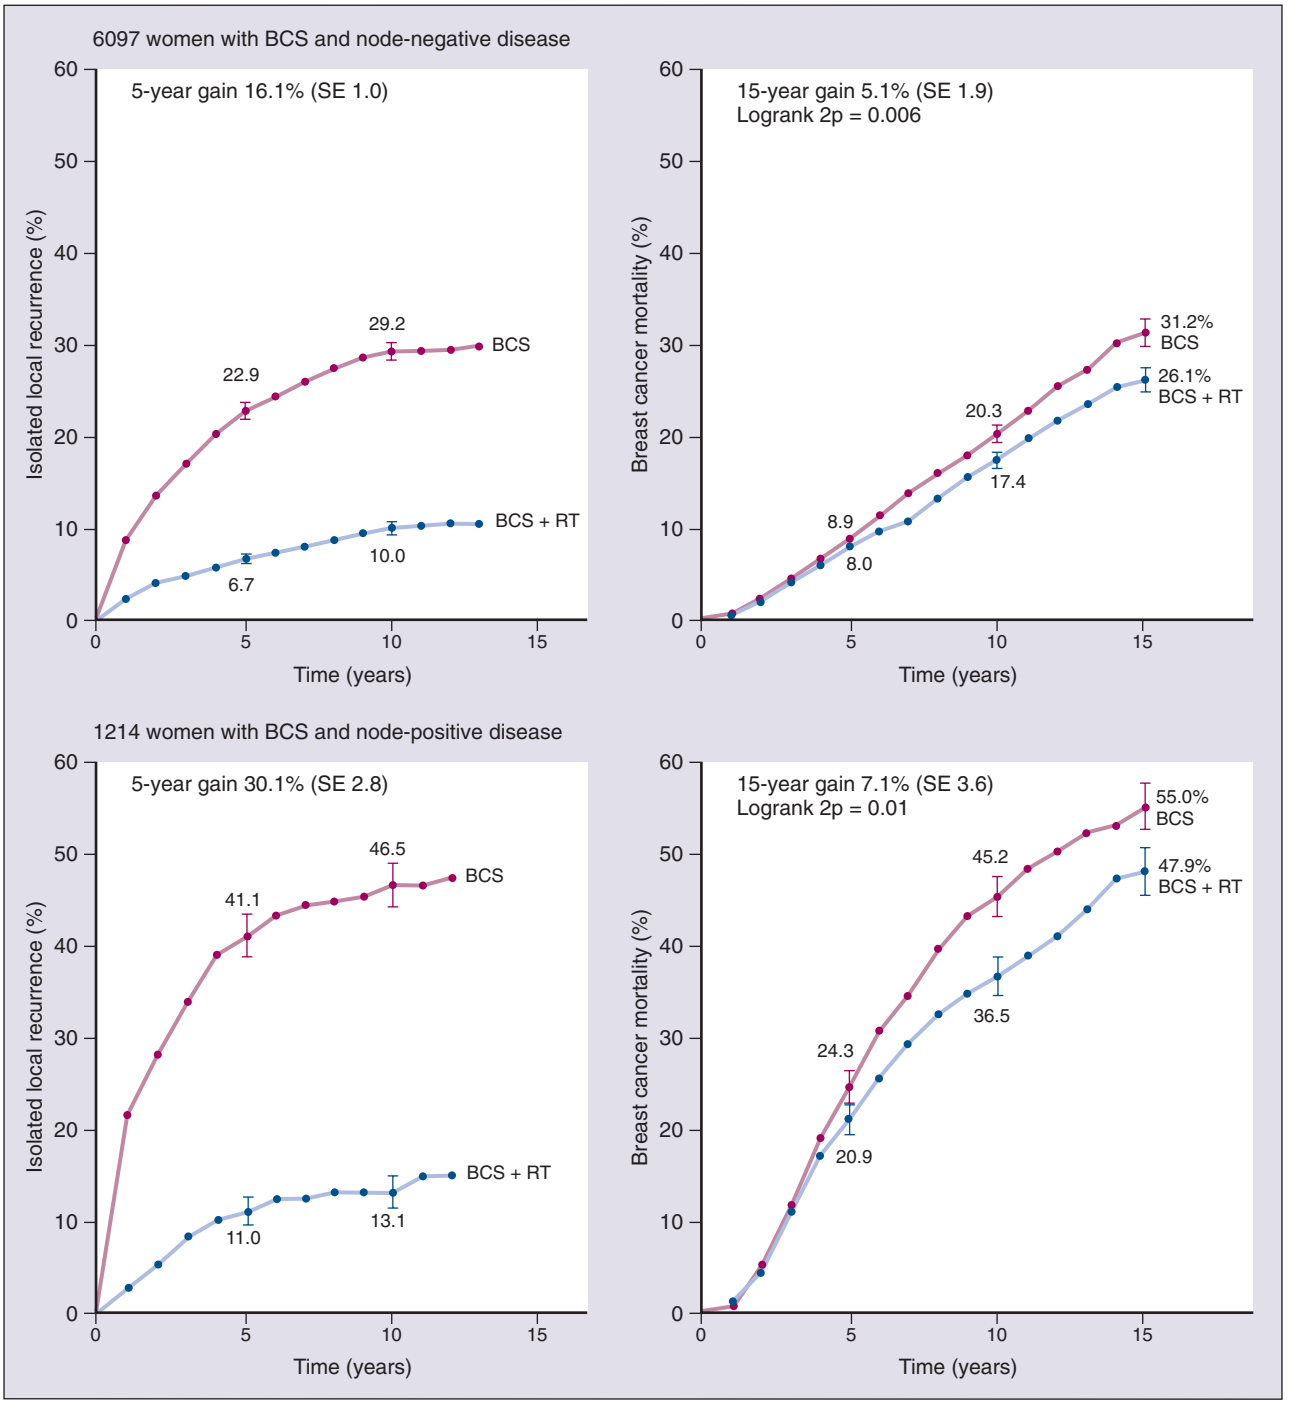

Figure 95-32 • Effect of radiation therapy (RT) after breast cancer study on local recurrence and on breast cancer mortality—15-year probabilities. Data from 10 trials. Vertical lines indicate 1 SE above or below the 5-, 10-, and 15-year percentages. (From Lancet 366:2092.)

Fig. 95-33. This device was easy to insert into the lumpectomy cavity, and rapidly appeared as a treatment in clinical practices. In order to address whether these PBI therapies are equivalent to standard whole-breast external beam radiation, the NSAPB and the RTOG together opened a phase III trial addressing this issue, in 2005. Women are randomized between whole-breast radiation or PBI using the RTOG schedule of twice per day treatments to a total dose of 3400 cGy. The PBI may be given by catheter brachytherapy, the MammoSite device, or an external beam PBI technique.[212] With more than half of the planned 4200 patients accrued by 2007, the PBI technique using the external beam, noninvasive system has proved to dominate the PBI arm. Other researchers have approached the technical issues with PBI by developing intraoperative radiation techniques. The group in Milan is working on a randomized trial using a portable linear accelerator that can be brought into the operating room, and the group at Memorial Sloan-Kettering Cancer Center has devised a special appplicator that uses high-dose-rate afterloading therapy. Both deliver a dose of about 2000 cGy directly to the lumpectomy cavity in the operating room before the surgeon closes the wound.[213]

Complications of Treatment

With increasingly sophisticated treatment planning and delivery systems, late complications of lumpectomy and radiation frequently seen 20 years ago are no longer common. Approximately 5% to 20% of patients have measurable arm edema with either lumpectomy or mastectomy, which suggests that the axillary procedure is the key factor in itself. Rib fractures are seen in approximately 2% to 5% of patients treated with radiation; most of these are asymptomatic and detected when a bone scan or chest x-ray is done for other reasons. Therefore, rib fracture should always be included in the differential diagnosis of a previously irradiated patient with breast cancer who has chest wall or rib tenderness and whose bone scan shows an area of tracer uptake in the ribs of the treated chest wall. No specific therapy is indicated, because most of these fractures heal spontaneously.

Approximately 1% or fewer of patients treated with radiation have symptomatic radiation pneumonitis. This complication is more common in patients who have received chemotherapy and radiation that included a supraclavicular field. In almost all patients, pneumonitis resolves either spontaneously or with a short course of corticosteroid therapy, and no long-term sequelae occur. Sometimes, radiation causes scarring in the small rim of lung treated in the tangential fields that can appear as a density in the lung field underlying the treated breast on routine chest x-ray and is confirmed by CT scan showing lung changes confined to the area of high-dose irradiation just underneath the anterior chest wall. Usually, no intervention is needed. Rarely, breast irradiation leads to late cardiac damage.[214] Much of this information comes from treatment of the postmastectomy chest wall, especially when radiation was directed specifically at the internal mammary nodes. Recent studies suggest that few patients have sufficient cardiac volume within the radiation port to place them at risk for later damage and that these patients can be recognized in advance so that such complications may be avoided with sophisticated treatment planning. A supraclavicular portal sometimes results in brachial plexus injury, and the risk appears increased if large daily dose fractions are used.

In rare cases, years later, radiation results in a soft tissue sarcoma within the radiation portal. The incidence of this extremely serious complication is approximately 0.1%. Recent studies have confirmed an increase in the risk of developing an ipsilateral lung cancer in women smokers with breast cancer who opted for lumpectomy with radiation.[215]

Local Recurrences

In most centers, local in-breast failure is managed with mastectomy. Although there are reports of successful treatment either by excision alone, especially for late recurrences, or by excision plus additional local radiation, these techniques are not considered part of standard care. An outstanding study of local recurrences came from pooling two randomized studies from the EORTC 10801 and the Danish study group DBCG-82TM prospective randomized trials comparing breast conservation surgery and radiation with mastectomy. Both therapies were associated with a similar risk of local failure and overall survival following salvage treatment, which in most cases consisted primarily of mastectomy in the conserved group and radiation in the mastectomy group.[216] Figures 95-34 and 95-35 illustrate the data for both BCT and mastectomy patients. There is increased interest in MRI for surveillance after breast conservation, but data are lacking

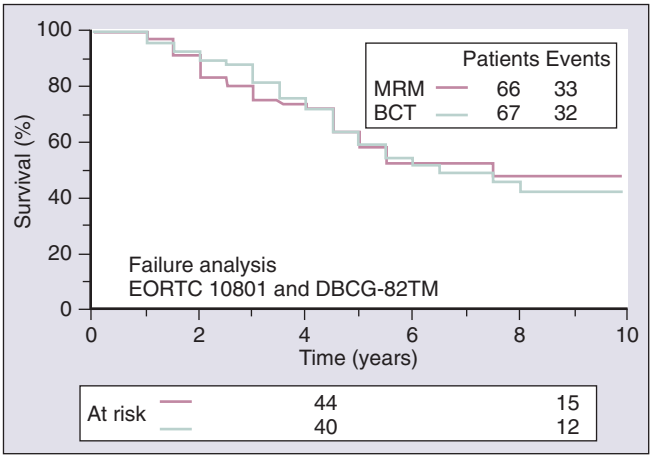

Figure 95-35 • Actuarial overall survival from salvage treatment by original group (MRM or BCT). Patients at risk at 4 and 8 years are indicated. BCT, breast-conserving therapy; MRM, modified radical mastectomy. on improved outcomes when compared with clinical examination and routine imaging with mammography and ultrasound, as appropriate.[217]

FACTORS THAT AFFECT OUTCOME

Patient Age

Younger patients (e.g., under 35 years of age) have a higher rate of lumpectomy failure (Table 95-14) as well as a higher rate of chest wall failure after mastectomy than do older patients. It is possible that age serves as a surrogate for higher risk tumors as younger women are more likely to have extensive intraductal carcinoma (EIC), high nuclear grade, lymphatic space invasion, and tumor necrosis.[218] It is likely that the recurrence patterns seen in these young women are related to a combination of these adverse histologic features.

Tumor Size

When lumpectomy and the use of radiation are examined as a function of tumor size, there is a dramatic fall-off in the application of breast-sparing therapy for T2 tumors in comparison with smaller T1 tumors. The important factor in the decision should not be tumor size, however, but cosmetic results. Women whose primary tumor size makes it difficult to perform a cosmetically acceptable excision can have their tumor reduced with preoperative chemotherapy and may then become candidates for breast-conserving therapy. In the NSABP B-18 preoperative trial, 67.8% of women in the preoperative arm vs. 59.8% in the postoperative arm underwent breast-conservation therapy, with no difference in survival outcome.[219,220]

Histology

Schnitt and associates in Boston noted that a new histologic pattern within a breast tumor was a strong predictor for subsequent in-breast failure after radiation. They observed a pattern containing intraductal carcinoma present both within and adjacent to the invasive breast cancer lesion, defined as an extensive intraductal component (EIC). DCIS had to be a prominent feature of the invasive cancer, in at least 25% of the tumor area, and no specific amount of DCIS adjacent to the tumor was required. Tumors that were predominantly DCIS with small areas of minimal invasion were classified as EIC-positive and are 4 times as likely to develop local recurrence. This suggested that there might be a greater tumor burden inadvertently left behind at the site of the primary excision in patients with EIC-positive disease. Follow-up studies demonstrated that this negative prognostic effect of the EIC could be overcome with the surgical removal of a larger volume of tissue in this patient subset. In other words, with wider margins, the effect of the EIC was removed.[189]

MASTECTOMY

For many decades, Halsted's radical mastectomy was the treatment of choice for all stages of breast cancer. This operation, which consists on the removal of a large portion of the breast skin, all the breast parenchyma, and the major and minor pectoral muscles en bloc with the axillary lymph nodes, is now limited to locally advanced tumours (T3, T4b) when preoperative chemotherapy is not an option. A less aggressive modified radical mastectomy, with sparing of the pectoralis major muscle, was described by Patey in 1948 and has proved to be equally effective in the local control of most tumors. SLN biopsy has made axillary dissection for staging unnecessary in women with no suspicious palpable lymphadenopathy and negative findings. Total or simple mastectomy with removal of skin, including nipple-areolar complex and all breast tissue without the axillary lymph nodes, has supplanted modified radical mastectomy for this group of node negative patients who require mastectomy.

Reconstruction of the breast is a valid option after mastectomy and can be done immediately or after the procedure (i.e., delayed). With attempts to improve overall cosmesis after mastectomy and breast reconstruction, more "conservative" mastectomy procedures have evolved. Skin-sparing mastectomy, in which removal of the skin is limited to the nipple–areola complex, sometimes with a small portion of the surrounding skin, has come to be accepted as an oncologically safe approach that minimizes deformity and improves cosmesis. The risk of local recurrences after skin-sparing mastectomy and breast reconstruction was compared to that of conventional

mastectomy in some retrospective series showing similar rates of local control, although selection bias may have partially influenced the results.[221] A few retrospective studies with relatively long follow-up reported good results after treatment with nipple-sparing mastectomy, in which only the breast parenchyma is removed without skin or the nipple and areola in selected early-stage breast cancer and high-risk women pursuing mastectomy.[222–224] The ductal tissue below the nipple represents the major oncologic concern in the preservation of the nipple during mastectomy, and complete removal of this tissue may affect the vascularization of the nipple, increasing the probability of necrosis.

Occult nipple involvement ranged from 0% to 50% in several retrospective studies of nipple-sparing mastectomy, in which the pathology blocks of the nipple were reanalyzed, but the percentage has been lower in more recent publications. Careful pathologic examination of the retro-areolar ducts must be performed in nipple-sparing mastectomy. Removal of these structures should be considered the most conservative approach.

In modified radical or total mastectomy, when surgery is performed through incisions other than circumareolar incisions, the incision is placed so that the scar will not be visible when the patient wears a bathing suit or low-cut dress. When elliptical or transverse incisions are used for a total mastectomy, it is ideal to excise any previous biopsy scar as well as the nipple-areolar complex. Skin flaps are carefully developed with a combination of scalpel and electrocautery dissection. The flaps are sufficiently thin to remove all apparent breast tissue, but it is not necessary to remove the subcutaneous tissue of the flaps. This tissue carries the blood vessels to the skin and is of cosmetic importance. Especially in young women, the cleavage plane between breast tissue and subcutaneous tissue may not be evident, and complete removal of the breast tissue is the priority. Depending on the patient's body habitus, the flaps may contain from 1 to 8 mm of subcutaneous fat. In a standard modified radical or total mastectomy, the inferior flap extends inferiorly below the inframammary crease for approximately 2 cm onto the interior fascia of the rectus muscle. If immediate reconstruction is to be performed, the dissection usually ends at the inframammary crease, unless additional breast tissue is present inferiorly to the crease. The superior flap is then dissected similarly, just to beneath the clavicle. The medial extension of the skin flaps reaches the lateral edge of the sternum, and the lateral extension reaches the anterior edge of the latissimus dorsi. In bilateral mastectomy, attention should be paid to not crossing the sternum, creating a tunnel between the two medial flaps, because this may affect the cosmesis of the breast reconstruction. Once the flaps have been developed, the breast is dissected from the chest wall by dissecting the pectoralis major fascia off the muscle superiorly and medially, progressing inferiorly. If total mastectomy is performed and the axilla is not to be dissected, as the breast is dissected from the lateral edge of the pectoralis major muscle, the pectoralis muscle is seen beneath it. The surgeon should spare the medial pectoral nerves, which wrap aound the lateral border of the pectoralis minor muscle and insert into the posterior aspect of the pectoralis major muscle. Division of these nerves leads to atrophy in the central portion of the pectoralis major muscle. If total mastectomy is performed, the dissection may progresses into the axilla above any apparent breast tissue, and sometimes may include some lower axillary lymph nodes, which are present in the axillary tail of Spence. During total or simple mastectomy, no attempt is made to remove the axillary lymph nodes. The breast is then swept inferiorly, with care taken to spare the thoracodorsal and long thoracic nerves in their lower extent as the breast tissue is removed. When the specimen is removed, a suture is used to identify the axillary tail and the retro-areolar ducts in case of nipple-sparing mastectomy so that the pathology department can orient it properly for assessing marginal clearance.

If the axilla is to be dissected, either in continuity or as a separate axillary dissection, the axilla is best entered from within the fascia of the pectoralis major muscle posteriorly. Coming down two fingerbreadths from the uppermost extent of the pectoralis major fascia posteriorly, a transverse incision is made. This incision goes through the pectoralis major fascia and 1 mm beneath it, through the clavipectoral fascia. Fat from the axilla then pops through this division of the clavipectoral fascia. The inferior border of the axillary vein is two fingerbreadths below the highest extent of the pectoralis major fascia. This is important because the lymphatics of the arm pass anterior to the axillary vein. Staying below the axillary vein minimizes the risk of subsequent lymphedema of the arm.

The landmark for the axillary anatomy is the thoracodorsal vein, which is one fingerbreadth out from the chest, 2 cm lateral to the chest wall and passing dorsally into the dorsal inferior aspect of the axillary vein. When it is identified, the thoracodorsal nerve is seen to emerge from behind the axillary vein, just medial to the thoracodorsal vessels. It joins these vessels, continuing onto the anterior surface of the thoracodorsal vein. Between 1 and 2 cm below the axillary vein, the highest branch of the intercostobrachial nerve is seen coming from the chest wall and going to the arm. It is important and usually possible to spare and clear this nerve branch to avoid the dysesthesias associated with its division and total numbness of the inner posterior arm. These technical steps minimize the sensory complications and lymphedema associated with axillary dissection. When the thoracodorsal nerve has been identified, sweeping the axillary fat downward off of the chest wall moves the level II axillary nodes out from behind the pectoralis minor muscle and clears the long thoracic nerve safely. The long thoracic nerve is always found in the same anterior-posterior plane as the thoracodorsal nerve, but is immediately applied to the chest wall. At this point, the three major midaxillary nerves have been identified. If the medial pectoral nerves were not previously identified by sweeping the fatty tissue off of the lateral border of the pectoralis minor muscle, the medial pectoral nerves will not be seen coming around the lateral border of the pectoralis minor and entering the posterior aspect of the pectoralis major. The axillary contents can now be cleared inferiorly, with all of the important nerves and vessels in view. When axillary dissection is complete, the remainder of the breast flap division allows the specimen to be handed off. If the mastectomy was performed through a circumareolar incision, the specimen may be too large to be delivered and a tennis racket incision 1 to 2 cm lateral to the circumareolar incision will allow the specimen to be retracted.

When suspicious palpable lymph nodes are present at level III, removal of these nodes is advised. If possible, the pectoralis minor muscle is preserved. The lateral borders of the pectoralis major and minor muscles are dissected, thereby preserving the medial pectoral nerve. In this way it is possible in nearly every case to dissect the apex without division or removal of the pectoralis minor. Both pectoral muscles are retracted medially to maintain the exposure of the level III region. After incising the surrounding fascia anteriorly to the axillary vein at its junction with the chest wall, just lateral to Halsted's ligament, careful traction in an inferiolateral direction makes the dissection of the specimen from the surrounding structures easily possible. Small branches from the axillary vein and lymphatic vessels usually can be cauterized. For larger blood vessels, clamping and cutting is mandatory.

The content of level III can be removed in continuity with the specimen of levels I and II. For the purpose of the pathohistologic examination, each level should be marked separately with a metallic tag. If division of the tendon, with or without removal of the pectoralis minor muscle, is indicated or unavoidable, dissection ends as soon as the border of the pectoralis major is visualized. The pectoralis minor remains in continuity with the breast and the axillary tissue.

When hemostasis is complete, the plastic surgeon can reconstruct the breast according to the patient's body habitus. For a very small-breasted woman, an expander can be placed beneath the pectoralis major and partially expanded to allow the skin anterior to the muscle to achieve normal tension. For a fuller breast, the latissimus dorsi can

be freed, swung around anteriorly, and joined to the lateral border of the pectoralis major muscle with a prosthesis lying deep to the muscle. This muscle cover provides the reconstructed breast with a very natural feel. For a larger-breasted woman, optimal reconstruction may involve various forms of pedicled or free (myo)cutaneous flaps.

ADJUVANT POSTMASTECTOMY IRRADIATION

At one point, irradiation of the chest wall after mastectomy was almost universally applied in the treatment of breast cancer, largely because of the more advanced nature of breast cancer in the early decades of the 20th century, with an attendant high rate of local chest wall failure. As surgical techniques improved and clinicians began to take a more rigorous scientific look at breast cancer therapy, the need for postoperative chest wall irradiation began to be questioned. Possibly the first randomized prospective clinical trial testing one form of cancer therapy against another was the Manchester, England, trial of immediate versus delayed chest wall irradiation in postmastectomy patients, begun in 1948. Since that time, more than 30 randomized trials of postmastectomy irradiation have been performed. Although chest wall radiation dramatically reduced the risk of subsequent chest wall recurrence and decreased the chance of dying of breast cancer, the overall survival rate in irradiated women remained unchanged, without the addition of systemic therapy. As systemic therapy improved, postmastectomy radiation was prescribed only in very locally advanced cases (Box 95-1).

However, two recent randomized trials of postmastectomy radiation versus none, with all women in the study receiving systemic CMF chemotherapy, did show a survival advantage for the addition of radiation in premenopausal women with 1 to 3 positive nodes, the trial target population.[225,226] With this new outcomes information, the added value of postmastectomy radiation, in addition to systemic therapy, became a controversial topic, with questions such as "Which patients are at highest risk for local failure?" and "What anatomic areas should be targeted for treatment?"

To address these issues, a guideline panel from the American Society of Clinical Oncology (ASCO) recommended postmastectomy radiation for patients with four or more involved nodes, and suggested the treatment for those with T3 tumors as well. However, it concluded that there was insufficent evidence to make a formal recommendation in the subsets of one to three involved nodes, women with reconstruction, and the use of internal mammary node radiation as part of the target volume.[227] The 2000 EBCTCG overview analyzed almost 10,000 women on trials of postmastectomy radiation (Fig. 95-36) and showed significant improvement of both local control and survival at 15 years in all groups, except node-negative women treated with mastectomy.[228]

Box 95-1. INDICATIONS FOR POSTMASTECTOMY RADIATION

Tumor >5 cm
T4 tumor
Involvement of 4 or more axillary lymph nodes
Gross extracapsular nodal disease
Residual disease after mastectomy

Additional Considerations

Involvement of 1 to 3 axillary lymph nodes
Gross multifocality
Extension into the nipple or skin

PREDICTIVE AND PROGNOSTIC FACTORS FOR INVASIVE DISEASE

Although it is possible to describe the average risk of recurrence and potential benefit offered by systemic therapy for a population of patients using clinical nomograms like Adjuvant! Online,[229,230] this exercise is difficult in an individual patient. A pure prognostic factor like TNM predicts patient outcome in the absence of therapy while a pure predictive factor predicts the likelihood of response to a specific therapy. HER2 and ER are examples of moderate prognostic factors with a strong predictive utility in predicting response to specific therapies that can help to individualize treatment recommendations for women with early stage breast cancer[75,184] at high risk for recurrence. Unfortunately, even commonly used markers such as ER/PR and HER2 suffer from lack of assay standardization and reproducibility, and many assays have not been properly validated (Table 95-15).[231] Other commonly used prognostic markers include tumor grade, lymphatic or vascular invasion, and specific histologies like mucinous and tubular cancers. Bone marrow micrometastases appears to be of prognostic significance, but assays lack standardization, while circulating tumor cells do not have sufficient sensitivity at present for use in the adjuvant setting.[232]

Women whose tumors overexpress or amplify the HER2 receptor may be less likely to respond to endocrine manipulations with tamoxifen or aromatase inhibitors. These women may consider the addition of adjuvant chemotherapy, even if their tumors do not exceed 1 cm

Table 95-15 Criteria for Evaluating Clinically Useful Tumor Markers

IDENTIFICATION OF A POTENTIAL MARKER
What is the distribution of the marker in normal and abnormal tissues?
What is the prevalence of the marker in the patient population of interest?
What is the source of specimens examined? Institutional or cooperative group tissue or serum banks?
Does the marker appear to predict outcome (prognostic factor) or response to therapy (predictive factor)?
DEVELOPMENT AND VALIDATION OF A CLINICAL ASSAY
Has the assay target that best correlates with the intended marker objective been identified (e.g., gene amplification, protein expression)?
Has the optimal specimen source for the assay been identified (e.g., paraffin block, fresh tumor tissue, peripheral blood, urine)?
Have the conditions of the assay been optimized and standardized? Has its reproducibility in other labs been tested?
Has a standardized and cross-validated scoring system been developed?
Have the sensitivity and specificity of the assay been validated against a gold standard?
VALIDATION OF THE CLINICAL USEFULNESS OF THE MARKER
Has this marker been validated in a patient population other than the one used to develop the predictive and prognostic model?
Does the presence of the marker discriminate between patient subsets according to the outcome of interest?
Is the prognostic or predictive information provided by the marker independent of other established markers?
Has a prospective randomized trial using the proposed marker been performed using the information provided by the assay to stratify patients according to risk or to select planned therapy?

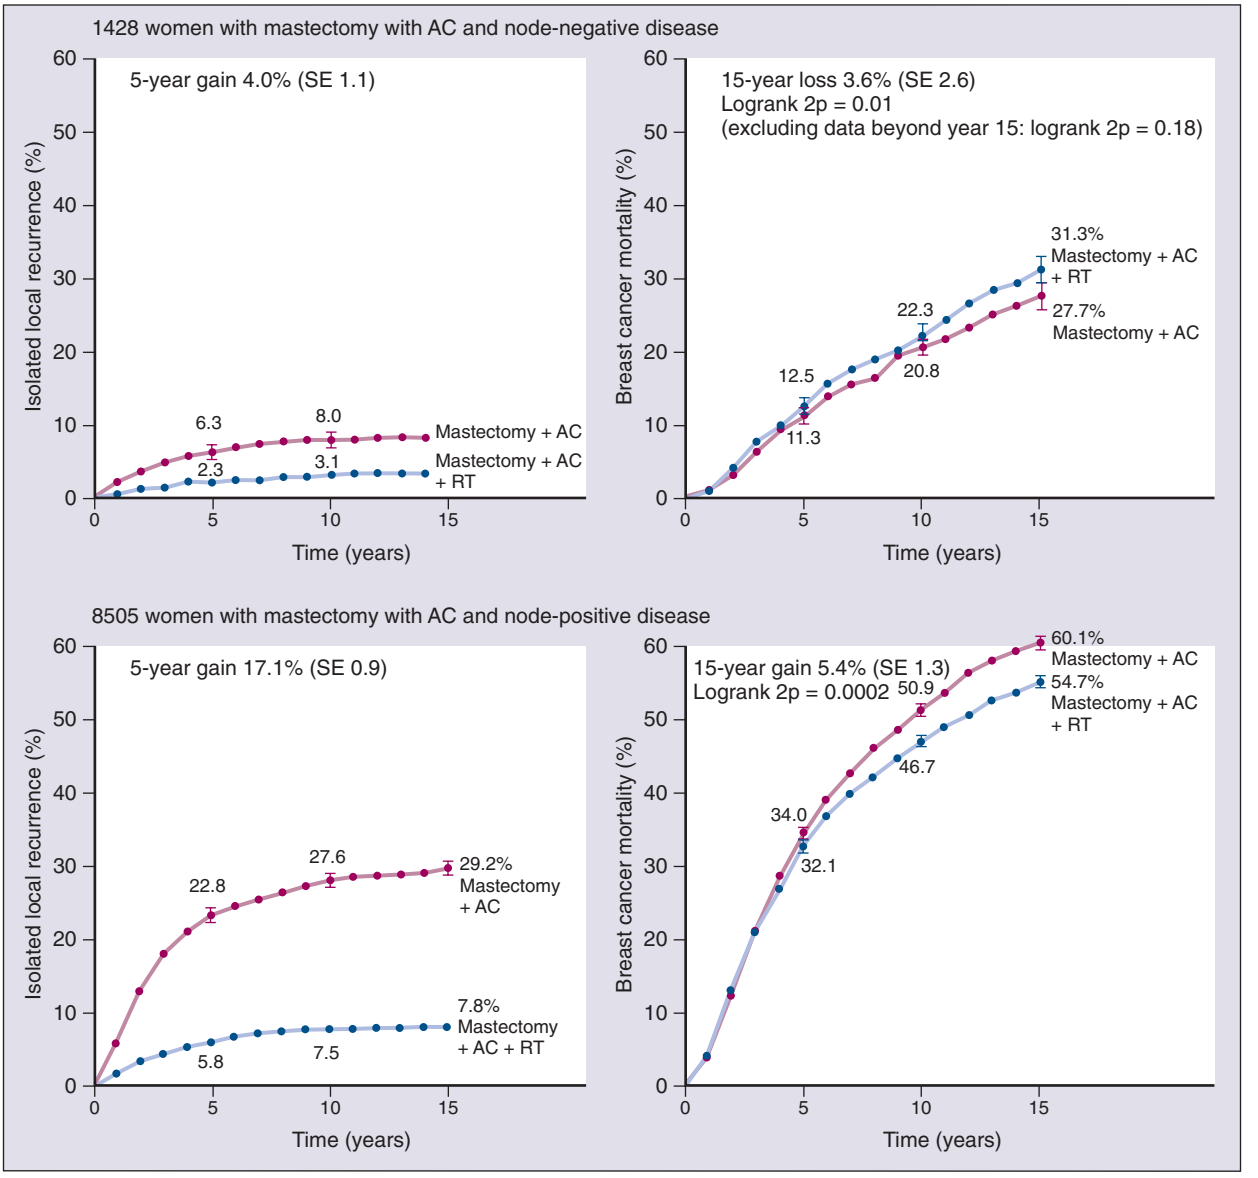

Figure 95-36 • Effect of radiation therapy (RT) after mastectomy and axillary clearance AC on local recurrence and on breast cancer mortality—15-year probabilities. Data from 25 trials. Vertical lines indicate 1 SE above or below the 5-,10-, and 15-year percentages. (From Lancet 366:2092.)

and carry ER or PR, although the adjuvant role of trastuzumab has not been tested in these small tumors. HER2 overexpression also identifies patients in the adjuvant[78,79,233] and metastatic[234] settings who might benefit from trastuzumab therapy. Many other individual prognostic or predictive factors are under investigation. Levels of urokinase-type plasminogen activator and its inhibitor PAI-1 had strong prognostic value in women with node-negative breast cancer who did not receive adjuvant systemic therapy and had more than 10 years of follow-up.[235]

In addition to individual factors, powerful emerging technologies, such as proteomics or gene arrays, hold the potential to identify patterns of expression of genes or proteins at baseline or in response to therapy that may have prognostic or predictive value, and to assist in treatment decision-making for individual women.[94,100,101,236] Initial studies with array-based expression profiling showed the ability of the technology to classify breast cancer according to five gene clusters: luminal subtype A, luminal subtype B, HER2-positive, basal, and normal breast-like subtypes (see Fig. 95-2) and that BRCA-1 genotype predisposes to the basal tumor subtype.[97] The ER-positive group was characterized by high expression of many genes expressed by breast luminal cells, and the ER-negative group showed gene expression characteristic of basal epithelial cells. However, a third group showed genes related to HER2 overexpression, suggesting that this molecular characteristic may have equal or greater weight than ER expression in subclassifying breast cancers. Finally, a small group of breast cancers cluster with normal breast epithelium and are referred to as *normal breast-like.* These distinct subtypes of breast tumors, described as *basal-like, ERBB2 (HER2), luminal A, luminal B,* and *normal breast-like,* show distinctive molecular signatures and appear to represent diverse biologic entities associated with distinct clinical outcome, and the comparison of several independently developed gene signatures appears to show similar prognostic information suggesting the existence of a common set of biologic phenotypes.[104] These patterns of gene expression appear to provide more specific information than identification of a single gene with a specific effect.

By late 2007, three gene expression profiles were available for commercial testing in the United States: the Oncotype DX (Genomic Health, Inc.) assay for women with ER-positive lymph node-negative disease based on a 21-gene profile developed by Paik and coworkers[102,103]; the MammaPrint (Agendia) assay based on a 70-gene prognostic signature developed by van't Veer and colleagues[100,101,237]; and the Breast Cancer Profiling (BCP) assay (AviaraDx) based on the two-gene ratio signature developed by Ma and associates.[238,239] Retrospective studies showed that the Oncotype DX assay has prognostic utility and identifies which patients who are lymph node-negative and ER-positive will do well or not (low vs. high recurrence score [RS], respectively). Of greater importance, this assay also has predictive utility in determining in a similar group of patients who will benefit from the addition of a non-anthracycline regimen to tamoxifen and who will not (high vs. low RS, respectively). The Oncotype DX also has been shown to predict the likelihood of response to preoperative systemic chemotherapy.[240] However, several questions remain about the utility of these various assays,[241] and ongoing trials will prospectively confirm and test, respectively, the clinical utility of the Oncotype DX (TAILORx trial, see http://www.cancer.gov/clinicaltrials/digestpage/TAILORx) and MammaPrint (MINDACT trial, see http://www.breastinternationalgroup.org/TransBIG/Mindact.aspx) as a sole determinant of therapy selection. Gene expression profiles with predictive utility such as the Oncotype DX[103] can help individualize the therapy benefit in a very specific subset of patients with ER-positive, lymph node-negative disease. Preliminary data presented at the San Antonio Breast Cancer Symposium in the fall of 2007 (see www.sabcs.org) suggest that the Oncotype DX assay also may help identify among postmenopausal women with ER-positive, lymph node-positive disease those who would benefit from the addition of anthracycline-based chemotherapy to tamoxifen.

ADJUVANT SYSTEMIC THERAPY

While adjuvant systemic therapy significantly reduces the odds of recurrence and death, mammography screening and earlier diagnosis are responsible for at least half of the breast mortality reduction observed between 1990 and 2003,[242] suggesting that the ability of tumors to metastasize may be acquired over time and would counter the prevailing so-called *systemic theory.*[182] Large databases also indicate that the 5-year survival rate in women with small endocrine-responsive tumors is not likely to be affected by their disease, and chemotherapy offers minimal potential benefit,[243] although data from the NSABP suggest improvements in both recurrence-free and overall survival in women with ER-positive and ER-negative tumors no more than 1 cm in size.[244] These uncertainties are due to the modest treatment benefits obtained with available systemic therapies on average and the considerable heterogeneity observed in breast cancer even when considering tumors with similar profile using standard pathologic parameters (e.g., tumor size, nodal status, and ER/PR expression). While systematic reviews and computerized nomograms have been quite useful to demonstrate the average benefit for specific patient subgroups, especially when the absolute benefit is otherwise small, these efforts fail to recognize this individual variability.

It is now understood that the small to modest therapeutic effects noted in individual clinical studies are of great value if applied to the large population of women with breast cancer. Since 1985, the EBCTCG (see www.ctsu.ox.ac.uk/~ebctcg) has performed, at 5-year intervals, an ongoing combined analysis, or meta-analysis, of all available randomized trials to detect whether a specific treatment modality used for patients with operable breast cancer had an effect on overall survival and to determine the magnitude of this effect.[228] General conclusions can be reasonably drawn about the effectiveness of various adjuvant systemic therapies. A significant survival advantage after polychemotherapy was unequivocally shown in all adequately studied age categories. However, the magnitude of benefit appears to be less in older women. Likewise, chemotherapy has been effective in patients with node-negative or node-positive disease. Polychemotherapy is superior to monochemotherapy, and chemotherapy administered for 12 months or longer has not been associated with greater benefit than shorter duration of treatment (e.g., 6 months). Increasing evidence indicates additional benefit of combining chemotherapy and tamoxifen in receptor-positive patients, and anthracycline-containing regimens appear to have greater effects on recurrence and survival than standard CMF regimens.

The Oxford Overview also shows that adjuvant tamoxifen improves survival, irrespective of age or menopausal status. The hormone-receptor status of the primary tumor is the strongest predictor of the magnitude of the treatment benefit of tamoxifen. In contrast to chemotherapy, more prolonged administration of tamoxifen (i.e., 5 years) provides greater benefit than a single year of administration. Some studies show no additional benefit when tamoxifen is continued beyond 5 years, which is now the standard in most centers, but this question has not been fully resolved. Ovarian function suppression reduces mortality rate in women younger than 50 years of age when compared with no therapy and is similar to the benefit offered by CMF-based chemotherapy, but its additive role after chemotherapy, in addition to tamoxifen, and its use with aromatase inhibitors are now the subject of large international clinical trials started in 2003 and led by the International Breast Cancer Study Group (IBCSG).

However, it is now accepted that breast cancer is a heterogeneous disease. Decisions about whether to consider adjuvant systemic therapy should first take into account the tumor phenotype according to predictive markers of response that help select therapy (e.g., ER, PR, and HER2) and provide estimates of relative risk reduction, followed then by traditional prognostic markers of risk (e.g., tumor size, node involvement, and grade) to help estimate the actual absolute risk reduction benefit, and finally the assessment of existing comorbidities that may affect toxicity risks. Approximately 70% of newly diagnosed breast cancers express ER and/or PR, and one fifth overexpress HER2 (half of them [10% of the total] are ER/PR negative), while the remaining 15% to 20% express none of them (the so-called *triple negative phenotype*). Published data from 2000 systematic reviews by the EBCTCG suggest a reduction in mortality in patients with ER-positive disease through the next 15 years of 38% (age < 50 years) and 20% (age 50–69 years) with chemotherapy, and an additional reduction of 31% of the residual risk with tamoxifen, thereby approaching a final mortality reduction that ranges from 57% to 45%, respectively.[228] However, it is important for clinicians to recall that the overview results provide information about predicted outcomes for populations, but do not provide insight into the distribution of benefit among individual patients. Breast cancer patients traditionally have overestimated the absolute value of systemic therapy, and a common misinterpretation is that the treatment benefit is shared among patients, with most having some benefit, and it is important to consider the estimated individual risk, comorbidity, and personal patient preferences when discussing the potential benefits of adjuvant systemic therapy.

Quantitative tools like Adjuvant! Online (www.adjuvantonline.com) were developed to help patients and health care providers estimate the potential actual benefit from adjuvant systemic therapy,[229,230] although estimates of benefit from adjuvant trastuzumab have not yet been included in this model. Clinical practice guidelines often are used, such as those from the National Comprehensive Cancer Network in the United States (available at www.nccn.org/professionals/physician_gls/default.asp).[154] Another good example comes from the St. Gallen International Expert Consensus Panel Meeting (Tables 95-16 and 95-17).[245]

The fourth cycle of the Oxford Overview 2000 published in 2005 included approximately 150,000 patients in 194 unconfounded randomized clinical trials of adjuvant chemotherapy or endocrine therapy started by 1995.[228] These were trials of CMF, FAC or FEC chemotherapy, and tamoxifen or ovarian suppression as endocrine

therapy. In that cycle, there were no trials of taxanes, trastuzumab, raloxifene, or third-generation aromatase inhibitors. In practice, the fourth cycle consisted of seven separate systematic reviews on anthracycline-based versus no chemotherapy (8,000 patients); CMF-based versus no chemotherapy (14,000 patients); anthracycline-based versus CMF (14,000 patients); tamoxifen for 5 years versus none (15,000 patients); tamoxifen for 1 to 2 years versus none (33,000 patients); tamoxifen for 5 years versus 1 to 2 years (18,000 patients); and ovarian suppression versus none (8,000 patients). Now in its fifth cycle of data analyses (started in 2005–2006), the Oxford EBCTCG Overview represents over 25 years of an international collaboration that has revolutionized adjuvant breast cancer therapy by offering reliable assessment of moderate differences affecting long-term survival. By 2006 the EBCTCG secretariat had received data from over 660,000 patients enrolled in over 820 trials. Table 95-18 describes the 15-year breast cancer mortality and proportional effects of chemotherapy alone (in ER-poor and ER-positive disease) and of endocrine therapy with or without chemotherapy (in ER-positive disease).[228]

Adjuvant Chemotherapy

Combination regimens are considered standard practice (including sequential regimens) over single-agent regimens, and the EBCTCG Overview also has confirmed the improved recurrence and survival outcome observed with anthracycline-based regimens.[228] However, the magnitude of this survival benefit is modest, and the numbers needed to treat are potentially high, on average. In view of the potential toxicities and costs, the actual absolute benefit offered by individual therapies must be considered. As such, predictive factors of benefit (e.g., hormone receptor and HER2 status) and prognostic factors of risk (e.g., size, node status, and grade) must be discussed with each patient along with preferences and comorbidities as part of a shared decision model. More intensive combination regimens, usually with an anthracycline and often including a taxane, are expected to offer higher benefit in patients with more chemoresponsive disease (e.g., hormone receptor-negative) but also are associated with greater toxicity risks, short- and long-term. Patients with lower-risk disease often are offered potentially more tolerable regimens such as CMF (cyclophosphamide, methotrexate, and 5-fluorouracil) or AC (doxorubicin plus cyclophosphamide), and sometimes just endocrine therapy if they are lymph node-negative and strongly ER-positive (especially if postmenopausal).[246] Examples of commonly used adjuvant chemotherapy regimens are listed in Table 95-19.

Gene expression profiling with Oncotype DX was validated retrospectively as a tool to identify the predictive benefit from adding chemotherapy to endocrine therapy in women with ER-positive, node-negative disease. Patients with strong ER-positive, low-grade tumors and low-risk histologies such as lobular cancer are likely to have a low recurrence score (low risk of recurrence when treated with tamoxifen and minimal/no benefit from chemotherapy). On the other hand, patients with tumors that are higher-grade and have weaker ER expression are more likely to have a high recurrence score (especially if HER2 is overexpressed). The main use of predictive assays like Oncotype DX appears to be in clinical situations where chemotherapy is being considered and the tumor phenotypes appear less conclusive. Approximately 30% of patients ultimately may be found to have an intermediate recurrence score. This patient subset is now the subject of a prospective randomized trial comparing endocrine therapy with or without chemotherapy (the TailoRx trial).

Not all anthracycline regimens are the same—improved outcomes over CMF were observed with anthracycline regimens containing three drugs (with 5-fluorouracil and methotrexate) for six cycles or with sequential use of anthracyclines and CMF,[247] but not with

Table 95-17 Selection of Treatment Modalities According to St. Gallen International Experts Consensus Meeting 2007

	Highly Endocrine Responsive	Incompletely Endocrine Responsive	Endocrine Unresponsive
HER2 neg	Endocrine therapy (consider adding chemotherapy according to risk)	Endocrine therapy (consider adding chemotherapy according to risk)	Chemotherapy
HER2 pos	Endocrine therapy + trastuzumab + chemotherapy	Endocrine therapy + trastuzumab + chemotherapy	Trastuzumab + chemotherapy

ER, estrogen receptor; FAC, fluorouracil, doxorubicin (Adriamycin), and cyclophosphamide; FEC, 5-fluorouracil, epirubicin, and cyclophosphamide.

Anthracycline: about 6 months of anthracycline-based adjuvant chemotherapy with regimens such as FAC or FEC, as in the reviewed trials.

Tamoxifen: about 5 years of adjuvant tamoxifen. The 15-year survival probability with treatment is calculated as (1 – M/100) to the power R. The webappendix 1 (appendix to table 4) gives the 15-year prognosis of untreated control patients, subdivided by ER and nodal status.

*For women of given nodal status the 5-year mortality is greater for ER-poor than for ER-positive disease, but the 15-year risks may be similar, as may the 15-year benefits of anthracycline-based chemotherapy (since the age-specific breast cancer mortality ratios for anthracycline-based vs no chemotherapy do not depend significantly on ER status). Combination of the direct and indirect randomised evidence yields breast cancer death rate ratios (treatment vs control) of 0.62 (SE 0.05) at younger than 50 years and 0.80 (SE 0.04) at age 50–69 years for allocation to anthracycline and 0.69 (SE 0.03) for allocation to tamoxifen. (Allowance for any inappropriate noncompliance with the treatment allocations in these trails would, in expectation, further reduce breast cancer mortality.)

From Early Breast Cancer Trialists' Collaborative Group (EBCTCG): Effects of chemotherapy and hormonal therapy for early breast cancer on recurrence and 15-year survival: an overview of the randomised trials. Lancet 365:2005;1687–1717.

short-duration regimens like four cycles of AC. Topoisomerase II gene alterations have been shown in various studies to predict for anthracycline benefit.[248] However, it is of interest that these studies included patients regardless of *HER2* gene expression status (also located on chromosome 17). This raises the question of whether anthracycline regimens also would be useful in patients with HER2-negative disease, because most patients with HER2-positive breast cancer larger than 1 cm will most likely be treated with a trastuzumab-based regimen.

Various taxane regimens have now been prospectively tested in high-risk node-negative (if ER-negative) and node-positive disease. Examples include AC followed by paclitaxel for a total of eight cycles (every 3 weeks or every 2 weeks in a dose-dense fashion)[249] and TAC with docetaxel for 6 cycles.[250] Abstract data from Intergroup trial E1199 suggest a potential survival benefit for weekly paclitaxel following AC over other forms of taxane schedules and drugs, which confirms previous pathologic response observations in the preoperative setting.[251] However, abstract data from trial ECOG 2197 showed no survival benefit over AC with just four cycles of AT (with docetaxel). Taxane regimens given as a three-drug combination or in a sequential dose-dense fashion require the use of colony-stimulating factor support to minimize risk of febrile neutropenia.[252] It is worth noting that the administration of taxane-containing regimens in lymph node-positive, early-stage breast cancer appears to be particularly useful in those with hormone receptor-negative[253] and HER2-negative[254] disease. However, it is important to note that these recent analyses were retrospective in nature. Along these lines, the Oxford Overview does not identify a preferential benefit from chemotherapy in ER-negative disease in its most recent published analysis of trials that did not include taxanes.[228]

HER2 Status

HER2 is amplified in approximately 18% to 20% of breast cancers,[75] and amplification is the primary mechanism of HER2 overexpression with abnormally high levels of a 185-kd glycoprotein with tyrosine kinase activity found in these tumors. HER2 overexpression is a poor prognostic marker and is associated with worse clinical outcomes in patients with breast cancer.[255] HER2 status also is predictive for several systemic therapies and affords relative, but not absolute, resistance to endocrine therapies in general.[32] HER2 status appears to be associated with relative, but not absolute, lower benefit from non-anthracycline, non-taxane-containing chemotherapy regimens.[256] On the other hand, retrospective data from prospectively conducted randomized clinical trials appear more definitive in suggesting that HER2-positive status is associated with response to anthracycline therapy, even though this effect may be secondary to co-amplification of HER2 with topoisomerase II, which is the direct target for anthracyclines.[257–259] Retrospective data from trial Cancer and Leukemia Group B (CALGB) 9344[260] suggest that HER2 overexpression is associated with a benefit from the addition of paclitaxel to an anthracycline-based adjuvant regimen in node-positive breast cancer, regardless of estrogen-receptor status.[254] At the same time, those with ER-positive, HER2-negative disease may gain little benefit from the addition of paclitaxel to AC, although these data require further confirmation.

Table 95-19 Examples of Commonly Used Chemotherapy Regimens in the Adjuvant Setting

NON-TRASTUZUMAB-BASED REGIMENS

FAC/CAF (fluorouracil/doxorubicin/cyclophosphamide) or FEC/CEF (cyclophosphamide/epirubicin/fluorouracil)

AC (doxorubicin/cyclophosphamide) ± sequential paclitaxel

EC (epirubicin/cyclophosphamide)

TAC (docetaxel/doxorubicin/cyclophosphamide)

A → CMF (doxorubicin followed by cyclophosphamide/methotrexate/fluorouracil)

E → CMF (epirubicin followed by cyclophosphamide/methotrexate/fluorouracil)

CMF (cyclophosphamide/methotrexate/fluorouracil)

AC × 4 (doxorubicin/cyclophosphamide) + sequential paclitaxel × 4, every-2-weekly regimen with filgrastim support

A → T → C (doxorubicin followed by paclitaxel followed by cyclophosphamide) every-2-weekly regimen with filgrastim support

FEC → T (fluorouracil/epirubicin/cyclophosphamide followed by docetaxel)

TRASTUZUMAB-BASED REGIMENS

Preferred adjuvant regimen

- AC → T + concurrent trastuzumab (doxorubicin/cyclophosphamide followed by paclitaxel plus trastuzumab)

Other adjuvant regimens

- Docetaxel + trastuzumab → FEC
- TCH (docetaxel, carboplatin, trastuzumab)
- Chemotherapy followed sequentially by trastuzumab
- AC → docetaxel + trastuzumab

Neoadjuvant

- T + trastuzumab → CEF + trastuzumab (paclitaxel plus trastuzumab followed by cyclophosphamide/epirubicin/fluorouracil plus trastuzumab)

Adapted from NCCN Clinical Practice Guidelines in Oncology: Breast Cancer. V.2.2008; www.nccn.org/professionals/physician_gls/PDF/breast.pdf

Perhaps most importantly, several studies have now shown that anti-HER2 therapy is effective in the adjuvant setting. (See Table 95-20 for study characteristics.) Five international, prospective randomized clinical trials have demonstrated that adjuvant trastuzumab reduces the risk of recurrence and mortality by one half and one third, respectively, in patients with early-stage breast cancer.[78,79,233,261] (See Table 95-21 for efficacy results of adjuvant trials of trastuzumab.) Based on its approval in the metastatic setting,[262] the small molecule, dual tyrosine kinase inhibitor lapatinib is now being tested with and against trastuzumab in the adjuvant setting in patients with HER2-positive, lymph node-positive disease. Trastuzumab therapy is associated with a small risk of cardiac toxicity, especially among older patients and those exposed to an anthracycline.[263] In the adjuvant setting, the risk of severe congestive heart failure may achieve 4%, approximately 14% of patients are unable to complete a full 1-year course of trastuzumab, and concerns have been raised about the actual reversibility of the cardiotoxicity of trastuzumab (Table 95-22).[264,265]

Many believe that trastuzumab optimally should be administered with chemotherapy. A commonly used regimen in the United States consists of AC followed by paclitaxel/trastuzumab, followed by trastuzumab to complete a year of therapy.[79] Non-anthracycline, trastuzumab-based regimens (e.g., TCH with a platinum drug and docetaxel) often are considered and are a reasonable alternative for those interested in minimizing the cardiotoxicity risk of trastuzumab. Optimal duration of therapy also remains unclear. Short exposure to trastuzumab in combination regimens for just 9 weeks (e.g., FinHER trial[233]) and trastuzumab given as a single agent for 1 or 2 years after all chemotherapy is completed (e.g., the HERA trial[78]) have been shown to lead to an improvement in overall survival.

These results confirm that that HER2 is a useful marker for decision making for patients with breast cancer, emphasize the importance of evaluating the assay accurately, and justify defining the HER2 status in the invasive tumor component in all patients with a new diagnosis of invasive breast cancer. The significant benefits coupled with the high cost and potential cardiotoxicity of trastuzumab require accurate HER2 testing. Predictive assay markers are unique in that they serve as the sole determinant of therapy selection, and both false-positive and false-negative results are unacceptable if they expose some patients to an uneccessary and toxic placebo and deny others therapy with a potentially useful drug, respectively. Excessive testing inacurracy was a problem observed early on with HER2 testing,[266,267] which ultimately led to a collaboration between the American Society of Clinical Oncology (ASCO) and the College of American Pathologists (CAP) that resulted in the establishment of testing guidelines for HER2 testing in breast cancer.[75] Data presented at the 2007 annual meeting of ASCO suggested that other HER2 subsets may derive benefit from trastuzumab, but those hypothesis-generating findings must now be further tested. In the meantime, accurate measurement of HER2 status is critical. Available data in 2007 indicate that patients with tumors showing either IHC 3+ or FISH amplification, and who would have qualified for the adjuvant randomized trials thus far reported, should be considered candidates for anti-HER2 therapy.

Adjuvant Endocrine Therapy

Breast cancer often is an estrogen-dependent disease, and endocrine therapy offers the most favorable risk-benefit ratio among existing systemic therapy options. Surgical hormonal manipulation (e.g., oophorectomy, adrenalectomy, and hypophysectomy) in metastatic disease, considered the first example of targeted antitumor therapy, has largely been supplanted by pharmacologic approaches with selective estrogen receptor modulators such as tamoxifen, aromatase inhibitors, and pure antiestrogens such as Faslodex (AstraZeneca). Tamoxifen is the standard agent for premenopausal women in the adjuvant setting,[228] and recent data suggest an increasing role for aromatase inhibitors in postmenopausal women.[268] Ovarian function suppression (OFS) also is a reasonable alternative to CMF-based chemotherapy, and ongoing studies are examining its role after chemotherapy in premenopausal women with hormone receptor-positive disease who also will be treated with an oral antiestrogen.

Tamoxifen

SERMs may function as estrogen-receptor agonists, antagonists, or mixed agonist-antagonists, depending on the target tissue. Major examples include triphenylethylene derivatives (e.g., tamoxifen), nonsteroidal antiestrogens (e.g., the benzothiophene raloxifene), and steroidal antiestrogens (e.g., fulvestrant). Tamoxifen is the SERM with the longest track record in breast cancer and is approved in the United States for risk reduction in high-risk women, for reduction in the risk of invasive breast cancer after breast conservation in women with DCIS, in the adjuvant treatment of hormone-receptor-positive disease, and in the management of advanced disease. Because of potentially undesirable effects in the uterus, vagina, and central nervous system, other SERMs have been evaluated in the laboratory and in the clinic, aiming for greater efficacy

and lower toxicity,[269] but they have not been approved in the adjuvant setting.

Tamoxifen is associated with an increase in bone mineral density in the axial skeleton and with stabilization in the appendicular skeleton in postmenopausal women. While it leads to bone mineral loss in the lumbar spine and hip in premenopausal women, the NSABP P-01 study showed a reduction (relative risk, 0.81; 95% CI, 0.63 to 1.05) in fractures of the hip, radius, and spine in all age groups, especially among those 50 years of age and older.[270] Data from the 2005 EBCTCG showed that 5 years of adjuvant tamoxifen for ER-positive disease reduced the annual breast cancer death rate by 31% regardless of age or chemotherapy use. Duration of tamoxifen (5 years versus 2 years) is important, and the annual breast cancer mortality rates are similar during years 0 to 4 and 5 to 14, with a cumulative reduction in mortality twice as large at 15 years as after 5 years since diagnosis.[228] Duration of adjuvant tamoxifen is limited to 5 years,[271,272] but two large, ongoing international trials (Adjuvant Tamoxifen Long vs. Short [ATLAS] and Adjuvant Tamoxifen Treatment, Offer More? [aTTom]) may help to answer this question. Host factors such as polymorphisms of the P450 *CYP2D6* gene may identify patients who are poor metabolizers (*4/*4 genotype variant) and have reduced levels of the active tamoxifen metabolite endoxifen,[273] but the clinical utility of this information is not fully settled, other than perhaps to identify patients who should avoid use of potent CYP2D6 inhibitors, including some of the selective serotonin reuptake inhibitors commonly used as antidepressants.

Ovarian Function Suppression

Adjuvant endocrine therapy arguably is the most effective targeted therapy in women with early-stage, ER-positive breast cancer, regardless of age or nodal status. Although breast cancer is primarily a disease of older women, up to 25% of all patients newly diagnosed with invasive disease are younger than age 50 (half with ER-positive disease).[274] It is unfortunate, therefore, that the survival benefit of tamoxifen was not fully recognized till the mid-1990s.[275] The ovary is the primary site of estrogen production in premenopausal women. In 1896, Sir George Beatson first reported the benefits of oophorec-

tomy as palliative therapy for several young women with metastatic breast cancer. Factors that confounded therapeutic decisions for younger women included an inverse correlation between age and hormone receptor status, the belief that chemotherapy was more active than endocrine therapy, and age-related chemotherapy effects on ovarian function and its indirect endocrine effect. Retrospective data show that young premenopausal women (age <35) fare worse when treated with chemotherapy alone,[276] which may be explained by a greater likelihood of remaining premenopausal after chemotherapy.[277,278] This may also explain the survival benefit offered by chemotherapy without endocrine therapy seen in younger versus older premenopausal women[277] and the need for longer duration of tamoxifen therapy in premenopausal women.[228]

Ovarian function suppression (OFS) is effective when compared to no therapy in women younger than age 50.[228] Similar outcome is seen with OFS versus CMF chemotherapy[279–281] and with OFS plus tamoxifen versus chemotherapy.[282–284] This is of particular interest because the substitution of OFS for CMF chemotherapy would result in a lower rate of permanent amenorrhea[278,279] and fewer complications associated with premature menopause, and would even allow younger women to consider pregnancies following a breast cancer diagnosis.[285] At this time, though, data comparing OFS with contemporary regimens containing anthracyclines and taxanes are lacking. Clinical benefit was seen in young premenopausal women who received OFS after chemotherapy,[280,286,287] but it remains unclear if it is of added benefit in this group of women when they also are treated with tamoxifen. Indirect evidence from the International Breast Cancer Study Group (IBCSG) trial 13–93 suggests that some degree of benefit from chemotherapy-induced amenorrhea (CIA) might exist even when tamoxifen also is given.[288]

Ongoing prospective randomized trials are examining various questions in premenopausal women. The Suppression of Ovarian Function Trial (IBCSG 24-02) is enrolling almost 3000 women with ER-positive disease who do not receive adjuvant chemotherapy or who remain premenopausal after chemotherapy and compares 5 years of tamoxifen, tamoxifen with OFS, or the aromatase inhibitor exemestane with OFS. It has been over 110 years since the first report by Beatson on oophorectomy as a therapeutic option in breast cancer, and yet much remains unknown as compared to the use of endocrine therapy in postmenopausal women. This and other studies will finally

answer critical questions on the optimal use of OFS in premenopausal women with ER-positive breast cancer; potentially will identify those able to forgo adjuvant chemotherapy, even among women with high risk, early-stage disease; and will minimize the risk of long-term complications related to premature menopause. A meta-analysis of OFS with LH-RH agonists in premenopausal women with ER-positive disease showed that chemical-induced ovarian suppression offered a signficant reduction in the relative risk for recurrence and death when added to tamoxifen, chemotherapy, or both.[289]

Side effects from LH-RH agonists occur earlier but are short-lasting when compared to chemotherapy, and may include hot flashes, decreased libido, mood lability, and potential cardiovascular and skeletal-related sequelae such as bone loss.[290,291] Existing guidelines in breast cancer do not yet address optimally the management and prevention of osteoporosis in premenopausal women being treated with OFS. However, annual bone density testing scans have been recommended in patients with therapy-associated premature menopause, in addition to calcium and vitamin D supplementation, advice on lifestyle, and bisphosphonates if necessary.[292] Promising data with regard to the role of clodronate in the adjuvant setting have been reported in three European trials, with survival benefit and reduction in bony recurrences identified in two of them.[293–295] Indirect evidence from these adjuvant trials and other studies reporting on the effectiveness of drugs such as risedronate in chemotherapy-induced premature menopause[296] suggest a potential role for bisphosphonates as primary or secondary prevention in women treated with LH-RH agonists in the adjuvant setting. In the meantime, ongoing studies in North America are testing the role of zoledronate in premenopausal women with breast cancer with adjuvant chemotherapy-induced ovarian failure and comparing zoledronate and ibandronate to clodronate in pre- or postmenopausal women to help elucidate the optimal role of bisphosphonates in early-stage breast cancer.

Aromatase Inhibitors

The conversion of androgen to estrogen in peripheral tissues is the primary source of estrogen in postmenopausal women, and the aromatase enzyme is present in a number of tissues (e.g., muscle, fat, skin, neural tissues, and breast). Levels of estrogen and aromatase are elevated in malignant breast tissue, and aromatase inhibitors can block the action of the enzyme and reduce estrogen production. Available drugs include type 1 steroidal nonreversible inhibitors (e.g., exemestane and formestane) and type 2 nonsteroidal reversible inhibitors (e.g., letrozole, and anastrozole).[297] First-generation inhibitors (e.g., aminoglutethimide) were associated with significant toxicity in the adjuvant setting because of the nonspecific effects that occur at several steps in the steroid biosynthetic pathway, and a marginal benefit was seen when compared with tamoxifen. The more specific (and less toxic) third-generation aromatase inhibitors supported the initiation of several adjuvant trials in postmenopausal women. By 2007, several studies had been reported testing 5 years of use of tamoxifen against an aromatase inhibitor upfront (the Arimidex, Tamoxifen, Alone or in Combination [ATAC],[298] and Breast International Group [BIG] 1–98 [299] trials); a sequential approach after 2 to 3 years of tamoxifen (Intergroup Exemestane Study [IES],[300] Austrian Breast and Colorectal Cancer Study Group [ABCSG] 8 and Arimidex-Nolvadex [ARNO] 95,[301,302] and the Italian Tamoxifen Arimidex [ITA][303] trials), or extended therapy (MA-17 trial[304]). Aromatase inhibitors are contraindicated in premenopausal women and must be used with extreme caution in women who are premenopausal and develop chemotherapy-induced amenorrhea. In the presence of an AI, the reduced feedback of estrogen to hypothalamus and pituitary may lead to an increase in the secretion of gonadotrophins and resumption of ovarian function, including the possibility of getting pregnant.[305]

Much has been discussed about the optimal time to introduce an aromatase inhibitor. ER-positive breast cancer has a long natural history, and half of all recurrences occur between years 6 and 15.[228] Many of the recurrences observed in the upfront trials ATAC and BIG 1–98 were local, and an overall survival advantage has not yet been observed. But while a survival advantage and improved hazard ratios for outcome have been observed in several trials that tested a sequential[300] or extended approach[304] (including one metanalysis[306]), all but the ABCSG 8 trial enrolled patients after several years of adjuvant tamoxifen, thereby ensuring the selection of patients who had not yet recurred and were more likely to have disease responsive to endocrine manipulation. Various theoretical models have been employed but with conflicting results based on the various assumptions employed.[307,308] Patients with HER2-positive tumors have a higher hazard of recurrence but not a preferential response to one class of agents over another, and expression of PR is of no prognostic importance.[34,309] Based on these observations and considering the long natural history of ER-positive tumors, it is therefore not unreasonable to consider a planned transition to an aromatase inhibitor after a few years of tamoxifen for patients with ER-positive, HER2-negative tumors, while those with HER2-positive disease (especially if higher nodal burden) may be considered for AI therapy upfront.

Data from BIG 1–98 comparing an aromatase inhibitor upfront versus tamoxifen followed by an aromatase inhibitor are eagerly awaited. There also is interest and theoretical concerns about the safety of administering tamoxifen after an aromatase inhibitor.[310] Safety data support the use of an AI for 5 years if used sequentially, and their extended use beyond year 5 is now the subject of randomized trials. Host factors in the form of polymorphisms of the P450 *CYP19* gene have been observed in various ethnic groups, but the clinical utility of these data remain unclear.[311,312]

Combined Chemoendocrine Therapy

Adjuvant endocrine therapy has a more favorable therapeutic index than chemotherapy in patients with endocrine-responsive breast cancer. In postmenopausal women, tamoxifen is a more efficacious adjuvant intervention,[246] and endocrine therapy is considered the primary component of any adjuvant systemic regimen in patients with hormone receptor-positive disease, regardless of age. However, patients who also have prognostic factors associated with an increased risk of recurrence and death (e.g., larger tumors or lymph node involvement) may benefit from the addition of chemotherapy to endocrine therapy as part of the adjuvant regimen. This is especially the case in premenopausal women, in part because of the ovarian suppression caused by chemotherapy. As mentioned earlier, specific gene expression profiling assays appear to add predictive utility in specific patient subsets. The role of adding chemotherapy in low-risk, older patients, such as those with node-negative, endocrine-responsive disease who will be treated with 5 years of adjuvant tamoxifen, is unclear. Few data are available on polychemotherapy in women 70 years of age and older.[228] Studies such as IBCSG trial IX (1669 postmenopausal patients)[313] and NSABP B-20 (2306 pre- and postmenopausal patients) in patients with node-negative disease,[314] and SWOG 8814 (Intergroup 0100 [1477 postmenopausal patients]) in patients with node-positive disease[315] confirm the survival benefit from even a short course of chemotherapy (e.g., three cycles of CMF) in older women with lymph node-negative, hormone receptor-negative disease. At the same time, they reinforce the cautionary tone that permeates recent clinical practice guidelines and consensus statements about the use of chemotherapy in postmenopausal women with endocrine-responsive disease who will receive 5 years of adjuvant tamoxifen.[154,316] These data on combined systemic therapy address whether additional benefit is associated with adding chemotherapy to tamoxifen. Approximately 20% of patients in the ATAC trial (usually node-positive patients) received chemotherapy in addition to endocrine therapy,[298] but it is not known whether these findings on combined chemoendocrine therapy are applicable to the aromatase inhibitors.

SWOG 8814 (Intergroup 0100) also addressed the important issue of timing when combining chemotherapy and endocrine therapy, and indicated a survival advantage associated with sequential versus concurrent administration of chemotherapy and tamoxifen,[317] and a smaller Spanish trial (GEICAM 9401) comparing epirubicin and cyclophosphamide with sequential versus concurrent tamoxifen showed a trend favoring a sequential approach.[318] Data released in late 2007 explored gene expression profiling as a prognostic and predictive marker using specimens from trial SWOG 8814 that tested the addition of an anthracycline-based adjuvant regimen to tamoxifen in postmenopausal woment with ER-positive, lymph node-positive breast cancer.

Preoperative Systemic Therapy

Adjuvant systemic therapy after surgery has been the gold standard for examining the effect of new treatment strategies on disease-free survival and overall survival rates in the adjuvant setting. Traditional adjuvant endpoints require trials with large sample sizes and long-term follow-up to achieve the number of events required to assess the effect of the investigational arm on the end point of interest. This problem is compounded by the increasing number of patients diagnosed with earlier stages of disease. Preoperative systemic therapy traditionally has been reserved for women with locally advanced breast cancer (LABC) to enhance the likelihood of negative surgical margins or even breast preservation, although preclinical data suggested that the administration of systemic therapy before surgery may be associated with early eradication of micrometastases and improved long-term outcomes by decreasing the risk of drug resistance and leading to more favorable growth kinetics. Preoperative systemic therapy offers a small increase in the rate of breast conservation over the same therapy given after surgery, although initial data did not show a survival advantage.[319,320] However, pathologic response (especially if complete) after preoperative chemotherapy correlates with improved disease-free survival or overall survival, and the initial response to preoperative systemic therapy offers the potential of in vivo assessment of sensitivity or resistance to treatment (clinical or tissue samples).[321,322] Of great interest, the identification of intermediate (surrogate) markers (imaging, tissue, and blood) that correlate with outcome (pathologic response and/or survival) in carefully selected patient groups may have clinical utility.[323]

There are concerns that preoperative therapy might lead to the loss of baseline parameters (e.g., tumor size and lymph node involvement) that generally are used to guide recommendations for adjuvant therapy. In patients treated with preoperative systemic therapy, it is advisable to request immunohistochemistry studies in the initial biopsy specimen, in case no residual disease is identified at surgery after therapy. Results from NSABP B-27[324] also confirm the feasibility of performing sentinel lymph node biopsy after preoperative chemotherapy,[325] although this issue remains controversial, and many radiation oncologists wish to know the axillary status at presentation. Patients with hormone receptor-positive disease will all receive 5 to 10 years of endocrine therapy after completion of local therapy, regardless of pathology findings. However, there is uncertainty about what to do for patients with ER-negative disease with residual disease at surgery, and studies are investigating the use of additional systemic therapy after surgery in this setting.

Preoperative systemic therapy might allow trials with smaller sample sizes and an adaptive design to test new strategies that can then quickly evolve into larger trials with survival as the primary endpoint. Preoperative trastuzumab as a single agent,[326] concomitantly with an anthracycline,[327] or with a non-anthracyline regimen[328] has been shown to induce a high rate of pathologic response. As an interesting example, the very rate of pathologic complete response observed in recent trials of preoperative trastuzumab could have presaged the survival benefit observed in traditional adjuvant trials.[329] These issues were the theme of a State of the Science Symposium on preoperative therapy in invasive breast cancer conducted at the US National Institutes of Health in March 2007 (see http://ctep.cancer.gov/bcmeeting/index.html).

Optimal patient selection for preoperative chemotherapy is key, especially if the immediate goal is tumor shrinkage (to allow breast conservation) and pathologic complete response (for prognostic purposes). Hormone receptor status and tumor histologies should be considered carefully, because patients with ER-negative disease and lobular histologies are less likely to respond to preoperative chemotherapy, even though their long-term outcome (especially among the small minority that achieve a pathologically confirmed complete remission) is improved overall.[155,330]

Preoperative systemic endocrine therapy also is an attractive alternative to chemotherapy, especially in older patients with strong ER-positive tumors who may not be good candidates for chemotherapy. However, clinical responses are slower to occur and are rarely complete. Aromatase inhibitors appear more active than tamoxifen in patients with ER-positive/HER2-positive disease, suggesting increased short-term sensitivity to estrogen deprivation.[331] Optimal markers to predict long-term outcome following preoperative endocrine therapy are lacking, but levels of tumor Ki67 after short-term endocrine treatment may help predict recurrence-free survival by combining the prognostic value of Ki67 level at baseline with observed changes in levels at 2 weeks.[332]

Secondary Effects of Adjuvant Systemic Therapy

Secondary Effects of Chemotherapy

As more patients with earlier stages of disease are offered adjuvant systemic therapy, its short- and long-term effects on quality of life must be carefully weighed. The chemotherapy regimens commonly administered to patients with breast cancer (e.g., CMF, FAC, FEC, AC, or taxane-based regimens) generally are well tolerated. Acute life-threatening toxicity in patients receiving the therapy is quite rare. Common short-term effects include alopecia, myelosuppression, gastrointestinal symptoms, and febrile neutropenia or neutropenic infection. Peripheral neuropathy, arthralgia, and myalgia also are seen with taxanes. The effect of anemia on quality of life has been the subject of ongoing investigation, but concerns now exist on a potential worse survival outcome with the use of erythropoeitin-stimulating agents,[333] which has diminished the enthusiasm for their use in the adjuvant setting, where the intent is cure. Although many women accept these short-term toxicities, attention is being placed increasingly on late effects from systemic therapy as the number of patients who will become long-term survivors is increasing. For some, the actual absolute reduction in risk of recurrence and death is relatively small compared with the potential risk of late toxicity.

Anthracycline-related cardiac toxicity is a potential concern. Approximately 8% of women may have asymptomatic systolic dysfunction 10 years after receiving doses of doxorubicin around 300 mg/m^2,[334] and cardioprotective drugs such as dexrazoxane are not approved in the adjuvant setting. Although the risk of clinical congestive heart failure associated with conventional doses of anthracyclines is small (≤1%),[335] this risk is increased with the subsequent use of adjuvant trastuzumab.[336] Older age and lower left ventricular ejection fraction at baseline appear to increase this risk, but good predictive models and existing tools (e.g., measurements of troponin and brain natriuretic peptide levels) are not sufficiently refined at present for use in clinical practice. Secondary acute myeloid leukemia and myelodysplastic syndrome are rare early events. They have been linked to exposure to alkylating agents, topoisomerase II inhibitors, and antimetabolites,[337,338] and the risk of acute myeloid leukemia or myelodysplastic syndrome after four cycles with conventional doses of AC (60 and 600 mg/m^2) at 5 years is 0.21%.

Young women are at risk for premature menopause after adjuvant chemotherapy, and the risk correlates with both age and choice of adjuvant chemotherapy (classic CMF for 6 cycles > AC followed by

paclitaxel = TAC with docetaxel > AC for four cycles).[278] Temporary cessation of menses during adjuvant therapy also correlates with earlier occurrence of menopause.[339] Although ovarian suppression as a result of chemotherapy may further decrease the odds of recurrence and death in premenopausal women with endocrine-responsive disease, premature menopause can have a significant effect on quality of life because of severe hot flashes and vaginal dryness. Hot flashes resulting from discontinuation of HRT or induction of menopause are a common symptom after chemotherapy, with only partial remedies.[340] For women who retain fertility, pregnancy does not appear to increase the risk of another breast cancer event,[341] but the safety and efficacy of LH-RH agonist use during chemotherapy to preserve fertility remains investigational. Women who have chemotherapy-induced ovarian failure after adjuvant chemotherapy are at risk for rapid bone loss and complications from osteoporosis,[342] and bisphosphonates may have a preventive role in this setting.[343]

Symptoms of fatigue, weight gain, and cognitive dysfunction are reported with some frequency after the completion of therapy. Weight gain is a common complaint.[344] Cognitive dysfunction has been observed, including short-term memory loss and long-term complaints of poor memory, impaired concentration, and language deficits.[345] An association with chemotherapy is confounded by factors such as onset of menopause, discontinuation of menopausal replacement therapy, and use of endocrine therapy with antiestrogens. While long-term survivors report more frequent physical and menopausal symptoms than do healthy women, their health-related quality of life and sexual functioning are comparable to those reported by healthy, age-matched control subjects.[345] Still, the various long-term needs of breast cancer survivors and the crucial role to be played by both oncologists in the short run and gynecologists and internal medicine specialists in the long run cannot be overemphasized.[346,347]

Secondary Effects of Endocrine Therapy

Although tamoxifen is associated with an increase in bone mineral density in the axial skeleton,[348] and the NSABP P-01 prevention study showed a reduction (relative risk, 0.81; 95% CI, 0.63–1.05) in fractures of the hip, radius, and spine in all age groups (especially those 50 years of age and older),[117] bone mineral loss is observed in the lumbar spine and hip in premenopausal women receiving tamoxifen. Tamoxifen is associated with a reduction in low-density-lipoprotein cholesterol, and individual studies have suggested that tamoxifen might reduce the risk of coronary heart disease. However, the Oxford Overview did not show any statistically significant effect of cardiac or vascular events on overall survival.[228]

Similar to its antiestrogen effects in breast tissue, the toxicity profile of tamoxifen also is related to its tissue-specific SERM. The 1995 Oxford Overview showed a higher incidence of uterine malignancies (ratio of incidence rates, 2.58; SD, 0.35),[275] and similar findings were observed in the three largest trials of 5 years of tamoxifen therapy—NSABP B-14, [271] the Scottish trial,[272] and the Stockholm trial B study[349]—with an absolute excess in deaths of 1 or 2 per 1000 after 10 years (0.2 per 1000 woman-years). Although uterine cancer is likely to be diagnosed at an early stage and cured with surgery alone, longer duration of tamoxifen therapy is associated with worse histology and higher grade,[350] and 2% to 5% of all cases represent uterine sarcoma.[351] It is important to know that tamoxifen is expected to cause endometrial thickness, and neither transvaginal ultrasound nor endometrial biopsy is a useful screening tool in asymptomatic patients.[352] Instead, women who are taking tamoxifen should simply continue their otherwise routine gynecologic evaluation and notify their physicians of abnormal vaginal spotting or bleeding.

Thromboembolic complications due to tamoxifen occur in fewer than 1% of patients,[117] although they are seen more commonly when combined with IV CMF. Tamoxifen is associated with increased rates of hot flashes, vaginal discharge, and night sweats, but without a statistically significant effect on quality of life.[353] Hot flashes are a common and vexing symptom.[354] Selective serotonin reuptake inhibitors such as venlafaxine are effective.[355] Venlafaxine in particular is less likely to inhibit CYP2D6 activity.[273] Other pharmacologic interventions like clonidine,[356] vitamin E, gabapentin,[357] and progestational agents have been tested and shown to be helpful. Popular remedies such as black cohosh are ineffective.[358]

Weight gain is commonly observed in breast cancer survivors.[344] The NASBP prevention P-01 trial showed no detrimental effects on quality of life, mood, or sexual function in the tamoxifen-treated group.[359] Sexual dysfunction is rare and is more commonly associated with chemotherapy.[360] Ocular toxicities (e.g., corneal changes, tamoxifen retinopathy, and posterior subcapsular opacities) are rare.

Toxicities such as low-grade hot flashes, arthritis, arthralgia, and myalgia were observed in patients treated in the various aromatase inhibitor trials, but so was a lesser frequency of vaginal bleeding. Unfavorable changes in lipid profile also have been noted, but implications regarding cardiovascular events remain uncertain.[268] The observed rate of osteoporosis is greater with aromatase inhibitors, and this may contrast with the favorable bone effects of tamoxifen. Women considered for aromatase inhibitor therapy should ensure adequate daily intake of calcium and vitamin D and have a baseline bone density test, and those with an abnormal test result should have it repeated according to established guidelines.[292]

Other Secondary Effects

As more women with early-stage breast cancer become long-term survivors, concerns about cancer recurrence are expected to decrease, and it sometimes is difficult for patients and their physicians to separate age-related symptoms from those that might be related to long-term effects of therapy. Data on the safety of menopausal hormone replacement therapy in breast cancer survivors are limited, and are derived mostly from cohort and case-control studies,[361,362] and prospective randomized trials are lacking.[363] The use of complementary and alternative medications is a common and unreported practice among patients,[364] but few prospective controlled studies have been conducted.[365] Fatigue is another common symptom, especially in patients with higher levels of depression, pain, and sleep disturbance. Increasing evidence also shows that adjuvant chemotherapy may have long-term effects on cognitive function.[345] A few years of ovarian function suppression is expected to be more tolerable than chemotherapy (short- and long-term) in premenopausal women with ER-positive disease.[291]

Long-Term Follow-Up

Post-treatment surveillance and long-term strategies must take into account the effect on several outcomes of interest, such as survival, quality of life, reduction in toxicity, cost-effectiveness, and the likelihood that most patients diagnosed with breast cancer in the United States are expected to survive this diagnosis. Breast cancer survivors should pursue monthly breast self-examination, annual mammography, and a clinical evaluation on a regular basis, because available evidence does not support any surveillance blood tests (e.g., tumor markers) and imaging studies other than mammography in otherwise asymptomatic patients with no abnormalities on clinical examination.[366] Equally or more important, cancer specialists should ensure adequate coordination of care in a shared care model with gynecologists and primary care physicians, who will have an increasingly important role in the long-term care of these breast cancer survivors. In late 2007 the American Society of Clinical Oncology released "treatment plan" and "treatment summary" templates to be completed by cancer specialists and shared with their patients and the noncancer specialists caring for them (available at www.asco.org) to facilitate this coordination. These tools have both a care and an

educational component, because they will be used to empower patients to become full participants in their care, smooth the transition back to their noncancer specialists in a "shared-care" model, and ovecome deficiencies inherent to the fragmented health care system of many countries, such as the United States. In many settings, noncancer specialists may assume the primary long-term follow-up care of these patients,[367] but it is critical that good communication be maintained with cancer specialists, especially in regard to patients with ER-positive disease, who may find themselves on endocrine therapy for 10 years (or more, pending ongoing studies). Increasingly, information regarding the long-term care of cancer survivors (including breast cancer) is becoming available in internal medicine journals,[368] which should help smooth the transition of patients likely to survive their disease. In addition to surveillance for possible late complications resulting from local and systemic therapies given as part of their breast cancer treatment,[347] breast cancer survivors also require routine health maintenance care to address common health issues that occur as they age.

New Strategies in Adjuvant Treatment

Greater understanding of the biologic subtypes of breast cancer is helping with the selection of treatment strategies targeting specific tumor subtypes. ER, PR, and HER2 are the most useful markers at present, and gene expression profiles are being tested prospectively as prognostic and predictive markers to ensure the optimal identification of the patients most likely to benefit from a specific strategy. Trastuzumab is now a standard treatment offered to patients with HER2-positive disease, and adjuvant trials with lapatinib (if HER2-positive) or bevacizumab (in HER2-negative disease) started in 2007. Ongoing studies also are addressing the role of bisphosphonates, the oral fluoropyrimidine capecitabine, and new formulations of taxanes. Host pharmacogenetic information will be of increasing interest and may help with therapy individualization too.[369]

MANAGEMENT OF LOCALLY ADVANCED BREAST CANCER

Locally advanced breast cancer (LABC) has always included a heterogeneous group of presentations. With the 2002 changes to the AJCC staging system, LABC technically can include a patient with a clinically apparent internal mammary or paraclavicular node as well as the more commonly accepted presentations, including a primary breast cancer larger than 5 cm, disease fixed to the chest wall or involving the skin, or bulky palpable disease in the axilla.[152,153] Inflammatory breast cancer also can be called LABC, but is discussed separately in this chapter. The approach to LABC has evolved considerably over the years. Surgery and radiation therapy at first were the only treatments available, but multimodality approaches that emphasize systemic therapy have become the standard of treatment. This includes delivery of systemic therapy early in treatment to attempt to reduce subclinical micrometastatic disease, reduce local and regional tumor bulk, and increase the likelihood of successful surgical resection. In addition, the appropriateness of the systemic agents chosen can be assessed by following the patient's locoregional clinical response.

Multiple retrospective studies have shown a survival benefit with the addition of chemotherapy to local therapy when compared with historical control subjects treated with local therapy only. In some series, chemotherapy was administered after surgery, but most recent series have combined preoperative and postsurgical therapy. Other endpoints for comparison of these studies include local control rates, clinical tumor response, and pathologic tumor response when patients undergo mastectomy. In some cases, the clinical response has been judged significant, and a significant proportion of women were able to undergo less invasive procedures than mastectomy. The preoperative approach was well documented by one study at the M.D. Anderson Cancer Center.[370] After preoperative FAC chemotherapy, 372 women underwent either segmental mastectomy and axillary node dissection (29%) or modified radical mastectomy (71%), as decided upon based on the clinical response of the tumor and initial prechemotherapy disease bulk. Thirty-one per cent of the primary tumors were smaller than 5 cm, and 20% of women had no clinically detectable axillary adenopathy at diagnosis. All the women received more chemotherapy postoperatively and then locoregional radiation therapy. Breast conservation is increasingly considered. Although in general, local control is maximally achieved with mastectomy and postoperative radiation therapy, in selected subgroups of patients who respond to preoperative chemotherapy, breast-conserving therapy appears to yield local control rates similar to those attainable with mastectomy and radiation therapy. Advances in breast imaging also are emerging as tools to select patients for further therapy after preoperative chemotherapy. Technetium-99 m sestamibi scans[371] and PET imaging with ^{18}fluorodeoxyglucose[372] have been tested as predictors of pathologic response.

Radiation therapy has been administered as an adjuvant to mastectomy for LABC, both pre- and postoperatively. Postoperative therapy usually is delivered to patients with operable disease. Preoperative radiation therapy has been used to convert unresectable or marginally resectable cancers into technically resectable disease. From series in which radiation therapy was delivered preoperatively, pathologic review of mastectomy specimens yields information about the ability of radiation therapy to sterilize disease. Despite delivery of 60 to 70 Gy to the breast and regional nodes, Zucali and associates[372A] found that 75% of mastectomy specimens contained residual tumor in patients with a complete clinical response. Clearly, the addition of systemic chemotherapy has placed these response rates in an historic context.

Breast Conservation Therapy

Induction chemotherapy can cytoreduce locoregional disease. Some patients receiving primary chemotherapy achieve complete clinical response. Attention has been directed toward the identification of patients with an excellent response to preoperative therapy who are possible candidates for breast conservation. The goals of this approach are the same as those for women with early-stage disease who are candidates for breast conservation (i.e., optimal locoregional control with acceptable cosmesis of the treated breast).

To study the feasibility of breast preservation in advanced disease, mastectomy specimens from 143 patients with stage IIB and III breast cancer who were treated at M.D. Anderson Cancer Center were retrospectively analyzed after preoperative chemotherapy.[372B] Using the criteria for breast preservation in early-stage disease, 23% of these women would have been good candidates for breast conservation after receiving preoperative chemotherapy. Based on this experience, breast conservation now is offered to appropriate candidates with LABC using similar criteria as in early-stage disease, as discussed earlier. Investigators at the NCI and the University of Michigan reported their results with breast conservation using a selection process based on biopsy-proven pathologic criteria.[372C,372D] Investigators at both institutions prospectively administered primary chemotherapy and performed a biopsy at the primary site, either after maximal clinical response (NCI study) or after a fixed number of cycles (Michigan study). For patients with a complete pathologic response, definitive locoregional radiation therapy was delivered. The more conventional mastectomy with postoperative radiation therapy was administered to patients with residual disease at biopsy. With a median follow-up of 5.3 years, the 5-year actuarial locoregional failure rate as first site of first failure was 23% with breast conservation in the NCI series.[372C] Similarly, with a median follow-up of 4.5 years, the 5-year actuarial estimate of locoregional failure as isolated first failure was 18% in the Michigan series.[372D] Examples of trials using breast preservation in LABC are shown in Table 95-23. Breast conservation in locally advanced disease is under study in many

centers in conjunction with aggressive induction chemotherapy. Although in general, local control is maximally achieved with mastectomy and postoperative radiation therapy, in selected subgroups of patients who respond to preoperative chemotherapy, breast-conserving therapy appears to yield local control rates similar to those attainable with mastectomy and radiation therapy.

INFLAMMATORY DISEASE

Inflammatory breast cancer is the most aggressive form of nonmetastatic breast cancer.[373] Although it accounts for only 1% to 4% of breast cancers in the United States, its presentation is striking. Characteristics essential to the clinical diagnosis include rapid enlargement and generalized induration of the breast, often without an associated mass. Diffuse skin erythema affecting more than one third of the breast is the most distinctive clinical feature of the disease. Flattening and retraction of the nipple with diffuse breast warmth and peau d'orange are commonly observed, and patients are at risk of having metastatic involvement at presentation, and not infrequently patients are thought to have mastitis and treated with antibiotics.

Pathologic Findings

Pathologically, inflammatory cancer is not a distinct histologic entity. However, dermal lymphatic involvement is the pathologic hallmark of the disease. Since the first description by Bryant in 1887, many studies have associated the clinical findings with carcinoma in the lymphatics of the skin. Thorough examination of mastectomy specimens confirms dermal lymphatic involvement in as many as 70% of women with clinical signs of inflammatory carcinoma.

Dispute exists in the literature about the criteria necessary to diagnose inflammatory breast cancer. Although some believe that clinical findings alone are adequate to make the diagnosis, others argue that a skin biopsy confirming dermal lymphatic involvement is needed, although both presentations share a similar poor outcome.[374]

Multimodality Therapy

Combined-modality therapy with chemotherapy and locoregional treatment has become the standard approach to the treatment of inflammatory breast cancer, similar to the evolution of treatment for other types of LABC. Retrospective data are convincing for a survival benefit and support the routine use of systemic therapy in this disease (Table 95-24). Depending on the choice of chemotherapeutic and locoregional treatment, disease-free survival rates at 5 years generally exceeded 25% to 30%, with 5-year survival rates approaching 40%.[375]

Although most series correlated response with outcome, more than 50% of women with inflammatory breast cancer die within 5 years after receiving optimal therapy. Locoregional control appears to be optimized in most series with the combination of surgery and radiation therapy in conjunction with systemic therapy. Breast conservation has been attempted in women with inflammatory disease. Despite reports of the successful use of breast conservation in the treatment of inflammatory disease, inferior rates of local control when compared to mastectomy plus radiation therapy in various series suggest that further studies on breast conservation as part of the treatment of inflammatory cancer are needed.

RECURRENCE AFTER BREAST-CONSERVATION THERAPY

In contrast to locoregional recurrence after total mastectomy, recurrence in the breast after breast-conservation therapy does not neces-

sarily signal great risk of systemic disease. It may represent actual recurrence at or near the site of the original primary lesion, or it may be a new primary lesion, especially when located in a different quadrant of the breast. The incidence of breast recurrence in patients treated with adequate local lumpectomy and breast radiation is 10% to 20% at 10 years, and the preferred treatment for patients who have a failure in the conserved breast is salvage mastectomy, with or without reconstruction. Other approaches, such as tumorectomy, result in lower rates of subsequent local control. In the surgical management of these women, it is important to consider the decreased blood supply and decreased skin elasticity from the previous radiation. Skin closure should be accomplished at salvage mastectomy, keeping the possibility of delayed healing in mind. For some of the same reasons, reconstruction with a tissue expander often results in increased incidence of necrosis, infection, and capsular contracture, and reconstruction with autologous tissue often is preferred.

Systemic staging is recommended at the time of diagnosis of an in-breast recurrence. The decision to use additional multidrug chemotherapy or hormone therapy is based on the nature of the breast recurrence as well as on whether the patient previously received adjuvant chemotherapy. Prospective studies to evaluate the optimal locoregional and systemic management of these patients are difficult to conduct, and these patients benefit from management by an experienced multidisciplinary breast team. In the absence of definitive data, adjuvant systemic treatment often is considered. Selection of regimens frequently accounts for prior adjuvant regimens and pathogy findings (e.g., ER/PR and HER2 expression).

Special Problems

Patients who undergo unsuccessful radiation therapy, chemotherapy, or a combination of the two in an attempt to control locoregional disease present a special challenge for the surgeon. Surgery should be attempted in these patients, because failure to control local disease results in a considerable decrease in quality of life. These patients often have painful, ulcerating, bleeding, and chronically infected local tumors. Surgery should be aggressive, frequently including the ribs and intercostal muscles. As emphasized, the extent of locoregional recurrence is a major influence on the design of a treatment plan. Therapy decisions also are significantly affected by the recognition that such disease is a marker for distant disease. For these reasons, a multimodality approach appears to have the best chance of providing real patient benefit.

MANAGEMENT OF METASTATIC DISEASE

The primary goal of therapy in patients with metastatic breast cancer is palliation of symptoms and prolongation of high-quality life, because most patients with metastatic (advanced) breast cancer ultimately die of their disease. At the same time, there has been an

improvement in the survival of of these patients with metastatic disease over the last few decades as a result of more effective therapies and diagnosis at earlier phases of metastatic disease (stage migration).[376] Chemotherapy trials with taxanes treating a mixed population of patients showed a median survival, on average, of approximately 2 years.[377] However, some patients survive long-term, and a very small number of patients with "oligometastatic" disease may even benefit from multimodality therapy that includes surgical resection of an isolated visceral metastasis with curative intent.[378] Also, specific therapies like trastuzumab have changed the natural history of HER2-positive metastatic breast cancer.[234]

Approximately 75% of metastases occur within the first 5 years after the diagnosis of early-stage disease, especially among patients with hormone receptor-negative disease. Unfortunately, a smaller risk of recurrence persists, and metastases have been documented as late as 20 to 30 years after the initial diagnosis. Although most patients with metastatic disease are expected to progress at some point, certain clinical and tumor characteristics are useful in predicting prognosis. Patients with a long interval since initial diagnosis, excellent performance status, hormone receptor-positive disease that primarily involves bone or soft tissue, and only a few sites of visceral involvement are likely to have a better long-term prognosis. Available locoregional systemic and supportive care treatments can result in significant regression of disease, relief of symptoms, and, in some cases, prolongation of survival. Although the goal of treatment of metastatic breast cancer seldom is cure, palliation with improved quality of life can be achieved in many patients.

Preliminary evidence indicates a role for combined multimodality therapy in patients with small-volume (preferably isolated) metastatic disease.[379,380] If confirmed, this also could have significant implications and force re-examination of the current recommendations for no surveillance in the absence of specific symptoms. Also, more effective surveillance tools would be required. Previous exposure to adjuvant therapy predicts a lower response to first-line chemotherapy in patients with metastatic breast cancer. However, retrospective data suggest that patients who have a recurrence long after completing adjuvant therapy may respond to similar regimens.[381] IBCSG data also suggest that quality-of-life scores may correlate with outcome in metastatic breast cancer,[382] and improvement in symptoms such as pain and shortness of breath may correlate with greater response to therapy.[383]

Evaluation of Suspected Metastases

Many patients present with nonspecific symptoms, such as new pain, weight loss, or dyspnea. Whenever possible, tissue acquisition for diagnostic confirmation and reassessement of receptor status (ER, PR, and HER2) should be considered. Clinicians should be wary of solitary lesions seen on bone scintigraphy or CT scan because they may not represent metastatic breast cancer. In the appropriate clinical setting, imaging studies without tissue confirmation may be acceptable evidence of metastatic disease, such as multiple areas of osseous lytic or blastic metastases or multiple sites with visceral involvement. Baseline imaging studies, including bone scintigraphy, CT, and plain x-rays, will provide a baseline for the evaluation of response to the planned treatment modality.

Prompt initiation of supportive measures and specific anticancer therapy in patients with significant symptoms or life-threatening complications (e.g., spinal cord compression, destructive bone lesions in weight-bearing areas, hypercalcemia, and symptomatic pleural or pericardial effusions and ascites) can offer significant palliation of symptoms. Skeletal scintigraphy (bone scan) remains the primary modality for screening for bone metastasis, but often needs to be complemented by other modalities (plain x-rays, CT, and MRI) as it primarily focus on bone metabolism.[384] Other metabolic studies like FDG-PET may have a role specially when integrated with conventional CT imaging for anatomic information (albeit frequently without iodide contrast),[385] but FDG-PET is inferior to bone scan for the assessment of blastic lesions,[386] and cost remains a barrier for many centers. Recent reports suggest an apparent increase in the prevalence of central nervous system (CNS) involvement, especially in patients with HER2-positive disease.[387] This is in great part due to improved control of systemic disease and lack of penetration of antibody therapy in sanctuary sites. This has also been observed in otherwise unselected patients who respond to conventional chemotherapy drugs and appear to be at risk for CNS relapse.[388]

Endocrine Therapy

Effective therapies with minimal toxicity, such as endocrine therapy, are highly desirable and should be considered a primary option over cytotoxic chemotherapy in patients with hormone receptor-positive disease. There is some evidence patients whose tumors co-express HER2 have less responsive disease to aromatase inibitor therapy alone and may benefit from the addition of trastuzumab,[389] but single-agent oral therapy with an anti-estrogen remains a viable option. Although the clinical factors discussed earlier are important in the selection of systemic therapy, routine measurement of ER and PR expression to identify patients who may respond to endocrine therapy may be the single most important initial test. Patients with ER/PR-positive and bone/soft tissue only or asymptomatic visceral disease should be considered for initial palliation with endocrine therapy. Examples of palliative endocrine regimens are listed in Table 95-25.

Selective Estrogen-Receptor Modulators

Tamoxifen, 20 mg daily, still is the most commonly used SERM in many countries. Toremifene is now available for use in this patient

Table 95-25 Examples of Commonly Used Endocrine Regimens in the Metastatic Setting*

INITIAL ENDOCRINE THERAPY OPTIONS
No prior endocrine therapy or over one year since endocrine therapy
Premenopausal → Anti-estrogen or OFS with endocrine therapy like postmenopausal women
Postmenopausal → Aromatase inhibitor or anti-estrogen
Prior endocrine therapy
Second-line endocrine therapy (see below)
SUBSEQUENT ENDOCRINE THERAPY OPTIONS
Premenopausal patients
Add OFS and treat like postmenopausal women
Postmenopausal patients
Nonsteroidal (anastrozole, letrozole) or steroidal (exemestane) aromatase inhibitor
Note: men of any age should not receive an aromatase inhibitor without concomitant use of an LH-RH agonist
Fulvestrant
Tamoxifen or Toremifene
Megestrol acetate
Fluoxymesterone
Ethinyl estradiol

*Consider chemotherapy if no clinical benefit (response or stable disease) after three endocrine regimens or symptomatic visceral disease.

Adapted from NCCN Clinical Practice Guidelines in Oncology: Breast Cancer. V.2.2008. www.nccn.org/professionals/physician_gls/PDF/breast.pdf.

population, but has a similar profile and is cross-resistant with tamoxifen. PET with either FDG or the estrogen analog 16α-^{18}fluoroestradiol-17β before and after treatment with tamoxifen can assess the functional status of the ER in vivo (metabolic flare) and may predict response to tamoxifen in patients with ER-positive disease.[390] Acquired resistance to tamoxifen may be explained by a variety of mechanisms, such as mutations in the ER, changes in tamoxifen metabolism, levels of intracellular tamoxifen, and differential expression of steroid-receptor transcriptional coactivators and corepressors.[391]

Aromatase Inhibitors

In postmenopausal women with no or distant previous exposure to antiestrogen agents, the aromatase inhibitors show similar or modestly superior efficacy compared with tamoxifen.[297] These drugs are ineffective in premenopausal women and should be avoided as single agents in this setting. Aromatase inhibitors are more active and less toxic than megestrol acetate as second-line therapy; they also are more active and less toxic than the first-generation drug aminoglutethimide. Letrozole appears to be a more potent suppressor of total-body aromatization and plasma estrogen levels than anastrozole in patients with breast cancer,[392] but direct comparison as second-line therapy in metastatic breast cancer show no convincing clinical advantage of one aromatase inhibitor over another.[393] Circulating levels of estrone and estradiol decrease similarly in both responders and nonresponders after therapy with an aromatase inhibitor, suggesting that intratumoral aromatase activity could play a more significant role in differentiating these two groups of patients.[394] There are few data regarding the optimal sequence of therapy (i.e., a SERM followed by an aromatase inhibitor, or vice versa), and most patients will be treated with both at some point. Aromatase inhibitors should be avoided as a single agent in men with metastatic disease, as their chronic administration may lead to a significant increase in levels of follicular stimulating hormone and testosterone without any change in levels of estradiol, but appear to be effective when combined with an LH-RH agonist as chemical castration.[395]

Ovarian Ablation

The prefered endocrine therapy in premenopausal women with endocrine-responsive disease and recent exposure to tamoxifen is ovarian function suppression with surgical or medical techniques (LHRH agonist).[396] Radiation ablation is less reliable and technically more challenging, and the results are not as immediate.[397] Available data show both an overall survival advantage and a progression-free survival advantage with the addition of tamoxifen to an LHRH agonist,[398,399] but there are limited data on ovarian function suppression and an aromatase inhibitor.

Other Antiestrogens

The nonsteroidal pure antiestrogen fulvestrant downregulates ER without the agonistic activity of tamoxifen. It appears to have inhibitory effects in breast and uterus with neutral effect in bones and lipids,[400] and clinical effects appear similar to aromatase inhibitors.[401] It is currently only approved in postmenopausal women as a monthly, deep IM injection. Data on the clinical benefit from a loading disease are conflicting.

Chemotherapy

Patients with symptomatic visceral disease, ER- and PR-negative disease, or disease that is resistant to endocrine therapy should receive chemotherapy. Given the palliative goal and the toxicities of cytotoxic therapy, the challenge for the oncologist is in deciding when to initiate chemotherapy. Many appropriate chemotherapy regimens are available, and little evidence recommends combination therapy over sequential single-agent chemotherapy (Table 95-26).

There often is a fine line between premature use of chemotherapy in the asymptomatic patient without disease-related complications versus delaying therapy until deterioration of performance status significantly decreases the likelihood of response. There is considerable interest in identifying biologic parameters that may predict the success of specific chemotherapy regimens such as the identification of patients with HER2-positive diseases who could be offered trastuzumab. Patients with disease that does not express hormone receptors are more likely to respond to chemotherapy.[402] The organ distribution of metastases and the patient's symptoms, history of exposure to chemotherapy, and general medical condition are helpful considerations when determining the time of initiation of chemotherapy. Age alone should never be a contraindication.

Single-Agent Chemotherapy

Commonly used single-agent chemotherapy drugs in patients with advanced disease include anthracyclines, taxanes, vinorelbine, and capecitabine. If no data suggest a markedly strong benefit of one class of drugs over another, decisions should be made based on patient convenience and toxicity profile. Other active agents include gemcitabine, platinum compounds, etoposide, vinblastine, and continuous-infusion 5-fluorouracil.

The activity of taxanes in patients with anthracycline-resistant disease is well documented,[403] and may extend to patients previously treated with another taxane. Taxanes appear to have a better toxicity profile compared with either doxorubicin[404] or a CMF. Capecitabine is active in patients who showed disease progression after previous taxane regimens.[405] The epothilone B drug ixabepilone also has clinical activity in patients with disease resistant to paclitaxel, doxorubicin, and capecitabine.[406,407]

Combination Chemotherapy

Commonly used combination chemotherapy regimens include FAC/CAF (5-fluorouracil, doxorubicin, and cyclophosphamide), FEC (with epirubicin), AC, epirubicin and cyclophosphamide, AT (doxorubicin plus docetaxel or paclitaxel), and CMF. A survival advantage was seen in randomized trials of first-line therapy with paclitaxel or docetaxel against combination regimens. However, such survival advantage correlates with whether or not patients who showed disease progression while receiving the nontaxane regimen were subsequently crossed over to a taxane drug. Similar findings were seen in a study of docetaxel with or without capecitabine in patients with metastatic breast cancer who were previously treated with an anthracycline.[408] In this study, only a small fraction of patients who were initially treated with docetaxel alone subsequently crossed over to capecitabine at progression. Combinations between anthracyclines and taxanes have been tested, but paclitaxel interferes with doxorubicin elimination and lowers the threshold for cardiac toxicity. Dexrazoxane appears to be cardioprotective in patients treated with FAC. Gemcitabine plus paclitaxel significantly improves progression-free survival when compared to paclitaxel alone,[409] and a similar study design led to FDA approval in 2007 of ixabepilone in combination with capecitabine.[410]

High-dose chemotherapy with autologous or allogeneic stem cell support remains investigational. Available data do not support its use as a standard approach.[411]

HER2-Targeted Therapy

Anti-HER2 therapy with the recombinant monoclonal antibody trastuzumab is another recent example of targeted therapy. Its potential benefits are restricted to women whose tumors overexpress HER2, and evidence does not support its use against HER2-negative disease. Although data do not show a survival advantage with combined cytotoxic therapy in metastatic disease whenever there is sufficient cross-over to the investigational agent, this benefit was seen when trastuzumab was added to anthracycline and cyclophosphamide or paclitaxel.[234] Excessive cardiac toxicity limits the ability to combine anthracyclines with trastuzumab.[412]

Many consider trastuzumab the mainstay of therapy in HER2-positive disease. However, the sequential approach of trastuzumab followed by chemotherapy (or the combination) versus upfront combined therapy has not been tested. Combination of an aromatase inhibitor with trastuzumab appears to offer improved survival.[389] Single-agent therapy with trastuzumab is an active option[413] and can be given once every 3 weeks.[414] The dual tyrosine kinase inhibitor lapatinib recently was approved by the FDA in combination with capecitabine for the treatment of patients who previously were treated with trastuzumab,[415] and also prolongs time to tumor progression, with superior results when combined with paclitaxel versus paclitaxel alone.[416] This drug also is active in HER2-positive patients who have not been treated with trastuzumab.[417]

Therapies Targeting Angiogenesis

New blood vessel formation plays a key role in breast cancer growth locally and at distant sites, and angiogenesis appears to be essential for tumor development, invasion, and metastasis.[418] Evidence exists that angiogenesis precedes transformation of mammary hyperplasia to malignancy. Hypoxia is a strong angiogenesis signal, and expression of the hypoxia-inducible factor HIF-1α increases from normal breast tissue through usual ductal hyperplasia, DCIS, and invasive disease.[419] Expression of HIF-1α is increased in poorly differentiated tumors and is associated with proliferation and expression of vascular endothelial growth factor (VEGF). Microvessel density (MVD) is associated with higher-grade DCIS and greater risk of developing metastatic disease.[418]

Angiogenesis inhibition has been observed with drugs such as tamoxifen and commonly used chemotherapy drugs in preclinical models, and these observations led to increased interest in the so-called "metronomic" schedules of chemotherapy administration. Agents targeting various angiogenesis receptors and ligands have been developed. The small-molecule tyrosine kinase inhibitor sunitinib modulates VEGF receptor (VEGFR)-1, VEGFR-2, platelet-derived growth factor receptor (PDGFR), c-kit, and Flt-3. It is approved by the FDA for the treatment of advanced renal cell cancer and has single-agent activity in refractory metastatic breast cancer.[420]

The humanized monoclonal antibody bevacizumab, which targets the VEGF-A ligand, is approved in the United States for patients with metastatic colon and lung cancer, and has a small risk of complications including bleeding, healing impairment, hypertension, and proteinuria. Bevacizumab has single-agent activity in patients with refractory advanced breast cancer[421] and when combined with the chemotherapy drug capecitabine.[422] Bevacizumab was shown to increase progression-free survival significantly when added to paclitaxel in a randomized first-line trial for women with metastatic disease (ECOG 2100),[423] and it is now the subject of a prospective randomized trial testing a sequential anthracycline/paclitaxel regimen with or without bevacizumab for patients diagnosed with high-risk, early-stage HER2-negative breast cancer (ECOG 5103).

Bisphosphonates

Bone is the most common site of metastatic disease and ultimately is affected in most patients.[424] Monthly injections of bisphosphonates for up to 2 years can reduce the risk of skeletal events in patients who have lytic bone metastases and are receiving systemic therapy. Zoledronate is an effective alternative to pamidronate because of its shorter infusion time.[425] However, these more potent third-generation bisphosphonates are associated with an increased risk of osteonecrosis of the jaw.[426]

New Approaches

The marked increase in understanding of the cellular and molecular biology of breast cancer led to a striking increase in novel therapies for breast cancer and a significant shift away from the high-dose-chemotherapy hypothesis that "more is better," to a more rational, targeted approach that first was attempted with endocrine therapy and now also is being used with anti-HER2 therapy. Other examples in patients with advanced disease include therapies targeting the epidermal growth factor family of receptors, VEGF receptors, and other angiogenesis targets. The redundancy of many of these pathways suggests the potential need for a combination of drugs targeting multiple steps or more promiscuous drugs that interact with multiple targets.[427] These studies include combinations of existing hormonal and cytotoxic drugs, and the design of these studies is challenging. Patients must have access to high-quality, well-conducted studies to

ensure that useful data are generated, are properly interpreted, and lead to improved cancer care. An important challenge in the treatment of patients with breast cancer is how best to identify those who are most likely to benefit from specific interventions while avoiding unnecessary toxic exposure in those who are unlikely to benefit. Circulating tumor cells, at baseline and after just 4 weeks of therapy, can identify patients early on who are not responding so that a potentially toxic therapy can be discontinued.[108,155] Ongoing trials are now examining whether therapeutic decisions made based on these findings will result in improved clinical outcome.

UNUSUAL PROBLEMS ENCOUNTERED IN BREAST CANCER

Male Breast Cancer

Male breast cancer is rare, accounting for 0.2% of male cancers and fewer than 1% of new breast cancers.[428] Mutations in the BRCA2 gene predispose men to breast cancer and may account for up to 40% of all cases. Most present as infiltrating ductal carcinoma with unilateral, firm, painless masses. Nipple discharge should be taken seriously and is an indication for FNA or core or excisional biopsy. Mammography and ultrasound may be of help and may contribute to differentiating a breast cancer from a gynecomastia. A negative finding on FNA or core biopsy requires an excision procedure, and cytologic findings that show gynecomastia require close follow-up. The tumor phenotype appears similar to that observed in women.

Treatment is modeled after female breast cancer, both locoregional and systemic therapies. There is evidence that SLNB can be safely applied in male breast cancer.[429] Because most patients have endocrine-responsive disease, orchiectomy or chemical castration with LH-RH agonists often is used in patients with advanced disease. Tamoxifen is the most common endocrine therapy used, although androgens, antiandrogens, corticosteroids, estrogens, and progestins have also been used. Aromatase inhibitors are of potential interest in men with metastatic disease. However, approximately 80% of circulating estrogens are derived from the aromatization of precursor androgens with the remaining estrogens come from direct testicular secretion. This explains the apparent lower response rate observed with the first-generation aromatase inhibitor aminoglutethimide compared with tamoxifen and with anastrozole.[430] These observations suggest that orchiectomy and tamoxifen remain the endocrine therapies of choice in men with breast cancer, although a recent report also suggests a role for aromatase inhibitors if given with an LH-RH agonist.[395]

Breast Cancer and Pregnancy

Breast Cancer during Pregnancy

Carcinoma of the breast, although rare in pregnant women, occurs in about 1 to 3 patients per 10,000 deliveries and is the most common malignancy associated with pregnancy. It is expected to become more common with the observed increase in the average age at first full-term pregnancy. The advanced level of disease and the poor prognosis associated with gestational breast cancer appear to be due primarily to delay in diagnosis. For this reason, a thorough examination of the breast should take place during the first obstetric visit, before the breast becomes engorged or hypertrophic, and the obstetrician must pursue early signs of breast cancer actively via a thorough breast examination. Diagnosis and staging are far more difficult in pregnant women because of physiologic changes in the mother and radiation risk to the fetus. Mammograms are not routinely performed—little information can be gained because of pregancy-related increased breast density. Ultrasonography and MRI can be used, although safety of the gadolinium for the fetus has not yet completely been determined. Routine bone scintigraphy is contraindicated in pregnant women.

Biopsy of a mass during pregnancy is difficult and must be undertaken with extreme care to avoid infection and milk fistulas in the lactating breast. FNA and stereotactic NCB are the initial procedures used in evaluating a breast mass, with lactation often suppressed preoperatively with bromocriptine. Biopsy can almost always be performed under local anesthesia; however, no evidence shows that general anesthesia poses significant risk to either the mother or the fetus if proper precautions are taken. There are some data in favor of the safety of SLNB in pregnant women.[431] Modified radical mastectomy is the treatment of choice for breast cancer during pregnancy. Depending on the extent of disease and the predicted delivery date, breast conservation may be considered. Tumor excision and axillary dissection are performed during pregnancy, followed by breast irradiation after delivery. Survival is not improved by therapeutic abortion, and pregnancy-associated breast cancer should be treated using the same decision tree that would be appropriate for a patient who is not pregnant.

While therapeutic abortion early in pregnancy greatly simplifies the treatment of early-stage breast cancer, it does not improve treatment outcome, and there are no reports show that breast cancer is harmful to the fetus, because breast cancer cells cannot traverse the placenta, as in some cases of melanoma, lymphosarcoma, or leukemia. In most cases, chemotherapeutic agents are not recommended for use in pregnant women because of concerns about teratogenesis. The effect on the fetus also is related to drug dosage, gestational age, and the individual patient's tolerance. However, cytotoxic chemotherapy has been administered, mostly after the first trimester, without identifiable damage to the fetus. Data from the M.D. Anderson Cancer Center suggest that women can be safely treated with FAC chemotherapy during the second and third trimesters without sugnificant short-term complications, though little is know about long-term effects on fertility and cardiac function on these children.[432] Administration of paclitaxel also appears feasible, as the drug is a substrate for placental p-glycoprotein and little is transferred to the fetal circulation.[433]

Pregnancy after Breast Cancer

Many women now emerge from treatment for breast cancer with fertility intact, and some will become pregnant. The IBCSG identified in their clinical trial database 94 patients who became pregnant after a diagnosis of breast cancer, including 8 women who had a relapse during pregnancy. The investigators compared the outcome of these patients with the outcome of 188 matched, controlled patients from the same database, and found no adverse effect from pregnancy on survival.[434] Thus far, there is no evidence that pregnancy after breast cancer treatment increases the risk of a worse outcome. However, women who remain premenopausal after chemotherapy are at risk for premature menopause.[339]

Axillary Metastases with Occult Breast Cancer

A woman with clinically suspicious axillary lymph nodes despite negative breast examination and mammogram requires careful evaluation for breast cancer. FNA often allows the diagnosis of adenocarcinoma versus other tumor types. Breast is the most common primary source when dealing with adenocarcinoma, although gastrointestinal (GI) sources or the thyroid often may be involved. It is not unreasonable, therefore, to order a CT scan of the chest and abdomen if further breast imaging with ultrasound and MRI is unrevealing.

The definition of "occult breast carcinoma" is a breast cancer presenting with metastatic axillary nodes without evidence of the primary tumor at the physical, mammographic, or ultrasound examination. Occult breast carcinoma presenting as axillary metastases is

rare, accounting for less than 0.40% of primary operable breast cancer. Occult breast cancer should be differentiated from a contralateral dissemination to the contralateral axillary lymph nodes, accounting for 4%, based on physical examination only. The Memorial Sloan-Kettering experience with 69 patients with occult primary showed that MRI was able to detect a breast carcinoma in 63% of the patients, and no carcinoma was found in the mastectomy specimen when the MRI was negative.[435] For a long time, ipsilateral mastectomy with complete axillary dissection has been the therapy of choice for patients presenting with axillary lymph node metastasis with occult primary.[436] Some reports are showing that conservation of the breast is possible. The Milan group reported, at 43 months' follow-up, a disease-free survival of 84% and two breast recurrences (supraclavicular and multiple metastasis).[437] The M.D. Anderson Cancer Center reported local recurrence in 4 of their 32 patients (13%).[438] These data are in favor of breast conservation in an occult primary. The routine use of MRI in this rare presentation of breast cancer allows detection of the primary tumor in a large number of patients. The 5- and 10-year survival rates are essentially the same as those for T1N1 and T2N1 tumors, and even patients in whom a primary breast cancer is not identified are treated in the same way as patients with N1 breast cancer.

Paget's Disease of the Breast

Paget's disease of the breast is a cutaneous manifestation of underlying breast malignancy. This eczematoid lesion (often weeping, red, and crusting in late presentation) occurs in approximately 1% to 4% of patients with breast cancer, and as many as 50% of patients with Paget's disease may have an underlying cancer. Paget's disease is a carcinoma of glandular origin, and Paget's cells are spread through the epidermis as a result of motility induced by a chemotactic factor released by epidermal cells. The greatest prevalence of Paget's disease of the breast occurs in the sixth decade of life. The infrequency of early diagnosis is associated with a delay in recognition of early symptoms. Although an early sign of Paget's disease is severe itching accompanied by erosive nipple changes, the median delay between first symptom and diagnosis is approximately 6 months, and often longer. Paget's disease associated with a palpable underlying tumor can be treated with breast conservation with removal of the nipple-areolar complex. This procedure usually leaves an acceptable breast mound for subsequent reconstruction of the nipple-areolar complex. SLN biopsy is an appropriate method for evaluating axillary status.

This disease shows the importance of physical examination and physician-patient education. Early-stage Paget's disease of the breast is almost universally associated with prolonged disease-free survival. Several conditions mimic Paget's disease of the breast secondary to underlying breast cancer, including erosive adenomatosis of the nipple and pemphigus vulgaris of the nipple. Although mastectomy has been the traditional surgical approach to this entity, breast conservation, with removal of the nipple-areolar complex, followed by whole-breast radiation, appears equally effective for Paget's disease. Of note in this collaborative study, the group had did not have mammographic or physical evidence of an underlying breast mass.

Cystosarcoma Phyllodes and Sarcomas

Sarcomas of the breast are rare, representing fewer than 1% of malignant breast tumors. Included in this group are benign and malignant forms of cystosarcoma phyllodes (CSP), accounting for approximately 0.5%; carcinosarcoma; and sarcoma. CSP tumors have a characteristic leaf-like architecture, with clefts lined by epithelial cells, and about 25% of the time are associated with fibroadenomas. Some authors refer to benign CSP as giant fibroadenomata, reserving the term CSP for the malignant lesion. The average age at presentation is the mid-40s.

Distinguishing benign from malignant lesions has been emphasized in describing CSP. Several histologic characteristics are considered indicators of malignant CSP, including increased cellularity, subepithelial stromal overgrowth, stromal anaplasia, tumor size, contour, degree of cellular atypia, and mitotic activity. Older series suggested a low risk of death when tumors had fewer than three mitotic figures per high-power field and that stromal overgrowth was associated with a risk of metastases.

Barrio and colleagues[439] at Memorial Sloan-Kettering Cancer Center reviewed the pathologic features and clinical course of 293 women who had CSP. Of these patients, 206 (70%) had benign CSP and 87 (30%) had malignant CSP. Breast-conserving surgery was the local therapy in 242 breasts; mastectomy was chosen in the remaining 48 breasts. With a median follow-up of 7.9 years, 35 patients recurred, for an actuarial 10-year rate of 14.4%. In this series, the classification into "benign" versus "malignant" types was not related to the risk of local failure. Using univariate analysis, the risk of a local failure was increased in women with positive margins, fibroproliferation, and necrosis.[439] CSP tumors usually are treated with wide local excision to include a sufficient margin of normal breast tissue from the tumor bed. Even benign tumors have a high incidence of local recurrence if they are simply shelled out of the breast tissue, and meticulous effort is required to obtain an adequate tissue margin. Recurrences of benign CSP may be re-excised, again with wide margins, but some cases are better managed by mastectomy and reconstruction. In a SEER series of 821 women diagnosed with malignant CSP, 52% were treated with mastectomy and the remaining 48% with lumpectomy. In this nonrandomized series, the patients treated with lumpectomy were younger, had smaller tumors, and had an improved cause-specific survival, but the role of radiation is not adequately described.[440]

Aside from malignant CSP, sarcomas of the breast include a wide range of histologic types, such as carcinosarcoma, osteosarcoma, liposarcoma, angiosarcoma, malignant histiocytoma, leiomyosarcoma, stromal sarcoma, and mixed types. Carcinosarcoma is different, in that it is composed of a combination of malignant epithelial cells, as would be found in breast adenocarcinoma, in addition to malignant stromal cells characteristic of sarcoma. These tumors may behave somewhat differently from pure sarcomas and can spread to axillary lymph nodes. Treatment of carcinosarcoma usually includes mastectomy with adequate tissue margins, including muscle and skin, if necessary, and decisions about chest wall irradiation are influenced by tumor size, location, and margins. North and colleagues at the Roswell Park Cancer Institute reported 25 patients treated for breast sarcoma (10 with angiosarcomas) between 1964 and 1995.[441] These patients had a median age of 55 years, 10 had a mastectomy, and their 10-year overall survival rate was 36%. In general, the type of surgery is determined by breast size, and, while wide local excision is adequate primary surgical treatment for most lesions, attention should be given to obtaining wide margins, including deep muscle, if needed. Tumors larger than 5 cm and high-grade tumors may require mastectomy, possibly with chest wall resection, and the surgeon should approach these tumors according to the established guidelines for sarcoma surgery. Lymph node dissection is not usually recommended due to the hematogenous nature of its dissemination. Imaging studies are recommended to rule out systemic dissemination (e.g., lung) at presentation. Adjuvant radiation therapy should be considered on a case by case basis, although data are limited, and little is known on the role of adjuvant chemotherapy. Therefore, while the rarity of breast sarcomas limits the rigorous evaluation of therapeutic options, it seems appropriate to approach sarcomas of the breast using therapeutic methods derived from the soft tissue sarcoma literature.

96 Sarcomas of Bone

Mark C. Gebhardt, Dempsey Springfield, and James R. Neff*

SUMMARY OF KEY POINTS

Incidence and Epidemiology
- More than 2400 new cases of bone sarcoma are diagnosed annually in the United States.
- No specific etiologic agents are identified in the majority of cases.
- Secondary neoplasms are related to known oncogenic factors (e.g., ionizing radiation, alkylating chemotherapy agents, combinations of both).
- Hereditary cancer syndromes (tumor suppressor genes) are responsible for some cases.

Diagnosis and Radiographic Staging
- Plain radiographs are recommended.
- Magnetic resonance imaging (MRI) scan of primary tumor is the best radiographic study to obtain.
- Chest x-ray is indicated; chest computed tomography (CT) is indicated for suspected malignant lesions.
- Whole-body technetium-99m (^{99m}Tc) bone scan is indicated.
- Positron emission tomography (PET) scanning is controversial and has yet to be generally accepted.
- Needle or open biopsy is necessary for a tissue-specific diagnosis and to determine histologic grade.
- In the pathology review, immunohistochemistry and cytogenetics are important.
- Electron microscopic tissue occasionally is required.

Prognostic Factors
- Metastasis at presentation is a worse prognostic finding.
- Histologic grade is the next most significant prognostic indicator.
- Size is less significant, but lesions larger than 10 cm in diameter have a poor prognosis.
- Tumor response to neoadjuvant chemotherapy
- Surgical margins of resection (minimum of a "wide" margin)

Staging System
- The American Joint Committee on Cancer now monitors location, grade (high and low), depth, and size (8 cm); designates "skip" lesions (T_3); and separates metastasis to bone from other sites (Mla, Mlb).
- The Musculoskeletal Tumor Society monitors location (intracompartmental and extracompartmental), grade (high and low), and metastasis ("skip" lesions, nodal, bone, and lung are all lumped together).

Primary Therapy
- A wide surgical margin is recommended.
- Limb-sparing procedures are appropriate for 70% to 90% of patients.
- Adjuvant irradiation is not routinely used for bone sarcomas.
- Local recurrence rates for limb-sparing procedures approach 5% or less.
- Reconstruction methods can be tailored to patients' needs.
- New and improved biocompatible implant materials and improved designs are available.

Future Trends
- The search continues for new drugs, drug schedules, potentiating agents, and improved dose intensity.
- Identification of risk factors (e.g., cytogenetic, molecular genetic, and signal transduction abnormalities) will improve to identify new methods of potential treatment.

INTRODUCTION

Approximately 2400 new malignant tumors of bone (excluding multiple myeloma) are diagnosed each year in the United States. The femur is the most common site, but primary sarcoma can occur in any bone. Osteosarcoma, Ewing's sarcoma, and chondrosarcoma account for approximately 90% of all primary sarcomas of bone. The management of osteosarcoma and Ewing's sarcoma includes chemotherapy and surgery, while chondrosarcoma is treated by surgery alone.[1] The management of these patients, from initial evaluation and biopsy through surgical therapy and long-term follow-up, is labor intensive and technically demanding. Patients with a bone sarcoma should be treated in a center that has expertise in the management of these tumors.

Surgical Staging System

Currently, the staging system adopted by the Musculoskeletal Tumor Society (MSTS) in 1980 and modified in 1986 is accepted by most musculoskeletal oncologists.[2–4] Malignant tumors are divided into only two histologic grades: low-grade malignant (G1) and high-grade malignant (G2). Low-grade malignant lesions (G1), comprising Broder's I and II lesions, have a low probability of metastasis (25%). The majority of these tumors can be managed by relatively conservative surgical procedures and do not require chemotherapy.

*Deceased.

The authors dedicate this revised and updated chapter to the memory of James Russell Neff (1940–2005) who was the original author. Dr. Neff was a leading specialist in treating cancer of the bone and soft tissues who was known internationally for performing innovative procedures to help people lead more normal lives following cancer.

High-grade lesions (G2), Broder's III and IV tumors, have a significantly higher incidence of metastases, requiring more radical surgical procedures and possibly neoadjuvant and/or adjuvant chemotherapy. Table 96-1 is a representative grouping of both low- and high-grade malignant tumors of bone and soft-tissue origin.

Bone sarcomas that are totally intraosseous are intracompartmental (T_1 or A). Those that penetrate the cortex are considered extracompartmental (T_2 or B; Table 96-2).

Patients without evidence of metastatic disease after radiographic staging are designated M0. In general, metastatic disease that is evident in the lung, in the lymph nodes, or as an intramedullary "skip" lesion indicates a poor prognosis and is designated M1.

Surgical procedures are defined by the relationship of the circumferential surgical plane of dissection and the pseudocapsule. Surgical margins are defined as intralesional, marginal, wide, and radical. Examples of intralesional margins include curettage of a presumed benign tumor and cytoreductive debulking procedures. Marginal margins, achieved when the plane of dissection passes through the reactive zone of the pseudocapsule, are suitable for management of the majority of benign tumors. Such margins are accomplished when the surgeon "shells out" a neoplasm, cleaving the tissue between the reactive zone and the zone of compression. This technique leaves behind viable tumor satellites at the periphery of the lesion; thus, marginal margins are not sufficient for local control of malignant or benign "aggressive" lesions.

A wide margin is obtained when the plane of dissection passes through absolutely normal nonreactive tissue that is well removed from the pseudocapsule. Wide margins are sufficient for virtually all bone sarcomas.

Radical margins of a bone sarcoma are achieved when the entire bone is removed. This usually requires an amputation. A radical margin is rarely necessary.[5]

The American Joint Committee on Cancer (6th edition) has adapted the TNM staging system to bone. The topography (T) of the primary tumor now includes size based on relevant published reviews, in which the greatest dimension (8 cm for Ewing's tumor, 9 cm for conventional osteosarcoma) has replaced the compartment concept. Also, T3 has now been assigned to patients who develop "skip" metastases (Table 96-3).

The problem of defining histopathologic grade (G) has been addressed and now essentially consists of low- and high-grade lesions (Table 96-4). G1 and G2 have been combined into low-grade and G3 and G4 into high-grade histopathology. Currently, all Ewing's tumors are classified as G4 or high-grade. This grouping is now identical to the G1 and G2 of the MSTS staging system. The stage groupings are shown in Table 96-5. Here, the committee has appro-

Table 96-1 Surgical Grade (G)

Low (G1)	High (G2)
Parosteal osteosarcoma	Classic osteosarcoma
Periosteal osteosarcoma	High-grade surface
Low-grade central osteosarcoma	Paget's sarcoma of bone
	Radiation sarcoma
Intraosseous osteosarcoma	
Secondary chondrosarcoma	Primary chondrosarcoma
	Dedifferentiated chondrosarcoma
	Mesenchymal chondrosarcoma
Clear cell chondrosarcoma	
Fibrosarcoma, Kaposi's sarcoma	Fibrosarcoma
Atypical malignant fibrous histiocytoma	Malignant fibrous histiocytoma (MFH)
	MFH of bone
	Undifferentiated primary sarcoma
	Giant cell sarcoma, bone
Hemangioendothelioma	Angiosarcoma
Hemangiopericytoma	Hemangiopericytoma
Myxoid liposarcoma	Pleomorphic liposarcoma
	Neurofibrosarcoma (schwannoma)
Clear cell sarcoma	Rhabdomyosarcoma
Epithelioid sarcoma	Synovial sarcoma
Chordoma	Ewing's sarcoma of bone
Adamantinoma	PNET (primitive neuroepithelial tumor)
Alveolar cell sarcoma	
Other and undifferentiated	Askin's tumor
	Alveolar cell sarcoma

Table 96-2 Surgical Sites (T)

Intracompartmental (T1)	Extracompartmental (T2)
Intraosseous	Soft-tissue extension
Intra-articular	Soft-tissue extension
Superficial to deep fascia	Deep fascial extension
Parosseous	Intraosseous or extrafascial
Intrafascial compartments	Extrafascial planes or spaces
Ray of hand or foot	Midfoot and hindfoot
Anterolateral leg	Popliteal "space"
Posterior leg	Groin-femoral triangle
Middle thigh	Intrapelvic (retroperitoneal)
Posterior thigh	Midhand
Buttocks	Antecubital fossa
Dorsal forearm	Axilla
Volar forearm	Periclavicular
Anterior arm	Paraspinal
Posterior arm	Head and neck
Periscapular

priately addressed the difference in prognosis of patients who have sustained metastases to lung (Mla) and to other sites, including bone (Mlb).

Radiographic Staging

Conventional bone radiography remains the single most useful initial study for bone tumor evaluation. The study should include anteroposterior (AP) and lateral projections of the lesion. Malignant neoplasms usually result in ill-defined or "poorly marginated" radiographic margins with little or no reactive bone, loss of medullary trabeculation, and endosteal cortical erosion, suggesting an active and destructive process at the tumor/host bone interface. The pathologic process biologically overwhelms the normal time-dependent reactive processes of bone formation. Therefore, the radiographic presence or absence of a reactive rim of bone is often useful in predicting the biologic aggressiveness of the pathologic process (Table 96-6). Neoplastic bone formation is often seen in osteosarcoma, and calcification is often seen in chondrosarcoma.

The use of technetium-99m (^{99m}Tc) bone scintigraphy remains the standard for surveying the skeleton for multiple osseous lesions. The test can be administered as a single delayed static study or can be displayed in multiple timed phases to evaluate the vascularity of the lesion. It is important to obtain a whole-body bone scan.

Computed tomography (CT) is superior to magnetic resonance imaging (MRI) only to evaluate a small lesion in the cortex, subtle bone formation, or calcification; otherwise, MRI is the study of choice. CT remains the standard for evaluation of the chest for occult metastases. The cross-sectional display usually provides sufficient resolution (<0.5 cm) to demonstrate subpleural metastases long before they become evident on plain chest films. Before definitive therapy or local management of a potentially malignant lesion, a staging CT evaluation of the chest and mediastinum should be performed.[6]

The majority of bone sarcomas are best evaluated by a single well-planned MRI using specific predetermined planes and images with

Table 96-5 Stage Grouping

Stage 1A	T1	N0	M0	G1, 2 low grade
Stage 1B	T2	N0	M0	G1, 2 low grade
Stage IIA	T1	N0	M0	G3, 4 high grade
Stage IIB	T2	N0	M0	G3, 4 high grade
Stage III	T3	N0	M0	Any G
Stage IVA	Any T	N0	M1a	Any G
Stage IVB	Any T	N1	Any M	Any G
	Any T	Any N	Mlb	Any G

Table 96-6 Radiographic Techniques Available

1. Plain films: loss of trabeculation, matrix identification, calcification, etc.
2. Polytomes: evaluate margination, matrix identification, calcification, etc.
3. Bone scan: three phases to evaluate vascularity, static skeletal survey
4. Rapid whole-body STIR MRI: excellent survey study with cooperative patients and in institutions using these techniques
5. CT: margination, matrix identification, calcification, cortical disruption, axial localization of lesion
6. MRI: excellent soft-tissue contrast, sometimes nearly diagnostic; T_1 best for anatomy, contrast enhancement, magnetic resonance angiography capability, best overall single study when properly monitored by a physician
7. PET: adds metabolic parameter used to monitor effectiveness of neoadjuvant chemotherapy
8. Other: ^{201}T1 scan, gallium scan, PET scan

intravenous contrast. The T_1-weighted images produce superior anatomic detail, while T_2-weighted images best characterize the structure and composition of the lesion (solid, homogeneous, heterogeneous, cystic, or combinations of these characteristics). The use of intravenous contrast is valuable in assessing the tumor's vascularity and to reveal the tumor's relationship to the neurovascular bundle.

Overall, MRI provides superior sagittal, coronal, and multiaxial anatomic detail in both soft tissues and bone. MRI data are indispensable in assessing the intramedullary extent of the lesion (e.g., osteosarcoma, osteomyelitis, Ewing's sarcoma) or assessing "skip" metastases either within the contiguous medullary canal or across adjacent joint surfaces.

Currently, MRI of the primary tumor appears somewhat predictive of tumor response to neoadjuvant therapy. Changes in the T_2-weighted image signal intensity correlate with an obvious reduction in tumor volume (especially in Ewing's sarcoma) and appear predictive of tumor necrosis.[7] The addition of contrast enhancement does not appear to provide more viable tumor/necrotic tumor contrast than do T_2-weighted images; however, the absence of contrast enhancement appears to be an indicator of tumor necrosis.[7–10]

Positron emission tomography (PET) has been used to predict an osteosarcoma's response to chemotherapy. PET scan might be valuable in the initial screening, but this has yet to be determined.

Staging Biopsy

The staging biopsy might well be the most important and difficult procedure that is performed in the patient's management (Box 96-1). The placement, length, and orientation of the biopsy scar and the anatomic compartments that are contaminated during the biopsy procedure dictate which tissues and how many surgical compartments will require removal for local tumor management and limb-sparing surgery. A thorough knowledge of the soft-tissue anatomic planes and muscle compartments is mandatory before proceeding with bone biopsy. Consideration should be given to the location and type of biopsy to be used, whether fine-needle aspiration biopsy, core-needle biopsy, or open biopsy. In addition, it is critical that adequate diagnostic tissue be obtained so that an accurate diagnosis can be made. Usually, a core-needle biopsy is sufficient.

OSTEOSARCOMA

Osteosarcoma, the most common primary sarcoma of bone, is a complex and heterogeneous set of neoplasms. It is defined as a

Box 96-1. GUIDELINES FOR BIOPSY

Excisional Biopsy: Soft-Tissue Lesions Less Than 2.5 to 3.0 cm

1. Planning: must provide potentially curative margins
2. Superficial lesions: must include contiguous deep fascia as deep margin
3. Deep lesions: myectomy where possible
4. Obtain appropriate sterile specimens prior to contamination of specimen (e.g., cytogenetics)
5. Absolute hemostasis
6. Avoid drain; when necessary, place drain tract in-line and 1 cm from incision to facilitate reexcision if necessary
7. Subcuticular closure and supportive skin adhesive strips

Incisional Biopsy: Soft-Tissue Lesions 2.5 to 3.0 cm

1. Planning: plan most appropriate biopsy tract, avoid transverse incisions
2. Use pneumatic tourniquet after gravity exsanguination
3. Avoid contamination of joint
4. Avoid exposure of neurovascular structures
5. Monitor biopsy with frozen sections
6. Microbiologic culture if question
7. Maintain integrity of deep tumor/host margin; could extend necessary surgical margin
8. Absolute hemostasis; thrombogenic agents (thrombin, Oxycel, Avitene, etc.)
9. Hemostatic closure of pseudocapsule
10. Subcuticular closure and adhesive strips

sarcoma that directly produces tumor osteoid or bone. The classical osteosarcoma is a high-grade lesion, but there are many variants that vary in grade and behavior. Classic osteosarcoma is characterized by a bimodal age distribution, with the first peak in the second decade of life and the second much later, in the sixth and seventh decades. Osteosarcoma in adults is often associated with other underlying disease processes.

Historical Review

High-grade osteosarcoma used to be a fatal neoplasm leading to metastases and death of 90% of patients despite aggressive local control, including radical amputations and/or radiotherapy. The version of this chapter in the previous edition outlined the evolution of the use of adjuvant chemotherapy and the dramatic improvement in survival and event-free survival (EFS) that followed. Initially, the benefits of adjuvant chemotherapy were questioned, leading to the need for a randomized study comparing surgical management alone to surgery followed by multiagent chemotherapy. The active drugs were shown to be doxorubicin, high-dose methotrexate, and cisplatin. A randomized study, including both the randomized patients and those who chose whether or not to have adjuvant chemotherapy, clearly demonstrated the benefits of adjuvant chemotherapy.[11,12]

Surgical advances paralleled the advances in medical management of osteosarcoma patients. Originally, disarticulation or resection of the entire involved bone was recommended for surgical management of osteosarcoma.[13] This was due in part to the intramedullary origin of the tumor with proximal intramedullary growth and the reported 25% incidence of intramedullary "skip" metastases.[14] Later studies reviewing the local recurrence rates for patients whose primary management was transmedullary amputation alone revealed local recurrences in approximately 5% to 10%, suggesting that the incidence of "skip" or intraosseous metastasis was probably lower than originally believed. The general standard of surgical management of patients with extremity osteosarcoma in 1980 included transmedullary amputation approximately 5 to 7 cm proximal to the intramedullary extent of the tumor.[15]

Limb salvage therapy became more widespread in the 1980s as chemotherapeutic advances were made. Surgeons learned from examining amputation specimens that the nerves and vessels could often be separated from the tumor with a plane of normal tissue between the tumor and the neurovascular bundle, and imaging improved, so this could be determined accurately before the operation. Initially, bone scans and angiography were used. CT imaging improved this further, but MRI revolutionized the surgeon's ability to determine the extent of the tumor preoperatively.

Initially, the reconstructions were biologic: arthrodeses about the knee and shoulder, for example, or resections of expendable bones that did not require reconstruction (fibula, clavicle). Advances in design of custom prostheses subsequently made it possible to preserve mobile joints, borrowing from the advances that had been made in arthroplasty for arthritis. Bone allografts were also used to reconstruct limbs following tumor resection and included osteoarticular grafts, allograft-arthrodeses, intercalary reconstructions, and allograft-prosthetic composites. Finally, the advent of modular prostheses, rather than custom ones, allowed the surgeon to custom design the implant for the specific defect in the operating room, and these modular prostheses are in current use and constantly undergoing design improvements.

One of the events that led to the popularization of limb salvage was the use of preoperative chemotherapy. Initially implemented during the time it would take to manufacture a custom prosthesis, it became apparent that the tumor showed clinical and radiographic "response" to the preoperative (neoadjuvant) chemotherapy. This seemed to make the subsequent surgery easier, if not safer, and gave the surgeon 10 to 12 weeks to work with the patient to decide on the best surgical option. There was initial concern that the delay in the resection might worsen the prognosis, but this issue was addressed in a randomized trial that showed no apparent advantage to having the surgery initially compared to the neoadjuvant mode of administration.[16] In addition, it was learned that the histologic response to the preoperative chemotherapy was a predictor of outcome and, second only to the presence of metastases at diagnosis, was the best predictor of survival.[16,17]

Epidemiology

Conventional, or classic, osteosarcoma makes up the majority of all osteosarcomas. It occurs primarily in the metaphyses of adolescents with open physes or in young adults. Most patients with classic osteosarcoma are under the age of 30 years, and many have no apparent predisposing factors.[18] The lesion most often arises in the larger, more active epiphyses (e.g., distal femur, proximal tibia, proximal humerus) but also can arise in the flat bones of the pelvis, skull, scapula, and ribs and in the spine. Overall, the majority of the lesions develop in the extremities and pelvis.[19]

An epidemiologic study conducted in Sweden between 1971 and 1984 investigated possible changes in the typical features of 227 conventional osteosarcomas. The mean annual incidence was 2.1 per million. The male-to-female ratio of 1.6 : 1.0 remained unchanged over the study period, as did the location and distribution of the tumors. The only clear change over the study period was an increase in the age of patients beyond the classical peak age range of 10 to 29 years.[20]

Ten percent of patients develop osteosarcoma after the age of 60. This group composes the second peak of the bimodal age distribution curve. In these older patients, the anatomic region of presentation differs substantially from the sites of classic osteosarcoma. Whereas more than 50% of patients with classic osteosarcoma develop lesions in the region of the knee (the largest and most active epiphyses), only 15% of the older patients develop osteosarcoma at that site. Moreover, osteosarcomas in the older population characteristically present in regions that have had previous radiotherapy, underlying Paget's

disease of bone, fibrous dysplasia, or some other pathologic abnormality. In many ways, the older group can be thought of as having "secondary" osteosarcoma.[21]

An estimated 2000 malignant bone tumors are diagnosed in the United States each year. Approximately 750 of these patients have classic or conventional osteosarcomas. Males are affected slightly more often than females. Females develop classic osteosarcoma slightly earlier than males, and there appears to be no race predilection.[22] Although the common histologic presentation of malignant cells producing osteoids would suggest a homogenous group of tumors, the morphologic appearance can vary considerably, ranging from classic osteoblastic osteosarcoma (45% of cases) through fibroblastic (9%), chondroblastic (27%), anaplastic (17%), telangiectatic, low-grade central, and other osteosarcomas (2%).[23]

A separate group of osteosarcoma variants, including high-grade surface, extraskeletal, pagetoid, intracortical, low-grade central osteosarcoma, parosteal and periosteal osteosarcomas, small cell osteosarcoma, secondary tumors, and therapy-related tumors, will be discussed in a later section of this chapter.

Pathogenesis

Osteosarcoma is a high-grade sarcoma comprising malignant osteoblasts that vary in size and shape and have bizarre mitoses. Proposed histologic grading systems for osteosarcoma appear to be of little value.[24] Attempting to grade an osteosarcoma presents many difficulties that limit the usefulness of any grading system. For example, many tumors are heterogeneous, and tissues sampled from separate areas of the same tumor may give different impressions. The number of mitoses, the degree of cellularity, and cellular anaplasia or pleomorphism can differ from site to site within the same tumor. Tumors of identical histologic appearance often differ in their clinical behavior. All "classic" or conventional osteosarcomas are considered high-grade. Osteosarcoma is a vascular tumor, and the tumor osteoblasts produce tumor osteoid or woven bone (Figs. 96-1A and B). These tumors are poorly differentiated and may take on a fibroblastic or chondroblastic appearance on light microscopy (Figs. 96-1C and D), but if there are areas of bone formation, they are considered osteosarcomas. In fact, a high-grade chondroblastic sarcoma in a child or adolescent on biopsy is considered to be an osteosarcoma (and treated as such) until proven otherwise from examination of the entire specimen (chondrosarcomas are extremely unusual in children). The tumor usually originates in the metaphysis of the bone and percolates between the pre-existing trabeculae of bone, incompletely destroying the existing bone, presumably because of its rapid growth (seen well in Fig. 96-1A). The tumor eventually follows the vascular Haversian and Volkmann canals in the cortex, partially resorbing the normal cortex and replacing it with tumor bone as it spreads to the adjacent soft tissue. The periosteum is lifted and tries to respond, but the response is incomplete, leading to the appearance of Codman's triangle on a radiograph. It may also cause perpendicular striations of bone, the so-called starburst appearance of osteosarcoma. Proximally, the tumor ends fairly sharply in the medullary cavity, but "skip metastases" may be detectable in the marrow surrounding the tumor in a small proportion of patients. The physis or growth plate is a relative barrier to tumor spread, but because the open physis has vascular channels, it is well documented that the tumor will cross the growth plate and enter the epiphysis. The articular cartilage is a more definitive barrier, and osteosarcomas seldom cross the articular cartilage unless there has been a fracture. It may spread into the joint at the periphery of the cartilage or enter the joint along ligaments such as the cruciate ligaments of the knee, but this is a relatively rare event (Fig. 96-2).

Telangiectatic osteosarcoma, a predominantly radiolucent, destructive osteosarcoma variant, becomes fatal rapidly. Histologically, it is composed of single or multiple dilated spaces containing blood or degenerated tumor cells and lined by anaplastic, mitotically active sarcoma cells.[25] Telangiectatic osteosarcoma must be differentiated from aneurysmal bone cyst, to which it can be similar in appearance both radiographically and histologically.

A review of 124 patients with telangiectatic osteosarcoma spanning the years 1921 to 1979 suggested no differences in survival

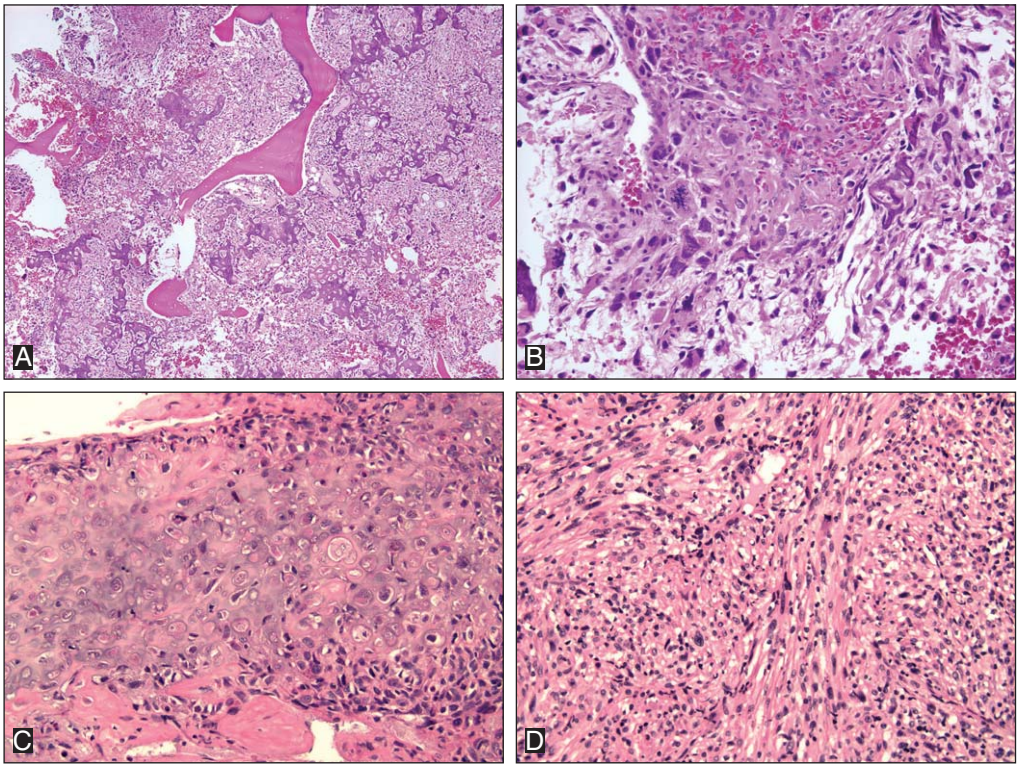

Figure 96-1 • **A,** Low-power photomicrograph of an osteoblastic osteosarcoma showing residual trabeculae of medullary bone surrounded by a cellular tumor. This pattern of invasion of bone indicates a malignant tumor even at this power. One can see the lacy, woven tumor bone formation by the sarcoma in contrast to the partially resorbed pre-existing lamellar bone trabeculae. **B,** High-power photomicrograph of an osteosarcoma showing bizarre, pleomorphic tumor cells that vary in size and shape and have large, aberrant nuclei. Some cells show abnormal mitoses, and intermixed is scant woven tumor bone. **C,** Field showing a chondroblastic osteosarcoma. The malignant cartilage formation is well demonstrated. One would have to search other areas of the tumor to document bone formation that was present in this case. **D,** Field showing a high-grade spindle cell sarcoma area that is characteristic of a fibroblastic osteosarcoma.

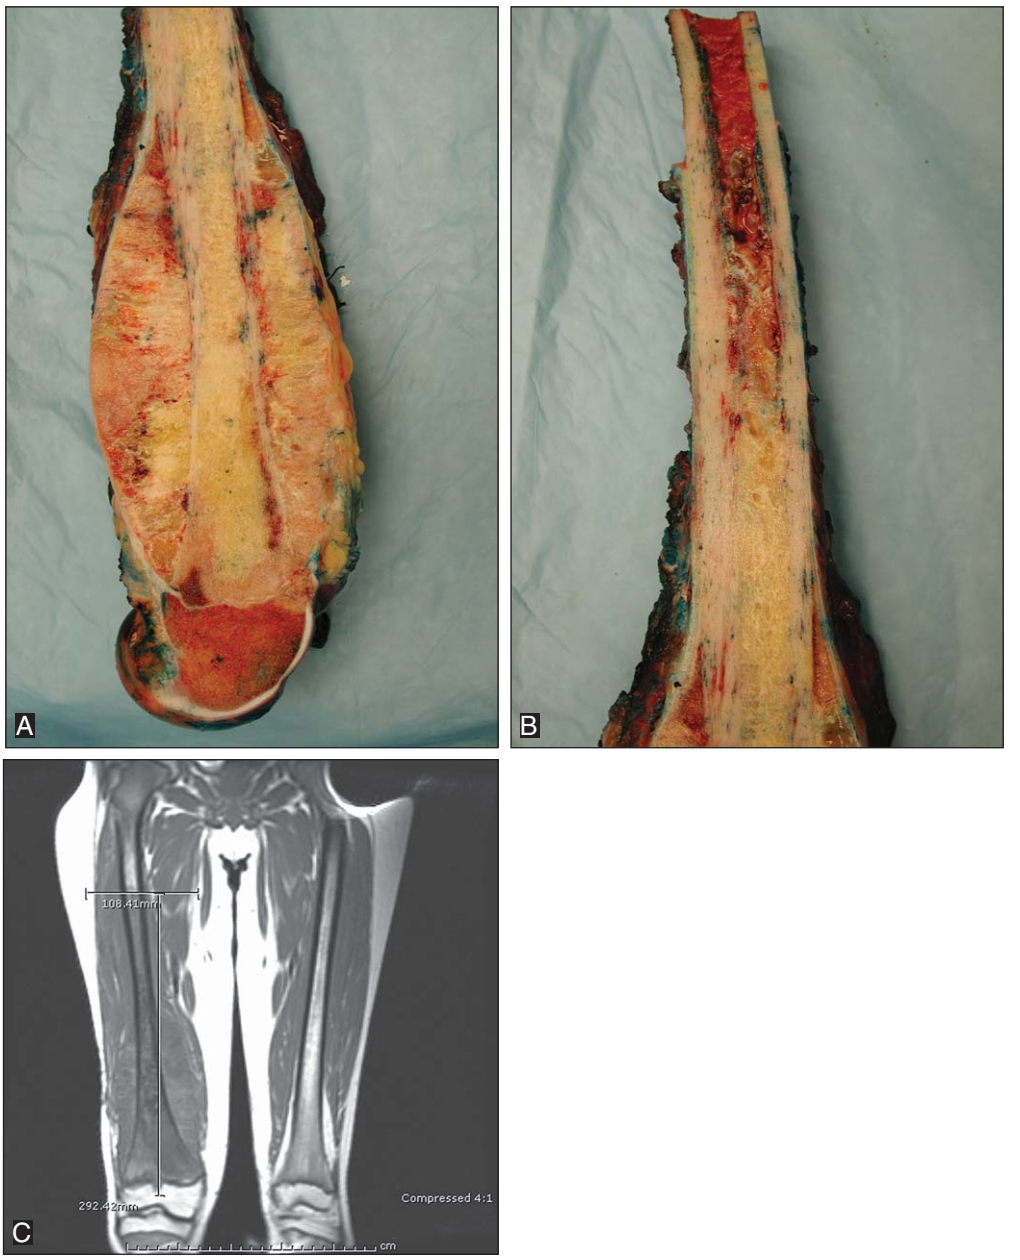

Figure 96-2 • **A,** Gross photograph of an osteosarcoma of the distal femur. The medullary cavity is filled with tumor, which has replaced the normal marrow contents. The tumor has penetrated and incompletely destroyed the cortex and penetrated through the growth plate distally. The Codman triangle, which is an incomplete host periosteal response, is well demonstrated. Histologically, this would show woven periosteal bone. One can also appreciate how this tumor could enter the joint under the synovium, anteriorly in this case. **B,** A section from higher in the femur shows where the medullary extent of the tumor ends rather abruptly. There is a margin of normal marrow proximal to the marrow extent. **C,** Coronal T_1-weighted image of this case nicely shows the extent of the tumor in the medullary cavity and the penetration of the growth plate. It corresponds to the preceding findings seen on the gross specimen.

compared with patients with conventional osteosarcoma. Further analysis demonstrated that the favorable outcome in 17 of the patients with telangiectatic osteosarcoma was related to their being treated with multiagent chemotherapy. Twenty-five patients had received this therapy, and 17 were free of disease at 5.5 years, demonstrating the response to chemotherapy in this highly vascular tumor.[26]

Cytogenetic Findings

A small subset of osteosarcomas is hereditary.[27] Osteosarcoma in siblings occurs in fewer than 1 in 1000 to 1 in 3000 osteosarcoma patients.[28,29] Observation of two or more affected siblings in a family indicates an underlying genetic predisposition.[29–36] When siblings in multiple generations are affected, an autosomal dominant disorder is most likely responsible. One example would be the hereditary form of retinoblastoma. Individuals with hereditary retinoblastoma (germline retinoblastoma gene mutation) have a 2000-fold risk of developing osteosarcoma in the second decade of life when compared with the general population.[37–42]

The gene for retinoblastoma (RB) has been localized to the long arm of chromosome 13 (13q14). The RB gene is recognized as the prototype of a tumor suppressor gene and has been implicated in the pathogenesis of a number of human neoplasms.[42,43] A tumor suppressor gene normally functions by restraining cell (tumor) growth, so loss of function or inactivation of a tumor suppressor gene results in tumor growth. Loss of 13q14 (the RB gene) is thought to be responsible for the development of retinoblastoma.[43–47] A two-hit kinetic model for this class of genes was proposed by Knudson.[48] For hereditary retinoblastoma, the primary mutation in one RB locus occurs in germinal cells; for sporadically occurring retinoblastoma, the primary mutation exists in somatic cells. The second step, responsible for malignant transformation, is the loss of function of the remaining normal homolog in somatic cells by some chromosomal rearrangement or mutation identified as loss of heterozygosity for markers in

or around the RB gene.[37,39–51] Molecular analyses of both sporadic osteosarcomas and osteosarcomas from patients with retinoblastoma have revealed homozygous loss of RB gene function in a high percentage of cases.[37,38,44–56] Assessment of loss of heterozygosity at the RB gene in a study by Feugeas and colleagues[57] revealed that RB gene locus loss of heterozygosity could be an early predictive feature for osteosarcomas with a potentially unfavorable outcome. Osteosarcoma develops in 12% of patients with bilateral retinoblastoma, yet as many as 70% of osteosarcomas have a dysfunctional RB gene product.[25,58–63] Thus, other oncogenes are likely implicated in the oncogenesis of osteosarcoma.

Several investigators have demonstrated that the mutational profiles of the RB gene in osteosarcoma are basically the same as those for retinoblastoma and that mutation of the RB gene plays an essential role in the development of osteosarcoma.[44,52] Besides loss of gene function at the locus on chromosome 13, however, loss of heterozygosity for other chromosomal loci, such as 3q, 17p, and 18q, has been implicated.[52,64–69]

Clinical Features

There are no specific clinical findings for osteosarcoma. Bone sarcomas usually present with pain around a joint and a mass. A traumatic event is often in the history, but it is unlikely that the trauma "caused" the tumor; rather, the trauma is the event that calls the tumor to the patient's attention. The symptoms are often missed initially because other causes of joint pain are much more common. It is not unusual for symptoms to date back to 6 months prior to the documentation of the tumor. This is perhaps changing with the recent abundance of MRI in the evaluation of even minor joint pain.

The plain radiograph is the best diagnostic tool. Osteosarcomas may either completely destroy the bone (radiolucent lesion) or replace the bone with a blastic response (radiodense), but they most often do both. The radiograph shows areas of destruction of the host bone and blotchy densities of new (tumor) bone production. The lesion is most frequently in the metaphysis of a long bone in the adolescent or child and in the flat bones in the adult, but any bone can be involved at any age (Figs. 96-3A and B). The tumor is usually large, destroys the cortex, and is associated with a soft-tissue mass. The mineralization of the matrix is often apparent, but because these tumors can contain areas of chondroblastic and fibroblastic as well as osteoblastic sarcoma, the pattern on mineralization might not be that of bone.

There are no blood laboratory studies that aid in the diagnosis of osteosarcoma, but it has been shown in several large series of patients that an elevated level of alkaline phosphatase and/or lactic dehydrogenase is associated with a worse prognosis.[70–72]

Radiographic Staging Studies

The ^{99m}Tc bone scan has been considered superior to other imaging studies for surveying the skeleton for metastatic or multiple lesions and for later detecting the development of skeletal metastases (Fig. 96-3C).[73]

MRI is the single most useful study in evaluating the intraosseous and extraosseous extent of the primary tumor and in detecting intramedullary or transarticular "skip" metastases. It has been well demonstrated that MRI better identifies the edema (high water content) in and around the reactive zone of the pseudocapsule illuminating the potential surgical margin. MRI has also been shown to be superior to CT in displaying the medullary canal extent of the tumor, suspected "skip" lesions, soft-tissue extension, and overall anatomic location of an extremity tumor (Figs. 96-3D–F).[74] MRI with or without magnetic resonance angiography is the single most valuable tool for planning limb-sparing surgical procedures.[75–77] Radiologic staging and presurgical planning have been improved significantly by the use of MRI.[78,79] Serial MRI studies are less reliable, however, in evaluating tumor response to primary chemotherapy and are more predictive of a poor rather than a good response. By demonstrating an increase in size of the tumor, more bone destruction, and soft-tissue invasion on serial studies, MRI is more accurate as a measure of a poor chemotherapy response.[7,80,81]

Metastases to bone and/or lung are usually assessed by a whole-body ^{99m}Tc bone scan and a complete CT of the chest and mediastinum. Regional lymph node involvement is unusual unless the tumor directly involves the skin or regional lymphatic structures.

PET scans have been used in an attempt to stage and separate high-grade from low-grade tumors.[82] Brenner and associates[83] summarized the current usefulness of ^{18}F-FDG PET in patients with osteosarcoma. High-resolution CT has been shown to be superior to ^{18}F-FDG PET for detecting pulmonary metastases and is not recommended to detect bone metastases except when a suspected "skip" lesion has been identified on MRI. PET does not make it possible to differentiate between high- and low-grade osteosarcoma. It could be useful, however, in determining the appropriate area to biopsy to identify viable representative tumor tissue and in distinguishing benign aggressive lesions from other lesions where local recurrence is likely.

^{18}F-FDG PET may be most useful in determining the response to neoadjuvant chemotherapy and in demonstrating a region of viable tumor.[84] The timing between the initiation of preoperative chemotherapy and the point at which ^{18}F-FDG PET becomes predictive remains uncertain. The response to soft-tissue postchemotherapy inflammation and healing surrounding the tumor must be characterized before this technique becomes predictive of preoperative response to chemotherapy. PET also has potential usefulness in patient follow-up, differentiating postoperative tissue changes and possible tumor recurrence especially in patients with metallic reconstructions. Orthopedic implants often hamper assessment by CT or MRI, and sequential ^{18}F-FDG PET scans could differentiate between recurrent tumors and the normal healing process. Also, because ^{18}F-FDG PET provides scanning of the entire patient, it may be useful when combined with CT of the chest to detect first evidence of pulmonary metastasis.[85]

Once the staging workup is complete, a biopsy is performed. This can be either an open biopsy or a needle biopsy (core-needle or fine-needle aspirate) depending on the experience of the surgeon, the interventional radiologist, and the pathologist. If an open biopsy is performed, it should be done by the surgeon who will be responsible for local control, with a view to placement in a site that can be resected with the definitive specimen. If a core-needle biopsy is performed by an interventional radiologist (which is becoming more frequent), the radiologist and the surgeon should agree on the placement of the needle track.

Differential Diagnosis

The diagnosis of a bone sarcoma is usually obvious, although differentiating between an osteosarcoma and a Ewing's sarcoma in a child or adolescent might need to await the biopsy; radiographically the two may appear similar. In general, osteosarcomas are metaphyseal lesions, and Ewing's tumors are diaphyseal or in the flat bones in young patients, but there are frequent exceptions to this rule, and both can present in any bone. Matrix production may be apparent in a Ewing's tumor because of the host response and absent in an osteosarcoma because the osteoid is incompletely mineralized or absent (as in telangiectatic osteosarcoma). In the adult, it can be difficult to differentiate osteosarcoma from malignant fibrous histiocytoma (MFH) and chondrosarcoma clinically, but a biopsy usually settles the issue.

Osteomyelitis and Langerhans cell histiocytosis may mimic an osteosarcoma and should always be considered, especially in getting tissue for a biopsy. A fatigue fracture (stress fracture) may also appear with an aggressive periosteal response, and the MRI shows extensive

marrow and soft-tissue edema. This can mimic an osteosarcoma, but a CT scan, especially with coronal reconstructions, is usually diagnostic.

In the adult, one must look for underlying causes of osteosarcoma, such as Paget's disease and prior irradiation. Since the bone is abnormal to begin with in these two circumstances, the diagnosis may be difficult. Paget's disease itself may be painful, but a change in the pain pattern and new destruction compared to old radiographs if available are helpful. Metastatic carcinoma and multiple myeloma are much more common causes of a destructive bone tumor in the adult, but it should always be remembered that, although rare, osteosarcoma can present as a purely radiolucent lesion.

Other bone tumors, such as giant cell tumor of bone, aneurysmal bone cyst, and chondroblastoma, may have an aggressive radiographic

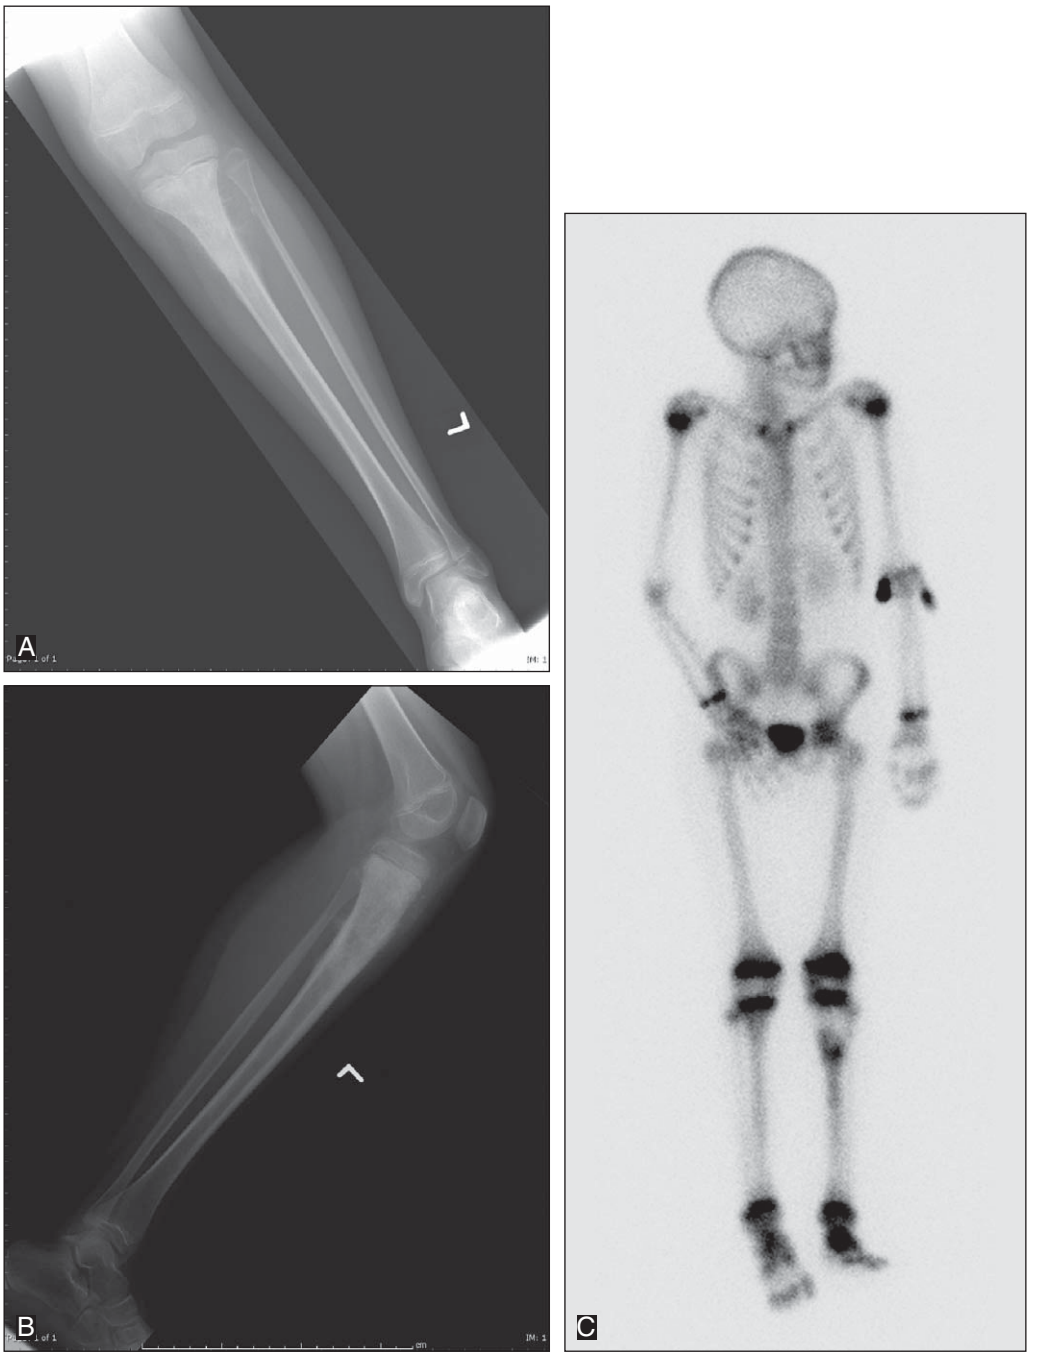

Figure 96-3 • **A,** AP radiograph of a 9-year-old girl with an osteosarcoma of the left proximal tibia. The tumor is both destructive of bone and osteoblastic, increasing the density of the proximal metaphysis of the bone. The mineralized soft-tissue mass is seen. **B,** Lateral radiograph showing the mixed radiolucent and radiodense characteristics of the tumor, and the mineralization of the soft-tissue mass is seen posterior to the bone. This flocculent mineralization of density similar to that of normal bone is characteristic. In this case, perpendicular striations of bone are seen posteriorly. **C,** Radionuclide bone scan showing increased uptake in the proximal metaphysis of the tibia. No skip lesions or other bony metastases were noted.

Figure 96-3, cont'd • **D,** Coronal STIR MRI image showing the extent of the tumor (bright on this sequence) in the medullary cavity and soft tissues. The tumor has transgressed the growth plate and may involve the knee joint. **E,** Axial T_1-weighted fat saturation MRI showing the soft-tissue mass and relationship to the posterior vessels. **F,** Sagittal T_1-weighted fat saturation image showing the medullary extent of the tumor and the extension into the epiphysis and further suggests involvement of the knee joint. In this particular case, the tumor did extend under the lateral meniscus but was covered by synovium and not technically in the joint proper. An extra-articular, above-knee amputation was done because of the potential joint involvement and her young age.

appearance and mimic an osteosarcoma, but the histology is usually diagnostic in these situations. An aneurysmal bone cyst, however, might have scant tissue from a biopsy, as does a telangiectatic osteosarcoma, so at times, the distinction is difficult. An experienced bone pathologist is essential in these instances even if it necessitates an outside referral. Similarly, osteosarcomas can have giant cell-rich areas that can mimic a giant cell tumor. Again, the expertise of the bone pathologist and a team of clinicians and radiologists working in concert are essential to making these distinctions.

Management

Adjuvant Chemotherapy

The use of adjuvant chemotherapy for osteosarcoma was introduced in the 1970s, and after initial concern relative to its efficacy, a randomized trial confirmed its benefit. It is now established as an essential part of the treatment of osteosarcoma. Initially used as an adjuvant following amputation or resection of a tumor, chemotherapy is now used in the neoadjuvant setting, although no clear survival benefit to

that approach has been documented.[16] The use of neoadjuvant chemotherapy does allow the assessment of histologic response to the chemotherapy, which has prognostic implications, allows time for planning of limb salvage operations, and makes those resections easier and probably safer.

A number of single- and multi-institutional studies have reported the results of treatment protocols, including multiagent neoadjuvant chemotherapy and limb-sparing surgery.[86–88] The specific drugs and their methods of administration are important. Delépine and colleagues[89] published a meta-analysis of the relationship of total dose and dose intensity of methotrexate from nine single-institution and nine multi-institution randomized trials. They concluded that both methotrexate dose and dose intensity had major prognostic value. Intravenous administration appears to be as effective as the intra-arterial route of administration.[90] A meta-analysis of 16 regimens published by a group from the National Cancer Institute found that dose intensity was the most important determinant of a favorable outcome, defined as a good histopathologic response to neoadjuvant chemotherapy.[91] Other studies likewise support the importance of doxorubicin treatment in patients with osteosarcoma.[92,93]

The use of preoperative chemotherapy was extended to selected patients in an attempt to contain growth of the primary tumor while awaiting construction of a custom prosthesis (usually 12 to 16 weeks).[86,88,94] The sequence of several courses of primary chemotherapy and subsequent surgery afforded the opportunity to examine and histopathologically grade the tumor tissue response to multiple chemotherapy agents. Patients with greater than 90% tumor necrosis (good) were shown to have a better disease-free survival than those with a poor (<90%) response to chemotherapy.[17,95,96]

Goorin and associates[16] completed a study of 106 patients admitted to the Pediatric Oncology Group Study 8651 who were randomized to immediate surgery or to preoperative chemotherapy with high-dose methotrexate, doxorubicin, and cisplatin for two cycles (10 weeks). Six patients were excluded from analysis. Of the remaining 100 patients, 45 were randomly assigned to immediate chemotherapy, and 55 were randomly assigned to immediate surgery. Sixty-seven patients remain disease-free. At 5 years, the projected EFS rate was 65% for immediate surgery and 61% for presurgical chemotherapy; There was no apparent advantage to the group that received preoperative chemotherapy. This was a difficult study to complete because at the time, there was a surgical bias toward neoadjuvant chemotherapy for limb salvage patients, making accrual slow. The number of limb-preserving procedures was nearly equal in both groups (55% with immediate surgery and 50% with presurgical chemotherapy). Although the percentages of patients in the two groups was similar, the overall percentage of patients receiving limb-sparing procedures was much lower than the usual 60% to 90% limb-preserving procedures reported. Only one local recurrence was reported among all 100 patients.

Surgical resection of the primary tumor is usually planned for 10 to 12 weeks following induction chemotherapy. Limb preservation is elected if the tumor responds favorably; that is, there is evidence of a clinically favorable response, including diminished local pain; radiographic evidence of mineralization of the previously unmineralized soft-tissue portion of the tumor on radiographs; and MRI evidence of retention of a normal fatty tissue plane between vascular and neural structures and the tumor. However, if the lesion enlarges and the vessels become involved secondarily (poor response), ablative surgery is recommended. Once the operative wound heals (usually within 2 to 3 weeks), adjuvant chemotherapy is initiated and is maintained for approximately 40 weeks, depending on the particular study.[97–102]

Wilkins and colleagues[103] described their results at two institutions with a dose-intensified neoadjuvant protocol using intravenous doxorubicin and intra-arterial cisplatin administered until a maximum angiographic response was observed (usually four courses). Despite showing results similar to others previously reported, it requires extraordinary resources, making it unlikely that a similar study could be carried out in an extensive cooperative manner.[104,105]

Long-term outcomes were studied by Bacci and coauthors,[106] who reported the results of treatment of 164 patients with nonmetastatic extremity osteosarcoma who were followed for a minimum of 10 years. Preoperative chemotherapy consisted of high-dose methotrexate, cisplatin, and Adriamycin. Postoperatively, good responders (≥90% tumor necrosis) received the same three drugs, while poor responders (<90% tumor necrosis) received ifosfamide and etoposide in addition to the three-drug chemotherapy regimen. Follow-up showed that 101 patients (61%) remained continuously free of disease, 61 had relapsed, and 2 had died of Adriamycin-related cardiotoxicity. There were no differences in outcome between good and poor responders.

Limb-preserving surgery was performed in 136 of the patients (82%) in the Bacci study, and 117 (71%) had a good histologic response. Despite the large percentage of patients with limb-sparing procedures, only four local recurrences developed (2.4%). The complications of chemotherapy included Adriamycin-induced cardiotoxicity (6 patients) and secondary malignancies (7 patients) at a median follow-up of 11.5 years.

In 1997, Bramwell[107] conducted a review to provide answers to important questions about the role of chemotherapy in the management of patients with nonmetastatic osteosarcoma of the extremities. Many studies were analyzed, including a study by Link and coworkers[12] that clearly demonstrated the role of adjuvant chemotherapy in the treatment of patients with conventional osteosarcoma. The role of adjuvant chemotherapy was also confirmed by another study that provided additional objective evidence for the efficacy of multiagent chemotherapy in preventing and/or delaying relapse.[108] The five studies that were reviewed by Bramwell[12,109–112] approached the results of Rosen and associates;[96] three were multicenter studies, and two were reports from a single institution. Bramwell concluded that although the Rosen T10 regimen is complex and toxic, it can be given in a multicenter setting without apparent major compromise in efficacy.

Bramwell concluded that reports of outcomes with multiagent chemotherapy were similar to regimens containing the most active drugs (doxorubicin and cisplatin) that were used in two consecutive European Osteosarcoma Intergroup protocols when compared with results from multicenter studies using the T10 regimen.[112,113]

It is apparent that histopathologic response to neoadjuvant chemotherapy correlates with improved survival. The reports by Picci and colleagues[114] (Bologna, 355 patients), Kempf-Bielack and coworkers[115] (Cooperative Osteosarcoma Study Group, 504 patients), and Delépine and associates[116] (Paris, 112 patients) all demonstrated that a good response to neoadjuvant chemotherapy was an independent prognostic factor. Meyers and colleagues[117] reported the relationship between duration of preoperative chemotherapy and histopathologic response. In univariate analysis, the duration of preoperative chemotherapy did not correlate with relapse-free survival. With longer preoperative treatment, a greater proportion of patients had a favorable histopathologic response to therapy, but the correlation of the response with outcome decreased. Bramwell[107] postulated that with prolonged preoperative chemotherapy, a good response to chemotherapy might lose its prognostic significance. The CCG-782 study published by Provisor and coworkers[118] involving 268 patients with nonmetastatic osteosarcoma of the extremity used the resected tumor histologic response to neoadjuvant chemotherapy to determine postoperative chemotherapy. In 206 patients, the tumor was morphometrically assessed for residual viable tumor; 28% displayed a good (<5% viable tumor) histologic response, while the remaining patients were judged to have a poor histologic response (>5% residual viable tumor). The patients who had a good response had an 8-year postoperative EFS rate of 81% and a survival rate of 81%. Patients with a poor histologic response had an 8-year postoperative EFS rate of 46% and an overall survival rate of 52%. They concluded

that event-free and overall survival appeared to be related directly to histologic response to neoadjuvant chemotherapy. If that is the case, then increasing the percent necrosis by intensifying chemotherapy should improve outcome even further. A recent study compared standard chemotherapy to an intensified arm to assess this contention. Conventional treatment consisted of six 3-week cycles of cisplatin (100 mg/m^2 by 24-hour infusion) and doxorubicin (25 mg/m^2/day by 4-hour infusion for 3 days). Intensified therapy was treatment with identical total doses of cisplatin and doxorubicin, planned as six 2-week cycles supported by granulocyte colony stimulating factor. In this study, 497 eligible patients were evaluated, and good histologic response (>90% tumor necrosis) was observed in 36% of standard arm and 50% of the intensified arm. However, there was no evidence of a difference in overall survival between the two treatment regimens. The study found that intensification of chemotherapy could increase the percentage of necrosis but not progression-free survival or overall survival.[119] Another study looked at increasing the dose of chemotherapy with the same drugs in 196 osteosarcoma patients. The authors failed to find a difference in percentage of necrosis, 5-year event-free survival, or overall survival, suggesting that response to chemotherapy is related to the specific drugs employed but that increasing the intensity is of little benefit.[120] The tumors either respond or do not, suggesting biologic differences in the tumors.

Currently, there are no strong data showing that changing drugs in the poor histologic responders improves the survival of those patients. A retrospective study reported by Benjamin and associates[121] compared outcomes from three consecutive cohorts of patients receiving intra-arterial cisplatin and intravenous doxorubicin between 1980 and 1992. In cohort 1 (37 patients), the postoperative chemotherapy was the same. In cohort 2 (59 patients), the postoperative chemotherapy for poor responders consisted of high-dose methotrexate, bleomycin, cyclophosphamide, and dactinomycin alternating between doxorubicin and dacarbazine. In cohort 3 (28 patients between 1988 and 1992), poor responders were managed with three alternating regimens of high-dose methotrexate, ifosfamide, and doxorubicin/dacarbazine. The significant 5-year relapse-free survival for poor responders for the three cohorts was 13%, 34%, and 67%. Bramwell believes that although the results appear significant, they could also be explained on the basis of small sample size, increasing dose intensity, total dose, and increased duration of preoperative chemotherapy.[122]

A current randomized multi-institutional study of patients from North America and Europe will attempt to address this question further by randomizing poor responders to continued preoperative therapy or an intensified arm in which ifosfamide and etoposide are added to the experimental arm.[123] The good responders will be treated with continued preoperative therapy with or without the addition of interferon-α. This is the first study to randomize the treatment of patients following determination of histologic response.

The issue of whether other agents incorporated into intensive multiagent regimens will improve survival further is less clear. Preliminary trials incorporating ifosfamide into multiagent chemotherapy appeared promising,[124–128] but a recent study of the Children's Oncology Group patients who were randomized to multiagent regimens that either contained or did not contain ifosfamide shed some doubt on this.[129] In this study, 677 nonmetastatic osteosarcoma patients were treated with one of four prospectively randomized treatments. All patients received identical cumulative doses of cisplatin, doxorubicin, and high-dose methotrexate and underwent definitive surgical resection of the primary tumor. They were randomly assigned to receive or not to receive ifosfamide and/or muramyl tripeptide, MTP, a pulmonary macrophage stimulant. The addition of ifosfamide in this dose schedule to standard chemotherapy did not enhance EFS. The addition of MTP to the ifosfamide arm appeared to add further benefit, but the study was not designed to test this, and this question remains uncertain but intriguing.

To test whether intensified ifosfamide therapy might be of benefit, a study of 182 patients treated with of two cycles of high-dose ifosfamide (15 g/m^2), methotrexate (12 g/m^2), cisplatin (120 mg/m^2), and doxorubicin (75 mg/m^2) was conducted. Postoperatively, patients received two cycles of doxorubicin (90 mg/m^2), and three cycles each of high-dose ifosfamide, methotrexate, and cisplatin (120 to 150 mg/m^2). Granulocyte colony stimulating factor support was mandatory after the high-dose ifosfamide/cisplatin/doxorubicin combination. No disease progression was recorded during primary chemotherapy. With a median follow-up of 55 months, the 5-year probability of EFS was 64%, and the overall survival rate was 77%. The addition of high-dose ifosfamide to methotrexate, cisplatin, and doxorubicin in the neoadjuvant setting was found to be feasible, but associated with major renal and hematologic toxicities. Survival rates were similar to those obtained with four-drug regimens using standard-dose ifosfamide.[130]

Growth factors do appear to offer a benefit in increasing dose intensity. In a pilot study, the European Osteosarcoma Intergroup demonstrated the use of granulocyte colony stimulating factor-supported increased dose intensity, making chemotherapy every 2 weeks feasible.[131] Thrombocytopenia remained dose limiting, and whether attainable dose intensification improves survival remains uncertain.

The histologic subtypes of osteosarcoma also appear to influence response rates. Bacci and colleagues[132] at the Rizzoli Institute in Bologna correlated the histopathologic response to preoperative chemotherapy in 1058 patients with conventional osteosarcoma of the extremity. They classified the tumors as osteoblastic (70%), chondroblastic (13%), fibroblastic (9%), and telangiectatic (6%). At diagnosis, 911 patients had localized disease, and 147 had resectable pulmonary metastases. The response to preoperative chemotherapy was good (90% or more tumor necrosis) in 59% of patients and poor (<90% tumor necrosis) in 41%. Notably, the rate of good responders was significantly higher ($P = 0.0001$) in patients with fibroblastic (83%) and telangiectatic tumors (80%) than in those with osteoblastic (62%) and chondroblastic (60%) tumors. In all subtypes (excepting the chondroblastic), the 5-year overall survival rate was significantly higher ($P = 0.0001$) in good responders (68%) than in poor responders (52%).

Essential to the improvement in survival in osteosarcoma is the combination of effective surgical resection along with the use of chemotherapy. Jaffe and colleagues[133] in the Department of Pediatrics at the University of Texas M.D. Anderson Cancer Center attempted the cure of 31 patients with nonmetastatic osteosarcoma. Their protocol for selection included initial treatment with chemotherapy comprising high-dose methotrexate and leucovorin rescue (MTX-LF) in three patients and intra-arterial cisplatin in 28 patients. After response at 3 months, entry into the study was permitted, and chemotherapy treatment was maintained for a total of 18 to 21 months with a combination of MTX-LF, intra-arterial cisplatin, and doxorubicin. Only 3 of 31 patients (10%) were cured exclusively with chemotherapy. Four additional patients requested surgical extirpation of the tumor after the cessation of chemotherapy. Histopathologic examination revealed no evidence of viable tumor. Adding these patients to the three mentioned previously yielded a total of seven patients (23%) who had a cure from chemotherapy alone. As the expected cure rate with conventional strategies is 50% to 65%, the authors concluded that their results do not justify the option of current forms of chemotherapy as exclusive treatments for osteosarcoma.

Local Recurrence

Two studies indicate that local recurrence within 18 to 24 months of surgery has a substantial negative influence on long-term survival. Ferrari and colleagues[134] at three Italian institutions reviewed the data on patients who were treated for nonmetastatic osteosarcoma of the extremities between October 1986 and June 1995, finding 162 patients with recurrence or relapse. The main prognostic factors for

postrelapse survival were the relapse-free interval, site of metastasis, and number of pulmonary nodules. Complete surgical resection of the recurrence was found to be pivotal in the strategy of treatment. When the risk factors were combined, patients with a relapse-free interval longer than 24 months and with only one or two pulmonary nodules had a postrelapse survival of 72%. Patients with a short relapse-free interval and three or more lung pulmonary nodules had a poor postrelapse survival of 5%. Patients with unresectable recurrence did receive benefit from second-line chemotherapy, but the authors' data did not support the generalized use of chemotherapy after complete surgical resection of the first recurrence.

Weeden and colleagues[135] reported the effect of local recurrence on survival of 559 patients entered into two randomized controlled trials of the European Osteosarcoma Intergroup using preoperative chemotherapy, but there was no survival benefit between chemotherapy arms. A landmark analysis allowed the assessment of 440 patients at 18 months, and 22 patients (5%) had experienced a local recurrence. Patients with a local recurrence had a fourfold greater risk of death during the 18 months after surgery. Similar analyses were conducted with landmark time points at 1 and 2 years. Using a multivariate proportional hazards model, 368 patients were assessed to investigate the relative prognostic importance of histologic response and local recurrence. It appears clear that histologic response to chemotherapy and local recurrence had a significant effect on survival. A study from St. Jude's Research Hospital analyzed prognostic factors for survival in 26 patients with a local recurrence of osteosarcoma who were treated between 1970 and 2000. The initial surgical procedure was amputation in 20 patients (76.9%) and limb salvage in 6 patients (23.1%). Eleven patients (42.3%) developed an isolated local recurrence, and 15 patients (57.7%) developed local and distant recurrence. The 5-year estimate of postrecurrence survival (PRS) for the 26 patients was 19.2%. The factors that affected survival after recurrence were as follows:

- Recurrence 2 or more years from the time of diagnosis (5-year PRS of 50.0% ± 20.4% compared with earlier recurrence (10.0% ± 5.5%) ($P = 0.037$).
- Patients with negative margins after initial surgery were found to have improved survival (5-year PRS of 33.3% ± 13.6%) compared with patients with positive margins (7.1% ± 4.9%) ($P = 0.015$).
- Patients who underwent complete surgical resection at the time of recurrence were found to have a better PRS (5-year PRS of 41.7% ± 14.2%) compared with patients who did not undergo surgery (0% ± 0%) ($P < 0.001$).

This demonstrated that the prognosis for patients after local recurrence of osteosarcoma is poor, but attempts at salvage should be made. Complete surgical resection at the time of recurrence is essential for survival.[136]

A study from the European Osteosarcoma Intergroup of 202 patients assessed the primary surgical treatment alternatives. Three centers differed in the rates of limb salvage, and all local recurrences arose in limbs with attempted limb salvage. Local recurrence was closely related to the adequacy of the margins of excision and to the chemotherapeutic response. Interestingly, patients who had undergone limb salvage surgery and who developed local recurrence still had a better survival rate than did patients who had primary amputation (37% versus 31% survival at 5 years), suggesting that they had a less aggressive tumor. Of patients who relapsed, 31% of those with local recurrence alone were cured by further treatment, compared with only 10% of those with metastases.[137]

Another retrospective analysis of the management and outcome of 44 patients who developed local recurrence after neoadjuvant chemotherapy of osteosarcoma of the extremities was performed in a single institution between 1983 and 1999. In 24 patients (54.5%), local recurrence was the first sign of recurrence; in 8 patients (18.2%), local recurrence followed systemic recurrence. and in 12 patients (27.3%), the two events were concurrent. The only prognostic factor that was identified for disease-free survival of patients following local recurrence was the presence of systemic recurrence at the time of diagnosis of the local recurrence or prior to it. The 5-year postrecurrence EFS rate was 29.1% for patients without metastases at the time of local recurrence versus 0% for those with metastases ($P = 0.02$). The analysis confirmed that patients with osteosarcoma of the extremities who develop local recurrence are at a very significantly high risk of developing metastatic disease and dying of the tumor despite the use of effective neoadjuvant chemotherapy.[138] Another study looked at 407 patients and found 23 patients with resectable local recurrence. Median time to local recurrence was 13 months. All patients were treated with chemotherapy following recurrence. The 5-year and 10-year survival rates in the recurrent cases were 29% and 10%, respectively. Increased risk of local recurrence ($P < 0.0001$) was strongly correlated with positive margins of resection. The strongest correlates with poor survival were local recurrence within the first year after primary resection ($P = 0.001$) and, as in the Bacci study, metastasis at the time of first local recurrence ($P = 0.04$). Failure to achieve clinical remission after disease recurrence ($P = 0.04$) was also a poor prognostic factor.[139]

To determine whether inappropriate surgical procedures based on an initial misdiagnosis affected recurrence and survival rates, one group retrospectively reviewed the surgical treatment and results of 117 patients with high-grade osteosarcomas.[140] Nine patients had intralesional curettage performed at other institutions based on an erroneous diagnosis of a benign lesion. Two of the nine patients had amputations, and seven patients had limb salvage procedures. Of the 108 patients who were not misdiagnosed, 6 patients had amputations and 102 patients had limb salvage procedures. All patients received neoadjuvant therapy. Fifteen of the 117 patients had local recurrences. Patients who had inappropriate surgical procedures at diagnosis had an increased risk of local recurrence and lower 10-year survival rate.[140]

Prognostic Variables

Morphometric analysis of pathologic specimens was instituted after it was recognized that chemotherapy-induced necrosis correlated with clinical outcome. Picci and coauthors[141] described their methodology in 50 patients. Necrosis was divided into three categories: good (100% to 80% necrosis), fair (80% to 50% necrosis), and poor (<50% necrosis).Other authors have used different classifications. Depending on the system that is used, tumor necrosis ranging from 60% to 95% is common. The information gained has prognostic significance. Winkler and associates[94] were early to report that patients with unfavorable pathologic responses to preoperative chemotherapy experienced a poorer (49%) disease-free survival than did patients with a favorable pathologic response (87%; $P = 0.005$). Glasser and coworkers[142] later reviewed 279 consecutive patients with stage II osteosarcoma of the appendicular skeleton who were treated between 1976 and 1986. Continuous disease-free survival for the overall group was 70% at 5 years and 69% at 10 years. The only independent predictor of a favorable outcome was found to be the histopathologic response to chemotherapy as defined by pathologic review of the surgical specimen.

A literature review by Davis and colleagues[143] attempted to identify prognostic factors that could influence survival in patients with nonmetastatic high-grade osteosarcoma of the extremities. Eight previously reported large series of patients included sufficient data to evaluate the numerous identified variables. Only two variables proved significant to univariate analysis: tumor size and chemotherapy-induced tumor necrosis after primary chemotherapy. Only tumor necrosis remained significant after multivariate analysis, however. Other large series have demonstrated similar prognostic responses to neoadjuvant chemotherapy.[86,95,98–102,117,118,142]

Table 96-7 summarizes recent data regarding treatments for nonmetastatic osteosarcoma reported by 10 internationally recognized

Table 96-7 Summary of Recent Studies of Patients Treated for Nonmetastatic Osteosarcoma

Institution	No. of Nonmetastatic Ext. Total*	Resection*	Rotationplasty*	Amputation*	Local Control*	Disease-Free Survival
M.D. Anderson	60	31	—	28	4 (7%)	74% (TIOS-III)
Dana Farber	74	36	—	38	1 (1%)	87%
Memorial Sloan-Kettering	271	159	9	103	18 (7%)	77%

*Number of patients.

institutions. The table suggests that results have improved owing to management by multiagent neoadjuvant chemotherapy combined with adequate local surgery performed by experienced musculoskeletal surgeons. Several conclusions can be drawn from these studies:

- Patients who request limb-sparing operations do not appear to be at greater risk for development of local or distant relapse than patients who have transmedullary amputations.
- The administration of sequential multiagent adjuvant chemotherapy has significantly improved the disease-free survival for patients without metastasis.
- The risk of local recurrence appears to be no greater in patients who complete limb-preserving procedures than for those who have an amputation.[98,100,117]

Relationship of Surgical Margins, Neoadjuvant Chemotherapy, and Local Recurrence

The role of neoadjuvant chemotherapy in facilitating limb preservation appears to be well established.[114,144] The relationship between margins, chemotherapy, and local recurrence is not as straightforward. Although in general, local recurrence is higher in patients with inadequate margins, some patients who are so treated do not develop recurrence, whereas some patients with wide or radical margins do recur or persist locally. The effect of neoadjuvant chemotherapy in this regard is suspected to be beneficial, but only retrospective data are available. Four of the institutions reporting data shown in Table 96-7 also provided data on the pathologic margins achieved at surgery and correlated the surgical margins with locally recurrent disease. Of the 271 margins reported by Memorial Sloan-Kettering, 266 were adequate (261 wide and 5 radical), and 5 were inadequate (3 marginal and 2 intralesional). Of the 18 locally persistent tumors, however, all developed in patients who were thought to have wide margins. There were no locally recurrent tumors from the 5 known inadequate surgical margins.[100] The University of Vienna group reported 61 margins as wide, with 12 inadequate (9 marginal and 3 intralesional) margins. Only two local recurrences developed, one in a patient having an intralesional amputation and the other with a marginal resection and reconstruction.[99]

A similar review from Birmingham, England, revealed 23 marginal and 15 intralesional margins in 99 patients, with a 4.5% recurrence rate.[100] A French study reported 100 patients with nonmetastatic osteosarcoma managed by neoadjuvant chemotherapy and surgery with "numerous" marginal margins but no intralesional margins. They reported one local recurrence.[101] A Rizzoli Institute study, reporting 125 patients retrospectively, identified 15 patients with inadequate margins. Only one patient developed a local recurrence.[98]

Investigators from the Rizzoli Institute in Bologna have shown by multivariate analysis that the incidence of local recurrence in 355 patients was related closely to surgical margins ($P < 0.0001$) and response to preoperative chemotherapy ($P < 0.0001$). There were 28 patients who experienced local recurrence (7%), and 3 of those patients survived (11%). Six of 10 patients who did not receive preoperative chemotherapy developed local recurrence. In the other limb salvage procedures, 110 patients had wide margins, 12 were marginal, 7 had intralesional margins, and 7 had wide contaminated margins. Although 27 patients had inadequate margins, only 3 developed local recurrence, all within the first 2 years after diagnosis.[102]

To better illustrate the relationship between surgical margins and local recurrence, Picci and colleagues[114] reported on a single-institution study retrospectively reviewing 355 patients with nonmetastatic high-grade osteosarcoma of the pelvis and extremities. The average length of follow-up was 65 months for surviving patients.

Pathologic review demonstrated less than wide margins in 65 of the 355 patients. The most common anatomic site for inadequate margins was the popliteal region near the vascular and neural structures, where 20 of 140 patients were found to have inadequate margins (either marginal or intralesional). Only 7 of the 20 patients developed local recurrence, however. Only 3 of 15 patients with inadequate margins associated with lesions around major joints developed locally persistent disease. The intramedullary canal was the site of inadequate margins in 20 of 237 patients, and 6 patients developed local recurrence. It is of interest that 7 of the 11 patients with intralesional surgical margins and 16 of 21 with contaminated margins did not develop local recurrence. These findings could not be explained on the basis of poor survival or early death. The observation is believed to be related to the effectiveness of preoperative chemotherapy at producing tumor necrosis and the development of a "mature" capsule surrounding the tumor where satellite tumor nodule formation had been suppressed.[145]

An analysis of a more recent group, 164 patients with nonmetastatic osteosarcoma of the extremities, also came from the Rizzoli Institute. Limb-sparing procedures were performed in 136 patients (83%), 18 patients (11%) had amputation, and 10 (5%) had rotationplasty. The surgical margins were reviewed. In amputations, 18 margins were wide or greater; in rotationplasty, nine were wide and one was intralesional. In the limb salvage procedures, 110 patients had wide margins, 12 were marginal, 7 had intralesional margins, and 7 had wide contaminated margins. Although 27 patients had

inadequate margins, only 3 developed local recurrence, all within the first 2 years after diagnosis.[102]

The unanswered question is whether the poor correlation with margin and recurrence relates to neoadjuvant chemotherapy or the underlying tumor biology or some combination of the two. Adequate surgical resection is certainly a worthwhile goal, but the causes of local recurrences are probably more complex than adequacy of margin.

Surgical Treatment

The goal of surgical management is complete resection of the tumor with a cuff of normal tissue surrounding the tumor (wide resection). This can be accomplished by either amputation or local resection as long as this goal is achieved. Radical resections are seldom performed today. The most important question regarding limb salvage surgery is "Is it safe?" Suffice it to say that no randomized studies have ever compared amputation to local resection, nor are they likely ever to do so. What is known is from retrospective analyses of tumor specimens and outcome of patients treated on clinical trials.

To identify the potential risks of awaiting limb-sparing surgery versus immediate amputation, the results of data on 279 patients treated at Memorial Sloan-Kettering between 1975 and 1984 were reviewed retrospectively. Sixty-three patients who completed primary surgery and adjuvant chemotherapy were compared with patients who had primary chemotherapy followed by surgery and adjuvant chemotherapy. Univariate analysis showed no difference in outcome between patients who had limb-sparing procedures and those who had amputations ($P = 0.34$).[117]

A multi-institutional retrospective study evaluating patients with nonmetastatic osteosarcoma of the distal femur reported treatment results for 227 patients who were managed by limb-sparing procedures, above-knee amputation, and hip disarticulation between July 1975 and June 1980. The Kaplan-Meier estimates for the three surgical groups revealed no significant difference in continuous disease-free and ultimate survival rates for each group (Mantel-Cox test, $P = 0.8$) after a median follow-up of 5.5 years. The continuously disease-free survival rate for the entire group was 42%, with an overall survival rate of 55% at five years. The researchers concluded that limb-sparing procedures for osteosarcoma of the distal end of the femur did not compromise either disease-free survival or overall survival. Outcome results showed that one third of patients with limb-sparing procedures required at least one additional surgical procedure, and one fourth eventually required amputation.[146]

A follow-up of the aforementioned study 8 years later reviewed the original 227 patients. In this study, 213 patients had been classified as having stage IIB osteosarcomas. Seventy-three patients had had limb-preserving procedures, 115 had had above-knee amputations, and 39 had had hip disarticulations. Eighty-four percent of patients were followed for a minimum of 10 years. The Kaplan-Meier estimate of disease-free survival for all patients at 10 years was 41%. Fourteen of the original 17 patients experiencing a local recurrence in the first study did so within the first 2 years after the index procedure, and only one of the original 17 patients survived. There were nine local recurrences after above-knee amputations and eight after limb-sparing procedures. No patient who had a hip disarticulation (radical margin) developed a local recurrence. Although the function of patients with limb-sparing procedures was superior to that of both the amputation and disarticulation groups, no differences could be identified regarding patient acceptance or psychosocial outcome (quality of life) among the three operative groups.[147]

Limb-preserving procedures are currently performed in approximately 60% to 90% of osteosarcoma patients with nonmetastatic extremity tumors, in contrast to the previously reported high amputation rates. Advances in chemotherapy, imaging technology, implant design and materials, and subspecialization in orthopedic oncology have reversed the trends of previous decades. Limb preservation, however, has not altered disease-free survival rates when compared with ablative procedures.[146–148] Local recurrence rates after neoadjuvant chemotherapy and resection or amputation appear to be similar; these are low-frequency but still serious events (0.8 to 7%). Although limb-sparing surgery in appropriately selected patients appears to be safe from an oncologic viewpoint, it is not clear that functional outcome and quality of life (QOL) are superior in limb salvage patients compared to those who have undergone amputation. The long-term outcomes and reoperation rate (including eventual amputation) of the various limb salvage constructs are unknown. Most patients prefer to keep their limbs, however, and limb-sparing procedures are now routinely offered. Advances in chemotherapy, imaging technology, implant design and materials, and subspecialization in orthopedic oncology have reversed the trends of previous decades.

Problems associated with limb sparing include an increased early complication rate of 25% to 35%.[98,102,149] Many reconstruction alternatives are available, and the method that is chosen depends on such variables as patient age and employability, tumor location and size, and the potential of the elected procedure to provide curative margins. Of paramount importance are recognition of the patient's desires and discussion of realistic expectations. In addition the surgeon's experience and expertise play a role in the choice of procedure.

Lindner and associates[150] from the University of Muenster reported their results of a study with 133 patients who had high-grade osteosarcoma of the extremities treated with intravenous neoadjuvant chemotherapy and surgery between 1978 and 1994. Seventy-nine patients had limb-preserving procedures, including 32 with endoprosthesis, 39 with allograft replacement, 6 with autograft reconstruction, and 2 with shortening procedures. Twenty-one patients had rotationplasty, and 33 patients elected amputation. Using the MSTS (1993) functional evaluation scale, major complications were experienced after all procedures; 20 of 32 patients with endoprosthetic procedures experienced a major complication, and 6 of the 20 required removal of the prosthesis. Twenty of the 39 patients with allografts developed a major complication, and 6 of those required removal as well. Ten of the 21 patients with rotationplasty also developed major complications, but none required revision to amputation. Eight of the 33 patients who were treated by transmedullary amputation developed a major complication, and 3 of the 8 required a more proximal reamputation. Lindner and associates concluded that the extent of preoperative primary tumor necrosis, surgical margins, and tumor volume were the most important oncologic prognostic factors and that functional outcome after rotationplasty was superior to that of amputation and other limb-preserving techniques.

A minimum of a "wide" margin should be achieved for adequate local control of high-grade primary sarcomas of bone (e.g., conventional osteosarcoma, high-grade surface osteosarcoma, MFH of bone, Ewing's sarcoma). If there is neural involvement from lesions arising around the knee, then the equivalent of a wide amputation must be performed. If the nerve is spared, then consideration should be given to limb-sparing resection. One issue is the definition of "wide." As defined, it is a cuff of normal tissue completely surrounding the tumor and reactive zone around the tumor. Initially, most surgeons desired 1 cm or more of soft tissue and 7 to 10 cm of uninvolved bone marrow when performing resections or amputations. As more experience was gained and neoadjuvant chemotherapy came into common use, the thickness of the margins has lessened for most surgeons, but it is unclear how close is too close to the tumor before risk of local recurrence increases. Most surgeons now are accepting 1- to-3 cm bone marrow margins and soft-tissue margins in the millimeter range (avoiding "ink on tumor"), especially if the histologic response is good. One problem is that the response is not known predictably until the resection has been carried out. Suffice it to say that this issue has not been resolved and the margins that are accepted vary depending on the experience and judgment of the surgeon and treatment team on any given case. It is clear that intralesional margins

are highly likely to lead to local recurrence, especially if there has been a poor response, but some osteosarcomas recur despite wide margins and good histologic response, suggesting that the aggressiveness of the tumor may play an important but, at this point, undefined role. Once the decision whether to perform amputation or limb salvage has been made, it is necessary to decide on the type of reconstruction. This requires lengthy discussion with the patient and, in the case of pediatric patients, the parents.

The type of reconstruction varies with the location and extent of the tumor, the age of the patient, the experience of the surgeon, and the desires of the patient. In general, patients who desire unrestricted athletic activities are encouraged to have amputations or rotationplasty in the lower extremity because they are more durable options and not subject to mechanical failure, loosening, or fracture. Patients who are more concerned with preserving the limb must first be carefully imaged to ensure resectability and understand the various reconstruction options. Following neoadjuvant chemotherapy, the plain radiograph and MRI are repeated. The surgeon and radiologist must critically assess these studies to determine whether the major neurovascular structures are free of the tumor and the extent of tumor in the medullary cavity and in the soft tissues. If sufficient muscle cannot be preserved, soft-tissue healing may be problematic, and the muscle power of the limb will be compromised. The presence or absence of tumor extending into the adjacent joint will determine whether an intra-articular resection or extra-articular resection can be carried out, and this will affect the type of reconstruction.

Intra-articular resections that preserve the joint muscles and adjacent bone are reconstructed with tumor prostheses, osteoarticular allografts, or allograft-prosthetic composites. Early function is excellent; however, the implants have a finite life span and will likely require subsequent revision surgery depending on the patient's age and activity level.

Extra-articular resections result in difficult reconstructive challenges. Resection-arthrodesis was employed exclusively by some surgeons in the past but is less commonly performed today for lesions around the knee or shoulder. Endoprostheses or allograft-prosthetic composites are more commonly used today. Extra-articular resections about the knee that include the patella and quadriceps mechanism can be treated with allograft-prosthetic composites that use a tibial graft with a patella and quadriceps that can be repaired to the host quadriceps tendon as an alternative to arthrodesis, amputation, or rotationplasty.

The age of the patient has a major influence of the type of reconstruction that is chosen. In young patients (younger than 10 years in girls and 12 years in boys) with lower-extremity tumors, limb length inequality becomes a major issue. It is less of an issue in upper-extremity lesions. In young patients with tumors about the knee, an amputation might be the optimal treatment option. Young amputees with modern prostheses do quite well, and these prostheses allow the child to return to unrestricted activities with a single operation. The complication rates and type of complications are much less than those with limb-sparing prosthesis. Alternatives to amputation include rotationplasty, expandable endoprostheses, and osteoarticular allografts. Some centers have tried novel techniques, such as distraction osteogenesis, transepiphyseal reconstructions, and combinations of allografts with vascularized fibulae that have growth centers.

Rotationplasty

Rotationplasty for tumors about the knee and hip is a very functional alternative to amputation (Figs. 96-4A–E), but carries a cosmetic disadvantage. For skeletally immature patients, patients with a pathologic fracture, or patients with large tumors, especially of the distal femur, a rotationplasty should be considered. A similar procedure of hip rotationplasty has been described and may be used at times for proximal femoral tumors.[151]

Tibial rotationplasty was first described by Borggreve in 1930 for management of a limb that was markedly shortened by tuberculous involvement of the knee.[152] In 1950, Van Nes[153] and others extended the use of the procedure to treat congenital femoral focal limb deficiencies.[154–156] The first tibial rotationplasty used for reconstruction after a radical resection of the distal femur for osteosarcoma was performed by Dr. Martin Salzer and coworkers in Vienna in 1974 and reported in 1981.[157]

The largest collective experience, reported in 1991, involved 70 patients with sarcoma of bone who were managed with rotationplasty.[158] Forty-seven patients had stage IIB osteosarcoma; other conditions included MFH of bone, parosteal osteosarcoma, chondrosarcoma, Ewing's sarcoma, giant cell tumor of bone, periosteal osteosarcoma, and undifferentiated sarcoma of bone. Sixty-two of the lesions originated in the distal femur, six involved the diaphysis, and two originated in the tibia. At a mean follow-up of 4.3 years, Kaplan-Meier analysis revealed a 70% probability of survival and a 58% probability of disease-free survival.[159]

The surgical oncology principles of tibial rotationplasty yield surgical margins that are comparable to those of a transmedullary amputation.[158,159] In patient selection, the only absolute requirement is the absence of tumor involvement of the sciatic nerve and a previously untraumatized, essentially normally functioning foot and ankle (Figs. 96-4F–N). The procedure is applicable for lesions that involve the distal one half of the femur and the proximal one third of the tibia that spare both the peroneal and tibial divisions of the nerve. Large, locally invasive lesions of the distal femur, even with knee joint involvement, are often amenable to tibial rotationplasty.

The procedure is ideally used in young, skeletally immature patients in whom the anticipated adult limb length inequality (associated with the loss of the distal femoral and proximal tibial epiphyses) would be substantial if other reconstructions were employed. The desired final effect is to have the axis of rotation of the rotated ankle joint slightly proximal to the axis of rotation of the normal knee at skeletal maturity.

Resection and Distraction Osteogenesis

Borrowing from techniques of the pediatric orthopedic surgeon, distraction osteogenesis has been used by some for limb salvage in children. This technique involves slowly transporting a segment of vascularized bone with an external fixation devise to fill the gap that tumor resection creates. It requires the ability to preserve the articular cartilage, and the potential risks include close margins and infection from the percutaneous pins in patients receiving chemotherapy. The results of treating patients who have a local resection for tumor of bone and treatment using bone transport (10 patients), shortening-distraction (3 patients), and distraction osteogenesis (6 patients) have been reported,[160] but distraction osteogenesis has not had widespread acceptance in this country.

Canadell and colleagues[161] have described an innovative physeal-sparing procedure in skeletally immature patients in whom the primary tumor was limited to the metaphysis. During the neoadjuvant chemotherapy phase, distraction forces were applied to the epiphysis, "pulling" the tumor away from the epiphysis and providing new, widened uninvolved metaphyseal bone for a margin of resection without sacrificing the adjacent joint. The procedure was used in 20 patients with a mean follow-up of 54 months without evidence of local recurrence (Fig. 96-5).

Expandable Prostheses

Limb length is an issue to be considered in a skeletally immature patient with a tumor of the lower extremity. In general, patients younger than 8 years of age are probably best treated by amputation or, when possible, rotationplasty. Those between the ages of 8 and 10 years (in girls) and 12 years (in boys) have significant growth remaining such that resection of a physis about the joint will lead to significant limb length discrepancy. One alternative for managing this issue in children is to use standard allografts or endoprostheses

Figure 96-4 • **A,** AP radiograph of an 8-year-old boy who presented with a pathologic fracture of the femur through an osteosarcoma. **B,** He was treated in a spica cast and received preoperative chemotherapy. This shows an AP radiograph in the cast. **C–E,** MRI appearance following neoadjuvant chemotherapy: Axial T_1 fat saturation (**C**); **s**agittal FSEIR (**D**); coronal T_1-weighted MRI (**E**). Because of the extent of the tumor, the pathologic fracture, and his age, a rotationplasty was chosen for his local control. **F,** The incision for rotationplasty of the distal femur (different patient). It is a rhomboidal incision creating an intercalary amputation while preserving the sciatic nerve and its branches.

Figure 96-4, cont'd • **G,** The appearance after completing the dissection prior to division of the vessels. The sciatic nerve can be seen posteriorly. In this case, we could preserve the femoral vessels. **H,** The appearance after removing the tumor. The K-wires are used to control the rotation. A Penrose drain is on the nerve, and the vessels can be seen behind the femur. **I,** Positioning of the leg before osteosynthesis to the distal femur. **J,** Postoperative radiograph showing the plate osteosynthesis. **K–N,** Postoperative appearance in and out of the prosthesis (another patient more than 20 years following a similar rotationplasty at age 7 years).

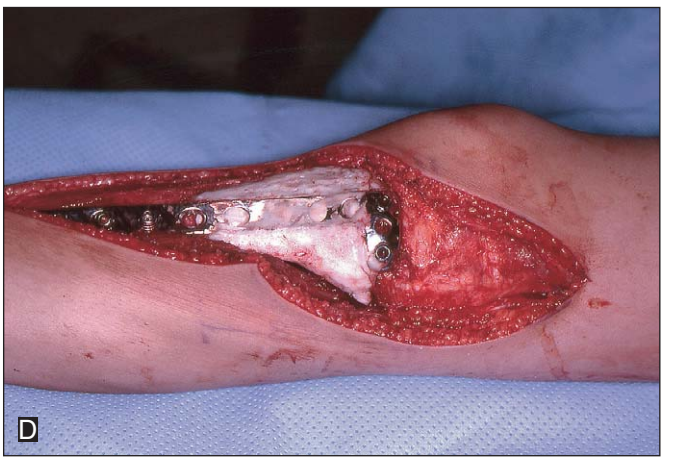
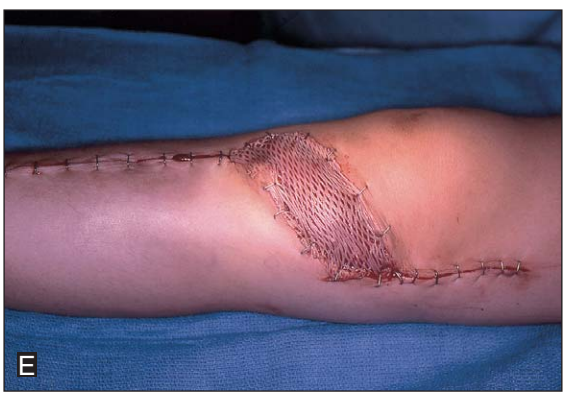
and rely on techniques of epiphyseodesis or subsequent limb lengthening to equalize the extremities. Another alternative is to use expandable prostheses to deal with limb length. There are several on the market, some of which require operations to expand the prostheses and others that can be lengthened by using electromagnetic devices in a radiology suite (Fig. 96-6).[162–164] The early reports of these prostheses are encouraging, especially to parents, but the long-term outcomes are unknown. They are very expensive and complex prostheses, and little data are available with respect to two key issues: whether a very young child can reach skeletal maturity with equal limb lengths and good function and whether the results of the required revision to an adult prosthesis at skeletal maturity will be successful. Early reports show that lengthenings can be achieved and that the complication rates are similar to those of adult endoprostheses. A higher rate of flexion contractures had been noted, since young children are not as cooperative with physical therapy, and loosening and failure of the implant also occur in these complex prostheses.[162–164] The optimal method of fixation of the stems to the host bone remains controversial. It is also unclear whether sufficient bone stock will remain when the patient needs to be converted to an adult prosthesis, owing to stress shielding of the stem in these immature bones.



Amputation



Ablation or primary amputation may be considered for patients with pathologic fracture and patients younger than 9 years of age in whom

Figure 96-5 • **A,** AP x-ray of a male, age 12 years and 6 months, showing increased density over the medial tibial metaphysis (*arrows*). **B,** Pretreatment AP fat suppression MRI illustrating the extraosseous extension of the tumor and sparing of the medial proximal tibial epiphysis. **C,** The response to preoperative chemotherapy was excellent, and at 12 weeks, the patient was essentially asymptomatic. A follow-up MRI scan demonstrated only minimal residual medial metaphyseal disease. The family refused rotationplasty, expandable prosthetic replacement, or amputation and requested a partial physeal-sparing procedure, sparing the articular surface medially and the growth plate and tibial apophysis laterally, followed by periodic operative procedures to correct the anticipated varus deformity associated with continued lateral tibial physeal growth. This photo demonstrates the heads of screws in the epiphysis (*black arrows*) with the tumor resected, sparing the tibial apophysis and lateral tibial epiphysis (*white arrows*). **D,** A plate has been attached to the tibial plateau and secured to the tibial shaft. The defect was filled with chilled methyl methacrylate, to be removed at a later date for periodic correction of the anticipated varus deformity. **E,** A medial gastrocnemius flap was rotated with a meshed split-thickness skin graft for closure and to use the underlying gastrocnemius fascia of the medial head to reconstruct the medial collateral ligament that had been resected. **F,** X-ray demonstrating the normal lateral tibial growth, resulting in a 15-degree varus deformity at 18 months. **G**, The patient was returned to the operating room, where the plate and methyl methacrylate were removed. A chevron osteotomy of the lateral aspect of the tibia metaphysis allowed correction of the deformity. **H,** X-ray representing the result 6 months after the first correction (total 24 months post therapy). It is anticipated that at least one or perhaps two additional corrections will be required before skeletal maturity is attained.

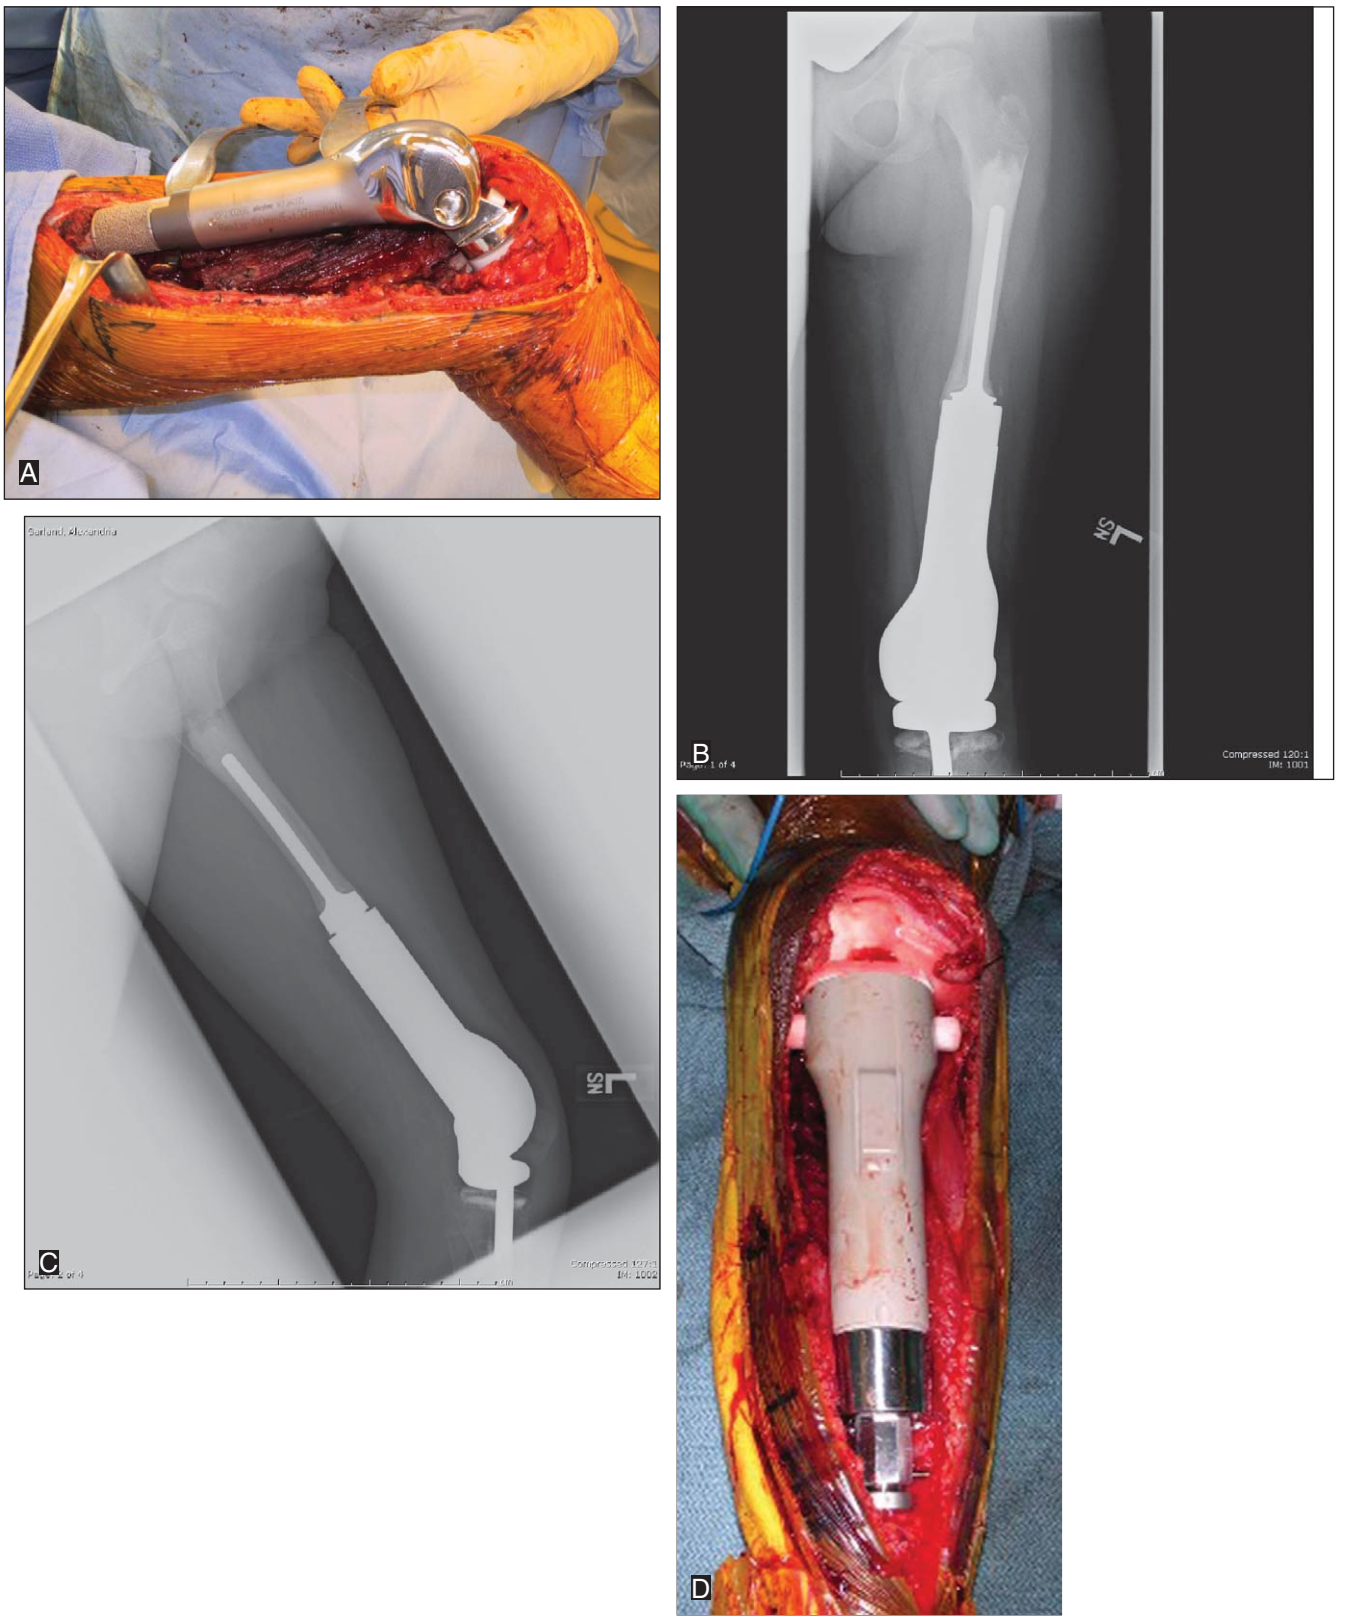

Figure 96-6 • **A,** Intraoperative photograph of an expandable prosthesis of the distal femur. This prosthesis contains an inner tube that will expand by turning a mechanical mechanism on the prosthesis periodically. It requires a small operation to turn the mechanism with a screwdriver near the knee. At times, the pseudocapsule around the prosthesis needs to be excised to allow for expansion. **B** and **C,** AP and lateral radiographs of the prosthesis shown above. At adulthood, the prosthesis will require conversion to an adult prosthesis. **D,** Intraoperative photograph of another type of expandable prosthesis. This prosthesis does not require an operation to expand. An electromagnetic coil is applied around the extremity under minimal sedation. The coil melts a component in the prosthesis, allowing a spring to expand the prosthesis under fluoroscopic control. When the coil is removed, the expansion stops.

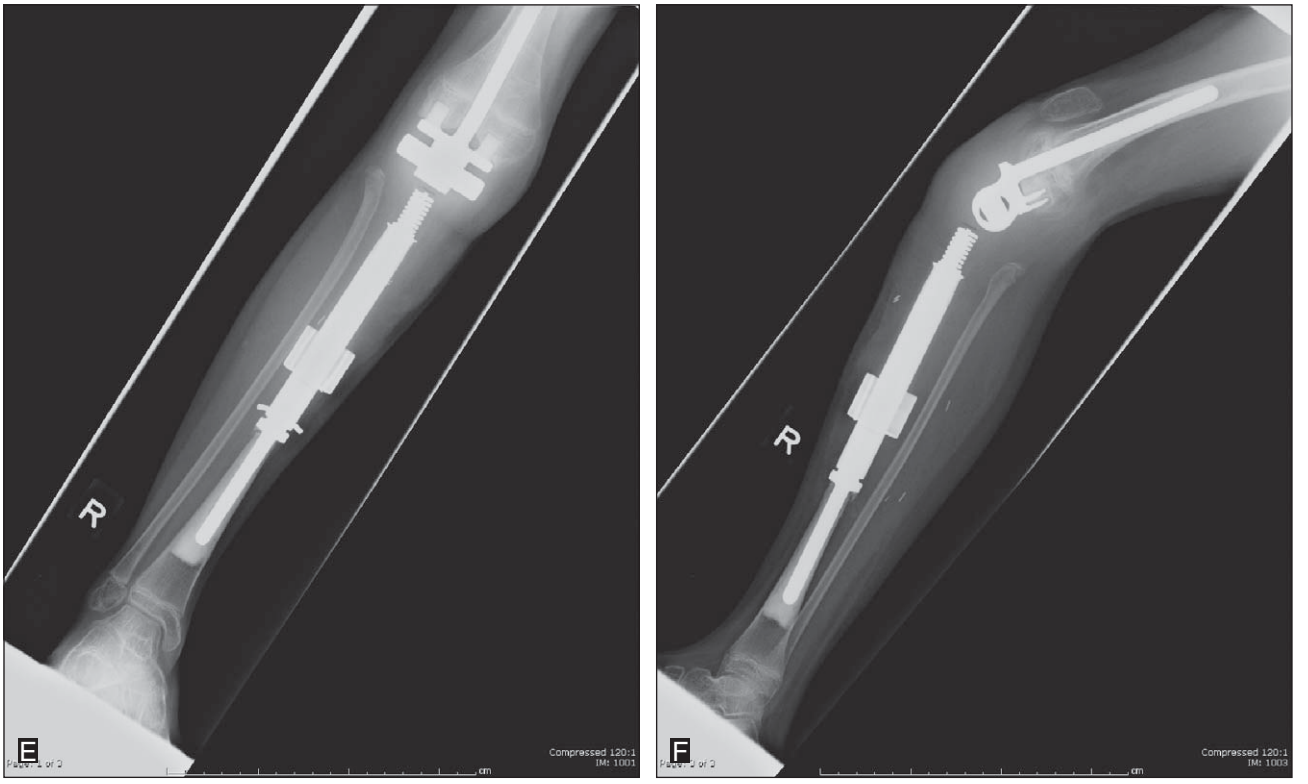

Figure 96-6, cont'd • **E** and **F,** Radiographs of the prosthesis shown in **A–D**.

lower-extremity limb length inequality would be considerable.[165,166] Also, stage IIB lesions that arise below the knee and below the elbow are best treated by primary amputation. It should be recognized, however, that selected patients with favorable lesions that arise below the knee and elbow might also be candidates for limb-sparing procedures. Also, some pathologic fractures have been shown to heal during intensive neoadjuvant chemotherapy.[167] We have become so accustomed to salvaging limbs that amputations are probably not being used enough. It is wise to remember that with modern prosthetics for the lower extremity, function can be quite good and perhaps better than that of limb salvage for tumors of the distal femur and below. Amputation should not be viewed as a failure or sign of defeat until we develop better methods for limb reconstruction.

Surgical Options for Limb Salvage Reconstruction

Endoprostheses

Early experience with metallic reconstructions for limb salvage of tumors required custom-made implants, which took time to manufacture and had design features that limited longevity. Now there are modular prostheses for most anatomic sites of the upper and lower extremities that allow the surgeon to reconstruct individual defects at the time of the resection without custom implants (Fig. 96-7).[168–174] Design improvements in rotating knee hinges and cementless stem options will likely lead to increased longevity of these implants. The advantages of endoprostheses include their relative ease of use, a lower reported infection rate, and a more rapid return to function, since there is no waiting for union, as in bone allografts. The main drawbacks include the concern for longevity of the implants and their fixation to the host bone. A recent stem design uses constant compression forces and a cementless fixation system that is purported to induce bone hypertrophy and lessen stress shielding, but results are preliminary.[175] In young children, it is unreasonable to expect a complex implant to last the patient's lifetime if the patient survives the disease, and multiple revisions are to be expected. Advances in fixation of implants to the host and design improvements in the joints will likely improve the longevity and usefulness of these implants.

Bone Allografts

Bone allografts are another alternative to limb salvage for sarcomas. They offer the potential advantage of incorporation by the host and greater longevity but are technically more demanding than prostheses. Availability of a bone bank with a variety of shapes and sizes of allografts is a prerequisite, although several large commercial bone banks that are accredited by the American Association of Tissue Banks are now available. Younger patients are more suitable because the recovery period is longer owing to the need to protect the osteosynthesis site until it heals. Allografts can be used as osteoarticular grafts (Fig. 96-8), replacing one side of a joint, or can be combined with standard prosthesis to create allograft-prosthetic composites (Fig. 96-9). Intercalary defects are particularly suited to allografts, since the joint on either end of the diaphyseal defect is intact (Fig. 96-10). An arthrodesis of a shoulder, knee, or hip can also be created by using allografts. The main drawbacks are the potential for disease transmission and the relatively high reported complication rates compared to endoprostheses.

The experience using large-bone allografts for reconstruction in high-grade osteosarcoma at the Rizzoli Institute in Bologna was recently reviewed by Donati and colleagues.[176] Between 1986 and 1994, 112 large-bone allograft reconstructions were performed. Forty-one were used for arthrodesis of the knee, and three were used in the ankle. Thirty-nine were used as intercalary grafts (see Fig. 96-10), and 22 were used as osteoarticular allografts (3 humeral, 6 in the distal femur, and 13 in the proximal tibia). Seven composite constructs were reported; two were in the proximal and distal humerus, one in the proximal femur, and four in the proximal tibia. Complications included delayed union (greater than 1 year without radiographic

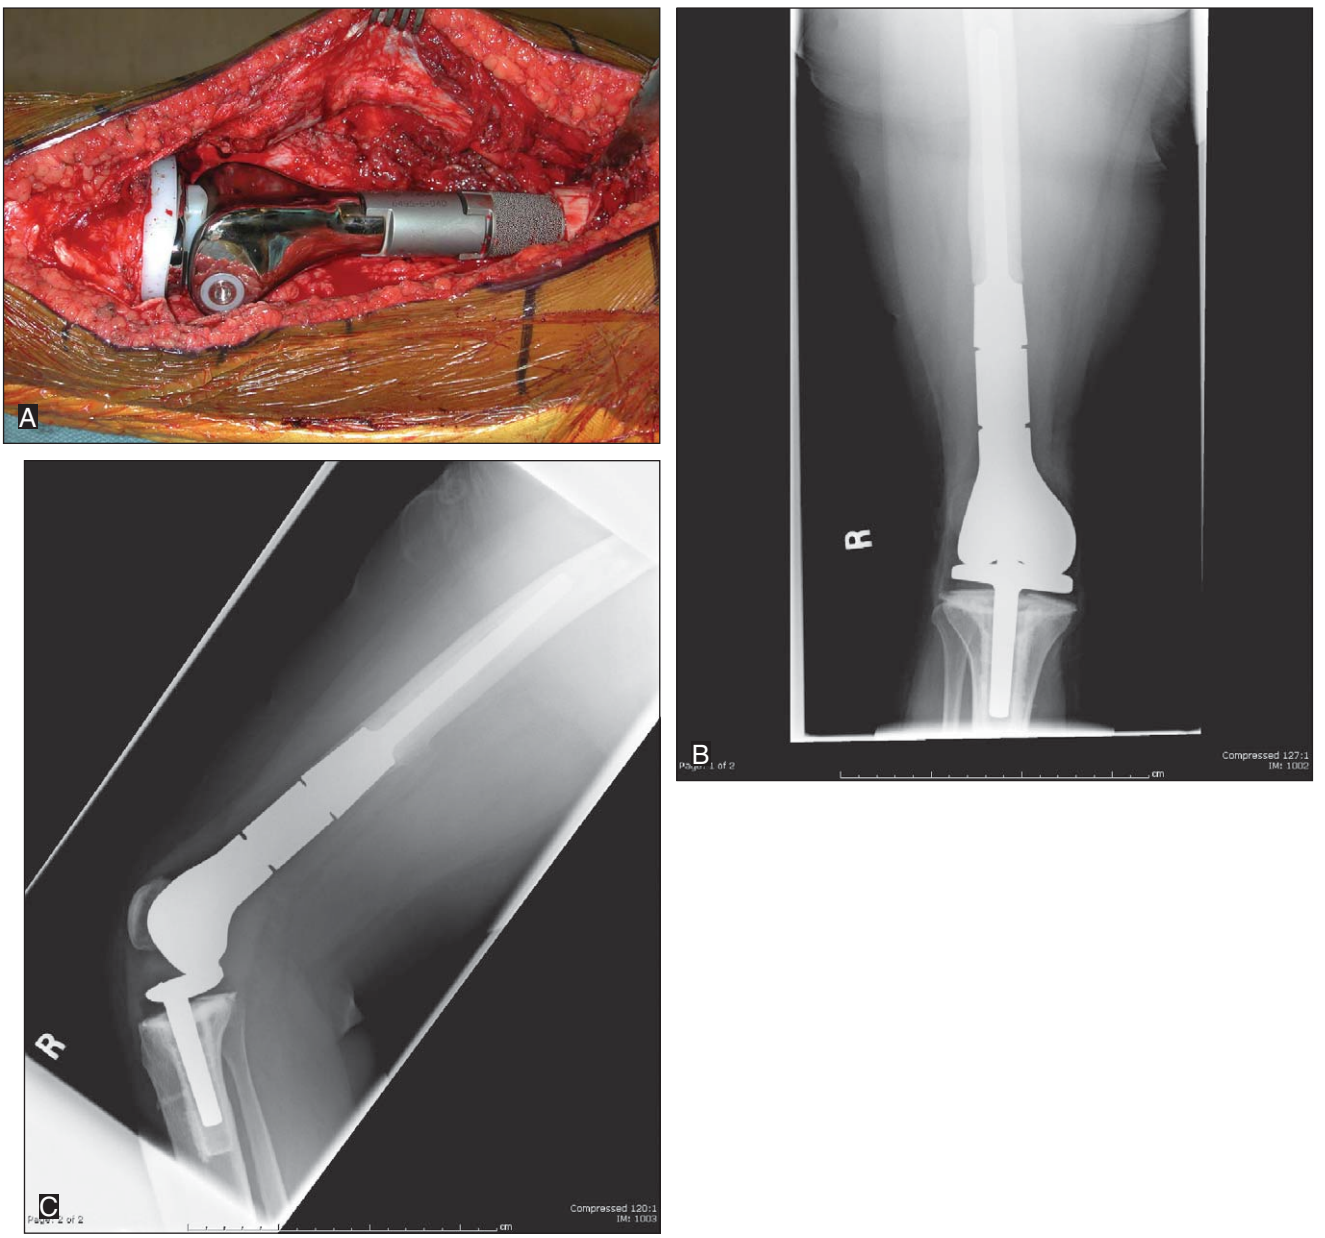

Figure 96-7 • **A,** Intraoperative photograph of a modular endoprosthesis for the distal femur. This prosthesis is cemented in place and has a rotating hinge knee design. The prosthetic stem is roughened near the femur implantation site to allow for tissue ingrowth. Length can be determined by selecting the proper body segment length and assembling it with Morse tapers. **B** and **C,** AP and lateral postoperative radiographs of the prosthesis shown above.

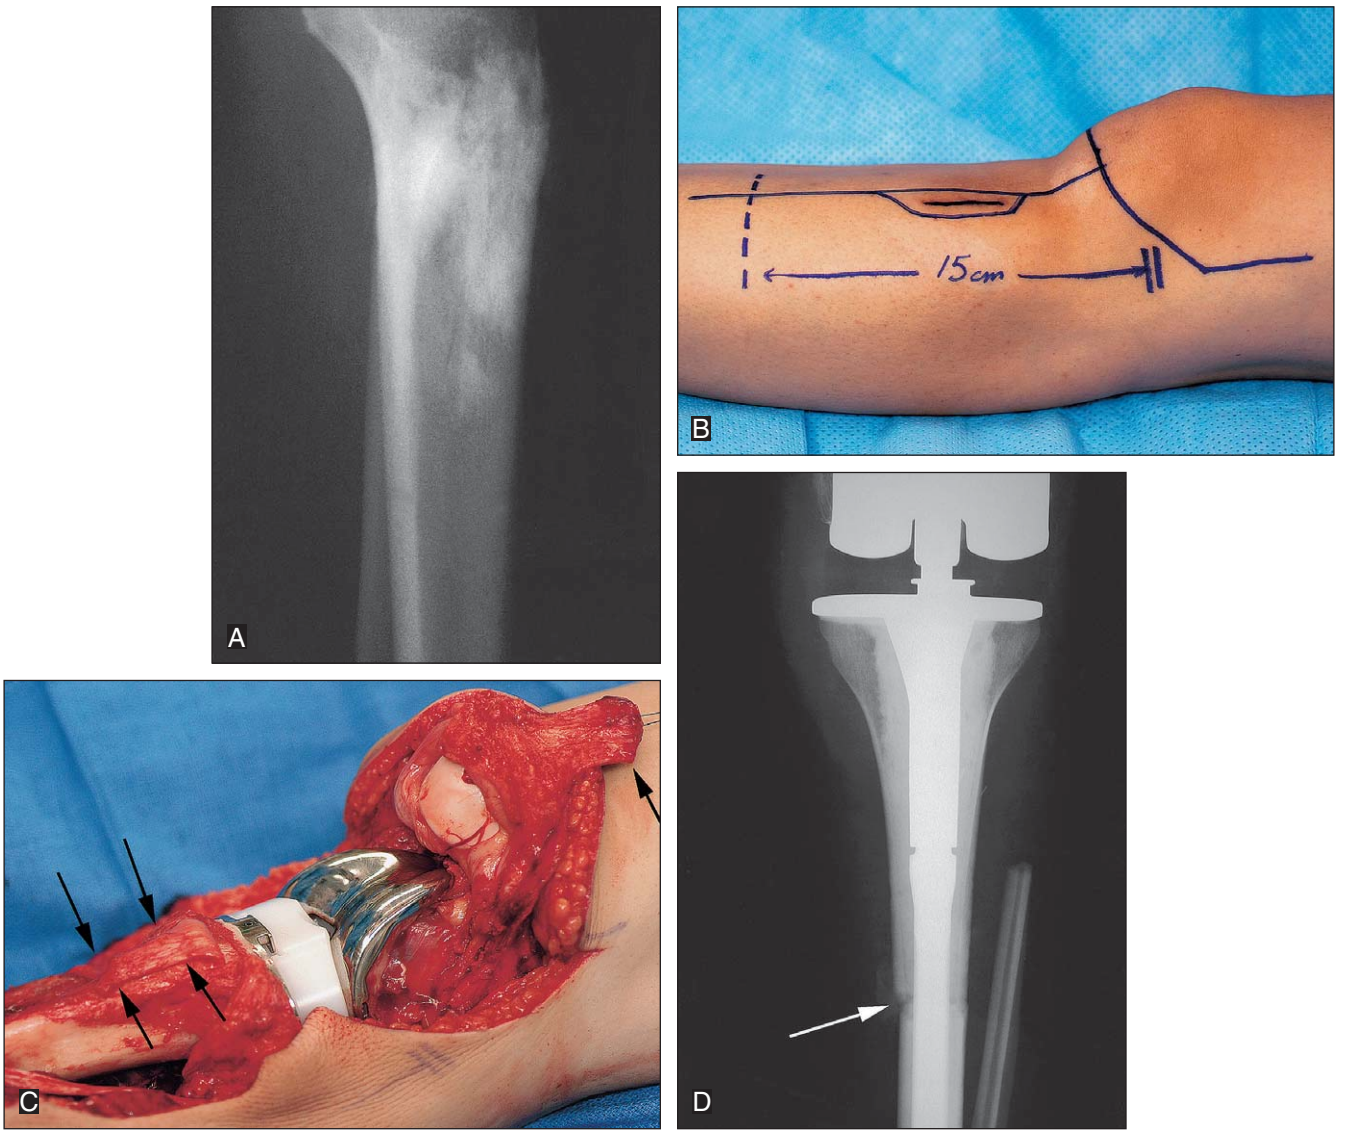
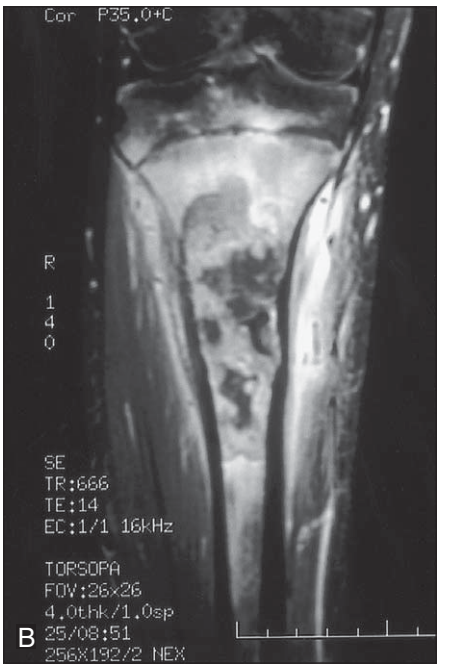
Figure 96-8 • **A,** Preoperative clinical photograph showing the incision for resection of the distal femur, including the biopsy tract. **B,** Intraoperative photograph of an osteoarticular allograft of the distal femur prior to repairing the capsule. **C,** Intraoperative photograph showing the osteosynthesis. **D** and **E,** Postoperative radiographs 3 years postoperatively showing healing of the osteosynthesis site.





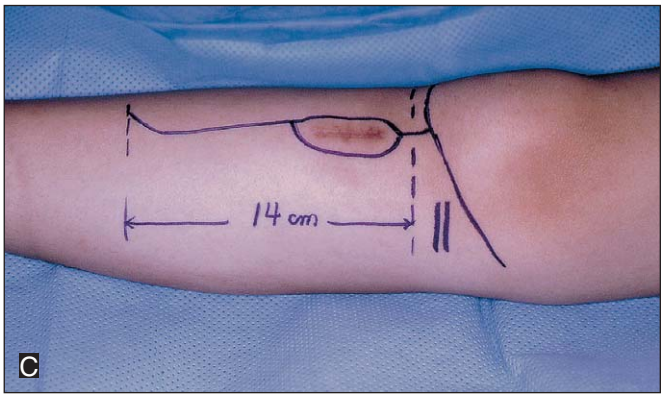


Figure 96-9 • **A,** A 27-year-old female developed a painful mass in the left proximal tibia approximately 3 weeks prior to medical evaluation. This lateral x-ray of the tibia demonstrates a dense, bone-producing lesion in the metaphysis associated with a soft-tissue mass in the anterior compartment. **B,** An open biopsy confirmed osteoblastic osteosarcoma, and all staging studies suggested that the patient was otherwise free of disease. After 12 weeks of standard preoperative multiagent chemotherapy, the patient was taken to the operating room to resect 15 cm of the proximal tibia and adjuvant soft tissue to include the patellar tendon and the proximal fibula while sparing the peroneal nerve. **C,** Intraoperative photo after the tumor was resected demonstrating the reconstruction using a deep frozen allograft with the retained allograft patellar tendon (*double arrows*). The prosthesis has been secured, and the host patellar tendon (*single arrow*) will be woven and sutured to the allograft tendon to restore the resected extensor mechanism. **D,** AP x-ray taken 3 months postoperatively demonstrating the composite allograft/prosthetic hybrid secured with methyl methacrylate and shows that the host/graft juncture (*white arrow*) with supplemental bone graft is healing with evidence of callus.

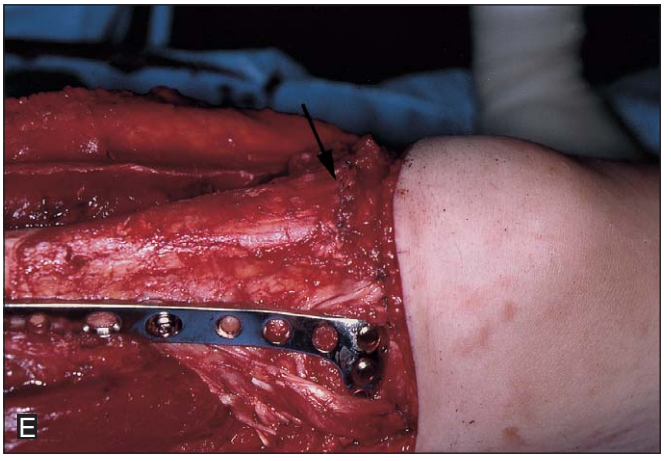

Figure 96-10 • **A,** This 16-year-old skeletally mature male athlete developed pain and tenderness in the right proximal tibia while practicing for a winter sport 6 weeks before medical evaluation. There was no history of trauma, fever, or chills. **B,** STIR image of the right proximal tibia demonstrating intramedullary destruction and a medial metaphyseal soft-tissue mass. The physis and physeal plate, although edematous, appear to be spared. **C,** The preoperative chemotherapy response proved to be excellent, with the clinical absence of pain, mass, and knee stiffness. The preoperative MRI also demonstrated loss of edema and consolidation of the small medial soft-tissue mass, with resolution of all signal adjacent to the closing proximal tibial epiphysis. The patient requested a joint-sparing procedure if at all possible. **D**, Intraoperative photo demonstrating the resection margin just proximal to the tibial physis, including the tibial tubercle and patellar tendon. A distal chevron osteotomy was performed 14 cm distal to the proximal osteotomy. The specimen was cut immediately on the back table to be certain that the proximal and distal margins were free of disease. **E,** A deep frozen allograft with ligaments attached was matched to the bone size and used to fill the defect anatomically while providing an allograft patellar tendon for reconstruction. The *arrow* demonstrates the suture line that was used to reconstruct the allograft/host patellar tendon while retaining the host tibial plateau and intra-articular ligaments. A medial gastrocnemius flap and meshed split-thickness skin graft were used to cover the construct. **F,** Composite AP and lateral x-ray representing the 18-month follow-up with complete proximal and distal host/allograft incorporation. The patient has returned to competitive swimming without external aids or a brace.

union) in 49% of patients and fracture in 30%. There were no deep infections. Using the modification of the Mankin scale by Gebhardt and coworkers,[177] good to excellent functional results were reported in 74% of the 92 patients who were available for review. Examples of these reconstructions at various sites will be briefly presented.

PROXIMAL HUMERUS. Proximal humeral osteosarcomas can frequently be resected while preserving all or part of the scapula. The motion, strength, and functional outcomes of these reconstructions vary depending on whether or not the rotator cuff muscles and deltoid can be preserved. A patient in whom the glenoid, rotator cuff, and deltoid can be preserved should expect reasonable function, whereas a patient who requires resection of the deltoid, rotator cuff, and portions of the scapula will have less good shoulder function. If the neurovascular supply to the hand can be safely preserved, however, the function is superior to amputation. By using current prosthetic designs augmented with muscle rotation flaps and synthetic grafting materials (Dacron, Gore-Tex, and others), a stable shoulder can often be achieved, and preservation of an innervated hand is paramount.

Wittig and coauthors[178] described the single-surgeon experience of 23 patients with osteosarcoma of the proximal humerus that included 1 stage IIA lesion, 18 stage IIB lesions, and 4 stage III lesions. Twenty-two of the 23 patients were treated surgically with an extra-articular resection that included the deltoid muscle and the rotator cuff, while 1 patient was treated with a transarticular resection that spared the shoulder abductors. The patients ranged in age from 10 to 77 years. Before 1988, 10 patients received custom proximal humeral replacements, and after 1988, 13 modular segmental prosthetic replacements permitting intraoperative sizing were used. Prosthetic survival for the 15 survivors was 100% at a median follow-up of 120 months (range: 24 to 234 months). No prosthesis required revision. There was one instance of aseptic loosening. Complications included transient nerve palsies. All nerve palsies resolved within 6 to 12 months after surgery. Functional outcome as recorded by the Musculoskeletal Tumor Society Extremity Functional Scores ranged from 24 to 27 (80% to 90%). All shoulders were stable, and all patients could perform the activities of daily living with the involved extremity.

Osteoarticular allografts (Fig. 96-11) or allograft prosthetic composites can also be employed at this site.[179–183] They offer the advantage of having sites for attachments of muscle tendons (rotator cuff and deltoid), and since this is a non-weight-bearing bone, the likelihood of fracture is less than that in the lower extremity. Allograft arthrodeses can also be employed.

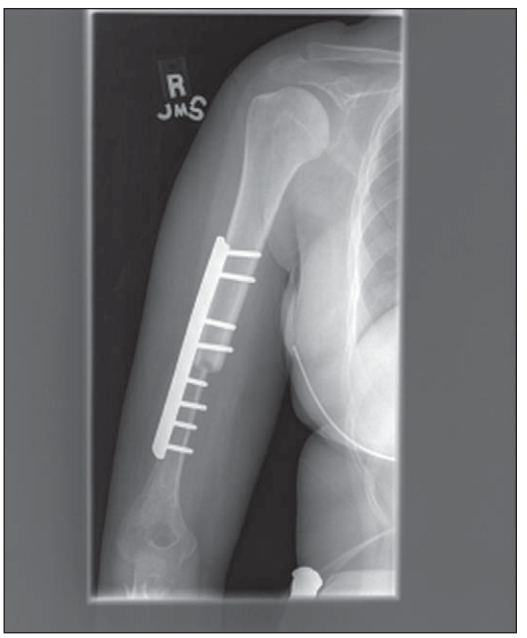

Figure 96-11 • Osteoarticular allograft for proximal humerus osteosarcoma resection.

The experience of the Mayo Clinic was reviewed by O'Connor, Sim, and Chao,[181] who described the treatment of 53 patients with malignant bone tumors of the shoulder girdle with an average follow-up of 5.3 years (median: 4.6 years). A variety of surgical procedures and reconstruction methods were used to achieve wide margins in 40 of 53 patients, with 13 patients having marginal resection margins. Four patients (two after wide resection, two after marginal resection) experienced locally recurrent disease. The functional results are the subject of another report.[184]

Rödl and colleagues[185] in 2002 retrospectively compared osteoarticular allografts (11), clavicula pro humero (15), and a tumor prosthesis (19) for reconstruction following resection of the proximal humerus. The glenoid was resected in 25 patients, and the axillary nerve was resected in 42. The functional results of all three types of reconstruction were similar, but the complication rate was lowest in the prosthetic group, leading the researchers to conclude that the prostheses were the most reliable reconstruction.

PELVIS. The pelvis is the most challenging site for resection, although in many cases, the tumor can be resected without a hindquarter amputation (hemipelvectomy). It should also be remembered that the prognosis of pelvic osteosarcoma remains poor despite modern multimodality treatment regimens, including neoadjuvant chemotherapy.[186] The difficulty comes in reconstruction when the acetabulum is resected. Removing the iliac wing or pubic ramu and ischium often requires no reconstruction and results in relatively good function if the sciatic nerve and acetabulum can be preserved. If the acetabulum is resected, the reconstruction options include leaving the hip flail, attempting an arthrodesis, or replacing the defect with an allograft or custom metallic prosthesis.

Schwameis and associates[187] described the results of the Austrian experience of reconstruction of the pelvis in children and adolescents. Thirty patients, ages 19 years or younger, with malignant tumors of the pelvic bones were treated by using an endoprosthesis in 10 patients, and in 20 patients, reconstruction was completed by using autologous grafts (7 patients), allograft/prosthetic composites (2 patients), methyl methacrylate reconstruction (1 patient), iliosacral arthrodesis (1 patient), modified Girdlestone procedure (3 patients), or resection/arthroplasty (6 patients). After a mean follow-up of 52 months (range: 2 to 241 months), 15 patients were continuously free of disease, 2 were alive with disease, and 13 had died of their disease. MSTS ratings revealed an 81% functional status after autograft, 73% functional status after allograft, and 60% functional status after endoprosthetic reconstruction. Reoperations were significant in that the patients who received allograft reconstruction required an average of 3.5 reoperations, while those who received endoprosthetic reconstruction required an average of 2.5 reoperations. Only 0.8 reoperations per patient were necessary after the other described methods of reconstruction.

Satcher and coworkers[188] described the results of 15 patients who underwent reconstruction for pelvic deficits associated with tumor resection in and about the acetabulum in a slightly older population. The review was limited to periacetabular resections and included patients with primary malignancies and metastatic disease. The authors described a reconstruction technique utilizing numerous Steinman pins placed within the residual and remaining bone to reconstruct the acetabular structures with methyl methacrylate and (occasionally) autoclaved autograft bone in combination with total hip arthroplasty. After tumor resection, the pelvis was reconstructed by using autoclaved autograft or the cement and Steinman technique. Functional results were graded overall excellent or good for 87% of the patients. Their recovery time in general approximated that of patients with routine total hip arthroplasty.

Pelvic allografts have had some success but are demanding procedures and, if the soft tissues are not ideal, subject to a high infection rate. One study of 13 patients looked at the results of reconstruction by massive allografts (some were combined with metal hip prostheses) after resection of a malignant tumor (primary in 10 patients and metastatic in three patients). Postoperative complications were one infection and two dislocations. At 3 years, one cup loosening and one acetabular fatigue fracture required surgery. The functional result was excellent in two patients whose gluteal muscles could be spared, good (allowing a normal family life) in six patients, fair in two patients, and poor in two patients. Seven patients had a MSTS rating greater than 60% of normal (the mean rating in 12 patients was 56.4%). The authors concluded that reconstruction of the hemipelvis with massive allografts and arthroplasty is a rewarding but demanding procedure that should be reserved for physically active patients who are in good general health and are expected to have a response to anticancer therapy.[189]

Despite the complexity of the pelvic resections or amputations, in patients without evidence of metastases, an attempt at resection seems reasonable. A study of 67 patients with pelvic osteosarcoma (15 of whom had metastases at diagnosis) who were registered in the Cooperative Osteosarcoma Study Group were analyzed. All patients received chemotherapy according to that group's protocols. Thirty-eight patients underwent limb-sparing surgery, 12 patients underwent hemipelvectomy, and 17 patients did not undergo definitive surgery. Local failure occurred in 47 of all 67 patients (70%) and in 31 of 50 patients (62%) who underwent definitive surgery. Five-year overall survival and progression-free survival rates were 27% and 19%, respectively. Primary metastasis, large tumor, no or intralesional surgery, no radiotherapy, and existence of primary metastasis were independent poor prognostic factors. The researchers concluded that an operative approach with wide or marginal margins improves local control but that if the surgical margin is intralesional or excision is impossible, additional radiotherapy has a positive influence on prognosis.[190]

PROXIMAL FEMUR. Two types of proximal femoral reconstruction are currently employed:

1. Megaprosthesis, a large metallic prosthesis, often modular in design, that is used to replace the entire proximal femur and occasionally the acetabulum. Reattachment of ligamentous structures to the prosthesis is facilitated by holes or rings designed into the prosthesis, to which the ligaments can be sutured securely. There is very little evidence to suggest secure long-term reattachment other than to the scar enveloping the prosthesis.
2. Allograft/prosthetic composite, consisting of a long-stemmed proximal femoral prosthesis placed within a proximal femoral allograft, securely cemented into the allograft and remaining shaft of the host bone (Fig. 96-12). Advantages over megaprosthesis include the ability to repair host ligaments to the retained ligaments on the allograft. There is histologic evidence that the host and allograft ligamentous structures do unite by scar formation, with less than normal tensile strength.

Survival of prostheses that replace the proximal femur is generally reported at a rate between 88% and 100% at 5 years.[191–193] A direct comparison of megaprostheses and allograft/prosthetic composites used to reconstruct the proximal femur has demonstrated a survival advantage for composites.[194] Stability of the hip remains a concern, with dislocation rates reported at between 2% and 14%, while aseptic loosening remains low for proximal femoral reconstruction.[191–193,195–198]

DISTAL FEMORAL PROSTHETIC REPLACEMENT. Two prosthetic designs are available:

1. The simple hinged-knee prosthetic does not allow for rotation but only for flexion and extension.
2. The kinematic rotation hinge knee prosthetic allows for rotation, flexion, and extension through an offset hinge that provides stability in full extension.

The most important cause of failure for distal femoral prosthetic replacement remains aseptic loosening, which is found in 0% to 11% of patients.[193,199,200] In 218 reconstructions, the overall survival rate for patients with the simple hinge design was 80% at 5 years, 65% at 10 years, and 53% at 20 years.[199] The rotating kinematic hinge design has a better record, with 5- and 10-year survival rates of 90% and 80%, respectively.[192] It is suggested that the rotation of the normal knee simulated by the improved design diminishes impact torsional loading of the cement/bone interface, which often is responsible for loosening.

At present, several modular tumor prosthetic systems are available for reconstruction of tumor resection about the knee (see Fig. 96-7). Results with one modular tumor system used in large numbers by two separate groups have recently been published. Mittermayer and associates[201] reported on the University of Vienna's treatment of 100 patients with primary lower-extremity uncemented reconstruction using the Kotz Modular Femur Tibia Reconstruction System between 1982 and 1989. Forty-one patients were followed for a mean of 138 months (51 patients had died, and 8 were lost to follow-up). Nine patients required revision for aseptic loosening, and two required two such revisions. Four patients developed deep infections. Fourteen patients required reoperation for early failure of the polyethylene bushings.

A large multicenter Canadian study reported by Malo and colleagues[202] addressed the question of stem fixation and fixed versus rotation hinge design of the knee in the Kotz design prosthesis. Thirty-one patients with Kotz fixed hinge and uncemented stem constructs were compared with 25 patients with the KMRS cemented stem and rotating hinge design using the MSTS (1987 and 1993) functional assessment, the Toronto Extremity Salvage Score, and the Short Form-36 Physical Component Score for a follow-up period of at least 1 year. Results in the two groups of implants were comparable, except that the uncemented group had an average of 2 cm greater length of resection. The outcomes of the MSTS (1993; $P = 0.006$) and the Toronto Extremity Salvage Score ($P = 0.03$) assessment suggest that cemented stem fixation and a less constrained knee design were preferable, even though the study was designed to assess functional issues from the patient's perspective.

No direct comparison between endoprostheses and allografts for distal femoral reconstruction are available, and allografts remain a reasonable alternative, especially in young patients. A study of 118 knee osteoarticular allografts in 114 patients was reported with long-term follow-up.[203] Ten patients were lost to follow-up, and 18 patients without allograft failures died of complications related to the tumor. Twenty-six allografts failed because of infection (13 allografts), local recurrence (8 allografts), massive resorption (3 allografts), and fractures (2 allografts). Sixty-four allografts were still in place at a mean of 98 months after implantation. The Kaplan-Meier 5-year survival rate for the knee osteoarticular allografts was 73%, and the limb preservation rate was 93%. Five patients required joint resurfacing to preserve the original allograft. Most of the allograft failures occurred during the first 4 years, and the allograft survival rate for this series remained unchanged after 5 years. Others[180] have reported more dismal results, attesting to the demanding technical aspects of this surgery and the need for experience with the surgical techniques and tissue banking.[204,205]

PROXIMAL TIBIAL PROSTHETIC REPLACEMENT. Two factors play a role in the rather poor performance of implants that are used to reconstruct the proximal tibia:

1. Difficulty in obtaining good soft-tissue coverage
2. Poor reconstructive options for extensor mechanism reconstitution

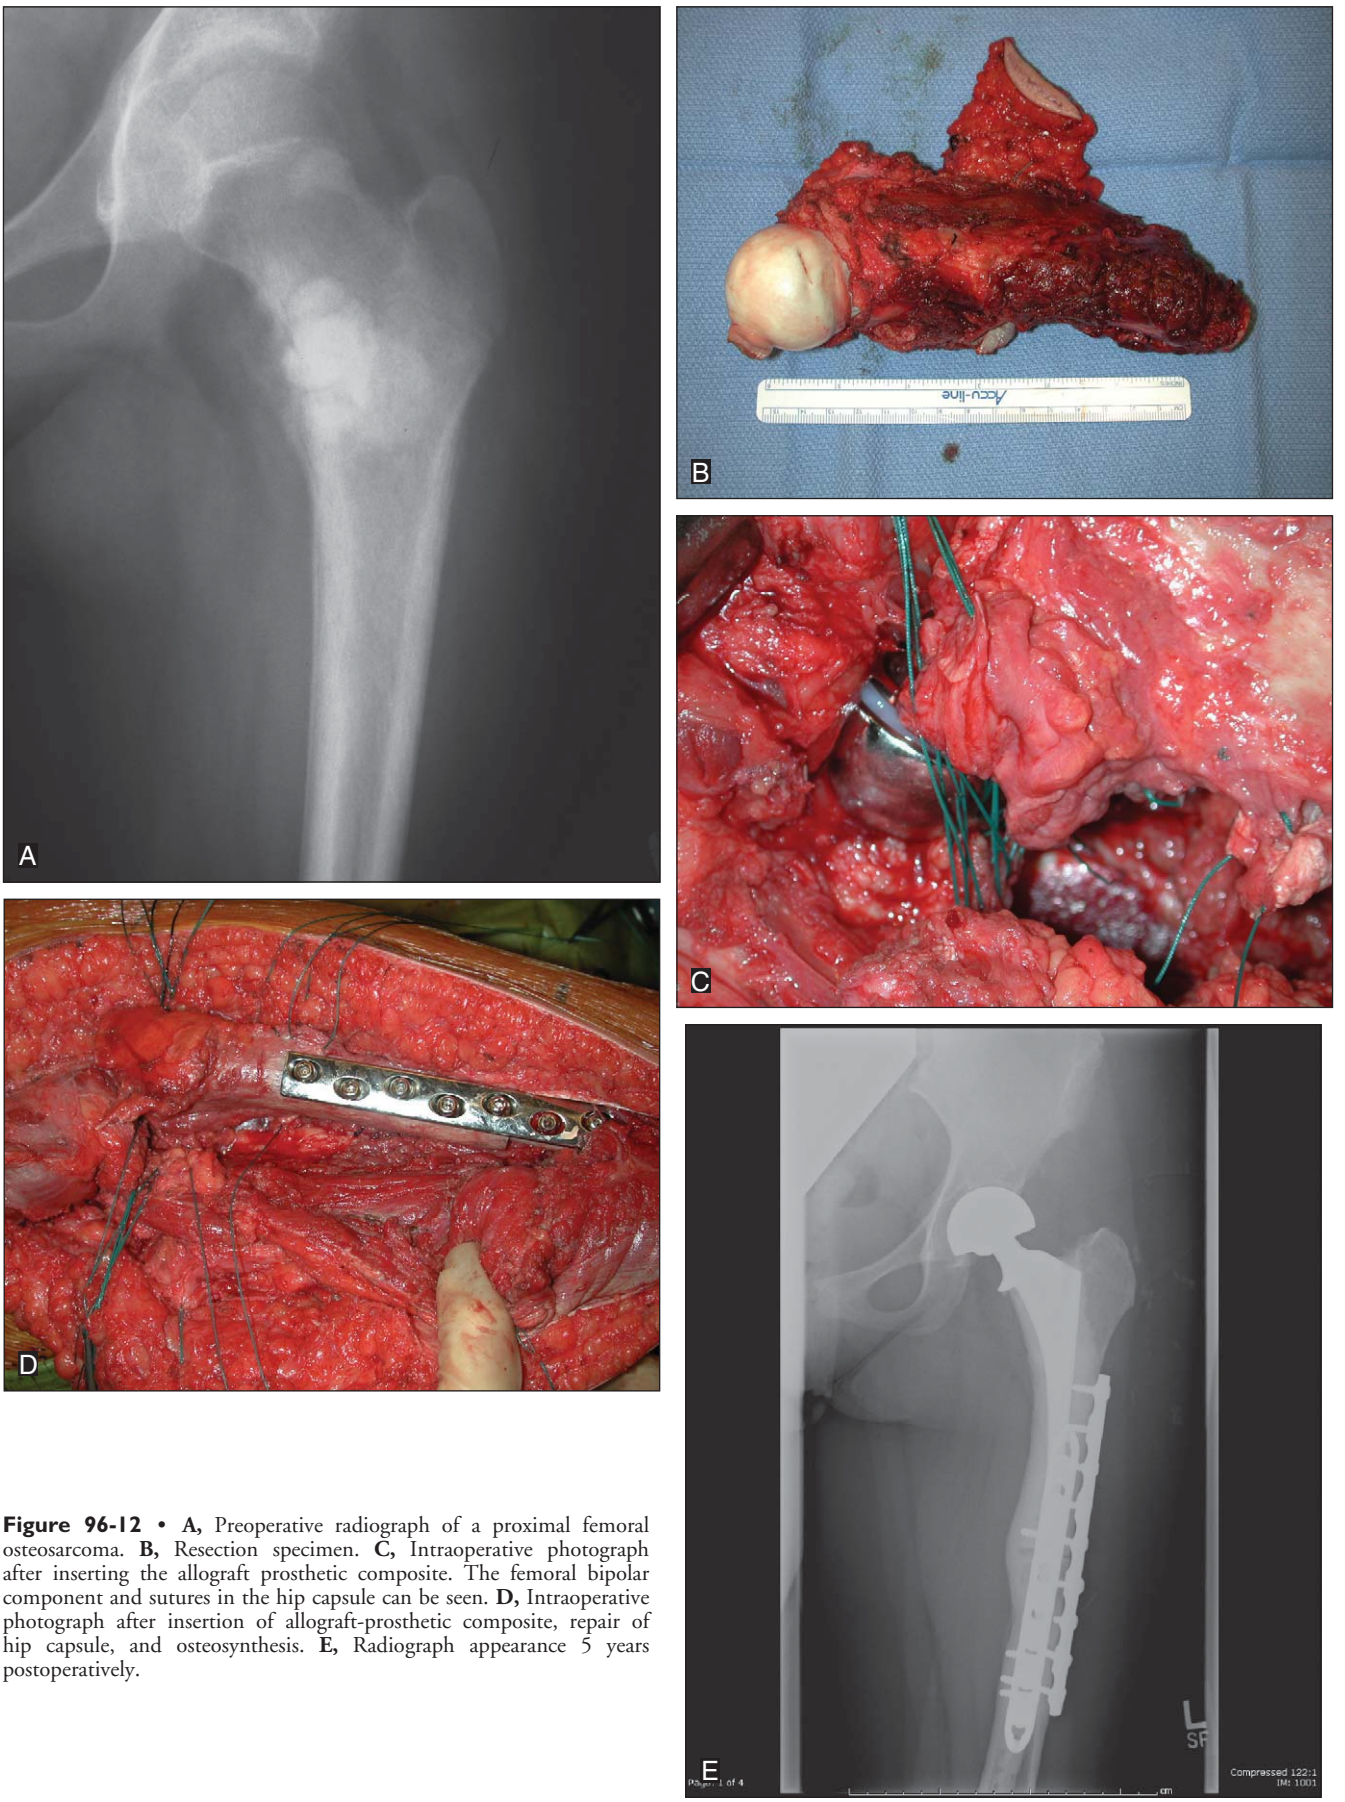

Figure 96-12 • **A,** Preoperative radiograph of a proximal femoral osteosarcoma. **B,** Resection specimen. **C,** Intraoperative photograph after inserting the allograft prosthetic composite. The femoral bipolar component and sutures in the hip capsule can be seen. **D,** Intraoperative photograph after insertion of allograft-prosthetic composite, repair of hip capsule, and osteosynthesis. **E,** Radiograph appearance 5 years postoperatively.

Allograft/prosthetic composites appear to have improved survivorship and function compared with megaprostheses and remain a favorite method of reconstruction because the composites provide the ability to reconstruct the host patellar tendon with the remaining allograft patellar tendon. The routine use of the rotation of a medial gastrocnemius flap either with or without skin has improved coverage of the prosthesis and local nutrition. However, there remains an inordinately high risk of infection, up to 31% (see Fig. 96-9).[191]

Functional Results of Surgical Therapy

The surgeon should consider the functional outcome of surgical therapy when assessing the patient's physical demands and needs. Upper-extremity reconstructive procedures should attempt to maximize function as much as possible, as the extremity does not need to be reconstructed to weight-bearing tolerance. The key issue is maintaining a functional hand, even if shoulder function is not optimal. Unlike the lower extremity, there are no prosthetic replacements that come close to reproducing the function of the hand. Lower-extremity and pelvic reconstructive procedures require greater attention to stability, durability, and mobility. Modern prosthetics for the lower extremity have dramatically improved the function of the lower extremity and can be adapted for nearly all sports activities as well as work environments. One issue is using a proper, validated functional evaluation and QOL assessment. Several are available, but the ideal one or ones are not yet clear.

Validation of a Functional Evaluation System

Lee and coworkers[206] evaluated the MSTS functional evaluation system using the Nottingham Health Profile, the Short Form-36, and the EuroQOL protocol to measure the QOL of patients with malignant musculoskeletal tumors. Forty-nine patients were assessed, and osteosarcoma about the knee was the most common condition. Prosthetic reconstructions had been completed in 55.1% of patients.

All of the items of the lower extremity were related to the same function: walking ability. The MSTS system had a strong correlation with other QOL measures in the construct validity and reliability, but the sociologic domains of the system were so comprehensive that it could not represent the QOL properly. The patients' preoperative and postoperative status could not be compared by using this system. The overall validity and reliability of the MSTS system appeared to be appropriate; however, the system could require the additional development of domains for evaluating the QOL in patients with musculoskeletal tumors. Other systems, such as the SF-36 and the Toronto Extremity Salvage Score, have also been used and validated for sarcoma patients.

Not many studies have compared amputees to limb-sparing procedures for sarcoma. Renard and colleagues[207] from the Netherlands reported retrospective results in 77 patients treated between 1975 and 1995 for sarcomas in the lower extremity. They compared functional results using the MSTS (1993) criteria and the QOL for groups of 52 patients who had limb-sparing surgery and 25 who had ablative treatment. Treatment of tumors involving the pelvis to distal femur and proximal tibia were included. When all anatomic groups of limb-preserving procedures were combined and these patients were compared with patients who were managed by amputation, the functional score of the limb-sparing group after a mean duration of 97 months follow-up was significantly better ($P = 0.0001$) than that of patients who had an ablative procedure.

A recent study compared QOL and subjective well-being between patients who underwent either amputation or limb salvage procedures for lower-extremity sarcomas. Sixty-six patients were evaluated at least 1 year after surgery and systemic therapy for lower-extremity sarcomas. Self-report questionnaires such as the Quality of Life Questionnaire (QLQ-C30), the Life Satisfaction Questionnaire (FLZ), and the Enneking Score (MSTS) were used. There were no differences in QOL and subjective well-being between the two groups. Small differences in scores were found in social functioning but not in scores of physical, cognitive, and emotional functioning. Global subjective well-being in both groups was also similar (219.5 versus 223.7). High satisfaction was found in marital life and partnership as well as in self-assessment. The least satisfaction was found in finances. Results in functional outcome after limb salvage procedures were better than for amputation (77% versus 65%), although more complications were reported after limb salvage procedures. They demonstrated that the type of surgery had no influence on QOL and subjective well-being after treatment of lower-extremity sarcomas.[208] A study of 408 patients with sarcomas who were treated with either limb salvage or amputation had postoperative follow-up of 2 years or greater when they completed a QOL self-report questionnaire. Limb salvage offered a functional advantage particularly at proximal tumor locations.[209]

Refaat and coworkers[210] used a computerized questionnaire that was automatically adjusted for gender, age, diagnosis, site, and treatment sent to 2200 patients with high-grade sarcomas who had been treated during the past 25 years. They compared the response from 66 patients who had an amputation and 342 patients with a limb-sparing procedure for a lower-extremity neoplasm. The outcomes for the two groups were similar. Patients who had limb-sparing procedures did not have a significant improvement in the ability to ambulate, climb stairs, drive a car, or be employed. More of the patients with amputations required walking aids and participated in sports activities at almost the same rate as the patients who had limb-sparing procedures. Patients who had amputations had no more anxiety, drug dependence, depression, sleep problems, or limitation of sexual performance than did patients who retained their limbs. The patients with amputations had more children and fewer menstrual problems; however, they were far less satisfied with their status at early ages than at later periods in their lives.

Oxygen consumption studies of gait suggest that patients with rotationplasty compare favorably with patients who have had a below-knee amputation and function better than most with an above-knee amputation.[211–214]

Harris and coauthors[166] studied the function of 22 patients who had surgical management for malignant neoplasms around the knee. Seven had an above-knee amputation, nine had resection/arthrodesis, and six had replacement arthroplasty. All patients were available for physical examination and measurement of consumption of oxygen, and all answered questionnaires on function and psychological effects.

All patients walked at similar speeds that were significantly slower than those of normal matched subjects. All patients walked with comparable efficiency at three velocities (free walking, 25% faster, and 50% faster), as measured by oxygen consumption and when compared with normal controls. For patients who had had an arthroplasty, efficiency tended to improve slightly at greater velocities. The times that were required to climb a flight of stairs and to step up and down a curb were similar for those with an arthroplasty and those with an arthrodesis, and both groups accomplished the tasks faster than did those who had had an amputation. The times taken to descend the steps, stand from a supine position, and stand from a sitting position were similar for all three groups.

Physical Capacity

AMPUTATION. Patients who had undergone amputation experienced difficulty walking up and down steep inclines, on slippery surfaces, and on uneven ground. They also had difficulty squatting (prosthetic ankles do not dorsiflex) and ran with a skip-hop pattern. They had little to moderate phantom limb pain, but skin irritation was frequent, and they required crutches to get into and out of a tub or shower. Overall, however, this group of patients worried least about damaging the prosthesis or injuring the involved limb.

ARTHRODESIS. Patients had undergone arthrodesis had the most stable affected limbs when walking on uneven ground and on

slippery surfaces or down hills. They ran with a skip-hop pattern and easily kept up with their peers. They could squat or kneel with the involved limb projecting in either the front or the back, with enough stability to have both hands free for work, and they could climb ladders and jump from short heights. As a group, these patients performed more physically demanding work than did the other groups.

ARTHROPLASTY. Patients who had undergone arthroplasty walked better in crowds and on snow, sat easily and could rise from a chair with ease, and could drive automobiles normally. Half of the patients required a hand rail while descending steps one at a time. More could flex the limb sufficiently to squat on the opposite (normal) knee. They often refrained from kneeling because of pressure on the prosthesis. These patients were the most protective of all, limiting their recreational activity, and were the most sedentary of any of the groups.[166]

ROTATIONPLASTY. Most of the rotationplasty patients were very active, with general disregard for the well-being of the limb or prosthesis. All of them shared problems associated with patients with a below-knee amputation (e.g., difficulty walking on steep slopes or uneven ground, inability to squat with ease). Oxygen consumption studies of gait suggest that patients with rotationplasty compare favorably with patients who have had a below-knee amputation, functioning better than most of those with an above-knee amputation and as well as those who have had endoprosthetic replacement.[212–215]

ACTIVITIES AND QUALITY OF LIFE AFTER ROTATIONPLASTY. At least two studies have examined general activities and QOL for people who have undergone rotationplasty. Hillman and associates[215] compared functional results in 34 patients treated with endoprostheses and 33 patients treated with rotationplasty. The rotationplasty patients were under the age of 24 years and had a minimum follow-up of 2 years. Results were evaluated by using the 1993 version of the MSTS functional scoring system and the core QOL questionnaire of the European Organization for Research and Treatment of Cancer. Patients who were treated by rotationplasty had better scores related to role functioning that included hobbies and work, had better ability to function without external aids, and were less inhibited when performing daily and sporting tasks. Most were less concerned than their counterparts about restrictions of activities involving sporting activities and work. Patients who were treated by endoprosthetic replacement had slightly more complaints of discomfort, and more (6 of 34 patients) used external aids than did those with rotationplasty (1 of 33 patients). Neither group was unhappy; however, some patients with rotationplasty appeared more self-conscious.

Veenstra and colleagues[216] from the Netherlands assessed the QOL and psychosocial functioning of 33 of 34 patients with a minimum age of 16 years who had large malignancies of the distal femur treated by rotationplasty between 1981 and 1994. The mean follow-up period was 6.3 years (range: 1 to 11 years). The general QOL was assessed with the European Organization for Research and Treatment of Cancer's QLQ-C30 cancer-specific QOL questionnaire. When compared with healthy counterparts, patients with rotationplasty had significantly poorer performance functionally but were superior psychosocially. Nine of 33 patients reported a negative effect on social contact, while 17 of 30 reported that the operation exerted no influences on social contacts. Seventeen did not feel limited in initiating intimate relationships, while 13 felt slightly to moderately limited, and 1 felt very limited. There was no apparent difference between males and females regarding the effect of surgery. Twenty-one of 33 patients reported that they were sexually active during the months before surgery. Eleven patients reported no sexuality problems, while 10 reported a small to moderate degree of inhibition. Physical function and prosthetic use assessment revealed that 21 of 33 patients did not use extended aids, and 8 of 33 used a single crutch periodically. No patient was confined to a wheelchair. Twelve patients used a normal bicycle regularly, and 15 required a shortened crank. Thirty-two of 33 patients reported wearing their prostheses from early morning to late at night, and all but 2 reported no difficulty sitting. The researchers concluded that rotationplasty was an excellent operative procedure for managing large tumors of the distal femur. Although the patients' level of physical functioning was below that of their normal peers, patients who were treated with rotationplasty experienced an overall QOL similar to that of their normal peers and functioned comparably in a psychosocial context.

Management of Patients with High-Grade Osteosarcoma and Pathologic Fractures

The incidence of the development of pathologic fracture of the extremity in patients with high-grade osteosarcoma varies from 10% to 13%.[217,218] The occurrence of a pathologic fracture is associated with a poorer prognosis and, in the past, was felt to demand an immediate amputation.[143] More recently, limb-sparing procedures have been used if there is a good response to preoperative chemotherapy.

The cause of a pathologic fracture is multifactorial and probably related to the type of osteosarcoma, the location of the lesion, the activity of the patient, and the type of trauma. The more destructive lesions, such as telangiectatic osteosarcoma, result in a thinned expanded cortex and are more subject to fracture than are other types. Lesions involving a weight-bearing bone, such as the femur, are also more likely to fracture.

Before the advent of neoadjuvant chemotherapy, the majority of patients who developed pathologic fractures were treated by amputation. Jaffe and colleagues,[217] however, observed that some pathologic fractures would heal while under the influence of systemic chemotherapy. They observed "reduction of the associated soft-tissue mass, repair of periosteum, and deposition of new mineral in the tumor and about the fracture." These observations made the closed management of some selected pathologic fractures feasible during treatment with neoadjuvant chemotherapy and in preparation for a limb-preserving procedure.

The subsequent healing of the fracture is also a function of the response of the tumor to neoadjuvant chemotherapy. Patients with healing fractures in general would be expected to have better overall outcomes than patients without a favorable histopathologic healing response to primary chemotherapy.

Current recommendations for treatment of patients who develop pathologic fractures from tumors that are potentially sensitive to chemotherapy include the following:

- The patient must have the ability to tolerate conventional intensive chemotherapy.
- The fracture must be treatable by closed means: either slings (usually upper-extremity fractures) or casts, external fixators that are well removed from the tumor margins, fracture braces, or traction for lower-extremity fracture management.
- The fracture should be monitored by physical examination (e.g., decreased fracture motion and pain) and the demonstration of a radiographically favorable response (e.g., increased maturation of the tumor, increased mineral deposition, subperiosteal new bone). If no evidence of improvement or favorable tumor response can be demonstrated after chemotherapy, then consideration must be given to immediate limb-preserving surgery or amputation.

Current small retrospective reviews suggest that patients with pathologic fracture who can tolerate both the proposed method of fracture treatment and intensive multiagent chemotherapy do not appear to have a greater risk of an unfavorable outcome compared to fracture patients who are treated with immediate amputation unless

the fracture demonstrates poor healing and unfavorable clinical response to treatment.[218,219]

Metastatic Disease

Metastatic disease is principally the result of hematogenous spread to the lungs and bone, followed by secondary involvement of the kidney, liver, and brain. Regional lymph nodes are involved in fewer than 10% of cases. Metastatic disease at diagnosis does not preclude long-term disease-free survival when the disease is sensitive to chemotherapy and all sites of disease can be surgically resected.[220–222]

Aggressive surgical treatment of pulmonary metastases (often requiring more than one procedure) can yield disease-free survival rates from 17% to as high as 40%.[223–225] Generally, favorable prognostic indicators include metastasis later than 1 year from original diagnosis, unilateral disease, presence of fewer than five nodules, and completeness of resection. Early pulmonary metastases, unresectable bilateral disease, and hilar, nodal, or pleural-based lesions have a poor prognosis.

Bacci and coauthors[226] from the Rizzoli Institute reported their results of treatment of 44 patients with osteosarcoma of the extremity with detectable pulmonary metastases between January 1993 and June 1995. Twenty-three patients were evaluable, having completed primary chemotherapy consisting of methotrexate, cisplatin, doxorubicin, and ifosfamide as defined by their protocol overall survival/N5. After primary chemotherapy, lung metastases disappeared in 3 of the 23 evaluable patients, whereas in 4 patients, the pulmonary disease was assessed as unresectable. All 7 patients received surgical therapy for the primary tumor only. In the remaining 16 patients, simultaneous resection of the primary tumor and of the pulmonary metastases was performed. Remission was complete in 15 of the 16 patients and incomplete in 1. Ten patients (55.5%) remained continuously free of disease at a mean follow-up of 30 months.

Kaste and coworkers[227] reported the experience of St. Jude Children's Research Hospital in evaluating 215 patients with extremity osteosarcoma, of whom 32 (15%) had evidence of metastatic disease. Thirty-one patients demonstrated evidence of pulmonary metastases, and only one demonstrated metastases to bone. The histologic subtype that was most commonly associated with metastases was the osteoblastic subtype ($N = 17$). Both the number of nodules and the number of lobes that were involved were found to be significant predictors of survival ($P = 0.0009$, $P = 0.04$, respectively); multiple nodes were bilateral in 61% of patients. In the nonmetastatic cohort, the 5-year survival rate plus or minus standard error was 69% ± 4%, and the 5-year EFS rate plus or minus standard error was 52% ± 4%. This is in contrast to the results of the metastatic group ($N = 32$), in which the 5-year survival plus or minus standard error was 29% ± 8%, and the 5-year event-free rate was 14% ± 7%. Notably, the risk of death increased 1.4-fold for each additional lobe that was involved with pulmonary metastases (95% confidence interval: 1.018). The authors found a 2-year EFS rate similar to those previously reported, in spite of the inclusion of cases accrued over a 20-year span. Bacci and colleagues[226] have reported an estimated 2-year survival rate of 45% for patients with resected pulmonary metastases. The 2-year survival rate estimated for their cohort was 52%. Meyer and colleagues[228] reported an estimated 5-year survival rate of 11% compared with the reported cohort estimate of 14% of patients presenting with metastases. They concluded that not only the number of pulmonary metastases but also their distribution among pulmonary lobes affected survival.

The Cooperative German-Austrian-Swiss Osteosarcoma Study Group reported their findings with patients with proven high-grade osteosarcoma of the extremities or trunk who were registered between 1979 and 1998.[229] Of the total 1765 patients, 202 (11.4%) had clinically detected metastatic osteosarcoma. In univariate analysis, survival of the patients with metastases was correlated significantly with patient age, site of primary tumor, number and location of metastases, number of involved organ systems, histologic response of the primary tumor to preoperative chemotherapy, and completeness and time point of surgical resection of all tumor sites. After Cox multivariate regression analysis, however, only multiple metastases at diagnosis and macroscopically incomplete surgical resection remained significantly associated with poor outcomes. At a median follow-up of 1.9 years, 60 patients were alive, and 37 of the original 202 patients were in complete and continuous surgical remission. Overall actuarial survival at 5 years was 29%, and that at 10 years was 24%. The researchers concluded that the number of metastases and the completeness of surgical resection of all clinically detected tumor sites are of independent prognostic value in patients with proven primary metastatic osteosarcoma. A more recent study of 21 patients with metastatic osteosarcoma showed a cumulative 5-year survival rate after complete resection of 34.2%. Complete resection was found to be a significant prognostic factor for survival following metastasectomy ($P = 0.04$). The authors concluded that every attempt should be made to completely resect all clinically detected metastases even if it meant repeat thoracotomy in recurrent disease.[230]

Attempts have been made to substitute newer drugs in an attempt to improve survival of patients with metastatic osteosarcoma. To date, many of these have been disappointing. Substitution of cisplatin with carboplatin does not appear to be effective.[231,232] The use of topotecan is similarly disappointing.[233]

Late Effects of Therapy

In addition to the psychosocial outcomes of therapy discussed previously, late effects of chemotherapy, including cardiomyopathy from doxorubicin,[234] ototoxicity from cisplatin,[235–239] and thyroid disorders,[240] remain problematic in survivors. The addition of dexrazoxane has been shown to reduce the toxic effects of doxorubicin on the myocardium.[241] Infertility is another concern for patients who receive chemotherapy especially with alkylating agents. A study recently showed that although patients who undergo chemotherapy should be informed of the possibility of infertility, many survivors of pediatric sarcoma treatment can be expected to have successful childbirths.[242] Teenage males might want to consider sperm banking.

Metachronous Osteosarcoma

Aung and colleagues[243] described a single-institution assessment of patients who developed metachronous skeletal osteosarcoma between 1973 and May 2000. A retrospective review of records from 426 patients with nonmetastatic high-grade and primary osteosarcoma showed 23 patients, with a median age of 18.7 years, who developed metachronous osteosarcoma. Initial therapy included combination chemotherapy and surgery. Treatment of the metachronous relapse consisted of chemotherapy or radiation alone or surgery with or without additional individualized chemotherapy.

The median time to the diagnosis of a metachronous lesion was 1.4 years, with a range of 0.2 to 11.3 years. Patients who developed late metachronous osteosarcoma experienced significantly longer postmetachronous osteosarcoma survival compared with those whose metachronous disease developed early. For the former group, the 2- and 5-year postmetachronous osteosarcoma survival rates were 72.7% and 61%, respectively. In contrast, all five patients who developed metachronous disease between 12 and 24 months died within 1.5 years of follow-up. Among patients who developed late metachronous disease, further analysis based on type of therapy suggested that those who were treated with a combined modality (including surgery and aggressive chemotherapy) for their metachronous disease fared better than did those who received monotherapy. The authors also concluded that local therapy with surgery directed at the bulky primary tumor is the only effective method for local control.

Rodriguez and associates[244] described the treatment of five patients in whom primary osteosarcoma had been treated effectively with

chemotherapy and resection of the primary tumor and in whom another osteosarcoma developed at another site but without pulmonary metastases. The interval between management of the primary tumor and the subsequent development of another, apparently unrelated metachronous osteosarcoma ranged from 99 to 150 months. All patients remained otherwise free of disease 24 to 96 months after treatment of the metachronous lesion, except for one patient who developed acute myelogenous leukemia, most likely as a late effect from chemotherapy. Fitzgerald, Dohlin, and Sim[245] reported that among 800 patients, 12 developed metachronous osteosarcoma, and none developed pulmonary metastases, a quite different response from that of patients who were reported with primary metastatic osteosarcoma. Others have observed that aggressive treatment of metachronous osteosarcoma is indicated and suggested that the etiology in some might be related to hereditary retinoblastoma or Li Fraumeni syndrome.[246]

Second Malignant Neoplasms

Aung and associates[247] retrospectively reviewed the experience of the Memorial Sloan-Kettering Cancer Center with long-term survivors of osteosarcoma and the subsequent development of secondary malignancies. The patients were treated between February 1973 and March 2000, and all had received chemotherapy and/or surgery. Chemotherapy consisted of a combination of agents that included high-dose methotrexate, doxorubicin, bleomycin, cyclophosphamide, dactinomycin, vincristine, cisplatin, and ifosfamide. Of 509 patients, 14 were identified as having developed secondary malignant neoplasms. The time interval from diagnosis of the primary osteosarcoma to development of the secondary malignant neoplasm ranged from 1.3 years to 13.1 years (median: 5.5 years). The second neoplasms occurred in the central nervous system in four patients. There were two cases of acute myeloid leukemia and one case each of myelodysplasic syndrome, non-Hodgkin's lymphoma, high-grade pleomorphic sarcoma, leiomyosarcoma, fibrosarcoma, carcinoma of the breast, and mucoepidermoid carcinoma. The standard incidence was 4.6% when patients with a history of retinoblastoma or Rothmund-Thompson syndrome were excluded.

OSTEOSARCOMA VARIANTS

This section discusses variants of classic osteosarcoma. Some of these subtypes are low grade and well differentiated, have low metastatic potential, and usually do not require adjuvant therapy. The more common high-grade variants will also be reviewed. Although osteogenic lesions arising in the jaw are more common than the recognized variants of osteosarcoma, this subtype will not be addressed in this chapter.

High-Grade Variants

High-Grade Surface Osteosarcoma

EPIDEMIOLOGY. Of the more aggressive surface osteosarcoma variants, the least common is high-grade surface osteosarcoma. It is most frequently reported in the second and third decades of life and, unlike classic osteosarcoma, is four times more frequent in males than in females. The femur appears to be the most frequent site of involvement; these tumors are rarely observed in the flat bones.[248]

RADIOGRAPHIC FEATURES. No roentgenographic features reliably distinguish high-grade surface osteosarcoma from other surface osteosarcomas. Some lesions appear radiographically destructive, while others tend to mineralize more heavily. Some may even present with a sunburst appearance. The only common denominator that is known is that high-grade surface osteosarcomas usually arise from the surface of long bones and tend to be slightly more diaphyseal in location. The tumors generally demonstrate intense uptake on ^{99m}Tc bone scintigraphy. CT best demonstrates the site of peripheral surface origin, while MRI shows possible marrow involvement and the anatomic features of the lesion on T_1-weighted images.[249]

DIFFERENTIAL DIAGNOSIS. In some instances, high-grade surface osteosarcoma can be radiographically indistinguishable from low-grade parosteal osteosarcoma and periosteal osteosarcoma. Occasionally, myositis ossificans can be confused with the lesion, but it is usually associated with trauma and the subsequent onset of tenderness.[250]

HISTOPATHOLOGY. The histopathologic appearance is best characterized by cartilage intermixed with high-grade anaplastic osteoid-producing cells. Often, histopathology is the only reliable method to differentiate these radiographically similar tumors of bone from one another.

CHEMOTHERAPY. Wold and colleagues[251] reported on nine patients with high-grade surface osteosarcoma. Seven of the nine died as a result of their disease. Currently, the majority of musculoskeletal oncologists would recommend conventional multiagent neoadjuvant chemotherapy as currently recommended for conventional osteosarcoma, followed by limb-sparing surgery and adjuvant chemotherapy for treatment, but since no large, controlled studies exist, this remains an area of controversy.[252,253]

SURGICAL THERAPY. Surgical management of the tumor requires a minimum of a wide surgical margin after primary chemotherapy, with a negative intramedullary margin as calculated from the preoperative MRI. Pulmonary metastases should be pursued aggressively with surgical removal and adjuvant chemotherapy.

PROGNOSIS. The number of patients who have been treated and reported with high-grade surface osteosarcomas is too small to analyze. It is likely, however, that the disease-free survival rate is similar to that for patients with conventional osteosarcoma. It is unclear whether a high-grade surface osteosarcoma has the same prognosis as that of a high-grade central osteosarcoma, whether chemotherapy is definitely indicated, or whether a high-grade surface osteosarcoma involving the medullary cavity worsens the prognosis. Since these lesions are so uncommon, these controversies are unlikely to be resolved in the near future.

Extraskeletal Osteosarcoma

Extraskeletal osteosarcoma is an uncommon variant of high-grade osteosarcoma, characterized histopathologically by the production of malignant osteoid and bone arising in soft tissue. Although primary osteosarcoma in rare instances arises in other organs, the majority of these lesions are found in soft tissues of the lower extremity and buttock, upper extremity, and retroperitoneum.[254–260] These are rare tumors, and very few series of more than one or two patients exist.[261]

EPIDEMIOLOGY. Extraskeletal osteosarcoma differs from conventional or "classic" osteosarcoma in that the majority of patients are older than 50 years of age. The tumors most often arise beneath the deep fascia, and 10% to 15% of patients have a history of antecedent trauma.[260]

The etiology of extraskeletal osteosarcoma remains unknown except for patients who have had external beam radiotherapy (postradiation sarcoma) for other reasons. The subsequent development of extraskeletal osteosarcoma within the radiation therapy field after a latent period remains a well-known risk. Of the 88 patients reported by Chung and Enzinger[262] with extraskeletal osteosarcoma, 5 had previously undergone radiotherapy.

RADIOGRAPHIC FEATURES. The majority of lesions can be palpated and identified with plain x-rays of the extremity using

soft-tissue techniques. Although the mass is commonly ill defined, matrix mineralization can often be identified as a "fluffy" density. If abundant cartilage is present, punctate calcifications can be evident.

As is expected in conventional osteosarcoma, extraskeletal osteogenic lesions are often well demonstrated by intense uptake on ^{99m}Tc bone scan. Pulmonary metastases and local lymph node involvement can occasionally be demonstrated by bone scintigraphy. To assess potential metastatic disease, a ^{99m}Tc three-phase bone scan or a rapid whole-body short TI inversion recovery (STIR) MRI and CT of the chest should be completed for appropriate radiographic staging.

CT of the lesion with both bone and soft-tissue techniques will often identify the mineralized tumor matrix or cartilaginous calcification. MRI offers no specific benefit over CT in evaluating this lesion because medullary canal involvement is not an issue. The cross-sectional display and compartmental anatomy that CT demonstrates generally identify both the axial location of the tumor and the anatomic compartment that is involved. The regional, retroperitoneal, and mediastinal lymph nodes should also be evaluated.

Radiographically, both myositis and extraskeletal osteosarcoma demonstrate bone production, and differentiation can be difficult. Myositis characteristically arises adjacent to bone and demonstrates a lucent zone between the lesion and the underlying cortex. Also, maturation of myositis often exhibits mature, well-marginated bone at the periphery of the lesion. Extraskeletal osteosarcoma, on the other hand, displays tumor bone more centrally with an indistinct, poorly marginated peripheral margin in the region of the frequently loculated advancing invasive tumor growth. Parosteal osteosarcoma pathologically and radiographically also demonstrates central maturation with peripheral immature tissue that is similar to extraskeletal osteosarcoma, but it arises immediately adjacent to bone.

CLINICAL MANIFESTATIONS. Extraosseous osteosarcoma must be distinguished from myositis ossificans, with which it is commonly confused. Patients with myositis usually have a distinct history of trauma, either acute or chronic, followed by pain and local tenderness. Extraskeletal osteosarcoma usually grows more slowly, remains mobile in the adjacent soft tissues, and is nontender until late in clinical stages of the disease. Myositis, on the other hand, usually appears rapidly, is tender and edematous, and can be fixed to deep osseous structures.

DIFFERENTIAL DIAGNOSIS. The most common ossifying lesion presenting in soft tissue is myositis ossificans. Parosteal osteosarcoma characteristically arises from the posterior aspect of the distal femoral metaphysis in young adults (third and fourth decades). The characteristic thin rim of mature reactive bone, which is often demonstrated best on CT, usually separates myositis from parosteal and extraskeletal sarcomas, which tend to be more mature centrally. The invasive, more immature peripheries of malignant tumors are often isodense and blend into the surrounding soft tissues. MRI probably provides better information than CT to differentiate between myositis ossificans, intramuscular hemangioma, parosteal osteosarcoma, high-grade surface osteosarcoma, and pseudotumors of the thigh.

SURGICAL THERAPY. Clinically, the lesion appears indurated when the relaxed surrounding muscle is palpated. Pathologically, lobulation is common and must be taken into account in planning surgical therapy and the biopsy tract. The preoperative staging CT and/or MRI should be reviewed carefully to avoid contamination of uninvolved anatomic compartments. Representative tissue must be obtained through a judiciously placed longitudinal skin biopsy incision. Experienced pathologists are often reluctant to interpret needle biopsies from this rare and unusual tumor.

The literature clearly illustrates that most surgeons do not appreciate the invasive and lobulated growth potential of this primary malignant tumor. In two large retrospective representative studies, the local recurrence rates were 50% (13 of 26 patients) and 43% (38 of 88 patients).[262,263]

CHEMOTHERAPY. Extraskeletal osteosarcoma is considered a high-grade tumor that produces metastases to lung, bone, and (occasionally) regional lymph nodes. For patients who can medically tolerate intensive neoadjuvant chemotherapy,[261] multiagent chemotherapy would usually be used before a limb-sparing procedure. With intensive primary chemotherapy that is tailored specifically to sarcomas of bone and soft tissue, the majority of lesions can be removed surgically, with wide margins for appropriate local control. Adjuvant chemotherapy should be initiated after wound healing. Results with multiagent adjuvant chemotherapy appear to yield event-free and overall survival results similar to those of conventional osteosarcoma,[261] although no comparison series exist. Radiotherapy is not used commonly as a therapeutic modality except for palliation in patients with systemic disease.

Pagetoid Osteosarcoma

Sarcoma originating as a complication of Paget's disease of bone was first recognized by Paget himself in 1877. The patient he described subsequently developed fibrosarcoma of the involved radius and died. Of his 23 reported patients, 5 similarly developed sarcoma within the involved bone and died.

EPIDEMIOLOGY. Approximately 5% of the osteosarcomas that have been reported in large series are complications of Paget's disease of bone. Pagetoid osteosarcoma is twice as common in males as in females. The exact frequency of sarcomatous change in patients with uncomplicated Paget's disease is unknown; reports range from 1% to 12%. Sarcoma tends to develop in patients with polyostotic bone involvement (90%) and is distinctly unusual in patients with monostotic disease (10%). The lesion develops in bone that shows the characteristic radiographic accentuated trabeculations of Paget's disease, not in otherwise normal bone.[264] Schmorl,[265] in an autopsy study, reported a 3% incidence of Paget's disease in humans over the age of 40 years. The distribution of involved areas in uncomplicated Paget's disease revealed involvement of the pelvis and sacrum to be most common (56%), followed by the spine (50%), right femur (31%), and cranium (25%). Sites that were less commonly involved were the sternum, pelvis, left femur, clavicle, tibia, ribs, and humerus. In contrast, the distribution of sarcoma arising in Paget's disease is most common in the pelvis (ilium, 34%), humerus (22%), and femur (19%) and is distinctly uncommon in the spine.[266] Lesions that arise in the vertebral bodies are usually associated with previous irradiation. The reason for the common sarcomatous involvement of the humerus and the rarity of involvement of the spine is unknown.[267]

RADIOGRAPHIC FEATURES. The classic conventional radiographic change that is observed with malignant degeneration in pagetic bone is loss or destruction of the usually distinct but accentuated trabeculation. A recent observation by Colarinha and colleagues[268] using ^{201}Tl to differentiate between benign and malignant polyostotic lesions might be helpful.

Scintigraphy using ^{99m}Tc methylene diphosphonate and ^{201}Tl was performed in a patient with polyostotic Paget's disease and sarcomatous degeneration in the right ilium. The ^{99m}Tc methylene diphosphonate imaging revealed abnormal uptake in both types of lesions, while the ^{201}Tl imaging showed increased uptake in the sarcomatous lesion only. These findings, in conjunction with the observation of a soft-tissue mass in and around the suspected lesion on MRI, could assist in earlier diagnosis and treatment.

PATHOLOGIC FEATURES. The histopathologic subtypes differ among pathologists. Huvos and coauthors[269] reported a fibrohistiocytomatous histology to be the most common (26%), while others have reported osteosarcoma (59%) as the most frequently

observed subtype.[264] Histopathologic interpretation appears to account for these differences.

PROGNOSIS. The overall prognosis for patients with sarcoma of Paget's disease is worse than that for patients with classic osteosarcoma. Furthermore, it appears that the prognosis has not changed appreciably in the last 50 years.[270] The disease is usually fatal with or without adjuvant chemotherapy. The majority of patients are best managed surgically by a "wide" amputation for local control and relief of pain. The majority of patients die within 3 years; a recent study showed a 14% survival rate at 2.5 years from diagnosis.[270]

Postradiation Osteosarcoma of Bone

EPIDEMIOLOGY. Postradiation sarcoma occurs after 3 to 10 years and arises within the radiation therapy portal of treatment for an osseous or extraosseous benign or malignant tumor; it occurs twice as commonly in females. Secondary osteosarcoma or MFH arises mainly in two groups of patients:

1. Those who have been treated for childhood tumors such as retinoblastoma, rhabdomyosarcoma, Ewing's sarcoma, Hodgkin's lymphoma, Wilms' tumor, and brain tumors.[271] Some of these patients could be genetically predisposed to secondary tumors developing both inside and outside the field of irradiation, whereas others may relate to the combination of alkylating agents and radiotherapy
2. Those who have been treated for adult tumors such as Hodgkin's lymphoma, who have little evidence of genetic disposition to secondary malignancies but develop the secondary tumor within the radiation field

In general, induction of the tumor appears to be related to dosage, type and site of radiation, age of the patient, and concomitant use of chemotherapeutic agents. The interval between exposure and the development of the tumor ranges from 2.75 years to 41 years, with an average of 13.4 years. Secondary solid tumors have a longer latency period than leukemia when they are related to chemotherapy and radiotherapy. Histopathologic subtypes that have been reported for radiation-induced sarcomas include osteosarcoma (50%), fibrosarcoma (40%), and, less commonly, chondrosarcoma (4%).[272]

CLINICAL MANIFESTATIONS. The development of increasing pain and swelling within a previously irradiated portal should alert the physician to the possibility of malignant change. In contrast to conventional osteosarcoma, the most commonly involved osseous sites are the ilium, proximal femur, and proximal humerus.[274] Whether the underlying bone was normal or abnormal at the time of initiation of treatment appears to make little difference in the latent period.

PATHOLOGIC FINDINGS. In Huvos and associates' series,[273] fibrohistiocytomatous lesions were most common (38%), followed by osteoblastic (18%) and chondroblastic (12%) lesions. The secondary neoplasm arose in the central marrow-bearing anatomic regions involved by the index disease process (e.g., sternum, spine, pelvis).

RADIOGRAPHIC FEATURES. The most common radiographic feature of malignant change is destruction of the underlying bone within the radiation portal. This can be very difficult to assess because of the radiographic changes in the bone resulting from the radiotherapy. Serial ^{99m}Tc bone scans might show evidence of increased uptake in the anatomic region in question when compared with earlier studies. CT often demonstrates destruction and an associated soft-tissue mass. The presence or absence of demonstrable calcification or tumor matrix mineralization is dependent on the differentiation of the tumor.

Using the criteria described by Arlen and colleagues,[274] Sheppard and Libshitz[275] identified 63 patients with postradiation sarcomas. There were 43 females and 20 males, with a mean age of 52.8 years. The mean radiation dose that was delivered was 50.1 Gy, with a mean latency period for the development of the sarcoma of 15.5 years. The most common primary diagnoses were carcinoma of the breast, lymphoma, and head and neck cancer. The most common histopathologies included osteosarcoma and MFH. The most common imaging findings were bone destruction with an associated soft-tissue mass. The authors concluded that postradiation sarcomas, although uncommon, are not rare. They could demonstrate no pathognomonic radiographic findings other than appreciation of the expected latency and knowledge of the anatomic site of the previous radiation porthole.

DIFFERENTIAL DIAGNOSIS. The development of pain in a previously irradiated anatomic region must be evaluated clinically. Differentiation between radiation necrosis and pathologic or insufficiency fracture may be very difficult. A helpful feature is the clinicoradiologic course of radiation necrosis, resulting in bone resolution that often is associated with multiple pathologic fractures (e.g., multiple ribs) and that occurs over a larger area of the therapy field.

SURGICAL THERAPY. Because of the usual overlying leather-like skin and soft-tissue changes, limb-sparing procedures for postradiation sarcoma are frequently difficult and associated with an increased complication rate compared to other limb-sparing procedures. When postradiation sarcomas occur as a complication of treatment of childhood tumors, however, procedures such as rotationplasty or limb-sparing procedures of the proximal or distal femur or proximal tibia occasionally can be offered for patients in whom the tumor and associated soft-tissue changes can be resected, leaving nonirradiated tissues for reconstruction. The majority of adult and elderly patients are offered an ablative procedure well above and proximal to the affected anatomic part. The outcome of patients with radiation-associated osteosarcomas appears to be similar to that of conventional osteosarcoma if aggressive therapy consisting of adjuvant chemotherapy and complete resection is employed.[276]

Small Cell Osteosarcoma

Small cell osteosarcoma, once thought to be a variant of another tumor type, now appears to be a recognized variant of osteosarcoma. A recent and detailed report by Nakajima and coworkers[277] reviewed 72 cases of small cell osteosarcoma (22 from the Mayo Clinic files and 50 from their consultation files) and described the clinicopathologic features of this unusual entity.

CLINICAL FEATURES. The patients who were reviewed included 39 males (63.8%) and 33 females (45.8%) ranging in age from 5 to 71 years (mean: 24.8 years; median: 20 years). More than half the patients were in the second or third decades of life. Forty-four tumors (63.8%) involved the long bones, and 22 tumors (31.9%) occurred in femurs, with 6 developing proximally, 4 in the midshaft, and 11 in the distal one third. Twelve tumors arose in the humerus, including 8 proximally, 3 in the midshaft, and 1 in the distal one third. Three patients presented with multiple lesions, and two presented with pulmonary metastases.

Pain and swelling were the most common symptoms and signs. One patient with a vertebral lesion developed sudden paraplegia. The duration of symptoms and signs varied from 4 days to 10 years (average: 15.4 months; median: 6 months).

RADIOGRAPHIC FEATURES. Imaging studies were available for 35 patients. The lesions were generally characterized as destructive and had the appearance of an aggressive process, with 20 of the 35 clearly suggestive of conventional osteosarcoma arising in the metaphysis. The remaining studies displayed primarily a destructive and

osteolytic process, with no mineralization of the adjacent soft-tissue mass.

DIFFERENTIAL DIAGNOSIS. The differential diagnosis includes Ewing's sarcoma, malignant lymphoma, and metastatic and small cell carcinoma of the lung.

PATHOLOGIC FINDINGS. Osteoid production was identified in all tumors. Nakajima and colleagues identified a round cell type and a short, spindle cell type; the round cell variety was subdivided into three additional groups based on size: very small (25 tumors), small (27 tumors), and medium size (16 tumors). Four tumors were identified as being of the short, spindle cell type. Cytogenetics and molecular genetic studies may be valuable in distinguishing small cell osteosarcoma from other round cell tumors.[278]

CHEMOTHERAPY. The data suggest that the chemotherapy regimen should be based on and similar to treatment of conventional osteosarcoma.

SURGICAL THERAPY. Although early reports suggested that amputation or disarticulation was required for local control, median survival time for patients who had surgery with additional chemotherapy was 13.4 years. Current recommendations for treatment include multiagent neoadjuvant chemotherapy, surgical resection, and limb-sparing surgery with a minimum of wide margins, followed by adjuvant chemotherapy. Patients who were reviewed who had had marginal or contaminated margins had poor prognoses.

Osteosarcoma over the Age of 40

A review by the European Musculoskeletal Oncology Society has made a significant contribution to knowledge of osteosarcoma in patients over the age of 40 years.[279] Using the retrospective experience of 12 centers, the reviewers studied outcomes of treatment in 481 patients with osteosarcoma, including 272 males, 206 females, and 3 unclassified, all over the age of 40.

Forty-two patients (28 males, 14 females) with pagetoid osteosarcoma had a mean age of 71 years (range: 47 to 88 years). The most commonly involved bones were the pelvis (12 patients) and the femur (12 patients). Only 14 of the 42 patients underwent surgery, and five procedures resulted in local recurrence (four of nine limb-preserving procedures and one of five amputations). Although the median survival was 9 months, one patient with an osteosarcoma of the tibia who was treated with an amputation lived for 8 years. Only two patients had chemotherapy.

Forty-one patients (29 females, 12 males) with a mean age of 58 years (range: 40 to 82 years) developed radiation-induced osteosarcoma. The majority of the tumors developed in the axial skeleton and were related to radiation treatment for ovarian or cervical carcinoma (pelvis: 12 patients) and breast cancer (scapula: 11 patients). Only 12 of the 41 patients had no axial tumors. Twenty-nine patients had surgery, including 19 patients with limb-preserving procedures and 8 with primary amputations. Eleven patients developed local recurrence, two occurring in the amputee group and six in the limb-preserving group. Patients with axial tumors did worse (5-year survival rate: 28%) than those with primary tumor of the limb (5-year survival rate: 55%).

Twenty-six patients had low-grade osteosarcoma (parosteal and low-grade central osteosarcoma), including 14 tumors in the femur. Only two of these patients had chemotherapy. Twenty-five had local limb-sparing procedures, and one had an amputation. Four developed local recurrence, and only one subsequently died as a result of local recurrence. The 5-year survival rate for the group was 88%.

The review covered 220 patients for whom follow-up data were available and who had high-grade nonmetastatic osteosarcoma not related to Paget's disease or radiation and not involving the pelvis, skull, or spine. Thirteen patients had intracompartmental disease (stage IIA), and 151 had extracompartmental disease (stage IIB), with 104 cases involving the distal femur, 48 the tibia, 34 the proximal femur, 19 the proximal humerus, and 8 the fibula. Eighty-six patients had an amputation, and 126 had a limb-sparing procedure (23 excision alone, 7 allograft reconstruction, and 78 endoprosthesis). One hundred twenty-nine patients had a minimum of a "wide" surgical margin, and 37 were believed to have marginal or intralesional margins. Local recurrence occurred in 25 patients (5% amputees, 13% with limb-preserving procedures, and 24% of those with excision alone). Eleven of 129 patients (9%) with what were believed to be "wide" or radial margins experienced local recurrence. Overall, the survival rate was 46% at 5 years and 33% at 10 years. Of the 154 patients who were able to receive chemotherapy (i.e., doxorubicin, cisplatin, ifosfamide, and methotrexate), 29% were over the age of 60 years, and 80% were under 60 years of age. Overall, improved outcomes were related to the ability to receive chemotherapy (age less than 60 years) and location of the lesion (lower extremity). These data suggest that patients over the age of 40 years who have conventional high-grade osteosarcoma and are capable of withstanding cytotoxic chemotherapy might do as well with comprehensive multimodal treatment as do younger patients under 40. A recent study has confirmed these observations.[280]

Low-Grade Variants

Low-Grade Central Osteosarcoma

EPIDEMIOLOGY. This well-differentiated osteosarcoma variant can be characterized by its presentation primarily in young adults and its intraosseous location. The original series described by Unni and colleagues[281] included 27 patients with pain and swelling as the most common presenting complaints; the onset of their symptoms occurred from 1 to 20 years before medical evaluation. The ages ranged from 10 to 65 years. A more recent review (from the same institution) of 80 patients with low-grade central osteosarcoma involved 41 males and 39 females, with a mean age of 28.2 years. Skeletal distribution of the tumors was similar to that seen with conventional osteosarcoma.[282]

RADIOGRAPHIC FEATURES. A review of 74 patients with histopathologically proven low-grade central lesions revealed 64 tumors involving the medullary canal and 10 of cortical origin.[282] Forty-three of the 64 long-bone lesions had a metaphyseal location, 11 were diaphyseal/metaphyseal, and 10 were diaphyseal. Eleven patients were skeletally immature at the time of diagnosis, and no tumor was observed to have violated or crossed the epiphysis. Larger lesions readily crossed the physeal scar after adult epiphyseal closure. Occasionally, the tumor penetrated and destroyed the cortex. Poor margination was observed radiographically in 50 of 74 patient x-rays reviewed, and 51 patients (69%) showed x-ray evidence of tumor matrix mineralization

HISTOPATHOLOGY. Many tumors appeared well differentiated, and some appeared strikingly similar to fibrous dysplasia. The tissue was composed primarily of spindle cells with scarce mitotic figures with minimal atypia. Osteoid content was variable.

DIFFERENTIAL DIAGNOSIS. As has been mentioned, differentiation of low-grade central osteosarcoma from benign bone tumors can be difficult. Low-grade central osteosarcoma appears histopathologically similar to fibrous dysplasia and to benign spindle cell lesions, such as desmoplastic fibroma and low-grade fibrosarcoma. Plain films show variable findings, and differentiation from benign lesions such as fibrous dysplasia may be difficult, but CT and MRI can aid in the differentiation by showing subtle cortical disruptions and soft-tissue extension in the low-grade osteosarcomas.[283]

SURGICAL THERAPY. Wide excision is the treatment of choice. Intralesional or marginal margins resulted in 11 patients, with 11

tumors reoccurring within a mean time of 3.9 years after suboptimal surgical therapy. Two of the 11 patients died as a result of their disease between 2 and 48 years after diagnosis.[282]

CHEMOTHERAPY. Chemotherapy is probably not useful in the initial treatment of this disease; however, 15% of patients experience tissue transformation from low-grade to high-grade osteosarcoma. Patients with high-grade tumors might benefit from conventional multiagent chemotherapy.

Periosteal Osteosarcoma

In 1955, Lichtenstein[284] described an unusual periosteal lesion of the humerus and another in the femur that produced cartilage as well as malignant osteoid. Vigorita and colleagues[285] later reported a recurrent lesion that had previously been managed by local resection of the ulna, which he described as juxtacortical chondrosarcoma. Schajowicz[286,287] brought attention to three brothers with juxtacortical chondrosarcoma. The publication by Unni and colleagues[288] in 1976 clarified the issue and focused on the osteoid component seen in the lesion. They described the entity that is currently recognized as periosteal osteogenic sarcoma.

EPIDEMIOLOGY. Periosteal osteosarcoma is an uncommon low-grade osteosarcoma variant that arises primarily in the cortical shaft of the tibia and femur. Radiographically, the lesion arises from the surface of the bone, contiguous with the cortex, producing a scalloped appearance. A soft-tissue mass within the scalloped lesion can be seen on CT or MRI. MRI frequently predicts the absence of marrow involvement beyond the scalloped margins.

PATHOLOGIC FEATURES. Histologically, the lesion consists of intermediate-grade malignant chondroblastic tissue, anaplastic spindle cells, and malignant osteoid. Metastatic disease occurs in approximately 15% of patients.[288]

SURGICAL THERAPY. Treatment consists of en bloc excision with a wide margin and reconstruction, sparing the limb in the majority of cases. When the lesion arises in the femur, the tumor could circumferentially involve the cortex, requiring an intercallary resection of the shaft and reconstruction. An update of the Mayo Clinic series showed no significant changes from the initial description of the lesion or outcome from treatment.[289] Neoadjuvant chemotherapy could be useful in some patients with large lesions; however, adjuvant chemotherapy is controversial unless pulmonary metastases are evident or develop postoperatively. Most centers employ adjuvant chemotherapy for periosteal osteosaroma, but because the numbers of patients is so limited, no definitive studies documenting the merit of chemotherapy have been reported.[253,290]

Parosteal Osteosarcoma

EPIDEMIOLOGY. Parosteal osteosarcoma comprises approximately 4% of all osteosarcomas and is slightly more common in adult females during the third decade of life. The most common site of presentation is the posterior aspect of the distal femoral metaphysis (72%), followed by the proximal humeral metaphysis and the proximal tibia.[291] The lesion consistently presents as a fixed, painless, hard mass.[288]

RADIOGRAPHIC FEATURES. Radiographically, the lesion consists of a dense lobulated bone and soft-tissue mass arising from the posterior aspect of the distal femoral metaphysis. Usually, there is an ill-defined separation or lucent zone between the lesion and the cortex (best demonstrated by polytomography or CT). The peripheral margin of the lesion (zone of maturation) is poorly marginated radiographically and less mature pathologically. The lesion is often demonstrated by intense uptake on ^{99m}Tc bone scan. Untreated lesions usually do not involve the medullary canal, which can best be evaluated with MRI.

PATHOLOGIC FEATURES. Histopathologically, the tumor consists of fibroblastic, cartilaginous, and osseous components, all of which are evaluated individually and graded according to the highest-grade malignancy. The most mature and well-differentiated elements are often seen centrally. The outer zone of the tumor is composed of less mature hypercellular elements.

A system of grading has been applied to parosteal osteosarcoma (grades I, II, and III). Patients with lesions containing foci of high-grade malignancy (grade III) have survival rates similar to patients with conventional osteosarcoma.[288,292] These patients are potential candidates for neoadjuvant and/or adjuvant chemotherapy.

SURGICAL THERAPY. After radiographic staging, treatment for lesions without intramedullary involvement requires local excision with wide margins, most often resulting in a limb-sparing procedure (Fig. 96-13). A two-incision approach is often useful.[293] Vascular displacement is usually not a contraindication for local resection and limb preservation. If the MRI demonstrates evidence of intramedullary involvement, the entire circumference of the involved bone and the contiguous overlying soft tissues must be resected. Patients with intramedullary involvement either primarily or secondarily from local recurrence do not necessarily have a worse prognosis. Outcomes following surgical treatment alone lead to survival in more than 80% to 90% of patients.[293–295]

CHONDROSARCOMA

Chondrosarcoma is second only to osteosarcoma in frequency as a primary malignant bone tumor. Chondrosarcoma characteristically produces cartilage matrix with calcification and myxoid changes.

Epidemiology

Chondrosarcoma comprises approximately 20% of all malignant bone tumors. The tumor arises predominantly in individuals over the age of 50 years, with nearly equal distribution among males and females. Pain (often ill defined) and a mass are the most common presenting complaints. The pelvis is most commonly affected (approximately 30%); the femur, ribs, and humerus are other common sites. Patients with multiple enchondromas (Ollier's disease or Maffaccui's disease) or with multiple hereditable osteochondroma are at particular risk of developing chondrosarcoma.

Etiology and Pathogenesis

Chondrosarcomas are often divided into primary and secondary lesions. Primary or central chondrosarcoma arises de novo from previously normal-appearing bone. Secondary chondrosarcomas arise from pre-existing benign cartilage lesions, such as the cartilaginous portion of an osteochondroma or a benign enchondroma. Both tend to appear at least 15 to 20 years after skeletal maturity and are recognized by their growth.[296] Pain is the most common initial symptom.

Primary chondrosarcomas comprise approximately two thirds of reported chondrosarcomas and are capable of infiltrating and invading the surrounding soft tissues and producing metastases. The risk of metastatic disease is directly correlated to histologic grade. Extraskeletal chondrosarcoma represents fewer than 5% of lesions.[297–299] Dedifferentiated chondrosarcoma is the most aggressive and malignant expression of chondroid tumors.

The secondary tumors are usually low grade, except for lesions that arise in patients with Ollier's disease or Maffucci's syndrome, in which dedifferentiation is known to occur.

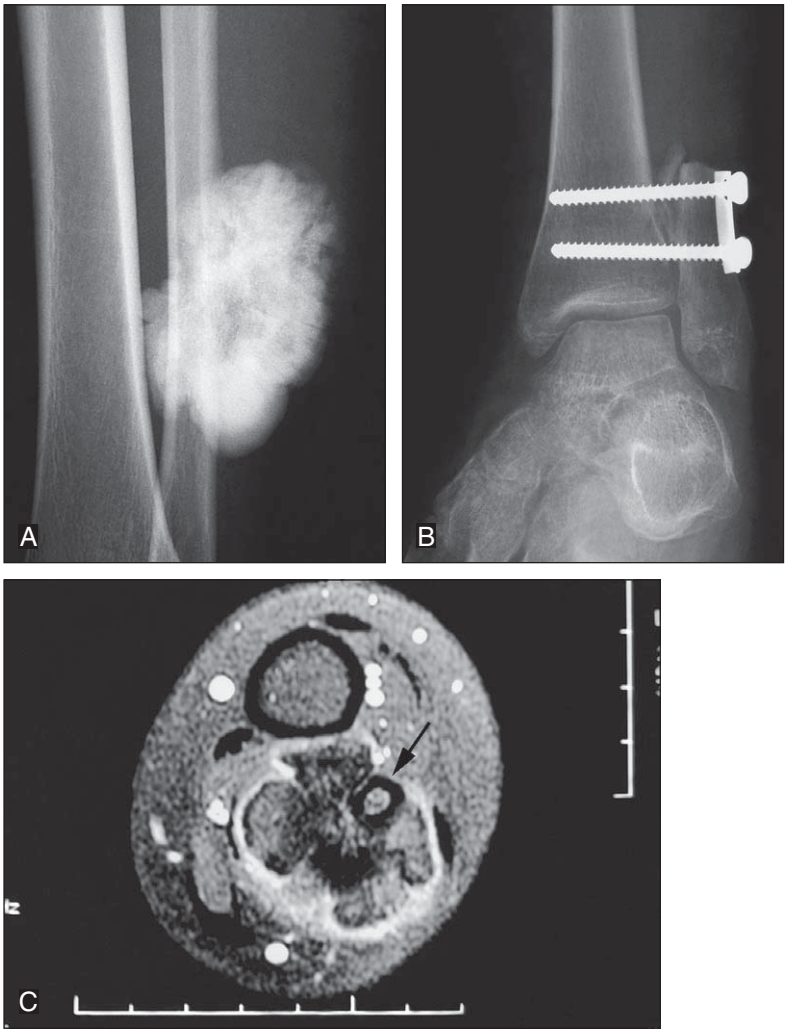

Figure 96-13 • **A,** This 31-year-old female had noted a painless mass posterior to the left fibula 24 months before medical evaluation. The patient denied any local trauma. **B,** AP postoperative x-ray demonstrating the resection margin of the distal fibula and the operative synostosis to stabilize the lateral malleolus. **C,** Axial fat-suppression MRI with contrast demonstrating the mineralized central position (*black areas*) with the typical bright circumferential ring of enhancement typical for parosteal osteosarcoma. Also note the normal fatty marrow signal (*arrow*) without the suggestion of tumor involvement.

Secondary chondrosarcoma can arise in a solitary osteochondroma (Fig. 96-14), multiple osteochondromas, a solitary enchondroma, Ollier's disease, Maffucci's syndrome, and synovial chondromatous fibrous dysplasia and as a complication of radiation therapy. Ahmed and asssociates[300] described the Mayo Clinic experience with 107 patients who developed secondary chondrosarcoma (61 with a solitary lesion and 46 with multiple lesions). They observed that the average age of onset was approximately 1 to 2 decades younger than patients who developed primary chondrosarcoma. The incidence of sarcomatous degeneration was 7.6% for the 802 patients with a single osteochondroma and 36.3% for the 120 patients with multiple osteochondromas. Metastatic disease from a secondary chondrosarcoma from a solitary osteochondroma is very rare. In both groups, the flat bones were the most common site for malignant degeneration (ilium: 19.7%; pubis: 19.7%), with the proximal femur and distal femur as the second and third most common sites. Males were more commonly affected than females (ratio in solitary osteochondroma: 1.2 : 1; ratio in multiple osteochondroma: 1.9 : 1).

Radiographic Features

Primary chondrosarcoma destroys and penetrates the cortex. Infiltration of trabecular bone is a histologic feature typical of chondrosarcoma. Magnetic resonance imaging most often demonstrates both the intramedullary extent of the tumor and the extraosseous extension and is necessary for appropriate preoperative planning. ^{99m}Tc bone scintigraphy is a useful screening examination, and it is recommended that patients with Maffucci's or Ollier's disease have bone scans every 3 to 5 years after recognition of their disease to monitor potential malignant transformation.

Distinguishing enchondroma from low-grade chondrosarcoma is difficult, and rarely can even an open biopsy definitively separate the two. PET scan might prove to be of benefit, but this remains controversial.

Clear Cell Chondrosarcoma

Clear cell chondrosarcomas are expansile and osteolytic lesions that most commonly arise in the epiphyseal regions of long bones (proximal femur and humerus). They are often described as cystic. They typically originate in the mature secondary ossification center, expanding and invading the surrounding soft tissues. The male-to-female ratio is 3 : 1, and the condition most often occurs after the first decade of life, with a rather even distribution up to the seventh decade. Clear cell chondrosarcoma is often diagnosed radiographically and confirmed histopathologically. Benign giant cells can be identified among the fine line of calcification between proliferating binucleated tumor cells. The tumor cells have a characteristic clear cytoplasm with distinct cytoplasmic borders. Lobulation is less prom-

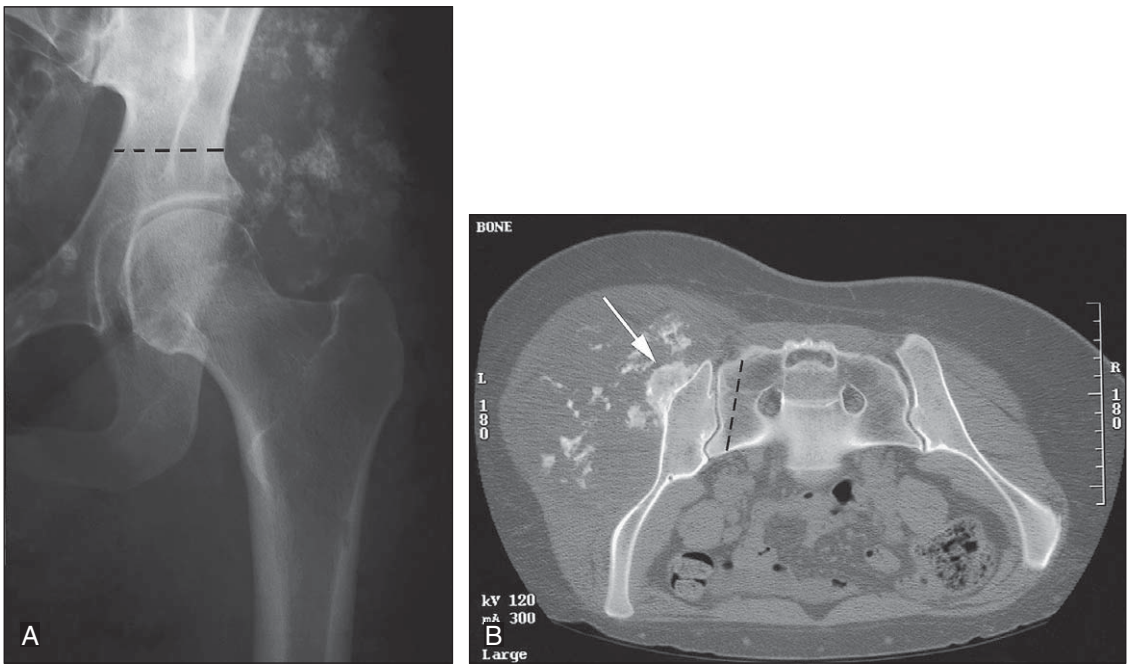

Figure 96-14 • **A,** AP x-ray of the left hip of a 33-year-old female revealing evidence of matrix calcification in the left buttock, thought to be responsible for pain and mass effect. The *dashed lines* illustrate the intended line of bone resection later used for resection. **B,** A CT scan was performed, illustrating calcifications within the lesion that are believed to have grown as a secondary chondrosarcoma from the small osteochondroma (*white arrow*) from the outer table of the left ilium. The *dashed line* also illustrates the intended osteotomy through the left ala of the sacrum, used later to accomplish the resection of the ilium.

inent. Clear cell chondrosarcoma is treated by wide surgical resection (Fig. 96-15).

Dedifferentiated Chondrosarcoma

Dedifferentiated chondrosarcomas also arise from pre-existing lesions that become more aggressive and malignant neoplasms, such as high-grade MFH of bone. The foci of dedifferentiated tissue usually destroy the underlying chondroid matrix and calcifications, leaving an area devoid of calcification and often producing a contiguous soft-tissue mass. These tumors have a high incidence of metastasis.

Pathologic Features

Chondrosarcomas are composed of chondrocytes with a cartilage matrix. The tumor is hypercellular compared to an enchondroma and may have myxoid and cystic areas. Invasion of cancelleous bone and penetration of cortical bone are hallmarks of chondrosarcoma.

Surgical Therapy

Surgical therapy is the primary treatment. Chemotherapy and irradiation are not sufficiently useful to be used on a routine basis. The surgical margin should be "wide." Because of the difficulty in distinguishing between enchondroma and low-grade chondrosarcoma, curettage can be used for these lesions provided that the anatomic setting is appropriate. Secondary chondrosarcoma from a solitary osteochondroma can be removed with a marginal margin, but the cartilaginous cap must not be violated during its removal. Recurrence risk increases if the cartilaginous cap is violated. Radiotherapy and multiagent chemotherapy may be used for palliation.

EWING'S SARCOMA

The pathologic process currently known as Ewing's sarcoma was described as early as 1866 by Lücke.[301] It became widely known in 1921, as James Ewing described the condition as endothelial myeloma, a lesion that he believed to be of perivascular endothelial origin. In 1939, Ewing reclassified the tumor as a neoplasm separate from osteosarcoma. Ewing's sarcoma is one of the recognized small round cell tumor variants that include neuroblastoma, embryonal rhabdomyosarcoma, osteomyelitis, small cell osteosarcoma, and non-Hodgkin's lymphoma. Classical Ewing's sarcoma and primitive neuroectodermal tumor are now considered to be the same tumor, characterized by nonrandom chromosomal translocations involving the EWS gene on chromosome 22 and one of several members of the ETS family of transcription factors. The translocation t(11;22)(q24;q12) is the most common (type 1) and leads to the formation of the EWS-FLI1 fusion protein, which contributes to pathogenesis by modulating the expression of target genes.[302] Other, less common translocations have been identified.[303,304] The translocations are detectable with both reverse transcriptase-polymerase chain reaction (RT-PCR) and fluorescence in situ hybridization (FISH) in fresh as well as formalin-fixed paraffin-embedded tissue. FISH is a more sensitive and reliable ancillary technique than RT-PCR for the diagnosis of Ewing's sarcoma/primitive neuroectodermal tumor in formalin-fixed paraffin-embedded tissue, although the latter provides additional information regarding fusion transcript subtype and prognosis.[305] Most authors now group these tumors into a combined family of tumors that have in common the 11;22 translocation and call these the Ewing's sarcoma family tumors (ESFTs). They include both bone and soft-tissue tumors, but this discussion will focus primarily on bone tumors. Treatment principles for the ESFTs are identical irrespective of their site of origin and most cooperative trials now include both soft-tissue and bone ESFTs.

Little is known about the potential prognostic significance of the different translocations. De Alava and colleagues[306] performed a clinical and pathologic analysis of 99 patients with Ewing's sarcoma in whom EWS-FLI1 fusion transcripts were identified by RT-PCR and for whom adequate follow-up data were available. Median follow-up for the 99 patients was 26 months (range: 1 to 140

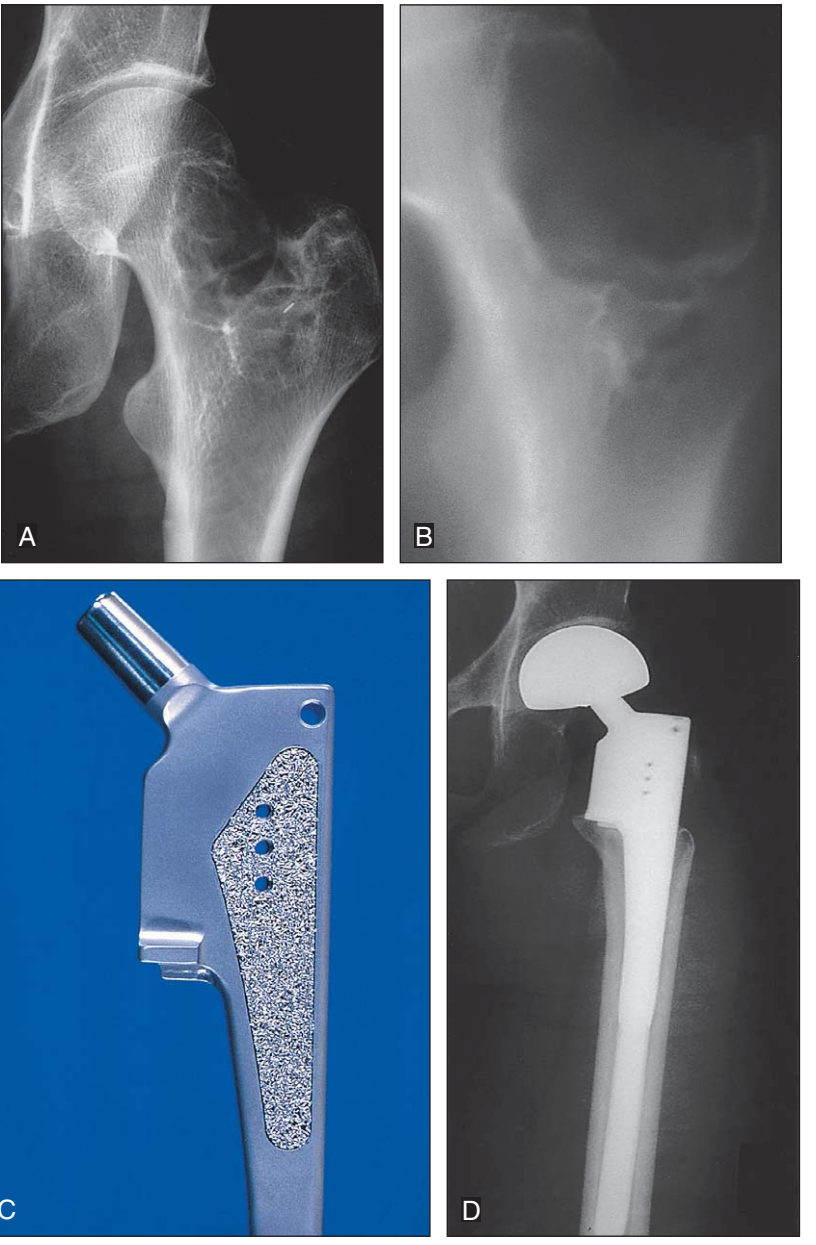

Figure 96-15 • **A,** After 6 months of pain and discomfort involving the left anterior thigh and groin, an AP radiograph of the proximal femur revealed a relatively well-marginated lesion involving the lateral neck and greater trochanter of the proximal femur in a 38-year-old male. **B,** Conventional AP polytomes of the lesion confirmed a relatively well-marginated lesion of the proximal femur and trochanter. No radiographically identifiable matrix could be identified within the lesion. Open biopsy was performed, revealing a cellular cartilaginous neoplasm composed of large cells with clear cytoplasm. The combination of the location of the lesion, its radiographic "soap bubble" appearance, and the histopathology confirmed the diagnosis of clear cell chondrosarcoma. **C,** Photo illustrating a press-fit custom titanium calcar-replacing prosthesis with titanium mesh for bone ingrowth used for reconstruction. **D,** Radiograph demonstrating the AP projection of the custom titanium press-fit (cementless) proximal femoral prosthesis.

months). Tumors in 64 patients contained the type 1 fusion, and 35 contained the less common fusion types. They hypothesized that the type 1 EWS-FLI1 fusion could result in a tumor that is intrinsically less aggressive or more chemosensitive than other fusion types. It appears that recognition of a type 1 EWS-FLI1 fusion transcript could be an indicator of favorable prognosis.

Epidemiology

Ewing's sarcoma is the third most common primary sarcoma of bone, comprising approximately 10% of all primary bone tumors.[307] As with many pediatric solid tumors, males are slightly more affected than females. The peak incidence in males is between 10 and 14 years of age; in females, it is 5 to 9 years (range: 1 year to 80 years). Ewing's sarcoma is distinctly rare in blacks and uncommon in Chinese. The majority of patients present for medical treatment between 5 and 30 years of age, although adult Ewing's sarcoma has been reported.[308]

Clinical Manifestations

Ewing's sarcoma arises from within the medullary canal of bone. Distant metastases are most common to the lung and other bone. The tumor often produces a painful soft-tissue mass that penetrates the cortex and surrounds the involved bone. Ewing's sarcoma of the extremities primarily affects the long tubular bones, such as the femur, tibia, proximal fibula, and humerus. Approximately 20% to 40% of lesions arise in the pelvis and flat bones and often produce symptoms that suggest other diagnoses, such as disk disease or hip pathology. This can result in delays in diagnosis. Tumors that arise in the pelvis are often large (>10 cm in diameter) at the time of diagnosis, and many patients have demonstrable distant disease at diagnosis. Primary tumors arising in the spine most often present with pain and can exhibit a rapidly progressive neurologic deficit. This symptom complex may precipitate an emergent decompressive laminectomy if the true nature of the cause of the symptoms is not appreciated. Patients may

appear systemically ill. Other clinical manifestations include rapid growth of the mass, local pain, and low-grade fever.

Radiographic Features

Ewing's sarcoma characteristically produces a permeative destructive pattern in bone often associated with a soft-tissue mass. In tubular bones, the lesions most often arise in the diaphysis or the metaphyseal/diaphyseal region and can demonstrate both an extrinsic pressure phenomenon and bone hypertrophy (Fig. 96-16A). Classically, the periosteum reacts with an "onion skin" appearance, although this is by no means pathognomonic. On plain radiographs, Ewing's tumors can appear identical to osteosarcoma, osteomyelitis, lymphoma, and Langerhans cell histiocytosis, and these entities are often considered in the differential diagnosis. Plain films of the pelvis can be deceptively normal, while a ^{99m}Tc bone scan, CT or MRI, and other investigative measures might demonstrate both the destructive process and the extent of marrow involvement. Consequently, plain films of the pelvis or other deep structures should not be used alone as a screening method but should be used only in conjunction with other studies.

Bone scintigraphy often aids in identifying the bone or bones that are involved and, to some extent, the degree of intramedullary involvement. The conventional ^{99m}Tc bone scan is primarily used to screen for metastatic disease.[309] To gain additional information about the extent and location of involvement of the primary lesion, single photon emission computed tomography is occasionally required.

CT of the chest to assess the presence of pulmonary metastases is mandatory to stage a patient with Ewing's sarcoma radiographically. The use of CT in the evaluation of the primary tumor can be valuable in illustrating bone destruction, but it might not demonstrate the associated soft-tissue mass, which is often isodense with the surrounding soft tissues. The CT information can be supplementary to the superior imaging data obtained from MRI.

MRI is ideally suited for evaluating the soft tissues, the intramedullary extent of disease, and adjacent soft-tissue involvement of the primary lesion and is an essential part of the evaluation of a patient with Ewing's sarcoma (Fig. 96-16B).

PET alone has little application in the management of patients with Ewing's sarcoma but has provided useful data regarding chemotherapy-induced tumor necrosis before and after neoadjuvant chemotherapy. Sequential PET and ^{201}Tl scans may be useful in predicting the effectiveness of neoadjuvant chemotherapy regimens.

Differential Diagnosis

The histopathologic similarity of ESFTs to other small round cell tumors results in a diagnostic challenge for the surgical pathologist (Fig. 96-16C). The lesion must be distinguished from lymphoma of bone, rhabdomyosarcoma, metastatic neuroblastoma, small cell osteosarcoma, osteomyelitis, metastatic small cell carcinoma of the lung, mesenchymal chondrosarcoma, and, occasionally, metastatic hemangiopericytoma. Pathologically, hemorrhage and necrosis are common, so the responsible surgeon or interventional radiologist must obtain viable tissue for routine histopathology, sterile tissue for cytogenetics, a small sample for electron microscopy, and tissue and fluid for culture and sensitivity.

The challenges of diagnosis were illustrated by Wurtz and associates[310] in a retrospective review of a single institution with 68 patients who had primary bone sarcoma of the pelvic girdle. They found that the average duration of symptoms before accurate diagnosis was 10 months (range: 1 month to 4 years). Common symptoms included buttock pain (35%), presence of a mass (30%), sciatica (29%), groin pain (26%), and low back pain (21%). Inaccurate diagnoses were

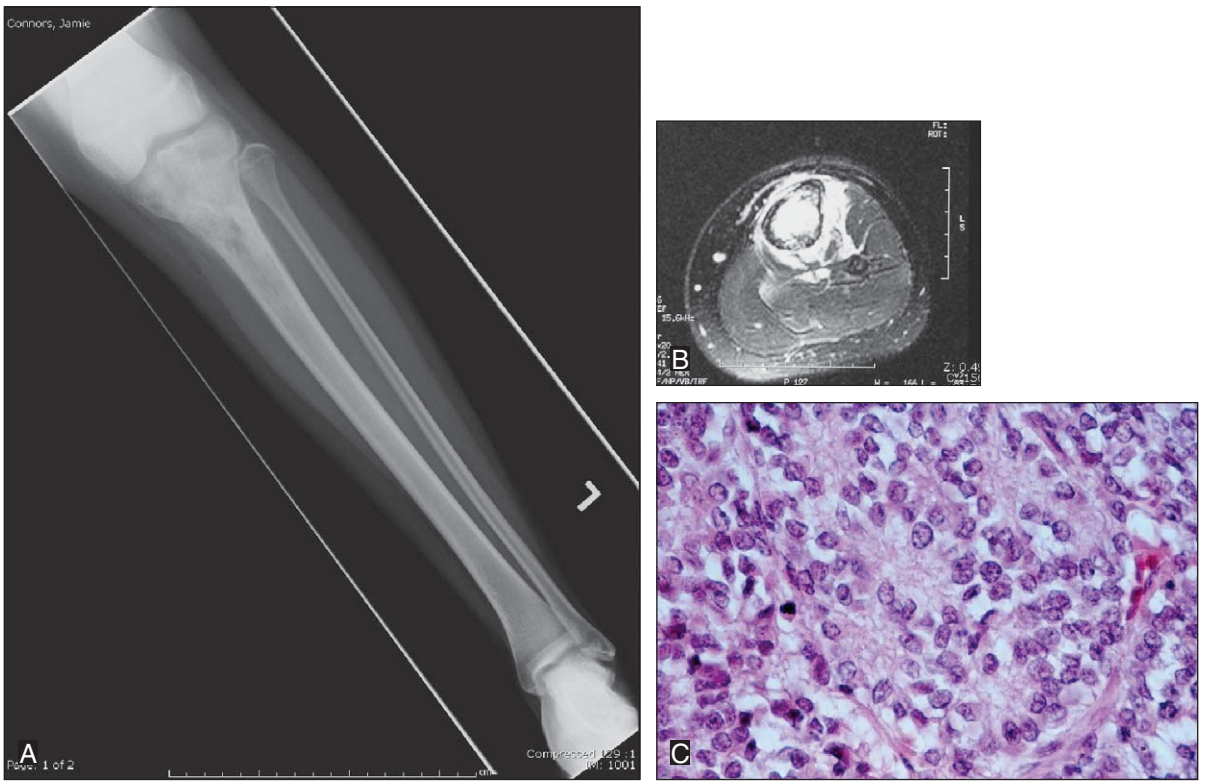

Figure 96-16 • **A,** Ewing's sarcoma of the proximal tibia showing a permeative pattern of bone destruction of the metaphysis. Because the soft-tissue mass is unmineralized, it is not apparent on the plain radiograph. **B,** The axial MRI shows the extent of the soft-tissue mass. **C,** Photomicrograph of a Ewing's sarcoma showing a round cell tumor. This alone would not establish the diagnosis. Immunohistochemistry and at time cytogenetics are necessary to distinguish this from other round cell tumors.

made in 44% of patients (e.g., herniated disc, spinal stenosis, spondylolisthesis, bursitis, stress fracture, urinary retention). Inappropriate treatment for these diagnoses included seven operative procedures (two laminectomies, two debridements, one hip arthrotomy, one total knee replacement, and one inguinal herniorrhaphy). On the average, 7 months elapsed before an accurate diagnosis was made.

Treatment

As with most sarcomas of childhood, therapy consists of multiagent chemotherapy and local control measures. The history and evolution of these treatments were fully discussed in the prior edition of this chapter. Since that time, considerable progress has been made. It is clear that adjuvant chemotherapy is essential.

Chemotherapy

The essential drugs that are used in Ewing's sarcoma have been vincristine, cyclophosphamide, dactinomycin (VAC) and doxorubicin; the combination of those agents with adequate local control led to substantial improvement in outcome of patients with Ewing's sarcoma compared to historic survival rates, which were dismal at best. The value of chemotherapy was confirmed by large cooperative groups coming together as the Intergroup Ewing's Sarcoma Group (IESS). The first study, IESS I, carried out in the 1970s, documented the value of chemotherapy compared to local control and established that doxorubicin augmented the benefits of VAC therapy alone. Pulmonary radiation also showed benefit in this study but has not been widely used in standard treatment protocols. The IESS II study showed that intensifying chemotherapy for high-risk patients with pelvic tumors improved the outcomes. More recently, the large cooperative groups (Children's Cancer Group and the Pediatric Oncology Group, now merged as the Children's Oncology Group in the United States) conducted several large trials to improve the event-free and overall survival of patients with ESFT. It was recognized that the combination of ifosfamide and etoposide was highly effective in patients with ESFT of bone who had a relapse after standard therapy; therefore, a study was designed to test whether the addition of these drugs to a standard regimen would improve the survival of patients with newly diagnosed disease.[311] Patients 30 years old or younger with ESFT of bone or primitive sarcoma of bone were randomly assigned to receive 49 weeks of standard chemotherapy with doxorubicin, vincristine, cyclophosphamide, and dactinomycin or experimental therapy with these four drugs alternating with courses of ifosfamide and etoposide. A total of 518 patients, of whom 120 patients had metastatic disease, were treated on this protocol. Of the metastatic patients, 62 were randomly assigned to the standard therapy group and 58 to the experimental therapy group. There was no significant difference in 5-year EFS rate between the treatment groups (P = 0.81). Among the 398 patients with nonmetastatic disease, the mean 5-year EFS rate among the 198 patients in the experimental therapy group was 69%, compared with 547 among the 200 patients in the standard therapy group (P = 0.005). The overall survival rate was also significantly better among patients in the experimental therapy group (72 percent versus 61 percent in the standard therapy group, P = 0.01). Thus, although no benefit from the addition of ifosfamide and etoposide to metastatic patients was demonstrated, substantial improvement in nonmetastatic patients was observed. Similar results have been reported by others.[312] This drug combination (minus the dactinomycin) is now considered the standard treatment, and two subsequent Children's Oncology Group (COG) protocols looking at intensifying the agents by increasing dose or compressing the interval between cycles have been carried out. The first of these two COG trials (INT-0154) took advantage of hematopoietic growth factors (filfrastim) to a standard five-drug regimen over 48 weeks to an intensified regimen over 30 weeks. Between 1995 and 1998, 492 patients were randomized, and to date, the analysis shows no difference in EFS or overall survival rates in the two arms. The results of this study, headed by Linda Granowetter, M.D., have been published in abstract form only. The successor COG trial (AEWS0031), chaired by Richard Womer, M.D., looked at interval compression of the drug cycles to yield dose intensification. In the experimental arm, patients received their cycles every 2 weeks compared to the standard regimen of every 3 weeks; the total doses of drugs were equal in the two arms. This study opened in 2001 and closed in 2005, and data analysis is pending. Others have tried intensifying treatment for high-risk sarcomas, including ESFT, and have shown that it is effective but associated with substantial toxicity, including death.[313] Adding other drugs such as topotecan or topotecan/cytoxan combinations to a five-drug regimen and the use of myeloprotectants were recently shown to yield no improvement in high-risk patients. Topotecan alone had limited activity in patients with Ewing's sarcoma or primitive neuroectodermal tumor that were metastatic at diagnosis.[314] A topotecan-cyclophosphamide combination was active, but overall results showed no improvement compared with previous studies.

Patients with metastatic disease at presentation have a much worse prognosis, and more aggressive therapies are directed toward them. Metastases most commonly involve the lung, but other bone, bone marrow, and other organ metastases can occur. Unfortunately, treatment regimens for these patients have not been very successful to date. Patients with metastases to the lung have a better survival rate (34% at 8 years, compared to 17% at other sites).[315] There is no apparent benefit to adding ifosfamide and etoposide in these patients, as was noted previously. Attempts have been made to intensify therapy by using autologous stem cell transplantation, but no definitive improvements have been seen.[316] Other studies in cooperation with cooperative groups in Europe are ongoing to look at stem cell transplantation or whole-lung irradiation in patients with lung metastases only. For patients with metastases, treatments with antiangiogenic drugs (celecoxib and low-dose vinblastine) are being tried in combination with standard chemotherapy.

Survival after Recurrence of Ewing's Tumor

Although the outcome is generally poor for patients who experience recurrent Ewing's sarcoma, certain patient subgroups could differ appreciably in their likelihood of survival, as has been shown in studies in the United States and Europe. Patients who relapse have a very poor outcome, depending on time of relapse following completion of initial treatment (the longer since treatment, the better the prognosis). Patients who have recurrences 2 or more years after diagnosis have a significantly better outcome compared to patients with earlier recurrence.[317,318]

A review of the St. Jude Children's Research Hospital experience between 1979 and 1999 included consecutive institutional protocols (ES-79, ES-87, and EW-92).[318] A retrospective medical chart and database review was performed to identify patients and disease characteristics at the time of diagnosis of Ewing's tumor and at the time of recurrence and to record the treatment that was received and the outcome after recurrence. Seventy-one patients were identified, 34 (47.9%) having distant recurrence, 25 (35.2%) having local recurrence, and 12 (16.9%) having both distant and local recurrence, all at a median of 1.7 years after diagnosis. The probability of a 5-year postrecurrence survival was 17.7% ± 4.5%. Interestingly, however, recurrence 2 years or more after diagnosis predicted a significantly better outcome (5-year postrecurrence survival rate: 34.9% ± 8.5%) compared with earlier recurrence (5.0% ± 2.8%; P < 0.001). Patients who had both local and distant recurrences fared more poorly, with a 5-year postrecurrence survival rate of 12.5% ± 8.3%, compared with patients who had local recurrence alone (21.7% ± 7.8%) or distant recurrence alone (17.6% ± 6.1%). Among patients with local recurrence alone, those who underwent salvage procedures with radical surgery had a significantly higher 5-year postrecurrence survival rate (31.4% ± 11.6%) compared with the other patients (9.1% ± 6.1%; P = 0.023). Pulmonary radiation also significantly improved the outcome of patients with isolated pulmonary recurrence (5-year

postrecurrence survival rate: 30.3% ± 12.5% versus 16.7% ± 10.8%; $P = 0.018$). The authors concluded that favorable outcomes are most likely among patients who experience recurrence 2 years or more after diagnosis and among patients who have local recurrence that can be treated with radical surgery and intensive chemotherapy.

Similarly, Catterill and coauthors,[319] in an analysis of 975 patients from the European Intergroup Cooperative Ewing's Sarcoma Study group, documented a relationship between survival and length of time before recurrence. Patients who relapsed within 2 years of diagnosis had a less favorable prognosis than those who relapsed later (5-year survival after relapse, 4% versus 23%, respectively; $P < 0.0001$), findings similar to those observed in osteosarcoma patients.

Local Control

Traditionally, local control for patients with Ewing sarcoma of bone has been radiation therapy. Now that patients are surviving longer, however, late effects such as growth disturbances in children, fractures of irradiated long bones, local recurrence, and secondary malignancies have caused a rethinking of this modality as the routine method of local control. Developments in surviving patients have led to a reassessment of the role of surgery in providing management of the primary tumor with sustained local control and minimal risk of developing a secondary malignancy. Several factors have led to a rethinking of local control recently. There is a definite local recurrence rate with radiotherapy alone as local control.[320,321] Improved combination neoadjuvant chemotherapy results in a marked reduction in the soft-tissue mass in most cases, and this often improves the feasibility of surgical resection and reconstruction. The outcome of limb salvage surgery has improved, allowing surgeons to achieve functional reconstructions and soft-tissue closure without a high complication rate that would delay chemotherapy. Finally, the risk of combined chemotherapy and radiotherapy for development of late secondary malignancies within the radiation portal and tumor bed of surviving patients have led many centers to prefer surgical local control. Several uncontrolled studies reporting an improved event-free and overall survival for patients who receive resection of the involved bone for Ewing's tumors and improvements in endoprostheses and allograft reconstructions for bone tumors in general have led to an increase in the number of patients who are treated surgically. Although no difference in survival or local control of the Ewing's tumor has been conclusively shown, resection and the avoidance of radiotherapy should reduce the incidence of second malignancy that is reported to occur in 5% to 20% of patients who are treated with chemotherapy and irradiation. Several older, noncontrolled studies have shown a benefit to surgical resection for local control.[322–324]

The radiotherapy data from the Pediatric Oncology Group 8346 Study determined that patients who had appropriate radiotherapy after induction chemotherapy with no deviations of radiation therapy had a 5-year local control rate of 80%.[325] Patients who were discovered to have minor deviations from appropriate radiotherapy had a 5-year local control rate of 48%, and those with major deviations had a 16% 5-year local control rate. The local control rate for the 21 patients who had a surgical resection with wide margins and an additional 16 patients (total 26%) who required postoperative radiation therapy with inadequate margins was also approximately 80%.

Donaldson and colleagues[325] reviewed the end results of POG #8346, evaluating 178 eligible patients, of whom 141 (79%) had only local disease and 37 (21%) had metastatic disease. Thirty-seven patients with localized disease underwent local resection, and 16 (43%) of those required postoperative radiotherapy. The 5-year EFS rate for the surgical patients was 80%. The remaining 104 patients with local disease were eligible for randomization or assignment to receive radiotherapy. The 5-year EFS rate for these patients was 41%. The 5-year local control rate for the surgical patients, either with or without postoperative radiotherapy, was 88%, while the rate for the patients who underwent radiotherapy alone was 65%. The quality of the radiotherapy correlated with outcome. Patients who had appropriate radiotherapy (treatment of appropriate volumes) had a 5-year local control rate of 80%, while those with minor deviations had a 5-year local control rate of 48%, and those with major deviations had a local control rate of only 16%. The local failure was within the irradiated volume in 62% of patients and outside the irradiated volume in 24% of cases. It was clear that adequate radiotherapy requires treatment to appropriate volumes, as defined by high-quality MRI images and full radiation doses.

Data reported from the Rizzoli Institute on 124 patients with nonmetastatic Ewing's sarcoma also concluded that surgery or surgery plus radiation therapy appeared to have a better overall patient outcome than did radiation therapy alone.[326] For patients with primary lesions presenting within the pelvis, surgery did not appear to modify the local recurrence rate (43% with radiation therapy alone versus 33% with surgery and radiation therapy). For tumors that presented in the extremities and/or other bones, local recurrences were observed in patients who were managed by surgery plus radiation therapy. Recurrence rates for those who received radiation therapy alone were 30% local recurrence in the extremities and 18% in other sites. The authors theorized that small foci of persistent tumor remaining within the primary tumor after radiation therapy might be responsible for relapse when the primary tumor was not resected.

Analysis of 62 patients entered on IESS-I who presented with nonmetastatic Ewing's sarcoma of the pelvis illustrated the benefits of surgery.[327] Other reports that demonstrate improved local control in surgically treated patients include those by Wilkins and colleagues[328] from the Mayo Clinic, Jürgens and coworkers[329] from Germany, and Sailer and associates[330] from Boston.

It has been suggested that this observed benefit of surficial resection is due to smaller tumor size. Göbel and associates[331] concluded that the improved prognosis that is enjoyed by patients managed by surgery was due in part to a biased distribution of smaller tumor volumes. It appeared that more patients with smaller tumors were being managed by surgical therapy. The majority of recent clinicopathologic studies have shown improved local control with the addition of surgery.[332,333]

Histopathologic response to chemotherapy appears prognostic for reduced local recurrence and/or improved survival; this finding is of major importance and similar for patients with osteosarcoma. Picci and coauthors[334] reported their results of treatment of 118 patients with primary biopsy-proven, nonmetastatic Ewing's sarcoma of the extremities. The response to chemotherapy was evaluated from the specimens of 118 Ewing's sarcoma patients, and their outcomes were correlated with the histopathologic response. For patients who achieved 100% necrosis (grade III), the estimated 5-year disease-free survival rate was 95%, in contrast to 68% for patients with a grade II (microscopic viable tumor) and 34% for patients with a grade I (macroscopic tumor) response ($P < 0.0001$). The researchers concluded that histopathologic response to chemotherapy had the greatest correlation to clinical outcome when compared with other parameters, such as size of the primary tumor and age of the patient. Local recurrence occurred in 2 of 37 grade III responders, in 10 of 35 grade II responders, and in 31 of 46 grade I responders.

Patients who present with primary tumors of sacrum, pelvis, and spine have a poor prognosis. The overall impact of operative treatment on outcome or survival of patients with Ewing's sarcoma of the pelvis or sacrum has been debated.[335]

Paulussen and colleagues[336] described the final results of the CESS 86 study that was aimed at improving EFS in patients with high-risk, localized Ewing's tumor of bone. Patients with small (<100 mL) extremity tumors were classified as standard-risk patients ($N = 52$), and patients with tumor volumes of greater than 100 mL ($N = 177$) and/or central-axis tumors (skull, shoulder, chest, spine, pelvic bones; $N = 164$) were classified as high-risk patients ($N = 241$). Eight patients could not be classified on the basis of these criteria. Local therapy was surgery for 68 patients (23%), surgery and radiation for

146 patients (49%), and radiotherapy alone for 82 patients (28%). The 10-year EFS rate was 52%. The EFS rate did not differ between the high-risk and standard-risk therapy groups. Tumor volume greater than 200 mL and poor histologic response had a negative impact on EFS. In multivariant analyses, small tumor volumes of less than 200 mL, good histologic response, and intensive chemotherapy argued for a fair outcome.

Bacci and coworkers[337] retrospectively reviewed 91 consecutive patients who were treated for Ewing's sarcoma of the femur in an attempt to eliminate selection bias toward those treated with surgery with or without radiotherapy and those treated by radiotherapy alone at other locations. The probability of survival without local recurrence was significantly higher ($P = 0.01$) for patients who were treated by surgery with or without radiotherapy (88%) than for patients who received radiotherapy alone (59%). The 5- and 10-year overall survival rates were 64% and 57%, respectively.

Surgical treatment of patients with Ewing's sarcoma arising in pelvic bones has improved, principally because of improved imaging techniques, improved neoadjuvant chemotherapy regimens, and an improved surgical understanding of the disease. Frassica and coauthors[338] reviewed 21 patients with nonmetastatic Ewing's sarcoma of the pelvis. Thirteen of the 21 received chemotherapy and radiation therapy, and 8 received chemotherapy and local operative resection with or without postoperative radiotherapy. The actuarial 5-year overall survival rate for patients who had chemotherapy and radiation therapy without surgical resection was 25%, while patients who had a surgical resection had a 75% survival rate ($P < 0.005$, log-rank method). The actuarial overall 5-year survival rate was 45% for patients who presented without evidence of metastases. The rate of local failure was 44% for the group that was managed by chemotherapy and radiation therapy alone, compared with 13% for patients with a local resection ($P > 0.25$, log-rank method).

All of these studies suffer from selection bias. One criticism is that the large, bulky tumors are treated with radiotherapy and the small ones are treated by surgery. Size alone, however, is not the sole determinant of who is eligible for an operation and who is not. Response to neoadjuvant chemotherapy and the precise location of the tumor are also important, and these factors have not been adequately controlled in the retrospective data that exist today. For instance, a large, bulky tumor of the ilium might be easily resectable after induction chemotherapy with little morbidity, whereas a small periacetabular tumor might be selected for radiation because we do not have good reconstruction options after removing the acetabulum. This type of bias is present in the published data. In the Grier study,[311] 38% of patients had surgery alone, 39% had radiation alone, and 23% had both. Whereas surgery alone had a better EFS in extremity tumors, there was no difference in the EFS for the pelvic tumors, suggesting that surgery alone is not the prognostic factor. It is unlikely that we will ever have a randomized study to address this issue, but the current practice in most centers is to attempt a resection whenever it is deemed possible to do so with negative margins and a good functional result. Other patients receive radiation. The prime reason for surgery is not local control in these cases, but avoidance of secondary malignancy in the survivors.

Shamberger and colleagues[339] reported the results of treatment of 98 of 869 patients (11.3%) who had primary tumors of the chest wall. The median follow-up was 3.47 years, and the 5-year EFS rate was 56% for chest wall lesions. Ten of 20 (50%) initial resections resulted in negative margins, compared with 41 of 53 (70%) negative margins with delayed resections after chemotherapy ($P = 0.043$). The EFS rate did not differ by timing of surgery ($P = 0.69$) or type of local control ($P = 0.17$). Initial chemotherapy decreased the percentage of patients who needed radiotherapy. Seventeen of 24 patients (70.8%) who had initial surgery received radiotherapy, compared with 34 of 71 patients (47.8%) who started with chemotherapy ($P = 0.061$). In cases of delayed operation, excluding patients who received only radiation therapy for local control, only 25 of 62 patients needed radiotherapy (40.3%; $P = 0.016$). The authors concluded that complete tumor resection with a negative microscopic margin and consequent avoidance of external beam radiation and its potential complications are increased with neoadjuvant chemotherapy and delayed resection of chest wall Ewing's sarcoma/primitive neuroectodermal tumor.

Current Guidelines for Surgical Therapy

All active multimodality Ewing's sarcoma protocols have provisions and recommendations for surgical resection in an effort to avoid the late effects of therapy when possible. It is routine to encourage resection of "expendable" bones. These include the rays of the hands and feet, the proximal four fifths of the fibula, the pubis and ilium of the pelvis, the ribs, the distal four fifths of the clavicle (Fig. 96-17), the body of the scapula, and other small, well-localized lesions. The majority of these procedures should not require reconstruction, which is best avoided, owing to the occasional need for adjuvant radiation therapy to the surgical bed and prolonged intensive adjuvant chemotherapy.[340] Surgical resection should be considered after induction chemotherapy in patients who present with small primary lesions of the metacarpals or metatarsals, when a ray amputation with a minimum of a wide margin may render the patient free of disease. In general, the hand and the foot do not tolerate radiotherapy well. Small midtarsal lesions and lesions that arise in the os calcis can sometimes be treated with radiation therapy in the mature skeleton, but the majority of larger lesions in skeletally immature patients are better managed by Syme's amputation or distal tibiotalar disarticulation or a below-knee amputation.

Commonly, the proximal four fifths of the fibula can be resected with satisfactory margins, aiming to leave at least 6 cm or more distally for satisfactory ankle function, and little or no morbidity results. A tibiofibular synostosis should be performed in skeletally immature patients to prevent proximal migration of the lateral malleolus. A report of five children with nonmetastatic Ewing's sarcoma of the distal fibula suggests that distal fibulectomy yielded near normal functional results, with a mean follow-up of 8 years.[341]

Lesions of the tibia that are deemed suitable for resection can be reconstructed with prostheses or allografts, as is described for osteosarcoma. Intercalary resections can be reconstructed with allografts or vascularized autografts (Fig. 96-18). Allografts or endoprostheses can also be used to reconstruct the shaft of the femur as an alternative to amputation.

Destructive lesions about the proximal femur and acetabulum can be managed by resection and reconstruction in cases in which pathologic fractures and poor joint function following radiation could be anticipated. Modular endoprostheses or allograft/prosthetic composites can be used to reconstruct the hip and proximal femur in patients for whom abduction function can be retained reliably.

Rib primaries are best managed by excision following preoperative chemotherapy to decrease the size of the soft-tissue mass and reduce the likelihood of contamination of the pleural cavity. A wide resection of the recommended entire rib and surrounding soft tissue is completed after induction chemotherapy. In most instances, this approach will eliminate the need for radiation or at worst reduce the amount of chest wall and lung that require radiation.[342]

Primary tumors presenting in the body of the scapula that preserve the glenoid structures and the chest wall can be resected without significant functional deficit. Lesions that present in the region of the glenoid are managed by radiation therapy or by resection/arthroplasty. Small lesions in the acromion and in the spine of the scapula might also be amenable to excision. Ewing's sarcoma of the clavicle can be resected without significant physical impairment.

Resection of the proximal humerus and reconstruction are associated with loss of active abduction if the deltoid and rotator cuff require resection, but reconstruction with endoprostheses (Fig. 96-19) and osteoarticular allografts or allograft-prosthetic composites offer decent function. The anticipated functional loss

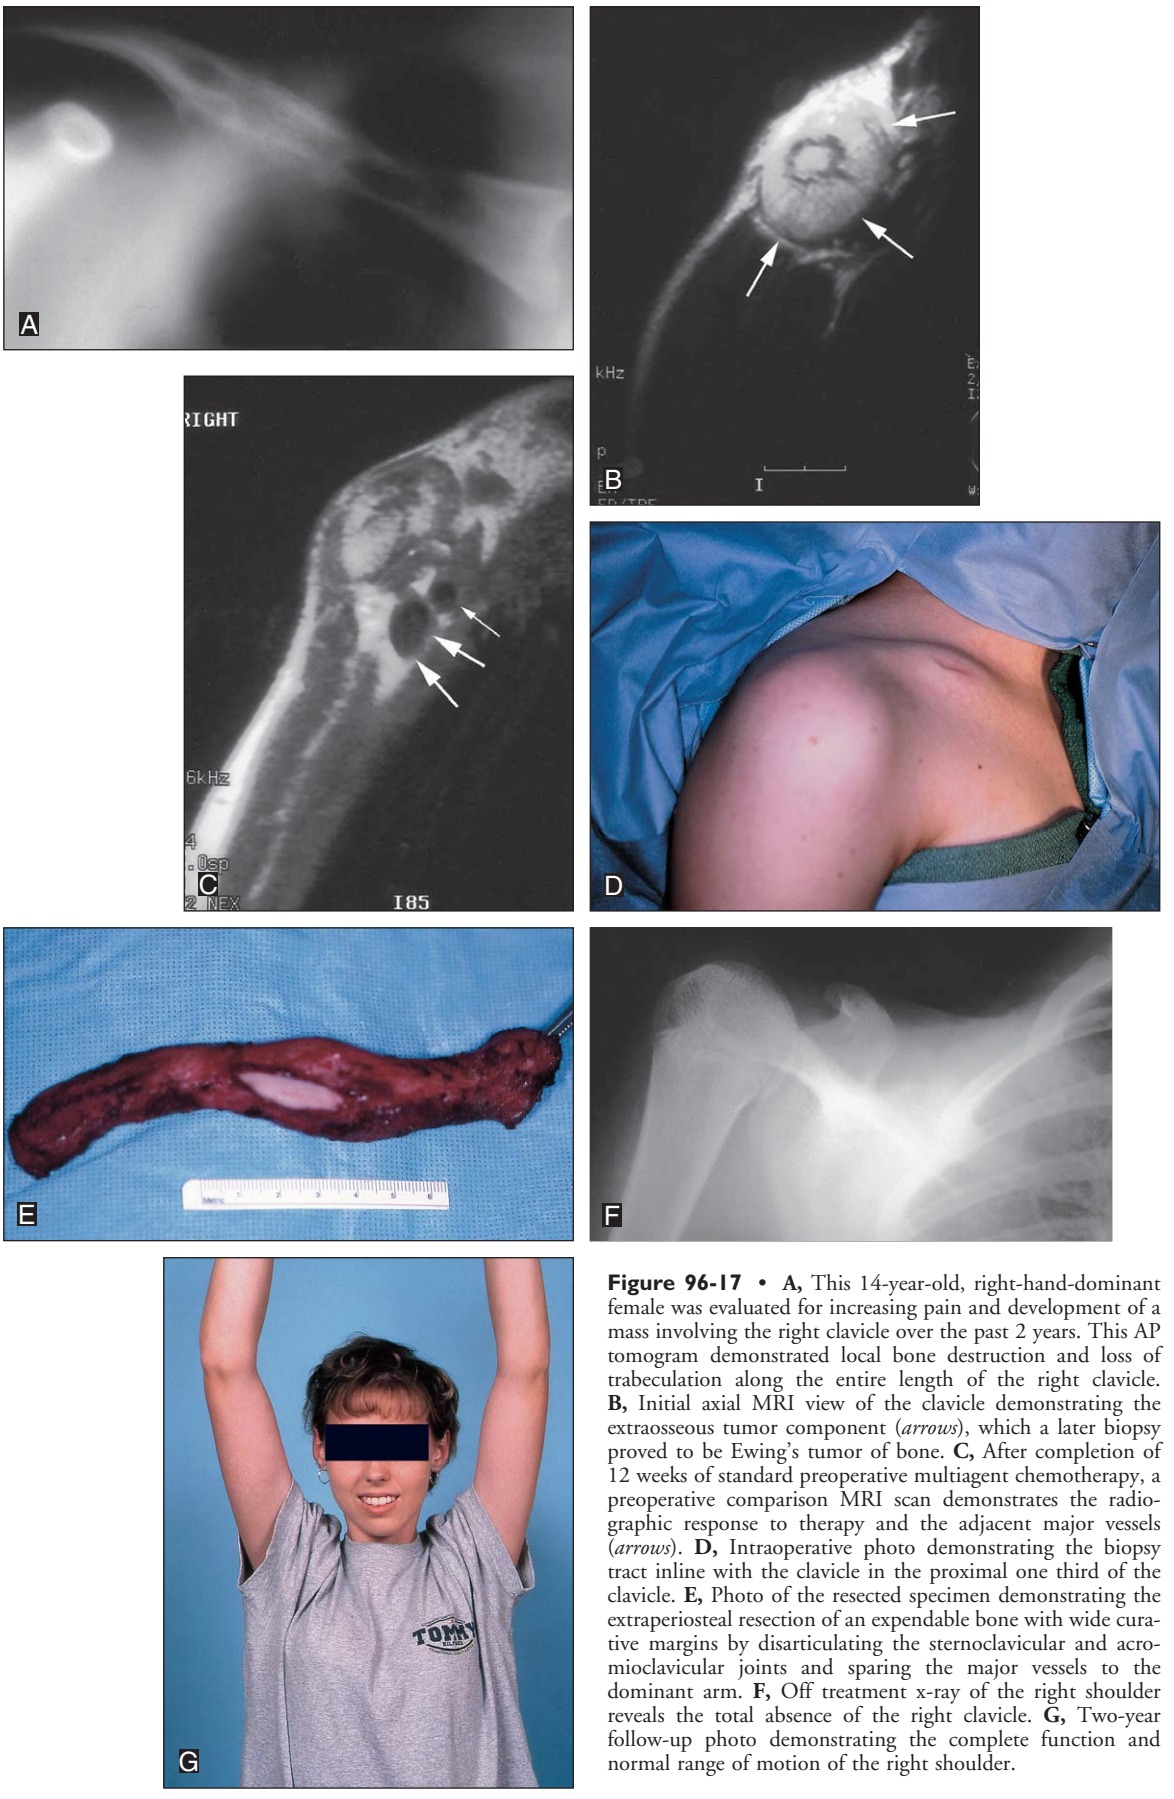

Figure 96-17 • **A,** This 14-year-old, right-hand-dominant female was evaluated for increasing pain and development of a mass involving the right clavicle over the past 2 years. This AP tomogram demonstrated local bone destruction and loss of trabeculation along the entire length of the right clavicle. **B,** Initial axial MRI view of the clavicle demonstrating the extraosseous tumor component (*arrows*), which a later biopsy proved to be Ewing's tumor of bone. **C,** After completion of 12 weeks of standard preoperative multiagent chemotherapy, a preoperative comparison MRI scan demonstrates the radiographic response to therapy and the adjacent major vessels (*arrows*). **D,** Intraoperative photo demonstrating the biopsy tract inline with the clavicle in the proximal one third of the clavicle. **E,** Photo of the resected specimen demonstrating the extraperiosteal resection of an expendable bone with wide curative margins by disarticulating the sternoclavicular and acromioclavicular joints and sparing the major vessels to the dominant arm. **F,** Off treatment x-ray of the right shoulder reveals the total absence of the right clavicle. **G,** Two-year follow-up photo demonstrating the complete function and normal range of motion of the right shoulder.

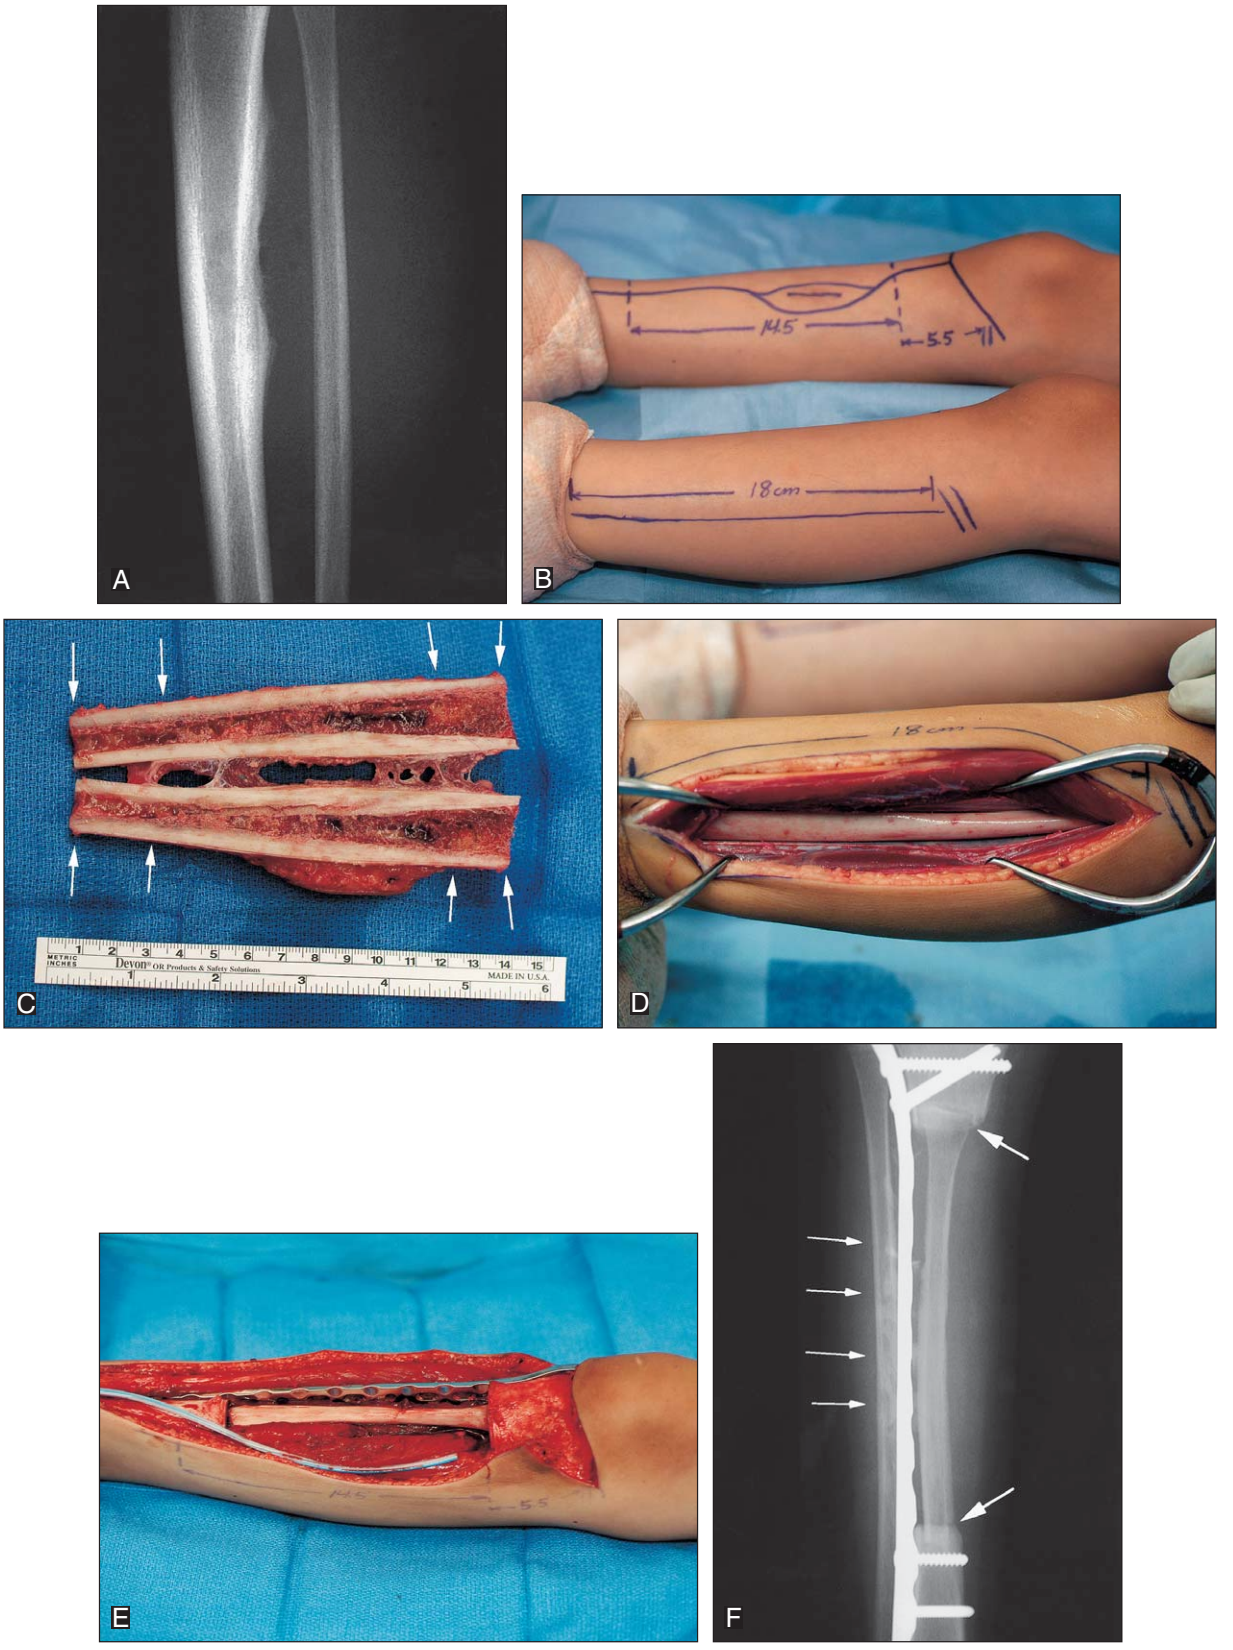

Figure 96-18 • **A,** Lateral x-ray of the right leg of a 7-year-old white male demonstrating a destructive lesion in the diaphysis, later proven to be Ewing's sarcoma. The patient was found to be otherwise free of disease. **B,** After completing 12 weeks of standard preoperative multiagent chemotherapy, a restaging MRI suggested an excellent response, with evidence of a normal marrow signal both proximal and distally to the diaphyseal tumor. The choice was made to proceed with a resection of 14.5 cm of the midshaft of the right tibia, sparing 5.5 cm of proximal tibia and reconstructing the surgical defect with an 18-cm left free fibular graft. **C,** The surgical resection specimen was taken to the back table and split to be certain that the proximal (*right arrows*) and distal intramedullary margin (*left arrows*) were appropriate. **D,** With the use of separate gowns, gloves, and instruments, a free avascular fibular graft was obtained from the left midshaft fibula with iliac crest graft as well. **E,** Intraoperative photo illustrating the fibular graft in place and secured with a bone plate. Iliac crest autologous graft was used to augment the proximal and distal host/graft bone juncture. **F,** Six-month postoperative x-ray demonstrating the developing synostosis between the fibula and free fibular graft (*small white arrows*) and healing of the proximally and distally host-graft bone junctures (*single arrows*).

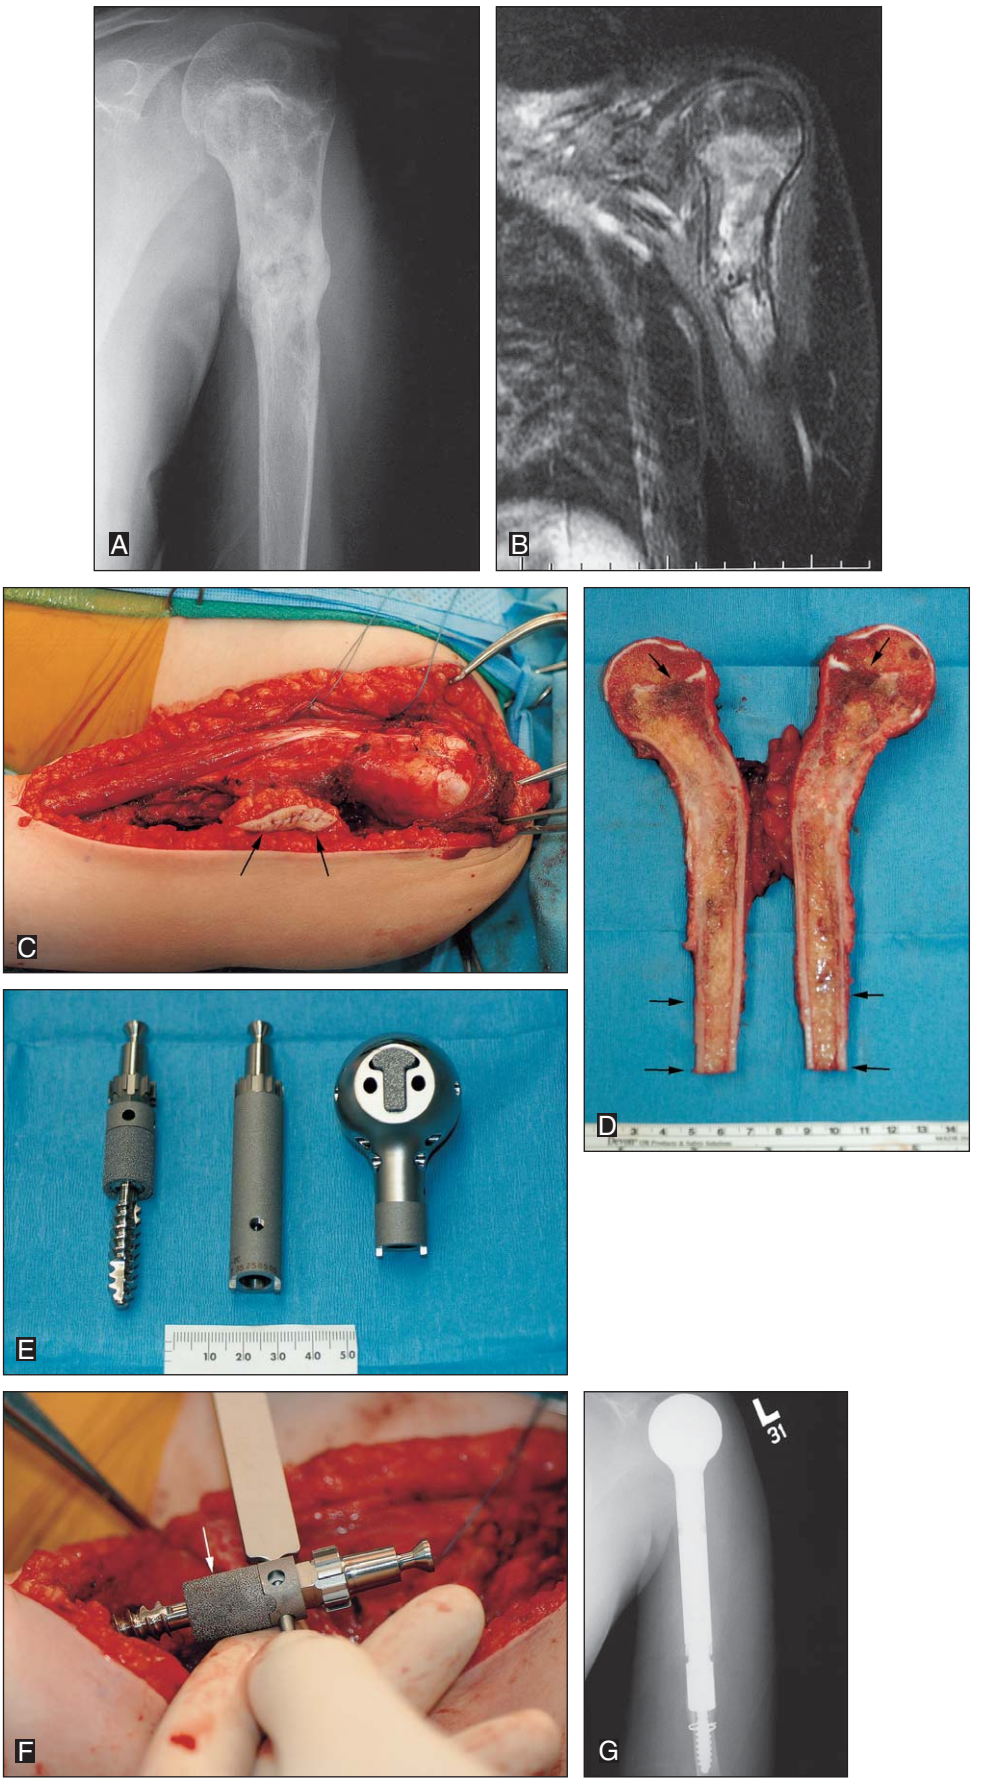

Figure 96-19 • **A,** Internal rotation AP x-ray demonstrating an attempt at healing of a pathologic fracture through a previously irradiated Ewing's sarcoma of the left nondominant humerus of a 12-year-old female after completion of chemotherapy. **B,** The coronal MRI better demonstrates a nonunion and angulation. There was a clinical concern regarding persistent tumor in the proximal humerus. After a prolonged period of conservative care, the choice was made to proceed with resection and reconstruction using a custom modular titanium prosthesis. **C,** Intraoperative view demonstrating the circumferential anterior exposure of the proximal two thirds of the humerus, sparing the rotator cuff and radial nerve. The *arrows* identify the contiguous previous biopsy incision and the humerus to provide an en bloc "wide" resection. **D,** Once removed, the specimen is split to confirm appropriate margins distally (2.5 cm; *arrows*). Note the closure of the epiphysis in the humeral head after external beam radiotherapy (*arrow in humeral head*). **E,** Custom modular titanium prosthesis designed and constructed using tantalum trabecular metal to allow bone ingrowth, promote extracortical fixation of the implant-host juncture, and allow for soft-tissue reattachment to the humeral head. **F,** Intraoperative view demonstrating securing of the implant to bone using a screw design to bring the tantalum trabecular metal (*arrow*) into juxtaposition with the shaft of the resection margin to promote extracortical bone bridging. **G,** Postoperative x-ray demonstrating the construct after reconstructing the rotator cuff to the implant and closure.

should be compared to the potential risks of radiation for local control. In general, functional deficits and limb length inequalities are better tolerated in the upper extremity than in the lower extremity. Preservation of a functional hand is the key measure of success.

Well-localized lesions presenting in the pelvis that are responsive to neoadjuvant chemotherapy—primarily those that are confined to the ilium and the pubis—are often resectable (Fig. 96-20). Also, tumors that arise in the lower portion of the sacrum and coccyx are amenable to sacral amputation with minimal neurologic sequelae. Before undertaking these technically demanding procedures, however, the surgeon should carefully consider the anticipated difficulty of resection and the resultant physical deficit. (See the later discussion

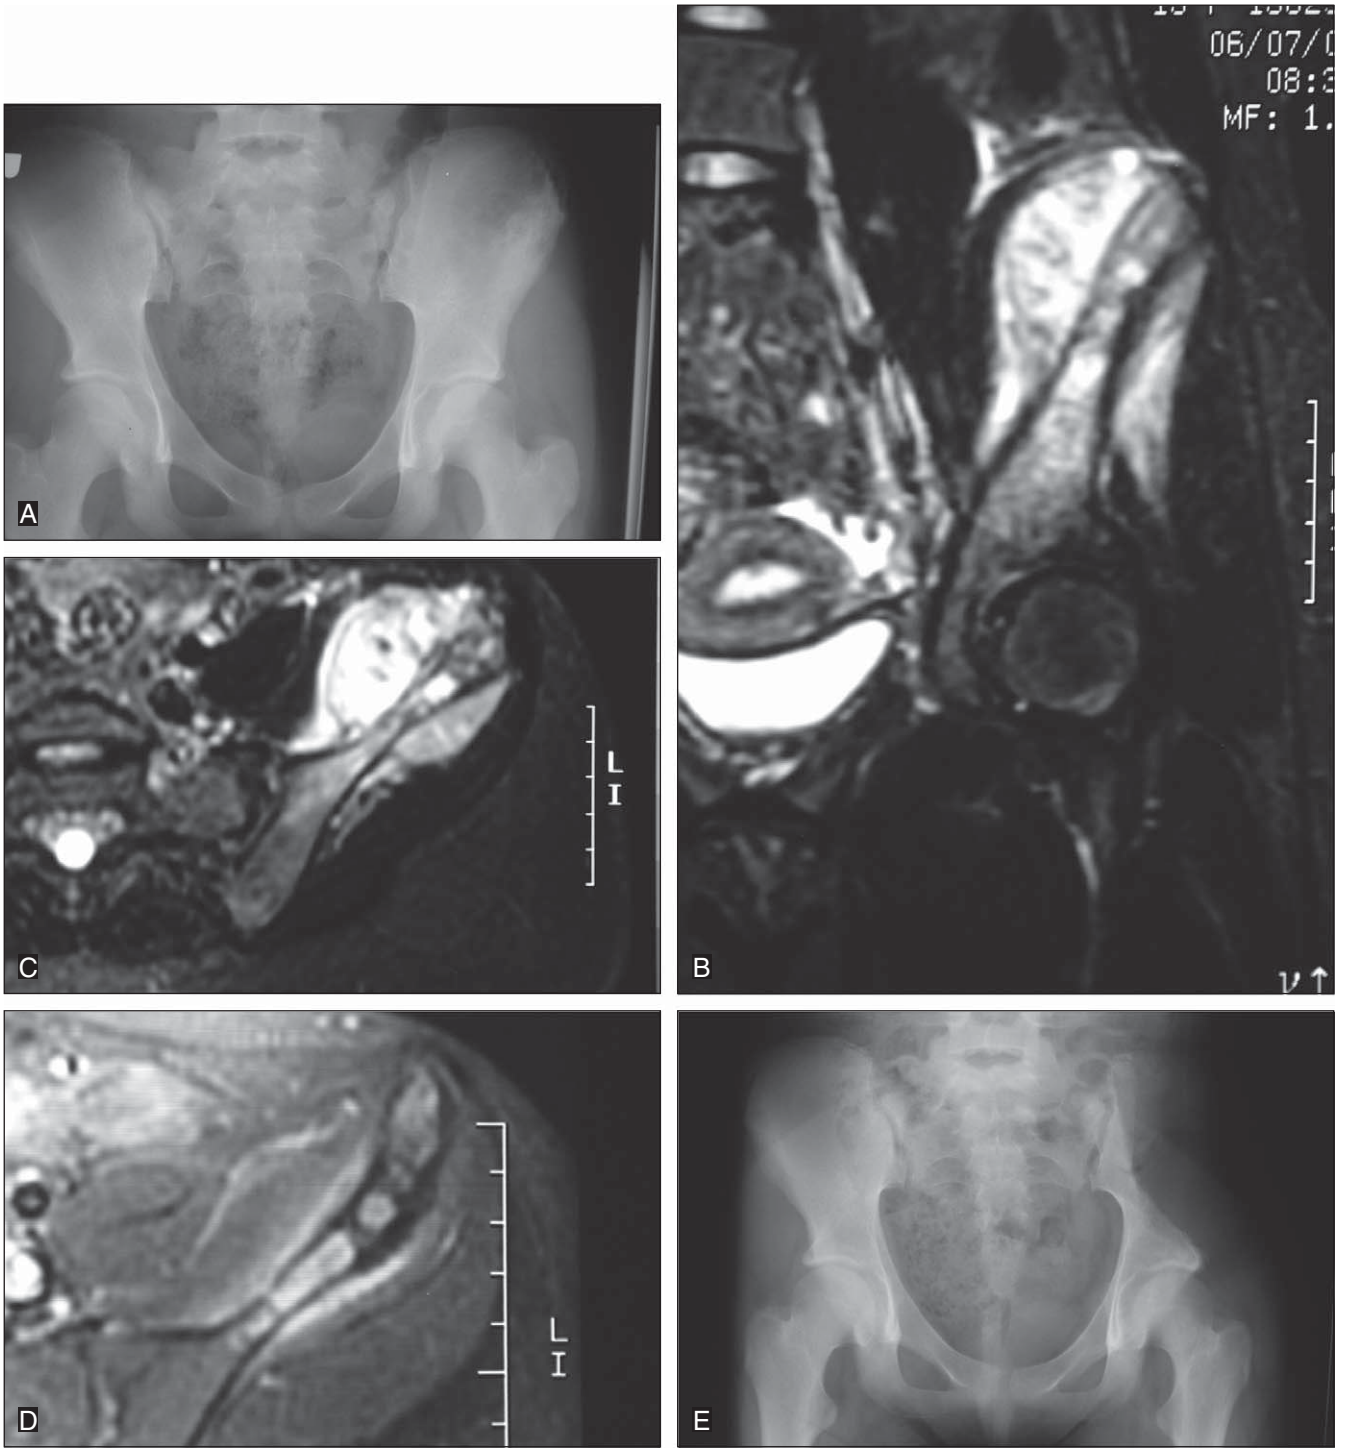

Figure 96-20 • **A,** AP radiograph of a 14-year-old girl with Ewing's sarcoma of the iliac wing. **B** and **C,** Coronal and axial MRI images at diagnosis show the extent of the soft-tissue and medullary tumor. **D,** Axial MRI following neoadjuvant chemotherapy showing a good response and near complete resolution of the soft-tissue mass. The acetabulum was thought to be free from tumor. **E,** Postoperative radiograph following resection of the iliac wing with preservation of the acetabulum. The margins were negative, and no postoperative irradiation was employed. The patient has remained free of disease for more than 5 years.

on sacral chordoma.). The most difficult site of resection is the acetabulum and upper sacrum. There are currently no decent reconstruction options for complete resection of the acetabulum, especially if the entire hemipelvis is resected. Attempts can be made to use pelvic allografts, but the rates of infection and other complications are high, especially if the soft tissues are of poor quality. This is often the case because of the extent of the soft-tissue mass and the need for radiation therapy.[189,343–345] The debate regarding whether or not the addition of surgery improves survival remains unanswered. There have been no randomized studies to address this issue. Several single-institution studies show an advantage to surgical resection, where others fail to show benefit (see previous discussion). In the Grier study,[311] the EFS and overall survival rates were similar for pelvic lesions irrespective of whether the primary was treated with surgery, radiation, or a combination of both. In the nonmetastatic patients in the study reviewed by Yock and colleagues,[346] 75 patients with pelvic tumors were treated and followed a median of 4.4 years. Twelve patients underwent surgery, 44 received radiation therapy (RT), and 19 received both. The 5-year EFS rate and cumulative incidence of local failure were 49% and 21%, respectively (16%, local failure only; 5%, local failure and distant failure). There was no significant difference in EFS or local failure by tumor size (<8 cm versus ≥8 cm), local control modality, or chemotherapy. The addition of ifosfamide and etoposide did, however, appear to positively influence local control. Patients who were treated with VACA-IE had 11% local failure versus 30% with VACA alone.

The author's bias is to resect pelvic lesions that can be done with little functional loss (Enneking Type I and III lesions), but resections that require resection of the acetabulum are probably best treated by irradiation. This obviously requires detailed discussion with the patient and his or her family by the surgeon, radiation therapist, and oncologist. The main benefit of resection is avoidance of secondary tumor. Since many of these patients who are treated with resection of the pelvis will require radiation and their prognosis is poorer than that of Ewing's sarcoma at other sites, the advantages of operative treatment are less clear and must be balanced with the morbidity of the given operation. This is also true for lesions of the upper sacrum. It may be possible to resect the lesion, but the potential loss of bowel, bladder, and sexual function should be carefully weighed against the alternative of radiation therapy.

It is advantageous in considering operative treatment for any site that a good response to chemotherapy be demonstrated. Signs of a satisfactory tumor response include a significant decrease in pain, a nearly complete regression in size of the lesion as shown by MRI, healing of a pathologic fracture, and improved range of near-painless motion of nearby joints. The fact that the patients who demonstrate these characteristics are the patients who are most likely to be deemed surgical candidates, whereas the lack of a response often leads to the use of radiation for local control, could explain the selection bias favoring surgical resection in the literature.

Amputation

Although the role of amputation in the surgical management of Ewing's sarcoma is limited, primary amputation or disarticulation might offer a clinical option that is superior to the prolonged morbidity associated with pathologic fracture or severe limb length inequality, which can result in late or delayed amputation. Lesions of the feet and distal tibia are excellent candidates for amputation. Large destructive lesions in males under the age of 10 years and in females under the age of 8 years can be managed by primary amputation or a primary limb-sparing option (rotationplasty, etc.). With the advent of expandable prostheses, many limbs are now reconstructed by that approach, although the long-term outcomes of these prostheses is still not well known. Amputation should be considered when epiphysiodesis of the opposite limb does not provide a reasonable treatment option to approach equalization of lower-extremity lengths at skeletal maturity.[347]

Prognosis

Location

Clearly, location of the primary lesion in patients with nonmetastatic disease has a profound relationship to long-term survival. Patients with lesions arising below the elbow and below the midcalf who are treated appropriately have 5-year survival rates approaching 80%. Large, bulky lesions that present in the pelvis in nonresectable sites yield 5-year survival rates of less than 25%.[338]

Histopathologic Response to Chemotherapy

Location and size of the primary lesion, however, are not the only determinants of survival. The histopathologic response of the tumor to neoadjuvant chemotherapy has been shown to be important in predicting outcome.[348] Patients completing systemic neoadjuvant chemotherapy and managed by surgical resection are evaluated by using a pathologic grading system independent of change in tumor volume. The resected specimens are sectioned and mapped for review to determine the extent of tumor necrosis. In one study, patients whose specimens displayed complete tumor necrosis with no identifiable foci of tumor tissue (grade III) were projected to have a 90% continuous disease-free survival. Those with lesser degrees of necrosis (grades II and I) were projected to have 53% and 32% 5-year disease-free survival rates, respectively. Of all the variables that were assessed, only grade of tumor necrosis was associated with disease-free survival ($P = 0.004$). There was, however, a trend for tumor volume to be associated with disease-free survival ($P = 0.06$).[348]

Wunder and coworkers[349] reviewed the histopathologic response to preoperative chemotherapy of 74 patients with an operative resection specimen, correlating the response as a predictor of the overall outcome of multimodality therapy. The minimum duration of follow-up was 5 years. The operative specimens were reviewed, and the histopathologic response to chemotherapy was graded semiquantitatively. Grade I represented 50% or less necrosis; grade II, 50% to 90%; grade III, 90% to 99%; and grade IV, 100% necrosis. Of the 74 specimens, 44 (59%) were either grade IV or grade III, while 14 (19%) were grade I, and 16 (22%) were grade II. The two most important predictors of EFS were histologic response to preoperative chemotherapy ($P = 0.0001$), followed by size of the primary tumor ($P = 0.001$). At 5 years, the EFS rate for grade I patients was zero. Grade II responders experienced a 6/16 (37.5%) EFS rate, and for grades III and IV, 37 of 44 patients (84%) experienced a 5-year EFS. The risk of local recurrence was also strongly associated with the quality of the operative margins. There were four local recurrences (6%) after 67 resections that were thought to have negative margins. The authors concluded that histopathologic response to preoperative chemotherapy and size of the primary tumor were the most important clinical predictors of outcome of operative treatment for nonmetastatic Ewing's sarcoma.

Late Effects of Treatment

Functional Results

It is generally accepted that the pathologic and biomechanical changes that are associated with high-dose irradiation of bone include decreased vascularity, cellularity, and bone metabolism, with increased porosity and loss of mechanical strength, impaired fracture healing, and periosteal fibrosis.[350]

The soft-tissue and skeletal effects of irradiation are related to the following factors:

- Skeletal maturity of the patient
- The volume of tissue treated
- The total dose and dose rate
- The energy and delivery system of the beam
- Concomitant chemotherapy treatment
- Inclusion of major joints or growth centers

Robertson and coauthors[351] reported limb length inequalities in 12 of 67 patients surviving childhood cancer who had received radiotherapy. All the children survived to skeletal maturity. Seven of the 12 patients reported symptoms. The development of limb length inequality was shown to be uniformly related to long bone physeal radiation of 45 Gy or greater.

Additional comorbidities include soft-tissue atrophy and fibrosis, joint stiffness, and pathologic fracture of the previously treated bone. Jentzsch and colleagues[352] reported that 9 of 40 patients who completed treatment sustained a pathologic fracture with Ewing's sarcoma of the lower extremity. They found slow and delayed fracture healing, with two patients sustaining refracture. All eventually healed by closed means. Later, Springfield and Pagliarulo[353] reported the results of a retrospective analysis of patients who had received chemotherapy and radiotherapy for primary Ewing's sarcoma of the extremities. Twenty-eight patients were followed for a minimum of 2 years or until their deaths. Seventeen patients had primary lesions presenting in the humerus or femur. All 17 patients received chemotherapy and radiation therapy, with doses ranging from 50 to 60 Gy administered by a shrinking field technique. Two of the eight patients with humeral primaries and five of nine patients with femoral primaries sustained pathologic fractures without significant trauma. Of the five femoral fractures, four were in the subtrochanteric region, and all had a cortical window removed at the time of biopsy. Only two patients developed pathologic fractures through the cortical defect. Springfield and Pagliarulo[353] strongly recommend rebiopsy to assess possible persistent disease, followed by internal fixation and the addition of autogenous bone graft.

Since most patients are now diagnosed by needle or incisional biopsy of the soft-tissue component and the primary is often resected after chemotherapy, the complication of fracture following radiation of long bones is less prevalent.

Late effects of radiation such as muscular atrophy, limb length discrepancy, and development of second malignancy in patients treated for Ewing's sarcoma were reported in one study of patients who were followed at least 5 years from diagnosis. Late effects were seen in 10 of 19 patients (52.6%) who received radiation as local control, 2 of 5 patients (40%) who received surgery and irradiation, and 4 of 16 patients (25%) who received surgery alone. Scoliosis and decreased range of motion of an extremity were seen regardless of local treatment modality. Three patients who had surgery alone had an amputation, whereas two who had RT had an amputation secondary to relapse or development of osteosarcoma.[354]

Although most children who are treated with RT for a pediatric extremity sarcoma have minimal late toxicity, another study of 15 survivors of children with sarcoma reported that late effects were seen in all patients and included atrophy in 12 (80%), fibrosis in 12 (80%), bone growth abnormalities in 10 (67%), impairment of mobility and extremity function in 6 (40%), edema in 3 (20%), and peripheral nerve injury in 2 (13%). The authors noted bone growth discrepancies, muscle and soft-tissue atrophy, and peripheral nerve complications. One patient developed a radial nerve palsy 3 years after marginal resection and postoperative RT and required tendon transfer repair. One patient had radiation-induced vasculitis with popliteal artery thrombosis 23 years after RT. Of particular note was the finding that five patients developed a fracture of the irradiated bone at a median time of 8 years after RT, and three of these patients were subsequently found to have a secondary bone cancer in the radiated field, leading the researchers to conclude that a fracture might be a presenting sign of second malignancy.[355]

The functional results following resection are also significant, but few studies have compared the results of radiation versus surgery of the primary tumor. Clearly, resecting a growth center has growth consequences similar to those of radiating one and, depending on the age of the child, has to be addressed with contralateral epiphysiodesis or an expandable prosthesis. The complications of surgical limb salvage were discussed in the section on osteosarcoma.

Secondary Malignancies

In 1979, Chan and coauthors[356] reported that among 24 patients with primary Ewing's sarcoma of the pelvis who had survived for 5 years, 4 patients developed secondary malignancies within the irradiated fields and died. Three of the four patients also had received intensive chemotherapy. Also, Strong and associates[357] reported an increased hazard of developing secondary malignancy in patients who were treated with radiation therapy, with a cumulative cancer risk of 35% over 10 years. The administration of intensive chemotherapy in five or more courses appeared to exert an enhancing effect, increasing the rate of development of new tumors. Li[358] also reported a 12% risk of developing a new cancer in 15 of 410 patients who survived childhood cancers.

Most recently, Tucker and coworkers[359] estimated the subsequent risk of development of bone cancer in 9170 patients who survived 2 or more years. Data on treatment were evaluated on 64 patients in whom bone cancer developed after childhood cancer. Patients who had received radiation therapy had a 2.7-fold risk of developing a secondary malignancy. The dose response appeared to reach a 40-fold risk after doses to bone of more than 60 Gy. Similar numbers of patients were treated with orthovoltage and megavoltage, and the patterns of risk among categories of doses did not differ according to the type of voltage. Also, after adjustment for radiation therapy, treatment with alkylating agents appeared to increase the subsequent risk of bone cancer.

Coleman[360,361] reported that an average latent period for development of treatment-induced solid tumors was 10 to 15 years, with a 10% actuarial risk at 10 years for pediatric patients. The Late Effects Study Group confirmed the risk in 1985.[362] Smith and associates,[363] summarizing the treatment of 25 long-term survivors of Ewing's sarcoma, reported that one patient developed acute myelogenous leukemia at 15 months and one patient developed osteosarcoma 3 years after treatment. The actuarial risk of developing a second malignancy at 5 years was 8%, with a 4% risk of developing a secondary bone sarcoma.

A study of secondary malignancy in 397 patients who were treated for Ewing's sarcoma at the Mayo Clinic over a 25-year period showed that 26 patients (6.5%) had 29 secondary malignancies develop. The mean age of the patients was 16 years, and the interval from the diagnosis of the Ewing's sarcoma to the development of the secondary malignancy averaged 9.5 years. The secondary malignancies included 8 hematopoietic cancers, 12 sarcomas, and 9 carcinomas. It was observed that the carcinomas most likely represent the general risk of developing cancer in the healthy population but that the sarcomas were caused by radiation therapy, and the hematopoietic tumors were caused by chemotherapy. Hematopoietic malignancies occurred at a mean latent period of 4.8 years (range: 1.7 to 12.9 years), and the sarcomas occurred after a mean of 10.9 years (range: 1.5 to 32.5 years). At the mean follow-up of 5 years (range: 0.5 to 28 years) from diagnosis of the second malignancy, 14 patients were alive (43%); however, patients with sarcomas or hematopoietic secondary malignancies had a poor prognosis.[364] Others have shown that with aggressive therapy, patients with radiation-associated osteosarcomas can have a prognosis similar to that of de novo osteosarcoma,[276] but it is clear that patients with Ewing's sarcoma are at risk for these secondary malignancies and need to be followed frequently and indefinitely.

Future Directions

With evolving and intensified induction and maintenance chemotherapy and improved imaging and patient selection techniques (e.g., MRI, PET), many patients who would not previously have been considered suitable for limb-sparing procedures have become candidates for resection and reconstruction. If the margins are not adequate for local control, postoperative radiation therapy can be administered without significantly altering the result in constructs that do not require bone graft healing and incorporation.

The use of intraoperative radiation therapy, proton beam irradiation, and other advances in radiotherapy and improvements in limb salvage surgery in all sarcomas have improved our ability to achieve local control of the primary. The increasing role of surgical therapy in the local management of patients with Ewing's sarcoma appears to be beneficial with respect to overall disease-free survival and reduction of treatment-related late effects. Adjuvant chemotherapy has dramatically improved the survival of patients with ESFTs. Current efforts are being directed at finding newer chemotherapeutic agents and intensifying therapy to improve outcomes further. The goal is to optimize therapy wherever possible to provide the patient with the best overall clinical and functional results.

MALIGNANT FIBROUS HISTIOCYTOMA OF BONE

MFH of bone is uncommon. The name is being changed to *undifferentiated spindle cell tumor*. It is classified into primary and secondary categories, which are related to the absence or presence of a known predisposing and underlying pathologic entity, such as bone infarction, fibrous dysplasia, or Paget's disease of bone. Some tumors also appear to be associated with orthopedic implants and could be metal-induced.[365]

Epidemiology

Approximately 70% of MFH of bone are primary tumors, and 30% are secondary.[366] There is a slight male predominance. The primary variety tends to affect younger patients, while the secondary neoplasms are seen predominantly in the sixth and seventh decades of life.

Radiographic Features

Pronounced loss of normal trabeculation associated with permeative cortical destruction is the characteristic radiographic appearance. Invasion into adjacent soft tissue with the development of a soft-tissue mass is not uncommon. The proximal tibia and distal femoral metaphyses are most frequently affected, followed by the pelvis, proximal humeral metaphysis, and scapula. A little more than one half of the tumors originate in the lower extremity.[367]

Destructive lesions originating in weight-bearing bones are often only mildly painful and often are discovered when the patient has a pathologic fracture. Periosteal new bone formation and endosteal scalloping are rarely seen in MFH of bone. CT is useful in defining the extent of bone destruction; however, MRI with contrast enhancement of the extremity is the single study of choice to provide maximum data.[368]

Secondary MFH of bone is by definition associated with an underlying or pre-existing condition. There appears to be a clear association with bone infarction as a pre-existing condition. Radiographically, the remaining punctate calcifications can be seen about the periphery of the lesion, with destruction and loss of radiographic detail evident within the lesion. Also, a contiguous soft-tissue mass is commonly present.

Patients with known Paget's disease of bone, hereditary dysplasias of bone, or prior treatment with radiotherapy are at risk to develop secondary MFH of bone. These patients are often older than those who develop the primary subtype.

Pathologic Features

Regardless of the primary or secondary classification, the overwhelming majority of these lesions are high-grade malignancies. Only 10% or fewer are low grade. Histologically, the tumor is composed of fibroblasts in a storiform (whorling or cartwheel) pattern with multinucleated giant cells, inflammatory cells, and histiocytes with numerous foamy mononuclear or multinucleated giant cells (xanthomatous variant). Mitotic figures are frequent, with considerable pleomorphism.

MFH of bone demonstrates immunoreactivity for vimentin, glycoprotein, α_1-antitrypsin, α_1-antichymotrypsin, and the bacteriolytic enzyme lysozyme.[369] These tumors are commonly S-100 negative. Ultrastructurally, the lesions seem to derive from a primitive mesenchymal stem cell that might be shared with the common progenitor cell of osteosarcoma.[369]

Surgical Therapy

Nonmetastatic primary MFH of bone is best managed in a manner similar to that of primary osteosarcoma of adolescents and young adults (Fig. 96-21). After diagnostic biopsy, neoadjuvant chemotherapy can be administered, and the primary tumor response can be monitored by clinical and radiographic parameters. A combination of doxorubicin, ifosfamide, and methotrexate is often used, but currently, there is no agreed-upon regimen. The majority of tumors respond clinically with relief of pain, resolution of the associated joint contracture, diminished local edema, and reduction in the size of the soft-tissue component. Radiographic response to neoadjuvant chemotherapy is best confirmed by a reduction in size of the soft-tissue component and diminished or absent contrast enhancement on follow-up MRI evaluation. Preoperative or neoadjuvant chemotherapy is not a requirement, and an immediate surgical resection is recommended if the patient is at risk of sustaining a pathologic fracture. Whether or not the patient receives preoperative chemotherapy, a "wide" surgical margin is recommended. Usually this can be done without the need for an amputation.

Adamantinoma of Bone

Although similar in name, adamantinoma of bone is not related to ameloblastoma of the mandible derived from Rathke's pouch. First described by Dockerty and Myerding and later refined by Cohn and colleagues[362] from the Mayo Clinic in 1962, this rare, low-grade malignant lesion arises predominantly in the tibia (90%), the next most common site being the fibula.[362,370–372] There is no definite sex predominance, and the majority of tumors appear in the second and third decades of life.

The most common symptom is pain and, later, a mass, most often in the midshaft of the tibia (70%). Radiographically, the lesion is radiolucent, arising within the cortex. It may be multilocular. Over time, it will usually extend into the medullary canal (Fig. 96-22). Adamantinoma is associated with osteofibrous dysplasia, and they often occur together. A wide surgical resection is the treatment of choice. Adjuvant irradiation or chemotherapy is not indicated.

PRIMARY SARCOMAS OF THE SPINE

It is estimated that less than 10% of all primary bone tumors—approximately 1 per million per year—arise in the spine.[373] Metastatic disease to the spine that results in spinal cord compression, on the other hand, approximates 8.5 per 100,000 per year.[374] The vertebral column remains the most common site of developing skeletal metastases, resulting in approximately 20,000 patients per year requiring treatment.[375] Autopsy studies of patients who died of disseminated cancer demonstrated vertebral metastases in 14% to 41%, intradural/extramedullary metastases in 5% to 8%, and intramedullary metastases to the cord in 1%.[376,377] Therefore, metastatic disease must be considered and excluded during evaluation of a patient who is suspected of having a primary bone tumor of the spine.

General Considerations

Symptoms

Back pain is the most common presenting symptom of a tumor of the spine.[378,379] The symptoms are often vague, ill defined, and slow

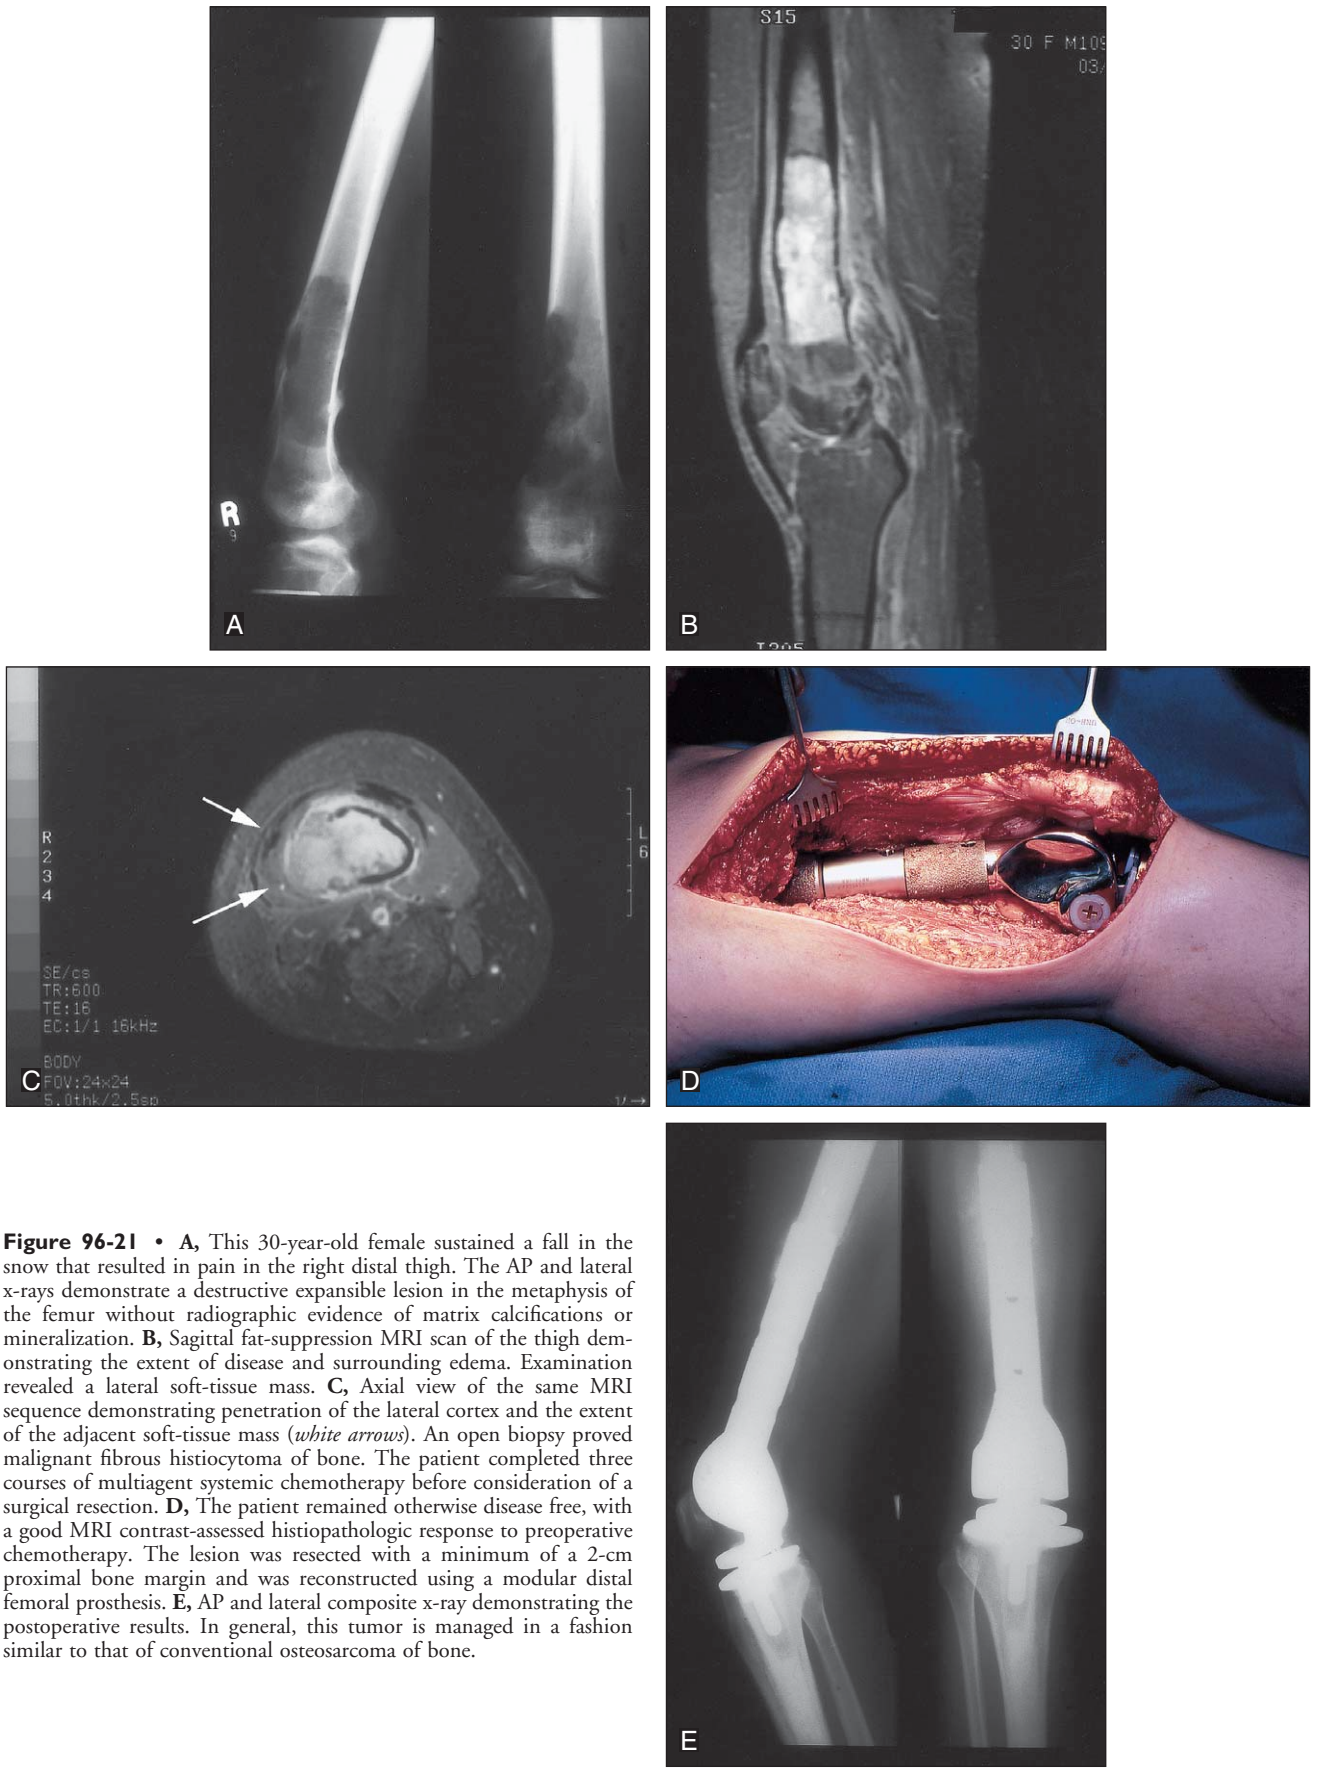

Figure 96-21 • **A,** This 30-year-old female sustained a fall in the snow that resulted in pain in the right distal thigh. The AP and lateral x-rays demonstrate a destructive expansible lesion in the metaphysis of the femur without radiographic evidence of matrix calcifications or mineralization. **B,** Sagittal fat-suppression MRI scan of the thigh demonstrating the extent of disease and surrounding edema. Examination revealed a lateral soft-tissue mass. **C,** Axial view of the same MRI sequence demonstrating penetration of the lateral cortex and the extent of the adjacent soft-tissue mass (*white arrows*). An open biopsy proved malignant fibrous histiocytoma of bone. The patient completed three courses of multiagent systemic chemotherapy before consideration of a surgical resection. **D,** The patient remained otherwise disease free, with a good MRI contrast-assessed histiopathologic response to preoperative chemotherapy. The lesion was resected with a minimum of a 2-cm proximal bone margin and was reconstructed using a modular distal femoral prosthesis. **E,** AP and lateral composite x-ray demonstrating the postoperative results. In general, this tumor is managed in a fashion similar to that of conventional osteosarcoma of bone.

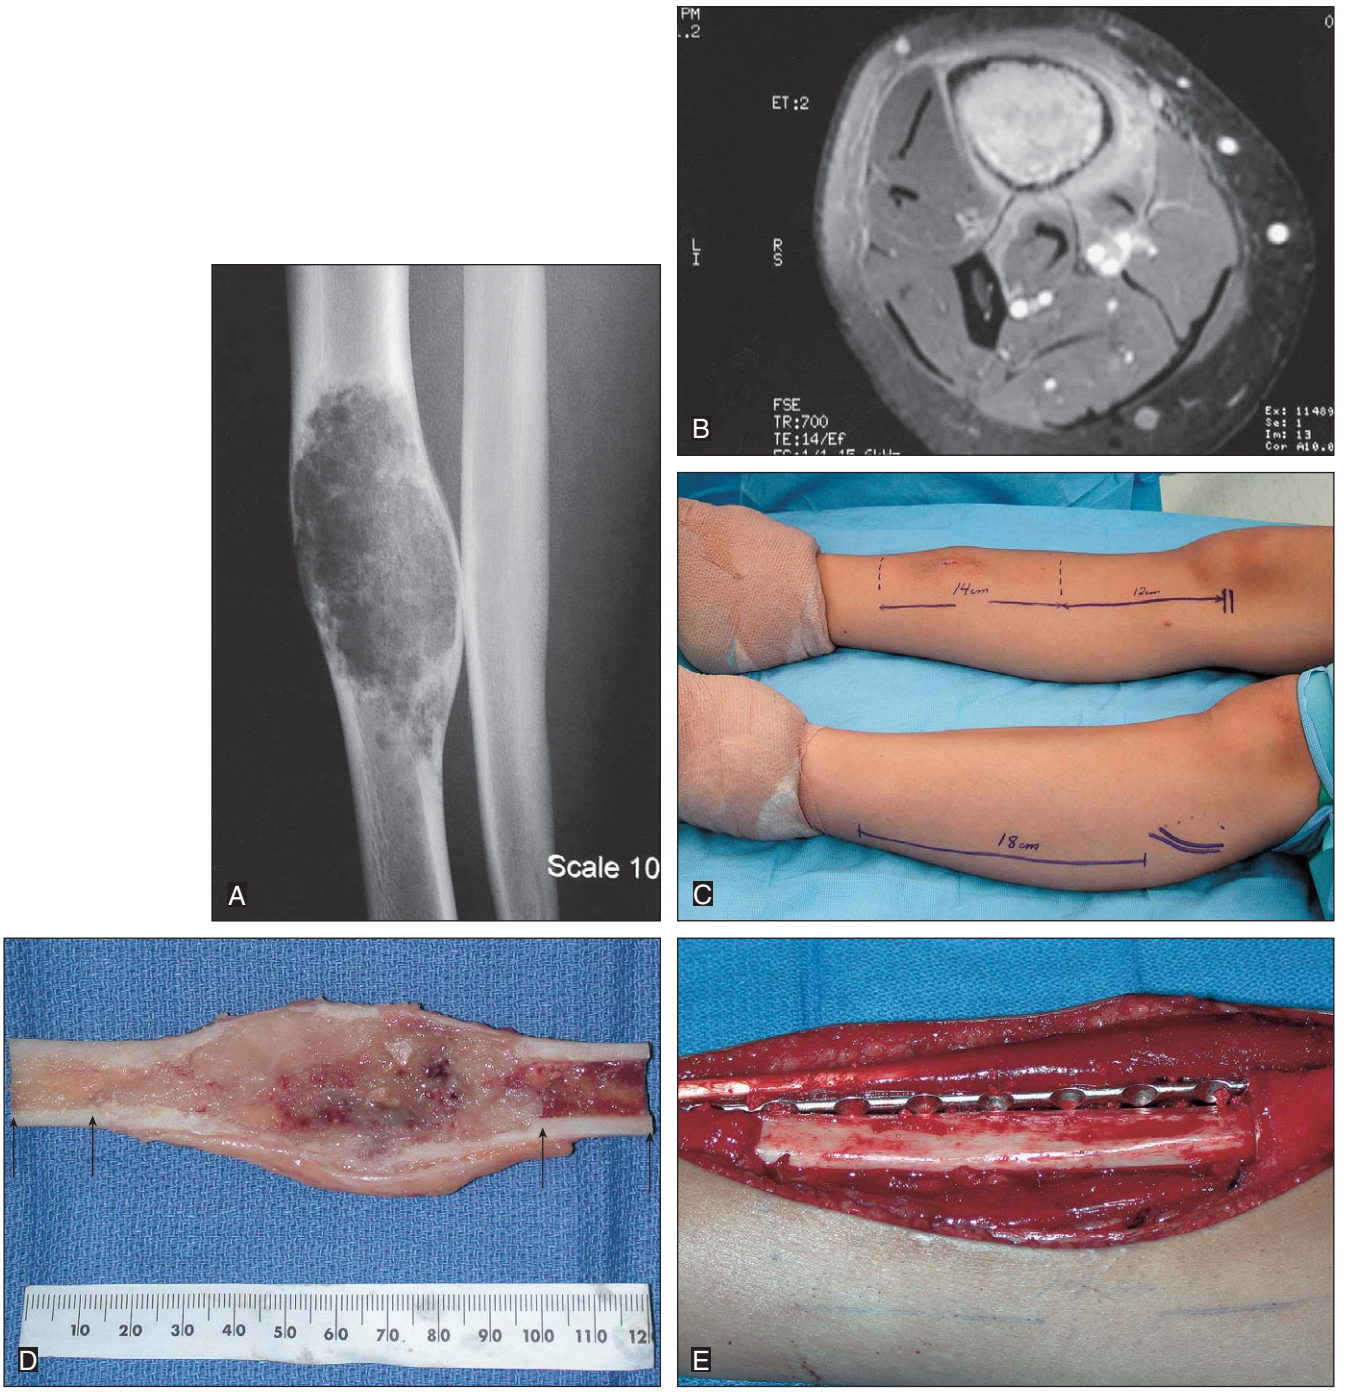

Figure 96-22 • **A,** This 16-year-old skeletally mature female was seen for increasing right leg pain that was made worse by weight bearing. The lateral digital film demonstrates an expansile intramedullary midshaft tibia mass with cortical thinning and destruction. A total body STIR MRI revealed no other detectable lesions. Physical examination revealed no café-au-lait cutaneous pigmentation. **B,** Axial MRI view demonstrating expansion and thinning of the cortex, destruction of the medullary bone and inner cortex without tumor necrosis, and surrounding soft-tissue edema. **C,** An open biopsy revealed adamantinoma of bone. This intra-operative view demonstrates the intended surgical procedure, resecting 14 cm of the diaphysis of the tibia and reconstructing the skeletal defect with a free avascular left fibula graft supplemented with autologous iliac crest bone graft. **D,** After resection, the lesion was taken to the back table and split to confirm appropriate proximal (*right arrows*) and distal (*left arrows*) intramedullary margins. **E,** A continuous strength locking screw plate was used to maintain reduction and to secure the fibular graft, having been shaped to fit within the proximal and distal medullary canal. The proximal and distal host/graft osteotomy sites were supplemented with autologous iliac crest bone graft.

Table 96-8 Anatomic Distribution of Vertebral Lesions

Anterior Elements of the Spine	Posterior Elements of the Spine	Both Anterior and Posterior Elements of the Spine
Multiple myeloma	Osteoid osteoma	Metastasis (spares disk end plates)
Hemangioma	Osteoblastoma	Infection (involves disk end plates)
Paget's disease of bone	Aneurysmal bone cyst	Classic osteosarcoma
Histiocytosis × (vertebra plana)		Postradiation sarcoma
Giant cell tumor of bone		Malignant histiocytoid variety
Reparative granuloma		Osteosarcoma
Ewing's sarcoma (PNET)		Osteochondroma
Lymphoma of bone		Primary chondrosarcoma
Malignant fibrous histiocytoma		Secondary chondrosarcoma
Chordoma		

to localize to a more specific region of the anatomy (Table 96-8). Less commonly, some patients present with the onset of spinal cord compression without any antecedent history of pain. Tumors of the spine can be difficult to see on plain radiographs; therefore, if a patient has persistent symptoms, a bone scan, CT, or MRI is recommended. MRI is probably the best examination and should be done with intravenous contrast.

Age

The age of the patient is important in evaluating a patient with a suspected lesion involving the vertebral column. Patients under the age of 18 years are 80% more likely to have a benign lesion than are those over 18 years of age.

Staging of Primary Tumors of the Spine

Boriani and coworkers[380] have proposed a surgical staging system for tumors of the spine. Using a 12-sector clock face staging system as viewed from cephalad to caudad, in which 1 and 12 represent the left and right sides of the spinous process, respectively, these authors distinguish five separate centrifugal surrounding tissue layers (A, B, C, D, and E), beginning with intradural involvement (A) and extending out to paraspinous muscle involvement (E; Fig. 96-23). Surgeons commonly use this staging system to plan the surgical treatment.

Biopsy

Fine-needle aspirate biopsy or core-needle biopsy is most often used. Some surgeons prefer a semiopen transpedicular fluoroscopic controlled biopsy from a limited posterior surgical approach, but percutaneous transpedicular biopsy can be done.[381] As in the management of all sarcomas of bone, the biopsy track must be considered contaminated and be included in the carefully planned en bloc resection.[382–384]

Primary Malignant Tumors of the Spine

Benign tumors of the spine are much more common than are primary malignant tumors of the spine. The benign tumors that commonly arise in the spine include osteoid osteoma, osteoblastoma, giant cell tumor of bone, aneurysmal bone cyst, and Langerhans cell histiocytosis.

Osteogenic Sarcoma of the Spine

Osteosarcoma of the spine is distinctly rare, and there are insufficient data regarding its natural history, but all indications are that it behaves like other osteosarcomas. Therefore, patients are treated with preoperative chemotherapy, and then a surgical resection is done with as wide a margin as possible. Usually, this means removing all of the vertebral body and posterior elements. Although there is limited experience, postoperative irradiation could be of benefit, especially for patients with less than 90% necrosis and close or positive margins.

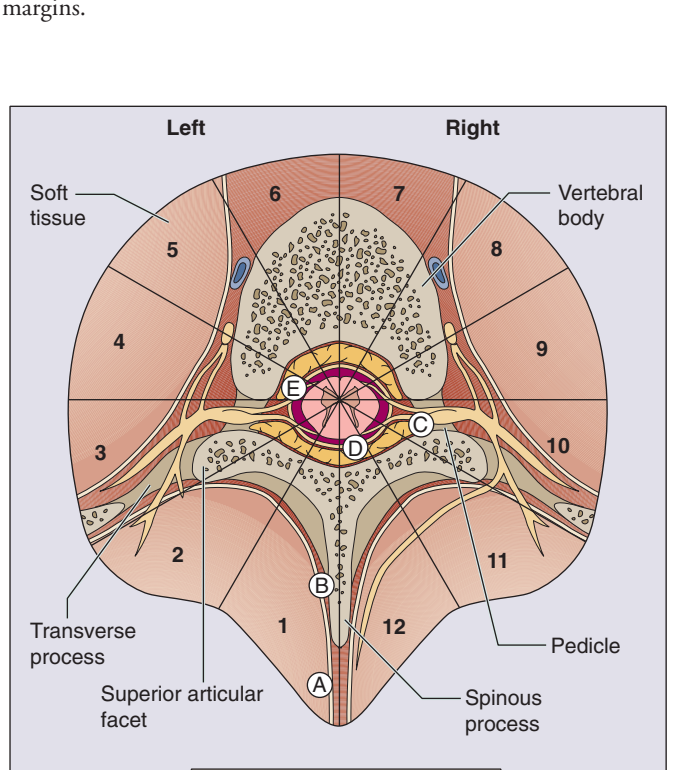

Figure 96-23 • Representation of the current staging scheme proposed by Boriani, Weinstein, and Biagini, with 12 radically distributed zones beginning at the spinous process and five separate tissue layers designed to distinguish intramedullary and extradural involvement from bone and soft-tissue paravertebral extension. The system does not recognize grade (G) or longitudinal compartmental margins (T).

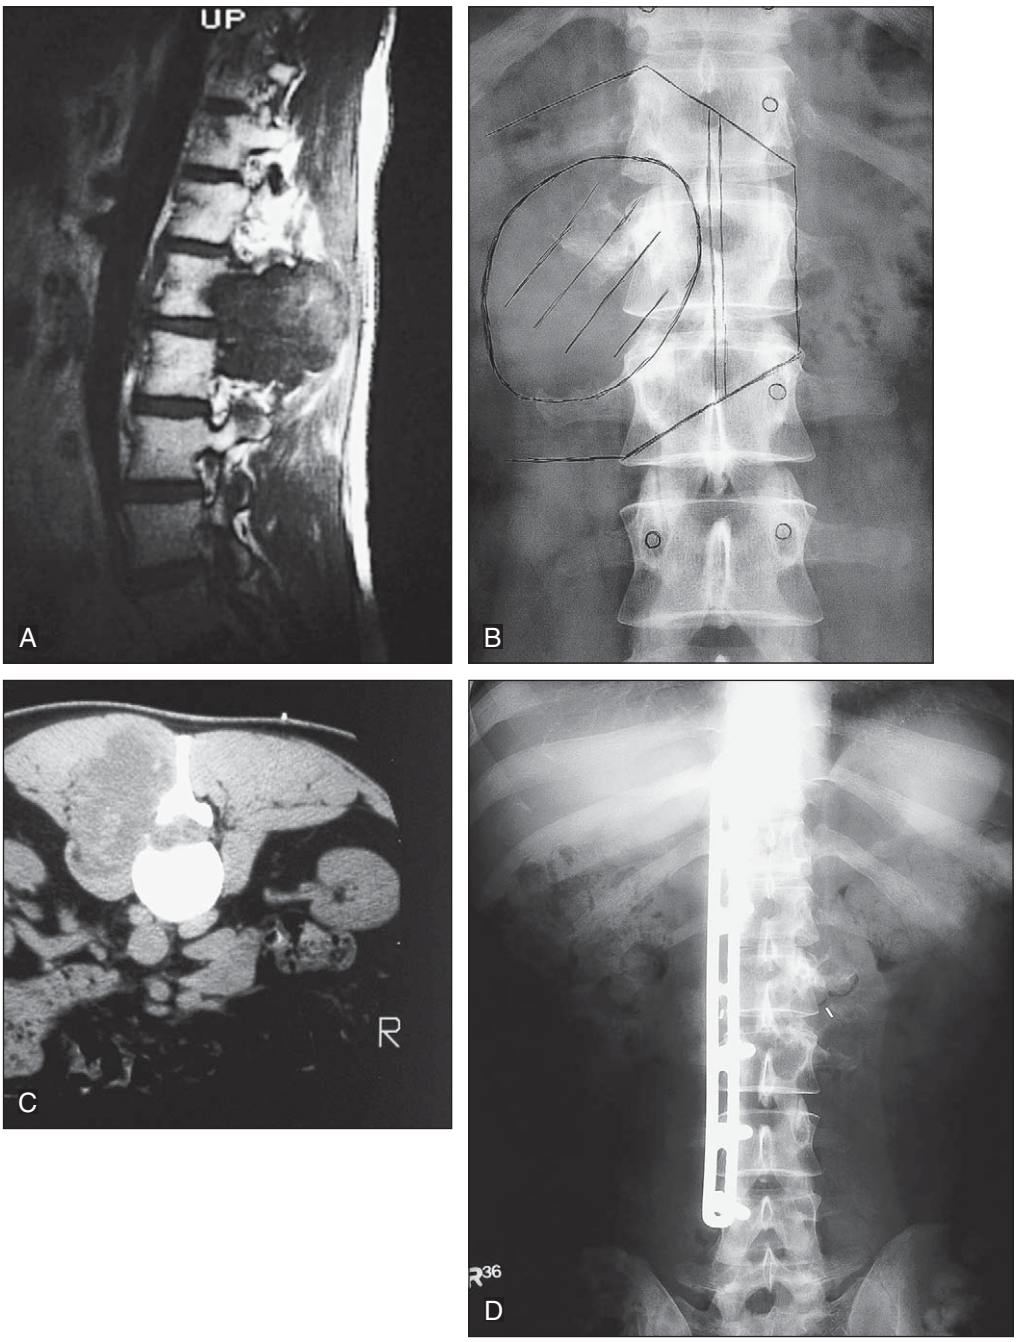

Figure 96-24 • **A,** This 30-year-old male was seen and evaluated 18 months after developing increasing left midlumbar spine pain. Plain films demonstrated the absence of the left transverse process of L1. The T_1-weighted MRI of the spine demonstrated an irregular infiltrative asymmetric lesion involving the left paraspinous musculature and lateral elements of L1 and part of T12 and L2. An open biopsy revealed grade II chondrosarcoma. **B,** Posteroanterior radiograph of the thoracolumbar junction demonstrating the region of the tumor (*crosshatching*) with the area outlined, demonstrating the structures that would require removal to obtain a wide surgical margin. A myelogram demonstrated tumor invading the canal through the left foramen of L1. A two-stage procedure was planned, whereby a right hemilaminectomy of L1 and transverse-oblique laminotomies of T12 and L2 would be performed from the right side posteriorly, followed by instrumentation of the right pedicles of T10, T11, T12, L2, and L3 with variable screw placement instrumentation. **C,** CT scan demonstrating the encroachment of the left L1 foramen and neural canal by tumor displacing the dura to the right. A fat plane can be identified between the tumor and the dura. These findings require the resection of the potentially involved dura with the specimen to complete an en bloc resection with wide margins. **D,** AP x-ray demonstrating the completion of the first stage of a two-stage procedure. The plate was applied to the right pedicles of T10, T11, T12 and L2, L3, and L4. Hemilaminectomies were performed on the right, as well as oblique laminectomies illustrated in **(B)**.

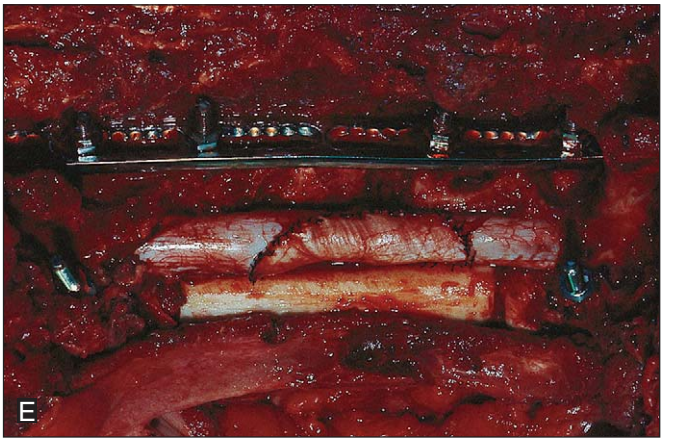
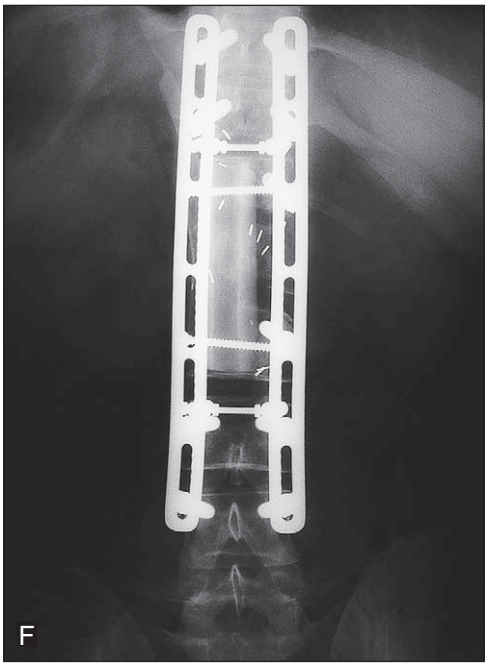
Chondrosarcoma of the Spine

Chondrosarcoma of the spine accounts for approximately 10% of all chondrosarcomas. The patient is usually over the age of 50 years. These tumors should be treated with a surgical resection (Fig. 96-24). Chemotherapy is not indicated. Tumors at the base of the skull are usually small but cannot be completely removed. The use of irradiation, usually administered by proton beam treatments, has proven to be effective.

Primary Ewing's Sarcoma of the Spine



Ewing's sarcoma of the spine is not uncommon, accounting for just under 5% of all cases. These patients are similar to other patients with Ewing's sarcoma. They are treated with adjuvant chemotherapy, but surgery is rarely used for Ewing's sarcoma of the spine. Irradiation is used to treat the primary tumor in almost all cases.



CHORDOMA

Cervical and Sacrococcygeal Chordoma

Embryology

The notochord is a unique tissue that reaches maturity in the 11-mm embryo. In the second gestational month, the notochordal tissue is essentially obliterated (Fig. 96-25). As the developing vertebrae emerge, notochordal tissue nests are displaced peripherally and caudally, leaving behind microscopic foci of notochord tissue adjacent to the vertebral bodies and distally in the body of the sacrum and coccyx.

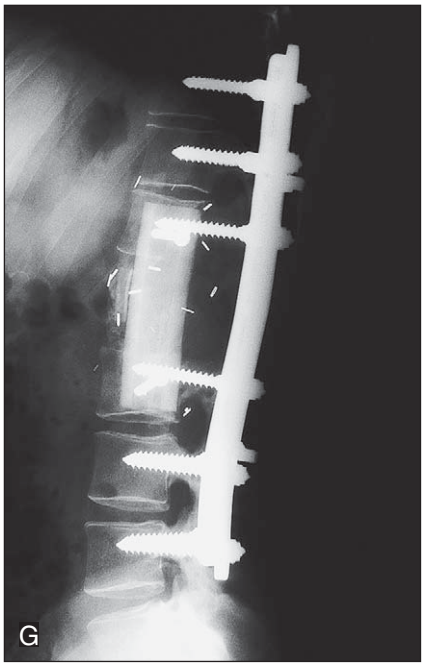


Figure 96-24, cont'd • **E,** Two weeks later, through a thoracoabdominal and communicating posterior midline exposure, the lesion was removed successfully en bloc with wide margins to include the lower oblique one half of T12, L1, and the upper oblique one half of L2 and in continuity with the involved dura of L1. A dural patch was required for repair. This intraoperative photo demonstrates the previously applied first-stage plate at the top with the dural repair beneath. A cylindric full-thickness segment of femoral allograft was used to restore the continuity of the anterior column (below the dura). A vascularized rib graft can be seen below, curving up to about the allograft. **F,** AP x-ray demonstrating the postoperative completed construct with four cross-connectors. The patient was immobilized in a thoracolumbar-sacral orthosis jacket for 1 year and has consistently used abdominal/lumbar support since his procedure. This AP x-ray was taken at the patient's 10-year reevaluation. **G,** Lateral x-ray also demonstrating a stable construct at 10 years without hardware failure or allograft resorption. The patient remains continuously disease free at 12 years.

It is from these aberrant tissue nests in the spheno-occipital and sacrococcygeal regions that the malignant neoplasm chordoma arises.

Incidence and Distribution

Chordoma is a rare tumor that arises anteriorly in the body of the vertebra; fewer than 1500 cases have been reported. The overall incidence is not well established because many chordomas are not reported. Two independent Scandinavian studies, however, estimated an annual incidence of approximately 0.5 per million population.[385,386]

The literature indicates that 50% of chordomas arise in the sacrum, 35% in the spheno-occipital region, and the remaining 15% in the vertebrae.[387–391] Vertebral lesions suggest that the tumor arises most often in the cervical spine, less often in the thoracic spine, and least often in the lumbar spine. The spheno-occipital variety usually occurs in individuals between the ages of 10 and 40 years, while those who develop sacrococcygeal lesions are generally over the age of 40. The male-to-female ratio is 2 : 1.[392]

Pathologic Features

Chordomas arise from the vertebral body. In the sacrum, the most common location, they are almost always central and extend anterior to the sacrum. They often invade the spinal canal (Fig. 96-26). Microscopically, the conventional subtype (the most common) consists of polyhedral cells with distinct cytoplasmic membranes and intracytoplasmic vacuoles. These "physaliferous" cells can be extraordinarily large.[393] Other tumors demonstrate chondroid and fibrous differentiation. Occasionally, an association with secondary MFH has been reported.[367,394–397] Chordomas are immunoreactive with cytokeratin, epithelial membrane antigen, S-100 protein, vimentin, and neurofilaments.[398–402] These characteristics are helpful in distinguishing chordoma from chondrosarcoma, MFH of bone, and metastatic mucin-producing adenocarcinoma.

Vertebral Chordoma

Clinical Manifestations

The clinical features and management of vertebral and sacral chordomas are sufficiently different that each will be described separately. Vertebral lesions are most often associated with ill-defined symptoms, usually occurring in younger middle-aged patients. The pain and discomfort is characteristically associated with either radicular pain or a disturbance of balance or gait. It is not uncommon for symptoms to be present for more than 1 year.[403] Thoracic and cervical vertebral involvement can be associated with the onset of a cough or dysphagia.[404] Because the tumors project anteriorly, they are rarely if ever palpable. Local tenderness could be elicited by percussion of cervical or lumbar lesions, while bilateral rib compression might identify the thoracic region of interest.

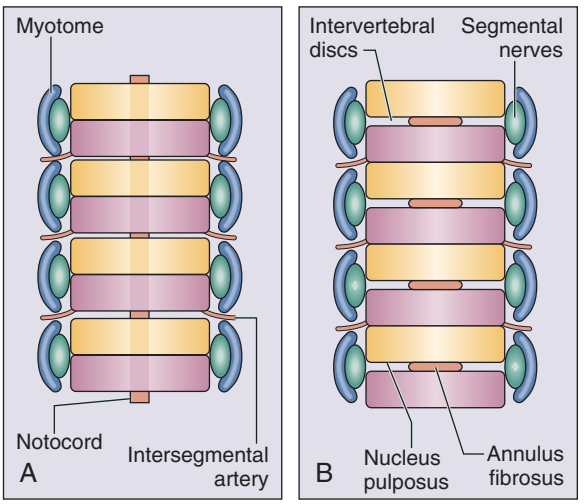

Figure 96-25 • **A,** The formation of less dense cephalic and more dense caudal sclerotoma surrounding the notochord at 4 weeks. **B,** At 11 weeks' gestation, the precartilaginous vertebral bodies have formed by the upper and lower halves of two successive sclerotomas, while the notochord has degenerated except in the region of the intervertebral disk.

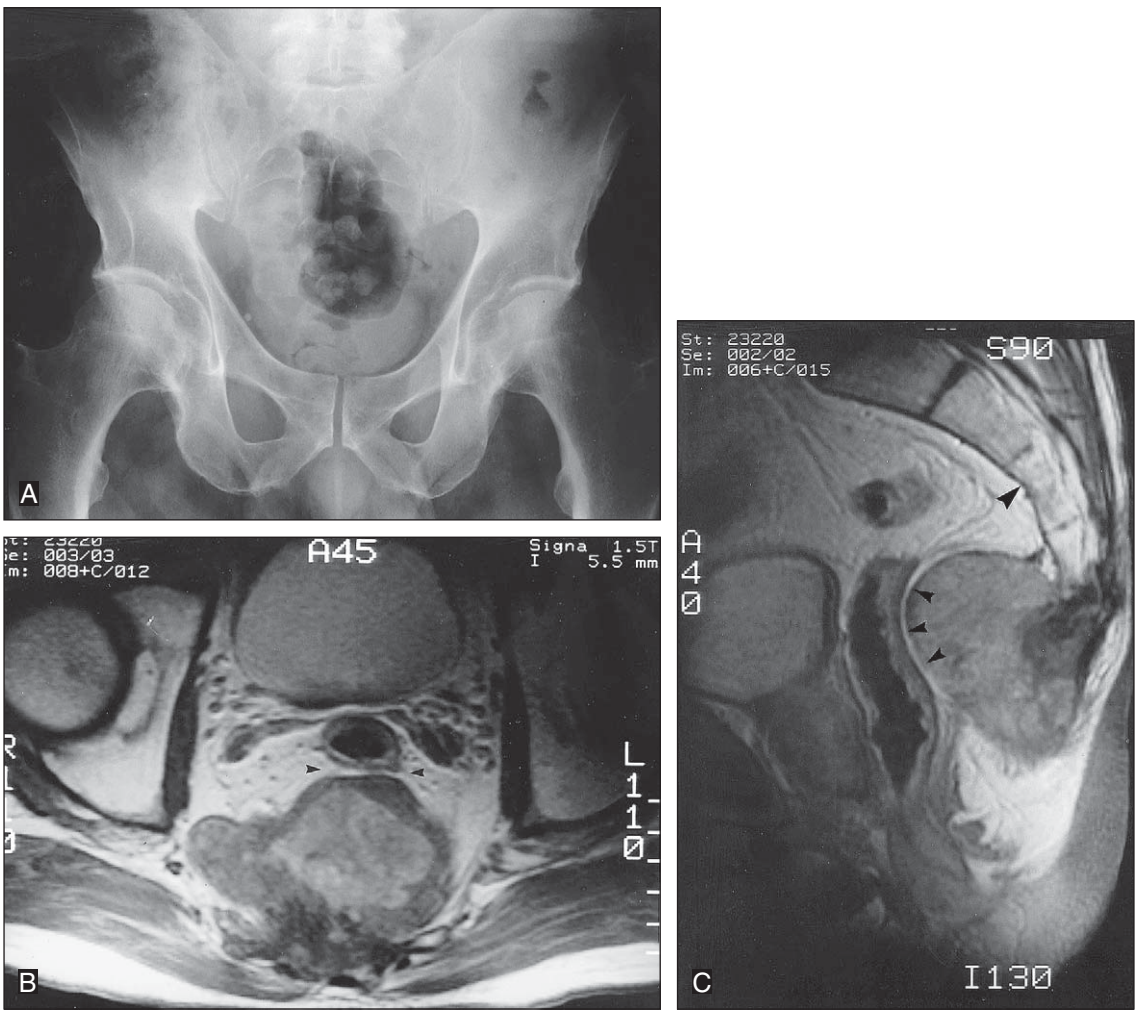

Figure 96-26 • **A,** AP radiograph of the pelvis of a 56-year-old male with a 3-year history of ill-defined low back and buttock pain. No rectal examination was reported to have been done until the patient was evaluated for bowel complaints. **B,** MRI of the pelvis demonstrated a mass projecting from the anterior lower (S3 and below) sacral elements. This axial view of the biopsy-proven chordoma demonstrates the preserved fat plane between the tumor and rectum (*arrowheads*). **C,** Sagittal T_1-weighted image clearly demonstrates the region of anterior sacral involvement and the preserved fat plane between the tumor and the rectum (*small arrowheads*). The *large arrowhead* indicates the location of the sacral amputation (S3) used to potentially cure this patient, who is currently 2 years free of disease.

Radiographic Manifestations

Radiographically, chordomas usually originate in the vertebral body as a destructive, well-marginated lesion. Characteristically, smaller lesions radiographically preserve the adjacent discs, while larger lesions involving more than one vertebral body can destroy the intervening disks. The often-associated soft-tissue mass projects anteriorly, elevating the anterior longitudinal ligament. When originating in the thoracic vertebrae, chordomas can present asymptomatically as a posterior mediastinal tumor.

MRI with and without contrast is the single most valuable study when correlated with the initial plain films. CT and MRI are comparable in detecting the neoplasm, but MRI is considerably better in delineating the full epidural and soft-tissue extent of the tumor.

Biopsy

The biopsy must be planned carefully if a potentially curative procedure is possible. Injudicious laminectomy in a neurologically negative patient followed by open biopsy unnecessarily contaminates the dura and surrounding structures and should be reserved as a last resort only. Fine-needle posterior CT-guided aspiration biopsy is the technique of choice for almost all spinal and sacral lesions. If the fine-needle aspiration does not provide a diagnosis, then a closed or limited open transpedicular Craig needle biopsy using fluoroscopic control should be considered.[405] Only after failure of these two techniques should an open decompression laminectomy/biopsy be performed.

Local Control

A "wide" margin is required for local control. Intralesional excision leads to locally recurrent disease. The majority of patients who are managed surgically require a one-stage posterior approach that includes laminectomy followed by a more complete removal of the tumor.[392,399,401,406–408] Many staged, well-planned procedures resulting in wide, clean-contaminated margins develop a local recurrence.[403,409,410] Rarely can a complete, uncontaminated resection be done on a chordoma. In the cervical, thoracic, or lumbar spine, adjuvant irradiation has been used and can decrease the incidence of local recurrence.

Sacrococcygeal Chordoma

Clinical Manifestations

The typical clinical history for a patient with a sacrococcygeal chordoma is a long history (approximately 12 months) of low back pain with the diagnosis being made by the first person to do a rectal examination. Sacrococcygeal lesions manifest most commonly with low back and perineal pain rather than with the typical radicular pain associated with intervertebral disc herniation. Often, the patient's modesty prevents disclosure of perineal symptoms until late in the disease process.[411] Also, because of the contribution of both the right and left sacral nerve roots to bladder and bowel sphincter function, symptoms of incontinence are delayed and sometimes do not present at all in asymmetric lesions.[412]

Physical Examination

The expansile portion of a chordoma characteristically projects anteriorly, deviating the presacral fascia and creating a smooth, minimally tender mass anterior to the sacrum that is easily palpated on rectal examination. Most patients will have no other abnormal physical findings.

Radiographic Evaluation

Sacrococcygeal chordomas are difficult to see on a plain radiograph. An MRI is the examination of choice, and the extent of the lesion can be accurately seen on the MRI. When a chordoma is suspected, the patient should also have a whole-body ^{99m}Tc bone scan and a CT of the chest.

Surgical Management

The surgical principles outlined and developed by Stener,[413] when used appropriately and by skilled surgeons, result reliably in a wide amputation of the sacrum. The resection is usually done through a midline posterior approach, and it is recommended that a biopsy be done in line with this incision. As rule, the tumors that do not extend proximal to the exit site of the S2 nerve roots can be removed with a single posterior operation. Those that extend more proximally should be approached anteriorly as well to clear the soft tissues off the most proximal extent of the tumor. This area cannot be reached from the posterior approach. These procedures are technically demanding and should not be undertaken by the unprepared. Even in the best of hands, however, 5% to 40% of patients will develop distant disease.

Neurologic dysfunction depends on the nerve roots that are removed. Clinically noticeable weakness in the lower extremities is unusual unless one of the L5 nerve roots is removed. If one L3 nerve root is salvaged, the patients usually have sufficient control of their bowel and bladder not to need catheterization or a special bowel regimen. Compromising the surgical margin to salvage nerve roots usually leads to a local recurrence, eventual loss of the nerve root, and rarely local control.

SUMMARY

The sarcomas of bone and chordoma represent a heterogeneous group of tumors that arise in somewhat predictable locations throughout the entire skeleton. Diagnosis and surgical planning have improved significantly with the addition of physician-monitored MRI and the other associated multiaxial display imaging techniques. Also, the addition of sophisticated immunohistochemistry and cytogenetic techniques has made differentiation of similar-appearing lesions easier. The increasing complexity of the management of these patients, including primary chemotherapy and limb- and function-preserving surgery, requires a dedicated team of nurses, technicians, and physicians working to provide and implement the therapeutic modalities that are necessary to cure previously incurable diseases.

97 Sarcomas of Soft Tissue

Robert Benjamin, Peter W.T. Pisters, Lee J. Helman, Vivien H.C. Bramwell, Brian P. Rubin, and Brian O'Sullivan

SUMMARY OF KEY POINTS

Incidence and Epidemiology
- 8300 new cases annually in the United States
- No specific etiologic agent identifiable in the majority of cases
- Occasional cases related to previous radiation, chemical exposure, alkylating chemotherapeutic agents, or chronic lymphedema
- Genetic conditions related to soft-tissue sarcoma include neurofibromatosis, tuberous sclerosis, basal cell nevus syndrome, Gardner's syndrome, and Li-Fraumeni syndrome.

Diagnosis and Evaluation of Extent of Disease
- Core-needle biopsy (large lesions) or excisional biopsy (small lesions)
- Pathologic review of histologic subtype, grade, and assessment of margins (excisional biopsies)
- Magnetic resonance imaging or computed tomography (CT) of primary site
- Chest x-ray for low-grade tumors and high-grade T1 lesions, chest CT for high-grade T2 tumors

Prognostic Factors
- High-grade histology, deep location, and T2 tumor size are independent adverse prognostic factors for distant metastasis and survival.
- Presentation with recurrent disease and positive surgical margin (gross or microscopic) are independent adverse prognostic factors for local recurrence.
- Individual patient prognosis can be predicted from a handheld computer-based nomogram.

Staging Systems
- The American Joint Committee on Cancer (International Union Against Cancer) system employs criteria that include grade, size, and location relative to the investing muscular fascia, nodal status, and distant metastases.

Primary Therapy
- Surgical resection with an adequate margin of normal tissue; for extremity lesions, a limb-sparing approach is possible in more than 90% of patients and offers survival comparable to amputation without the associated morbidity.
- For most patients, local control is improved with preoperative or postoperative radiotherapy.
- The role of chemotherapy for high-risk patients remains controversial, but chemotherapy is used at several major centers for high-risk patients, especially for extremity tumors and, when possible, preoperatively.

Recurrent Disease
- Local recurrence rates vary depending on the anatomic site of the primary and the adequacy of local therapy; for extremity lesions, approximately 20% of patients develop locally recurrent disease.
- Chemotherapy with selective use of metastasectomy is the mainstay of therapy for patients with metastatic disease.
- For the small subset of patients who develop isolated (solitary) pulmonary metastases, 20% to 50% 3-year survival rates have been reported with pulmonary metastasectomy.

INTRODUCTION

STSs comprise a group of relatively rare, anatomically and histologically diverse neoplasms. These tumors share a common embryologic origin, arising primarily from tissues derived from the mesodermal or ectodermal germ layers, in contradistinction to carcinomas that arise from the endodermal germ layer. Although the somatic soft tissues account for as much as 75% of total body weight, neoplasms of the soft tissues are comparatively rare, accounting for 1% of adult malignancies and 15% of pediatric malignancies. The relative rarity of these tumors, coupled with the histologic diversity of tumors, has led to studies that often lump diverse tumors (STSs) into a single study group, making it difficult to develop specific therapies for specific tumor types, especially in adult STSs. The annual incidence of STSs in the United States is about 8300 new cases, comparable to the incidence of testicular cancer.[1] However, an estimated 3900 patients die annually of soft-tissue sarcoma—a rate nearly 10-fold greater than is seen with testicular cancer—emphasizing the comparatively high overall mortality rate that is seen with this type of tumor.

The first portion of this chapter reviews the available literature on the evaluation and treatment of extremity sarcomas (which account for 50% of all lesions). Other specific anatomic sites are reviewed at the end of the chapter.

ETIOLOGY AND EPIDEMIOLOGY

Environmental Factors

No specific etiologic agent is identified in the majority of patients with soft-tissue sarcoma (STS). There are a number of recognized associations between environmental factors and the subsequent

Table 97-1 Soft-Tissue Sarcoma: Predisposing Environmental Factors

Factor	Agent	Patient Population	Comment
Radiotherapy	Orthovoltage and megavoltage radiation	Therapeutic radiation patients	Most commonly osteosarcoma; dose-response relationship
Chemotherapy	Alkylating agents: cyclophosphamide, melphalan, procarbazine, nitrosourea, and chlorambucil	Pediatric cancer patients	Relative risk of bone sarcoma increased with cumulative drug exposure
Chemical exposure	Phenoxyacetic acids: 2,4-dichlorophenoxyacetic acid (2,4-D); 2,4,5 trichlorophenoxy acetic acid (2,4,5-T); 2 methyl-4 chlorophenoxyacetic acid (MCPA)	Forestry and agricultural workers	Phenoxy herbicide and defoliant exposure
	2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD); dioxin	Vietnam veterans	No clear link demonstrable for dioxin (Agent Orange)
	Chlorophenols	Sawmill workers	
	Thorotrast	Diagnostic x-ray patients	Hepatic angiosarcoma
	Vinyl chloride	Vinyl chloride workers	Hepatic angiosarcoma
	Arsenic	Vineyard workers	Hepatic angiosarcoma after exposure to arsenical herbicides
Chronic lymphedema		Postsurgery patients Postradiation patients Patients with congenital Lymphadema or filariasis	Stewart-Treves syndrome (lymphangiosarcoma)

development of sarcoma; these are summarized in Table 97-1. The development of sarcoma has been reported after the use of ionizing radiation for the treatment of lymphoma;[2] solid tumors of the head and neck,[3] breast,[4,5] gynecologic organs, and skin; and benign conditions including endometriosis, tuberculous arthritis,[6] and benign thymic enlargement. The vast majority of radiation-associated sarcomas are high-grade lesions (87%), and the predominant histology is osteosarcoma;[7,8] this is a historical observation before the era of megavoltage radiation that is possibly linked to the greater absorption of orthovoltage radiation by bone as compared to soft tissue. Malignant fibrous histiocytoma, angiosarcoma, and other mesenchymal subtypes have also been reported after therapeutic radiation.[7-9] By criteria that were described initially by Cahan and colleagues,[10] radiation-induced sarcomas arise no sooner than 4 years after the therapeutic radiation[11,12] and often arise decades later. More recently, however, a shorter 2-year period after diagnosis has been utilized to define radiation-related disease. Contrary to early theories, recent studies have suggested that both orthovoltage and megavoltage treatments are sarcomagenic[8,13] at doses of 8.8 to 70 Gy. In a carefully conducted case-control analysis, the Late Effects Study Group found 64 cases of osteosarcoma in 9170 patients who had survived more than 2 years after the diagnosis of a variety of cancers. A clear dose-response relationship was found between the radiation dose and the subsequent development of osteosarcoma, with a relative risk ranging from 0.6 in patients who received less than 10 Gy to 38.3 in those who received more than 60 Gy.[14] A complete understanding of the underlying biology of radiation-induced malignancy remains elusive. Host-related factors (especially young age) and treatment (especially its intensity) both seem to play a role in a complex relationship.[15] Underlying genetic susceptibility is also important and is governed by factors such as deletion or mutation of tumor suppresser and DNA repair genes, which likely means that subgroups of the populations have more vastly enhanced risk than had previously been anticipated while others are at lower risk than was appreciated in the past. In addition it is highly probable that the greater intensity of multimodality treatments for cancer that have been introduced over recent years with the goal of improving cancer control and survival are going to result in an increase in the rate of radiation-induced malignancies. Of the latter, the overwhelmingly at-risk tumor is sarcoma, especially if one considers its baseline incidence rates.[15]

Sarcomas have also been associated with exposure to various chemical agents. A number of conflicting reports have emerged that suggest a relationship between occupational exposure to phenoxyacetic acids (found in some herbicides) and chlorophenols (found in some wood preservatives). Several studies from Sweden have established a link between phenoxy herbicide exposure in forestry workers and the subsequent development of sarcoma.[16–19] However, additional investigations in the United States, New Zealand, and Finland have not confirmed this relationship.[20–22] Similarly, there has been no demonstrable increase in the risk of sarcoma in Vietnam veterans exposed to Agent Orange (dioxin or TCDD [2,3,7,8-tetrachlorodibenzo-p-dioxin]).[23] Hepatic angiosarcomas have been associated with exposure to a number of compounds, including Thorotrast (a colloidal suspension of thorium dioxide that was formerly used as an intravenous contrast agent in radiologic imaging procedures),[24–26] vinyl chloride,[27–29] and arsenic.[30,31]

Recent studies have suggested a relationship between exposure to alkylating chemotherapeutic agents and the subsequent development of sarcomas. Osteosarcomas have been reported after cyclophosphamide treatment for pediatric acute lymphoblastic leukemia.[32,33] In the recent report from the Late Effects Study Group, prior chemotherapy, particularly with melphalan, procarbazine, nitrosoureas, or chlorambucil, was found to be an independent risk factor for the development of sarcoma.[14] The relative risk of sarcoma increased with cumulative drug exposure.

Chronic lymphedema can be a factor in the development of lymphangiosarcoma. These neoplasms have been noted to arise in the chronically lymphedematous arms of women who were treated for breast cancer with radical mastectomy (Stewart-Treves syndrome).[34,35] Lower-extremity lymphangiosarcomas have also been observed in patients with congenital lymphedema or filariasis complicated by chronic lymphedema.[36]

A recent history of trauma is often elicited from sarcoma patients, particularly those with extremity sarcoma. Usually, the interval between the traumatic event and the diagnosis of sarcoma is short, making a causal relationship unlikely. Some reports have suggested, however, that chronic inflammatory processes may be a risk factor for sarcoma. Shrapnel, bullets, intramuscular iron injections, and foreign body implants have been implicated.[37]

Genetic Predisposition

Germline mutations may play an important role in the development of STSs (Table 97-2). These genetic changes are identified with or similar to the genetic changes that are seen in corresponding sporadic sarcomas (Table 97-3). Mechanistically, the proteins encoded by the altered genes are involved in maintenance of the genome through DNA repair and the cell cycle.

The epidemiologic relationship between the development of STS and inherited syndromes associated with a predisposition to neoplasia (e.g., neurofibromatosis and Li-Fraumeni syndrome) has been appreciated for more than two decades.[38,39] For example, patients with neurofibromatosis have a 7% to 10% lifetime risk of developing a malignant peripheral nerve sheath tumor (MPNST).[40] A sudden increase in the size of any neurofibroma suggests malignant transformation.[41,42] The mechanisms underlying the transformation from a benign neurofibroma to MPNST are not completely understood.

However, loss-of-function mutations in the NF1 gene, which are found in patients with neurofibromatosis, result in activation of the RAS signaling pathway, a well-known mechanism that has been identified in a variety of cancers.[43] It has been observed that secondary MPNSTs (arising from a prior neurofibroma) have deletions and mutations of 17p (particularly 17p12–17p13.1) at the region of the TP53 tumor suppressor gene.[44–46] Thus, it has been postulated that an initial alteration in the NF1 gene contributes to the formation of a benign neurofibroma through activation of the RAS pathway and that secondary mutations in the TP53 gene allow the transformation into MPNST. Since mutations in TP53 lead to an inability to control DNA damage via the cell cycle, they also enable rapid accumulation of other mutations, which encode mutant proteins that undoubtedly play an important role in sarcomagenesis.

The Li-Fraumeni syndrome was identified when relatives of pediatric STS patients were noted to have an increased frequency of diverse and often multiple primary cancers.[38,47] The neoplasms that were noted in relatives included some STSs, premenopausal breast cancers, brain tumors, adrenocortical carcinomas, leukemias, and sometimes germ cell tumors.[48] Follow-up of Li-Fraumeni kindreds over two decades has revealed that the majority of individuals develop cancer at young ages, with 79% of those affected younger than 45 years at the time of diagnosis of malignancy.[49] The observed cancer distribution in families is believed to fit a rare autosomal dominant mode of genetic transmission with high penetrance.[50] Recent molecular genetic studies have identified germline TP53 mutations in the majority of patients with Li-Fraumeni syndrome.[51] Germline mutations in CHK2, another component of the cell cycle checkpoint machinery encoded by a gene located on 22q11, are responsible for another subgroup of patients with Li-Fraumeni syndrome.[52]

Pediatric patients with familial retinoblastoma have a 13q chromosomal deletion[53] and an increased incidence of osteosarcoma and other neoplasms, including STS.[14,54,55] The retinoblastoma (Rb1) protein is expressed ubiquitously in normal cells and is a well-known tumor suppressor, involved in maintaining the integrity of the genome through control of the cell cycle. Interestingly, not only is the Rb1 gene that is mutated in osteosarcomas associated with retinoblastoma, but abnormality or absence of the Rb1 gene product has also been observed in multiple other malignancies, including sporadic osteosarcomas, breast cancer,[56] small cell lung cancer,[57] and STSs.[58]

Familial infiltrative fibromatosis, also known as hereditary desmoid disease, is caused by germline mutations in the APC gene.[59–61] Patients with this syndrome develop desmoid fibromatosis at a younger age than do patients with sporadic desmoids. Patients with familial adenomatous polyposis also harbor germline mutations in the APC gene; this helps to explain Gardner's syndrome, which is characterized by the development of desmoid tumors as well as polyposis.[62] The APC gene is involved in the WNT or wingless cell-signaling pathway. One of the normal functions of the APC protein is to bind β-catenin.[63] Thus, loss-of-function mutations of APC result in the activation of transcription of oncogenes by β-catenin. Mutations in APC and β-catenin are also identified in sporadic desmoid fibromatosis.[64–66]

Rhabdoid predisposition syndrome is due to inactivating germline mutations in the INI1 gene.[67] Patients with this syndrome develop one or more extrarenal and/or renal rhabdoid tumors. INI1 is a member of the SWI/SNF protein complex, which controls gene expression globally through its ability to alter chromatin structure.[68] Thus loss of INI1 gene expression results in other changes in gene expression, specifically activation of oncogenes. Rhabdoid tumors have loss-of-function mutations in both copies of the INI1 gene.[69]

Werner's syndrome is a rare genetic instability syndrome caused by mutations in the WRN gene.[70,71] Affected patients age prematurely and are at greatly increased risk for a variety of cancers, including STSs. The WRN gene encodes a protein believed to be involved in DNA repair, and loss of WRN protein function leads to genetic instability, accumulation of genetic mutations, and ultimately predisposition to rapid aging and cancer.

Germline mutations in the KIT oncogene are found in patients with familial gastrointestinal stromal tumor syndrome.[72,73] Activating KIT mutations are also identified in approximately 90% of sporadic gastrointestinal stromal tumors (GISTs).[74] Patients with the familial

Table 97-2 Germline Mutations Associated with Soft-Tissue Sarcomas

Syndrome	Inheritance Pattern	Locus	Gene	Associated Soft-Tissue Sarcomas
Familial gastrointestinal stromal tumor syndrome	AD	4q12	KIT	Gastrointestinal stromal tumor
Familial infiltrative fibromatosis	AD	5q21	*APC*	Desmoid fibromatosis
Li-Fraumeni syndrome	AD	17p13	*TP53*	Multiple types
		22q11	*CHK2*	
Neurofibromatosis type I (von Recklinghausen's disease)	AD	17q11	*NFI*	Malignant peripheral nerve sheath tumors
Retinoblastoma	AD	13q14	*RBI*	Multiple types
Rhabdoid predisposition syndrome	AD	22q11	*SNF5/INII*	Malignant rhabdoid tumors
Werner's syndrome	AR	8p11–12	*WRN*	Multiple types

AD, autosomal dominant; AR, autosomal recessive.

Table 97-3 Molecular Alterations Identified in Sarcoma

Tumor Type	Characteristic Cytogenetic Events	Molecular Events	Frequency (%)	Diagnostic Utility?
Alveolar soft part sarcoma	t(X;17)(p 11;q25)	*ASPL-TFE3* fusion	>90	Yes
Extraskeletal myxoid chrondrosarcoma	t(9;22)(q22;q12)	*EWS-NR4A3* fusion	>75	Yes

syndrome develop, to varying degrees, skin hyperpigmentation, urticaria pigmentosa, and cutaneous mast cell disease in addition to one or more GISTs.[75] Activating KIT mutations have been shown to lead to ligand-independent activation of the KIT receptor tyrosine kinase pathway, which results in dysregulated cell growth, and are thought to be the first step in the pathogenesis of GISTs.[72] Interestingly, the identification of the important role of KIT in the pathogenesis of GISTs has led to treatment with imatinib mesylate.[76] A small molecule drug specifically inhibits the KIT pathway (see sections on Prognostic Factors as Therapeutic Targets and Gastrointestinal Stromal Tumors).

Genetics of Sporadic Soft-Tissue Sarcomas

Sarcomas tend to fall into two major subsets. In one group, the tumors are cytogenetically simple and are characterized by near diploid karyotypes with few chromosomal rearrangements, resulting in the formation of fusion proteins. These translocations are highly diagnostic of specific histologic subtypes of STSs. Also included within the cytogenetically simple STSs would be GIST tumors, which are characterized by a specific activating mutation of the c-Kit gene but few other genetic abnormalities.

Chromosomal Rearrangements

A large number of sarcomas have been found to have consistent chromosomal abnormalities (see Table 97-3).[77] These chromosomal rearrangements are important diagnostically, may be important prognostically (see the section on Potential Molecular Prognostic Factors), have shed light on the pathogenesis of sarcomas, and may provide targets for pharmacologic therapy (see the section on treatment of GISTs). Benign soft-tissue neoplasms also harbor chromosomal rearrangements.

Chromosomal translocations are the most common cytogenetic abnormality in soft-tissue neoplasms and are likely responsible for the initiation of tumorigenesis in most cases.[77] Deletions and trisomies have also been reported and are thought to represent secondary changes involved in tumor progression. Deletions tend to represent loss of tumor suppressor genes, whereas trisomies indicate the presence of an oncogene. Although we know a lot about the primary tumorigenic events in many sarcomas, defining the secondary changes has been much more problematic and is an area of intense study.

Cloning and molecular analysis of the various genetic aberrations that characterize different sarcomas have revealed the different pathogenetic mechanisms that underlie these tumors. Translocations typically create chimeric transcription factors or growth factors that result in deregulation of transcription or growth control. A typical example of a chimeric transcription factor is the PAX3-FKHR fusion protein, which has been shown to activate a complex myogenic transcriptional program when the protein is expressed in a fibroblast cell line.[78] Infantile fibrosarcoma is characterized by a translocation involving chromosomes 12 and 15 that encodes a chimeric ETV6-NTRK3 constitutively activated growth factor receptor.[79] Other oncogenic proteins appear to act by a mechanism that remodels chromatin structure, which is known to have a profound influence on gene expression (e.g., INI1 mutations in rhabdoid tumors).[69]

Specific chromosomal rearrangements are very useful in the diagnosis of STSs. Beyond the obvious benefit of providing further objective proof of a diagnosis in morphologically typical cases, the detection of chromosomal aberrations may facilitate the diagnosis of lesions that are difficult to characterize by standard histopathologic, ultrastructural, and immunohistochemical techniques.[80,81] For example, the presence of the translocation t(X;18)(p11;q11) has been used to confirm the diagnosis of synovial sarcoma in poorly differentiated cases that were diagnostically very challenging.[82–84] Similarly, the finding of the characteristic translocation t(11;22)(q24;q12) in a small round blue cell tumor supports the diagnosis of Ewing's sarcoma/primitive neuroectodermal tumor (PNET).[85]

Translocations can be identified by cytogenetic analysis, fluorescence in situ hybridization, or reverse transcriptase polymerase chain reaction. A detailed description of these techniques is beyond the scope of this chapter, but each technique has its advantages and disadvantages. Cytogenetic analysis requires fresh (living) tissue, since the cells need to be cultured before karyotypic analysis. This technique is becoming more widely available than before, owing to the availability of overnight transport of biologic specimens and for-profit core facilities. Fluorescence in situ hybridization is a technologically sophisticated technique that does not require fresh or frozen tissue. Fluorescence in situ hybridization is easier to perform on cytogenetic cultures or frozen tissue, however, so these are still preferable to paraffin-embedded material. Reverse transcriptase polymerase chain reaction is an extremely sensitive technique that can be performed on fresh, frozen, or paraffin-embedded tissues. The major drawback of reverse transcriptase polymerase chain reaction is the relatively high false-positive rate, which results from its sensitiveness. Meticulous care is required to prevent problems from contamination.

Although reverse transcriptase polymerase chain reaction can be performed on paraffin-embedded tissue, it is preferable to perform the analysis on fresh or frozen tissue. Since all of these techniques either require or are easier to perform on fresh or frozen tissue, it is advisable to freeze and store a portion of any suspected sarcoma or poorly differentiated neoplasm for potential molecular analysis.

Many sarcomas are characterized by several different translocations, some of which are mutually exclusive (see Table 97-3). For instance, alveolar rhabdomyosarcoma is characterized by a translocation involving chromosomes 2 and 13, which results in fusion of the PAX3 and FKHR genes, or by a translocation involving chromosomes 1 and 13, which results in fusion of the PAX7 and FKHR genes.[86–89] Sarcomas within a subtype may also have differences in the specific exons that are involved in each of these different translocations. It has been proposed that this heterogeneity may result in differences in prognosis (see section on Potential Molecular Prognostic Factors). For example, Ewing's sarcoma/PNET and synovial sarcoma possess genetic variations that have been suggested to have prognostic significance.[90–93] Future research might establish whether cytogenetic and molecular factors can be used as a basis for therapeutic decisions and the prediction and evaluation of response to treatment.

The identification of genetic alterations with high specificity for different sarcomas will also identify specific therapeutic targets. This has already resulted in the successful treatment of two different sarcomas: GISTs and dermatofibrosarcoma protuberans (DFSP).[76,94] About 90% of GISTs harbor activating mutations in the KIT oncogene, which result in ligand-independent activation of the KIT receptor tyrosine kinase pathway.[74] Imatinib mesylate, a small molecule drug that is administered orally and inhibits the KIT pathway, has been shown to be very efficacious in the treatment of GIST (see the section on investigational new drugs in the Chemotherapy section). DFSP is characterized by translocations involving the COL1A1 and PDGF-β genes, which result in activation of the platelet-derived growth factor-β PDGF-β pathway. Imatinib mesylate is also active against the PDGF-β pathway and has been shown to be effective in the treatment of a small number of DFSPs.

It is noteworthy to mention two common benign soft-tissue tumors—leiomyomas and lipomas—that have a high frequency of chromosomal rearrangements of chromosome 12q that involves the high-mobility protein group gene HMGIC.[95] These translocations are not seen in the corresponding leiomyosarcomas or liposarcomas, indicating that in these tumors, the benign form is not a precursor of the malignant counterpart.

Sarcomas with Complex Karyotypes

A second major subset of STSs is characterized by aneuploidy and the lack of specific fusion genes. This group of sarcomas includes

Table 97-4 Sarcomas with Complex Karyotypes

Type of Sarcoma	Resembles
Fibrosarcoma (other than congenital)	Fibrous tissue
Leiomysarcoma	Smooth muscle
Malignant fibrous histiocytoma	Poorly differentiated
Osteosarcoma	Bone
Chondrosarcoma (types other than extraskeletal myxoid)	Cartilage
Liposarcoma (types other than myxoid)	Fat
Embryonal rhabdomyosarcoma	Skeletal muscle
Malignant peripheral nerve sheath tumor*	Nerve sheath
Angiosarcoma	Blood vessels

*Some have NF1 mutations.

such tumors as leiomyosarcomas, MPNST, and fibrosarcomas (see Tables 97-3 and 97-4). These tumors tend to occur in the older age group and appear to have a relatively high frequency of mutations in the p53 and RB signaling pathways.[96,97] These tumors are characterized by chromosomal gains and losses that presumably target tumor suppressor genes (in the event of losses) and oncogenes (in the event of gains). Currently, the best-characterized targets of amplifications are the cell cycle regulatory genes CDK4 and HDM2, but others remain to be identified and remain a current challenge in the field. Thus, it appears that alterations disrupting chromosomal mechanics and DNA repair can lead to sarcomagenesis.

PATHOLOGY

STSs have been described at virtually all anatomic sites. The anatomic sites and site-specific histologic subtypes of 4207 sarcomas treated at a single referral institution are outlined in Figure 97-1. Approximately half of all STSs occur in the extremities (lower: 34%; upper: 14%), where the most common histopathologic subtypes are well-differentiated, myxoid, and round cell liposarcoma (28%) and malignant fibrous histiocytoma (pleomorphic undifferentiated sarcoma) (24%). Retroperitoneal sarcomas make up 15% of all STSs, well-differentiated or dedifferentiated liposarcoma being the predominant histologic subtype (42%). The visceral sarcomas make up an additional 14%, while the head and neck sarcomas make up approximately 4%.

Classification

In broad terms, sarcomas can be classified into neoplasms that arise in bone and those that arise from the soft tissues. However, even this seemingly simple distinction is fraught with difficulty, as is illustrated by Ewing's sarcomas. These tumors often arise in close association with bone and are often classified as bone sarcomas. However, it is now clear that these tumors can also arise in soft tissues, and it is

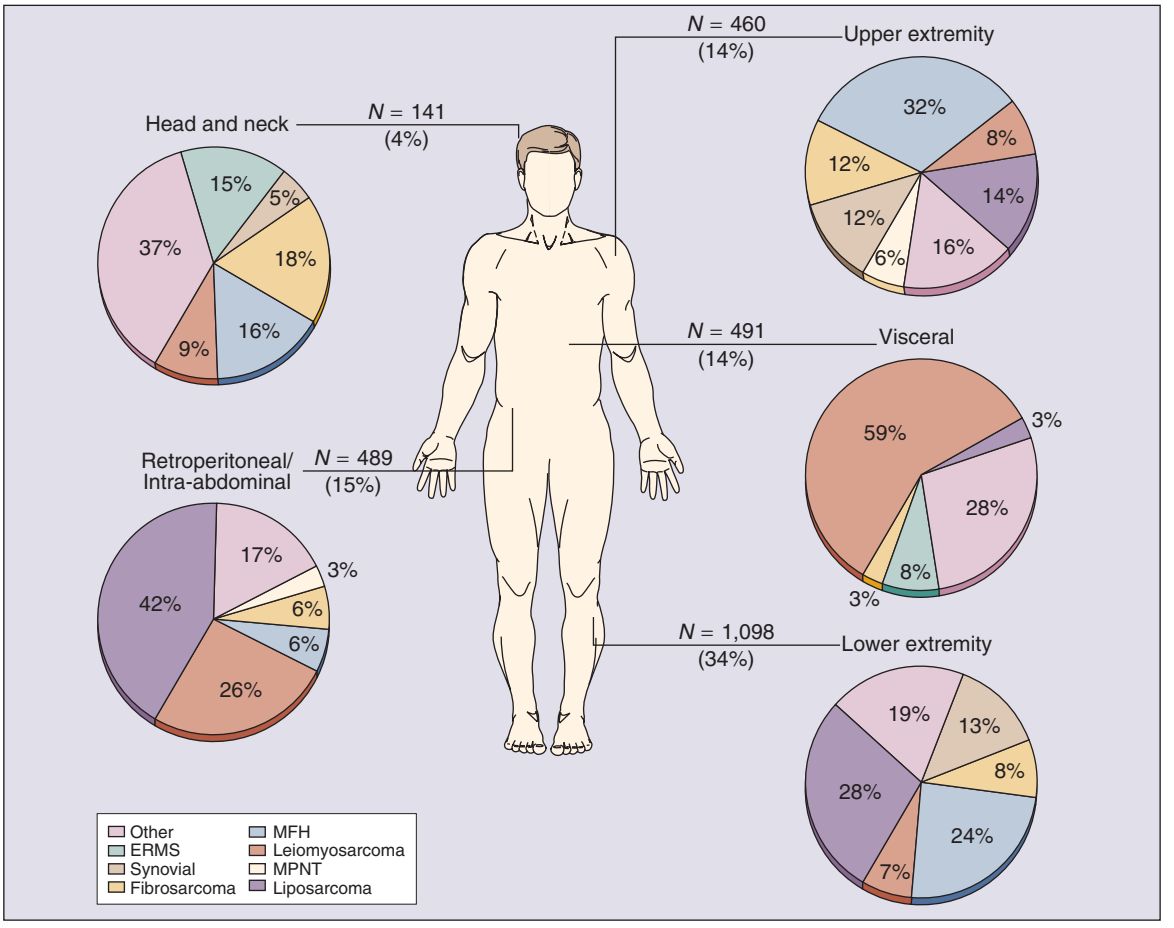

Figure 97-1 • Anatomic distribution and site-specific histiotypes of 4207 adult patients with soft-tissue sarcomas seen at the University of Texas M.D. Anderson Cancer Center, 1996–2003.

becoming increasingly clear that these tumors arise from primitive cells of mesenchymal origin. So are they bone sarcomas or soft-tissue sarcomas, and does it really matter in terms of classification? Sarcomas of the soft tissues can be further grouped into those that arise from viscera (gastrointestinal, genitourinary, and gynecologic organs) and those that arise from nonvisceral soft tissues (muscle, tendon, adipose, pleura, and connective tissue).

An alternative way to index STSs is by their differentiation. Tumors can be grouped broadly into adipocytic tumors, fibroblastic/myofibroblastic tumors, so-called fibrohistiocytic tumors, smooth muscle tumors, pericytic (perivascular) tumors, PNETs, skeletal muscle tumors, vascular tumors, osseous tumors, and tumors of uncertain differentiation (Table 97-5).[98] Classification is based on clinical, histologic, ultrastructural, immunohistochemical, and genetic features. Electron microscopic evidence of cellular substructures, neurofibrils, microfilaments, actin-myosin complexes, dense bodies, and so on often helps to clarify the tissue of origin.[99] However, the widespread availability of commercial antibodies for immunohistochemical analysis has diminished the need for electron microscopic examination in many cases. Immunohistochemical staining for proteins that are characteristic of smooth muscle (smooth muscle actin and desmin), skeletal muscle (muscle-specific actin, desmin, and myogenin), blood vessels (factor VIII, CD34, and CD31), and epithelial tissue (epithelial membrane antigen and cytokeratins) often facilitates reliable classification.[100,101]

The tissue of origin classification scheme is the most commonly used scheme and is the basis for the recent World Health Organization classification system for sarcomas.[98,102] The World Health Organization classification system is reproducible for most sarcomas. As the degree of histologic differentiation declines, however, the determination of the tissue of origin becomes increasingly difficult. In particular, despite advanced immunohistochemical techniques, electron microscopy, and molecular analysis, determining the tissue of origin for some soft-tissue tumors is difficult, occasionally arbitrary, and sometimes impossible. This leads to significant disparities in diagnoses among pathologists. Discrepancies between the original histologic diagnosis and the subsequent diagnosis by an expert reviewer have been noted in as many as 25% of cases.[103,104] Review of tissue specimens by an expert at a regional sarcoma center is therefore imperative, because the degree of expertise in correctly diagnosing rare and unusual sarcomas is directly related to the number of sarcomas that a pathologist has seen.

It is important to classify STSs as precisely as possible because of major differences in their clinical behavior and in their susceptibility to different therapies. For example, a few STSs, including epithelioid sarcoma, clear cell sarcoma, angiosarcoma, and rhabdomyosarcoma, have a greater risk of regional lymph node metastasis.[105,106] In one single-institution study, the overall rate of nodal metastasis at the time of sarcoma presentation was only 2.7%; however, the rate was much higher for angiosarcoma (13.5%), embryonal rhabdomyosarcoma (13.6%), and epithelioid sarcoma (16.7%).[105]

Patterns of distant metastases also differ for subtypes of sarcoma. For example, myxoid liposarcoma tends to metastasize to soft-tissue sites, including the retroperitoneum,[107] and patients with myxoid liposarcoma often present with metastatic disease. Therefore, if a myxoid liposarcoma is identified in the abdomen, the thighs should be examined for an occult primary tumor. The vast majority of so-called primary myxoid liposarcomas of the abdomen and retroperitoneum are actually metastatic myxoid liposarcomas or misdiagnosed dedifferentiated liposarcomas, which often mimic myxoid liposarcoma.[108]

Patterns of local spread also differ dramatically among subtypes of sarcoma. For example, DFSP has a propensity to infiltrate subcutaneous adipose tissue in a manner that is very difficult to detect; therefore, wide surgical excision of DFSP is essential. When planning a surgery for DFSP, the surgeon should regard the grossly observable lesion as the tip of the iceberg. Angiosarcoma also spreads very diffusely and is difficult to define grossly.

Table 97-5 Histologic Classification of Soft-Tissue Sarcoma

ADIPOCYTIC SARCOMAS
Atypical lipomatous tumor/well-differentiated liposarcoma
Dedifferentiated liposarcoma
Myxoid liposarcoma
Pleomorphic liposarcoma
FIBROBLASTIC AND MYOFIBROBLASTIC SARCOMAS
Malignant solitary fibrous tumor
Inflammatory myofibroblastic tumor
Myxoinflammatory fibroblastic sarcoma
Infantile fibrosarcoma
Adult fibrosarcoma
Myxofibrosarcoma (myxoid malignant fibrous histiocytoma)
Low-grade fibromyxoid sarcoma
Sclerosing epithelioid fibrosasrcoma
SO-CALLED FIBROHISTIOCYTIC SARCOMAS
Pleomorphic malignant fibrous histiocytoma/undifferentiated high-grade pleomorphic sarcoma
Giant cell malignant fibrous histiocytoma/undifferentiated pleomorphic sarcoma with giant cells
Inflammatory malignant fibrous histiocytoma/undifferentiated pleomorphic sarcoma with prominent inflammation
SMOOTH MUSCLE SARCOMAS
Leiomyosarcoma
SKELETAL MUSCLE SARCOMAS
Embryonal rhabdomyosarcoma
Alveolar rhabdomyosarcoma
Pleomorphic rhabdomyosarcoma
VASCULAR SARCOMAS
Epithelioid hemangioendothelioma
Angiosarcoma
OSSEOUS SARCOMAS
Extraskeletal osteosarcoma
SARCOMAS OF UNCERTAIN DIFFERENTIATION
Synovial sarcoma
Epithelioid sarcoma
Alveolar soft part sarcoma
Clear cell sarcoma of soft tissue
Extraskeletal myxoid chondrosarcoma
Desmoplastic small round cell tumor
Extarenal rhabdoid tumor
Intimal sarcoma

Histologic Grading

Histologic classification alone does not always provide enough information to predict the clinical behavior of STSs. For many sarcomas, histologic grading provides additional information that can aid in predicting biologic behavior and planning treatment. The spectrum of grades varies among specific histologic subtypes (Fig. 97-2). For

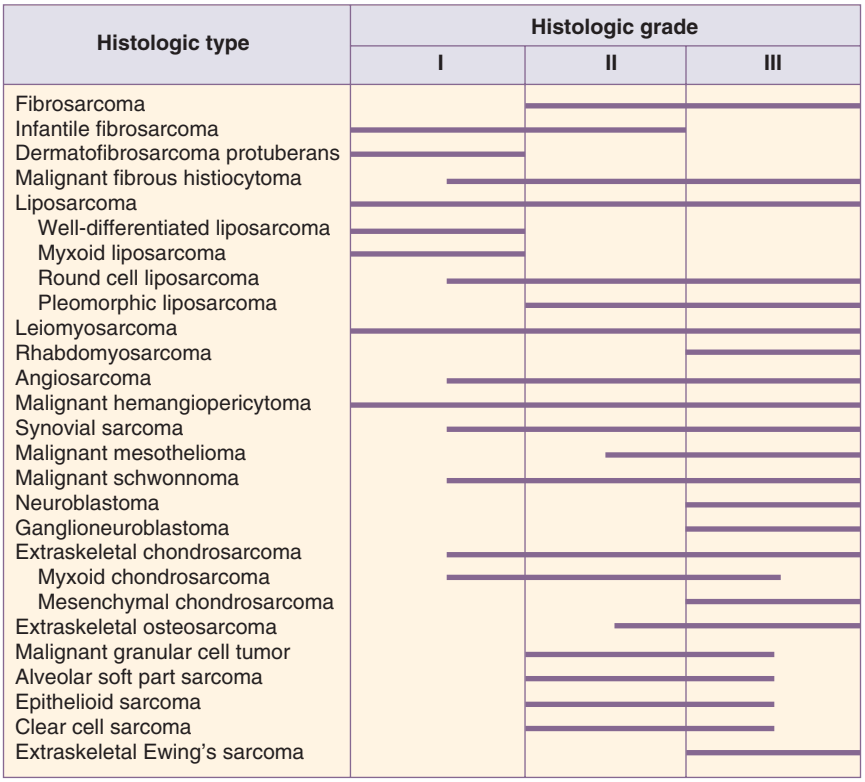

Figure 97-2 • The spectrum of grades observed among histologic subtypes of soft-tissue sarcoma. (Reprinted with permission from Enzinger FM, Weiss SW: Malignant tumors of uncertain type. In Enzinger FM, Weiss SW [eds]: Soft Tissue Tumors, 3rd ed. St. Louis, Mosby, 1995, p 1067.)

example, leiomyosarcomas exhibit wide variations in grade and should always be graded, while Ewing's sarcomas/PNETs are always high-grade and therefore do not require grading. In careful comparative multivariate analyses, histologic grade has been the most important prognostic factor in assessing the risk for distant metastasis and tumor-related mortality.[109–111] Several grading systems have been proposed, but there is no consensus regarding the specific morphologic criteria that should be employed in the grading of STSs. The two most important criteria appear to be the mitotic index and the extent of tumor necrosis.

Two of the most commonly used grading systems are the U.S. National Cancer Institute (NCI) system developed by Costa and colleagues[112] and the FNCLCC system (Federation Nationale des Centres de Lutte Contre le Cancer) developed by the French Federation of Cancer Centers Sarcoma Group.[113] The NCI system is based on the tumor's histologic subtype and amount of tumor necrosis, but cellularity, nuclear pleomorphism, and mitotic index are considered for certain subtypes. The FNCLCC system employs a score generated by evaluation of three parameters: tumor differentiation, mitotic rate, and amount of tumor necrosis. The prognostic values of these two grading systems were retrospectively compared in a population of 410 adult patients with nonmetastatic STS.[114] Significant discrepancies were observed in one third of cases. An increased number of grade III tumors, a reduced number of grade II tumors, and better correlation with overall and metastasis-free survival were observed in favor of the FNCLCC system.[114] Thus, in the absence of other comparative data, the FNCLCC system may be the best presently available grading system.

CLINICAL PRESENTATION AND DIAGNOSIS

The majority of patients present with a painless mass, although pain is noted at presentation in up to one third of cases.[115] Delay in diagnosis of sarcomas is common, the most common incorrect diagnosis for extremity and trunk lesions being lipoma or hematoma.

Physical examination should include an assessment of the size and mobility of the mass. Its relationship to the fascia (superficial versus deep) and nearby neurovascular and bony structures should be noted. A site-specific neurovascular examination and assessment of regional lymph nodes should also be performed.

Biopsy

Biopsy of the primary tumor is essential for most patients presenting with soft-tissue masses. In general, any soft-tissue mass in an adult that is asymptomatic or enlarging, is larger than 5 cm, or persists beyond 4 to 6 weeks should be biopsied. The preferred biopsy approach is generally the least invasive technique required to allow a definitive histologic diagnosis and assessment of grade. In most centers, core-needle biopsy provides satisfactory tissue for diagnosis[116–118] and has been demonstrated to result in substantial cost savings compared to open biopsy.[118] Direct palpation can be used to guide needle biopsy of most superficial lesions, but less accessible sarcomas often require an image-guided biopsy to safely sample the most heterogeneous component of the mass. Needle tract tumor recurrences after closed biopsy are rare but have been reported,[119] leading some surgeons to advocate tattooing the biopsy site for subsequent excision or for inclusion in radiotherapy treatment volumes (Fig. 97-3). In some centers, fine-needle aspiration may be an acceptable biopsy technique for primary soft-tissue masses, provided that an experienced sarcoma cytopathologist is available.[120–122] Owing to the frequent difficulty in accurately diagnosing these lesions even when adequate tissue is available, however, the major utility of fine-needle aspiration in most centers is in the diagnosis of suspected recurrent sarcoma.

Incisional or excisional biopsy is rarely required but may be performed when a definitive diagnosis cannot be achieved by less invasive means. Several technical points merit comment. Relatively small, superficial masses that can easily be removed should be biopsied by complete excision with microscopic assessment of surgical margins.

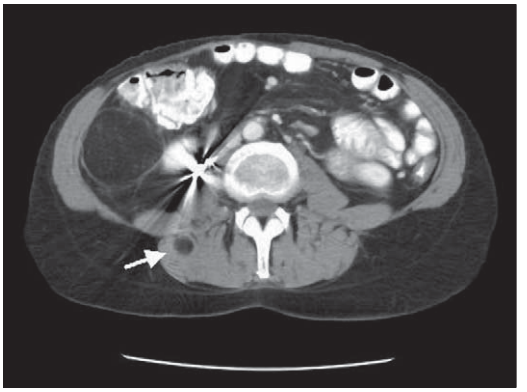

Figure 97-3 • Axial CT image of a recurrent well-differentiated low-grade liposarcoma of the retroperitoneum. Note the tumor nodule (*arrow*) representing a tumor implant within muscle from a previous needle biopsy that was obtained through the posterior abdominal wall. It is beneficial to consider the location of biopsy tracts so that subsequent surgery or radiotherapy includes the area of the biopsy (see text for details).

Incisional and excisional biopsies should be performed with the incision oriented longitudinally (for extremity lesions) to facilitate subsequent wide local excision. The incision should be centered over the mass at its most superficial point. Care should be taken not to raise tissue flaps. Meticulous hemostasis should be ensured to prevent dissemination of tumor cells into adjacent tissue planes by hematoma. All excisional biopsy specimens should be sent fresh, sterile, and anatomically oriented for pathologic analysis. At definitive resection of a previously biopsied sarcoma, the previous surgical biopsy scar should be excised en bloc with the tumor.

Imaging

Optimal imaging of the primary tumor is dependent on the anatomic site. For soft-tissue masses of the extremities, magnetic resonance imaging (MRI) has been regarded as the imaging modality of choice (Fig. 97-4). This is because MRI enhances the contrast between tumor and muscle and between tumor and adjacent blood vessels and provides multiplanar definition of the lesion.[123,124] Despite the fact that a study by the Radiation Diagnostic Oncology Group that compared MRI and computed tomography (CT) in patients with malignant bone ($N = 183$) and soft-tissue ($N = 133$) tumors showed no specific advantage of MRI over CT from a diagnostic standpoint,[125] the majority of musculoskeletal radiologists and almost all oncologists prefer MRI for soft-tissue tumors. For pelvic lesions, the multiplanar capability of MRI may provide superior single-modality imaging (Fig. 97-5). The multiplanar capability is also helpful for visualization of disease in noncoplanar ways when conformal radiotherapy technique is being employed and is an especially helpful adjunct in using image fusion techniques or to visualize peritumoral edema that may harbor sarcoma cells. In the retroperitoneum and abdomen, CT usually provides satisfactory anatomic definition of the lesion (Fig. 97-6). Occasionally, MRI with gradient sequence imaging can better delineate the relationship of the tumor to midline vascular structures, particularly the inferior vena cava and aorta. More invasive studies such as angiography or cavography are almost never required for the evaluation of STSs.

The utility of [^{18}F]fluorodeoxyglucose positron emission tomography (FDG PET) in the evaluation and treatment of STS has been a subject of recent studies and has been reviewed in detail elsewhere. The technique utilizes radiolabeled glucose analogs,[19] which are taken up at increased rates by malignant tumors. Pilot studies of PET in STS suggest that by evaluating tumor metabolic activity, PET scans may allow for noninvasive assessment of tumor grade.[126] Recent preliminary studies have demonstrated that PET may be helpful in

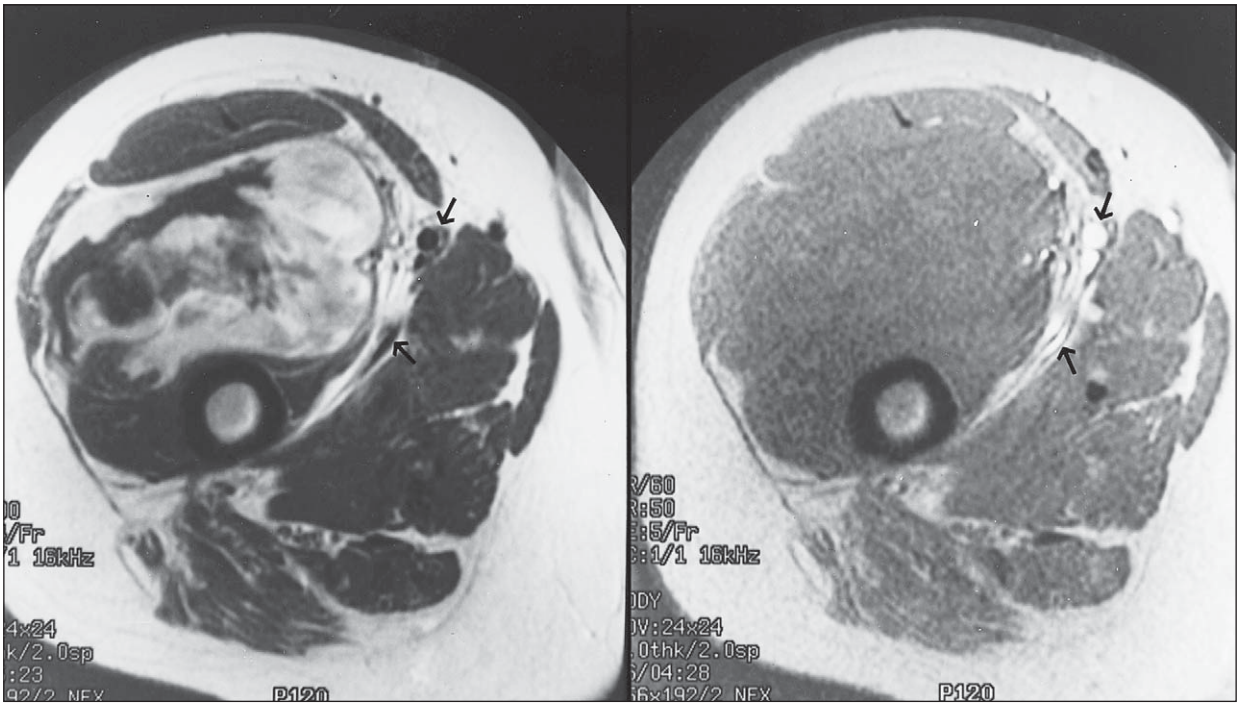

Figure 97-4 • A 47-year-old male with malignant fibrous histiocytoma of the left thigh. Axial contrast-enhanced T1-weighted (*left*) and flow sensitive gradient (*right*) images reveal a large mass in the vastus intermedius muscle. A plane is identified between the mass and the profunda femoris and superficial femoral vessels (*arrows*).

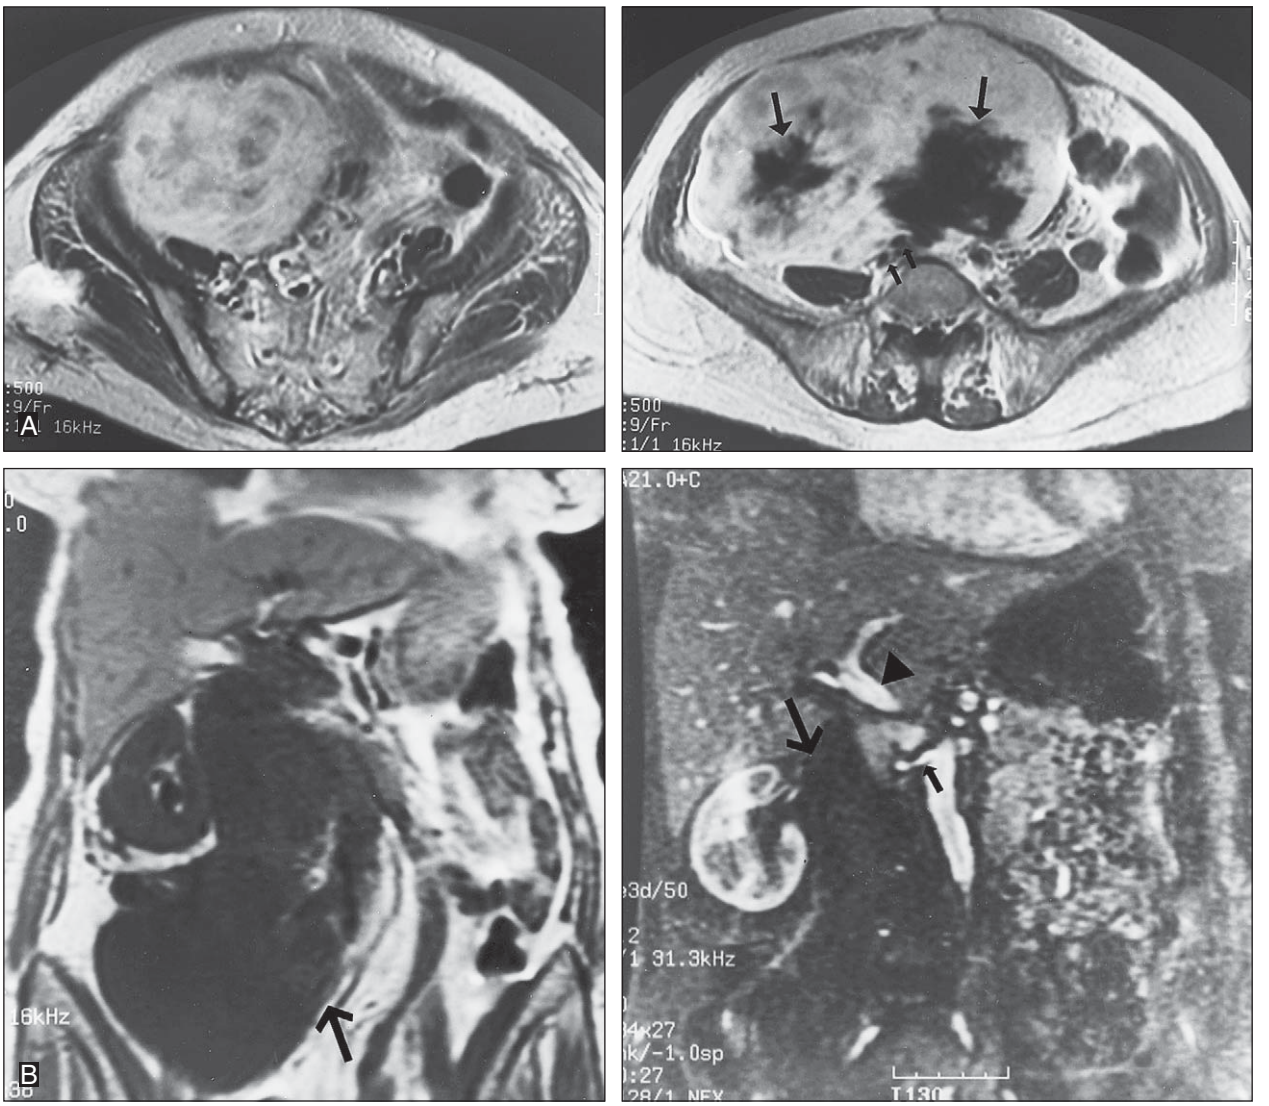

Figure 97-5 • **A,** A 74-year-old female with retroperitoneal malignant fibrous histiocytoma extending into the upper pelvis. Axial contrast-enhanced T1-weighted images reveal a large heterogeneous mass with foci of necrosis (*large arrows*). Note the relationship to the common iliac vessels (*small arrows*). **B,** The same patient as in **(A).** Coronal T1-weighted (*left*) and source MR images (*right*) from contrast-enhanced 3D MR angiogram reveal a large abdominal mass (*large arrows*) closely abutting the right renal capsule. Note the relationship to the aorta. The right renal artery is visualized *(small arrow*) as is the portal vein (*arrowhead*).

the assessment of locally recurrent STS[127] and in the evaluation of response to therapy.[128,129] The role and cost-effectiveness of PET in the staging of STS remain incompletely defined; therefore, further studies will be required to fully define the role for FDG PET in the diagnosis, evaluation, and treatment of STS.

STAGING

The relative rarity of STSs, the anatomic heterogeneity of these lesions, and the presence of more than 30 recognized histologic subtypes of variable grade have made it difficult to establish a functional system that can accurately stage all forms of this disease. The recently revised staging system (sixth edition) of the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (UICC) is the most widely employed staging system for STSs.[130] This staging system is a revision of the original AJCC system, which was first published in 1977; it incorporates histologic grade into the conventional TNM system (Table 97-6). The 2002 sixth edition classification has T and N categories that are identical to those of the 1997 fifth edition TNM, but some modifications have been made to the stage groupings. For the detailed background to these changes, the reader is referred to a more complete discussion. All STS subtypes are included except dermatofibrosarcoma protuberans, a condition that is considered to have only borderline malignant potential. Four distinct histologic grades are recognized, ranging from well-differentiated to undifferentiated. Histologic grade and tumor size are the primary determinants of clinical stage (see Table 97-6). Tumor size is further substaged as "a" (a superficial tumor that arises outside the investing fascia) or "b" (a deep tumor that arises beneath the fascia or invades the fascia). The system is designed to optimally stage extremity tumors but is also applicable to torso, head and neck, and retroperitoneal lesions; it should not be used for sarcomas of the gastrointestinal tract. This staging system has been validated by analysis of 1146 patients presenting with primary extremity STS at the Memorial Sloan-Kettering Cancer Center. Stage-specific survival plots are outlined in Figure 97-7.

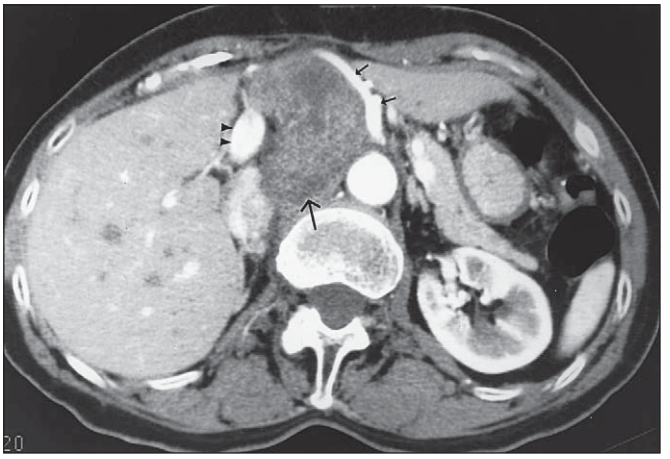

Figure 97-6 • Contrast-enhanced CT scan of the abdomen demonstrating a retroperitoneal malignant fibrous histiocytoma. Note the large mass (*large arrow*) between the aorta and inferior vena cava with abutment and displacement of celiac axis and hepatic artery (*small arrows*). The portal vein (*arrowheads*) is well visualized, and low attenuation foci in the liver, which are unopacified hepatic veins, are incidentally visualized.

A major limitation of the present staging system is that it does not take into account the anatomic site of STSs. Anatomic site, however, is an important determinant of outcome. Patients with retroperitoneal and visceral sarcomas have a worse overall prognosis than do patients with extremity tumors. Although site is not incorporated as a specific component of any present staging system, outcome data should be reported on a site-specific basis.

Table 97-6 AJCC/UICC Staging System for Soft-Tissue Sarcoma

T1		≤5 cm		
T1a		Superficial to muscular fascia		
T1b		Deep to muscular fascia		
T2		>5 cm		
T2a		Superficial to muscular fascia		
T2b		Deep to muscular fascia		
N1		Regional nodal involvement		
G1		Well-differentiated		
G2		Moderately differentiated		
G3		Poorly differentiated		
G4		Undifferentiated		
Stage IA	G1, 2	T1a, b	N0	M0
Stage IB	G2, 2	T2a, b	N0	M0
Stage IIA	G3, 4	T1a, b	N0	M0
Stage IIB	G3, 4	T2a	N0	M0
Stage III	G3, 4	T2b	N0	M0
Stage IV	Any G	Any T	N1	M0
	Any G	Any T	Any N	M1

PROGNOSTIC FACTORS

Conventional Clinicopathologic Factors

A thorough understanding of the clinicopathologic factors that are known to affect outcome is essential in formulating a treatment plan for the patient with STS. Over the past decade, many multivariate analyses of prognostic factors for patients with localized sarcoma have been reported. With few exceptions,[109,110,131,132] most studies have analyzed fewer than 300 patients (range: 82 to 297 patients). At least three detailed analyses of prognostic factors in STS merit comment.[109,110,131] The initial study of prognostic factors in extremity sarcoma from Memorial Sloan-Kettering Cancer Center evaluated clinicopathologic prognostic factors in a series of 423 patients with localized extremity STS seen from 1968 to 1978.[128] This analysis, among the first to discriminate between specific clinical endpoints, clearly established the clinical profile of what is now accepted as the high-risk patient with extremity STS: the patient with a large (>5-cm), high-grade, deep lesion. The adverse prognostic significance of a high tumor grade, deep tumor location, and tumor size greater than 5 cm was also noted in the recent report of the French Federation of Cancer Centers study of 546 patients with sarcomas of the extremities, head and neck, trunk wall, retroperitoneum, and pelvis.[110]

A follow-up report from Memorial Sloan-Kettering evaluated clinicopathologic prognostic factors that had been documented

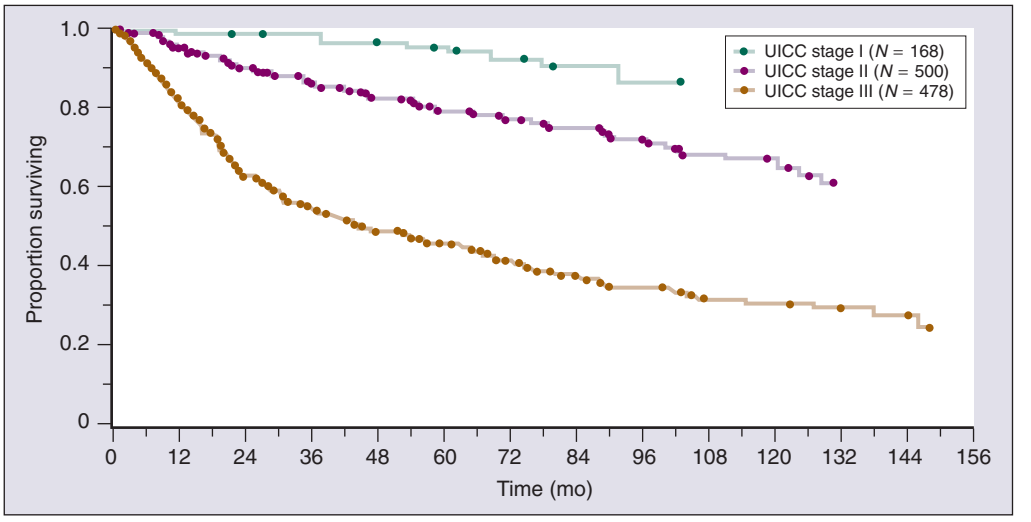

Figure 97-7 • Overall survival by AJCC stage in a population of 1146 patients with primary extremity sarcoma treated at the Memorial Sloan-Kettering Cancer Center.

Table 97-7 Multivariate Analysis of Prognostic Factors in Patients with Extremity Soft-Tissue Sarcoma

Endpoint	Adverse Prognostic Factor	Relative Risk
Local recurrence	Age > 50 years	1.6
	Local recurrence at presentation	2.0
	Microscopically positive margin	1.8
	Fibrosarcoma	2.5
	Malignant peripheral nerve tumor	1.8
Distant recurrence	Size 5.0–10.0 cm	1.9
	Size > 10.0 cm	1.5
	High-grade	4.3
	Deep location	2.5
	Local recurrence	1.5
	Leiomyosarcoma	1.7
	Other nonliposarcoma histology	1.6
Disease-specific survival	Size > 10.0 cm	2.1
	Deep location	2.8
	Local recurrence at presentation	1.5
	Leiomyosarcoma	1.9
	Malignant peripheral nerve tumor	1.9
	Microscopically positive margin	1.7
	Lower-extremity site	1.6

Adverse prognostic factors identified are independent by Cox regression analysis.

Modified from Pisters PWT, Leung DHY, Woodruff JM, et al: Analysis of prognostic factors in 1041 patients with localized soft tissue sarcomas of the extremities. J Clin Oncol 1996;14:1679.

prospectively in a population of 1041 patients with extremity STS.[109] The endpoints for the multivariate analyses were local recurrence, distant recurrence (metastasis), and disease-specific survival. Results of the regression analyses for each of these endpoints are summarized in Table 97-7. These results, using prospectively acquired data, confirm the initial observations made at that institution using an independent data set.[131] In addition, the previously unappreciated prognostic significance of specific histologic subtypes and the increased risk for adverse outcome associated with a microscopically positive surgical margin or locally recurrent disease were noted. Unlike for other solid tumors, the adverse prognostic factors for local recurrence of a STS are different from those that predict distant metastasis and tumor-related mortality (see Table 97-7).[109] In other words, patients with a constellation of adverse prognostic factors for local recurrence are not necessarily at increased risk for distant metastasis or tumor-related death. Therefore, staging systems that are designed to stratify patients according to risk of distant metastasis and tumor-related mortality using these prognostic factors (such as the AJCC/UICC system) will not stratify patients according to risk of local recurrence. The results of these multivariate analyses should be incorporated in the design of new staging systems and clinical trials for STS, and the identification of individual patients who are at high risk for distant recurrence and death.

It should be emphasized that the prognostic factors that have been identified have been derived primarily from studies of patients with localized extremity sarcomas. Despite the fact that extremity sarcomas make up the majority of sarcomas, these results may not be optimally generalized to the greater population of STS patients. Separate reviews of prognostic factors for sarcomas of the retroperitoneum,[133,134] head and neck,[135–138] gastrointestinal tract,[139,140] colon and rectum,[141] uterus,[142] synovial sarcomas,[143,144] malignant fibrous histiocytoma,[145–147] and Ewing's sarcoma[148–151] have been reported.

Potential Molecular Prognostic Factors

Attention has recently been focused on the evaluation of molecular pathologic prognostic factors. Specific molecular parameters that have been evaluated for prognostic significance have included p53,[152] mdm2,[152] Ki-67,[152] altered expression of the retinoblastoma gene product (pRb)[58,153] in high-grade sarcomas, and the presence of the SYT-SSX fusion transcripts in synovial sarcoma[92] or EWS-FL11 fusion transcripts in Ewing's sarcoma.[90,91]

A preliminary report evaluating the prognostic role of pRb expression in 44 primary and 12 metastatic high-grade human sarcomas by immunohistochemical methods and Western blotting demonstrated that alterations in pRb are more commonly associated with high-grade tumors, metastatic lesions, and decreased survival.[58] However, a subsequent report from the same group in an expanded population of 174 adult patients with STS revealed that pRb alterations were frequently observed in both low- and high-grade lesions and that altered pRb expression did not correlate with known predictors of survival and was not an independent predictor of long-term outcome.[153] These studies and the now well-documented phenomenon of late (>5 years post-treatment) recurrence of STS[154] underscore the importance of long-term follow-up and relatively large sample size in these types of analyses.

p53 is a tumor suppressor gene located on chromosome 17. Somatic p53 mutations have been reported in 4% to 65% of patients with STS.[155–159] Detection of p53 has also been correlated with reduced overall survival in immunohistochemical studies of paraffin-embedded STSs. Data on the underlying prognostic significance of p53 status are conflicting; some investigators report no independent adverse prognostic significance by regression analysis,[152,160] and others report a highly significant correlation between p53/mdm2 status and outcome.[161]

Ki-67, an antigen that is expressed throughout the majority of the cell cycle, is utilized as a measure of dividing cells.[162] Preliminary reports of series of heterogeneous sarcomas in adults suggested that proliferative index as measured by Ki-67 nuclear staining correlated with histologic grade but was not of independent prognostic significance when histologic grade was taken into account.[160,163] However, additional studies in larger numbers of patients have demonstrated that Ki-67 status is an independent prognostic factor.[152,164,165] An initial immunohistochemical analysis of a cohort of 65 STSs and a subsequent analysis of 132 STSs from the French Federation of Cancer Centers Sarcoma Group demonstrated the adverse prognostic significance of increased Ki-67 activity.[164,165]

Heslin and colleagues evaluated the potential prognostic significance of pRb, p53, mdm2, and Ki-67 by immunohistochemical techniques in a population of 121 patients with primary, high-grade extremity sarcomas and compared these factors to conventional clinicopathologic prognostic factors (median follow-up: 64 months).[152] Clinicopathologic and molecular factors that were found to be statistically significant adverse prognostic factors in both univariate and multivariate analyses for the separate endpoints of distant metastasis and tumor-related mortality included tumor size greater than 5 cm, microscopically positive surgical margin, and a Ki-67 score greater than 20 (>20% nuclear staining). Overexpression of p53 or mdm2 or deletion of pRb did not correlate with an increased risk of distant metastasis or tumor-related mortality.

Synovial sarcoma is characterized by a specific chromosomal translocation, t(X;18)(p11;q11), which is seen in more than 90% of these tumors.[82,84] This had led to studies evaluating the potential prognostic significance of SYT-SSX fusion transcripts, which arise from this translocation.[92] The t(X;18)(p11;q11) translocation fuses the SYT gene from chromosome 18 to either of two homologous genes at

Xp11, SSX1, or SSX2. The fusion transcripts SYT-SSX1 and SYT-SSX2 are believed to function as aberrant transcriptional regulators. The prognostic significance of these alternative forms of the SYT-SSX fusion gene and the relationship of these fusion transcripts and synovial sarcoma tumor morphology (monophasic versus biphasic subtype) were examined in 45 patients with synovial sarcoma.[92] There was a significant correlation ($P = 0.003$) between histologic subtype and fusion transcript type; all 12 biphasic synovial sarcomas had an SYT-SSX1 fusion transcript, whereas 17 (52%) of 33 monophasic tumors were positive for SYT-SSX1. Moreover, the presence of the SYT-SSX1 transcript was an independent adverse prognostic factor for metastasis-free survival. Thus, SYT-SSX fusion transcripts may be used as a diagnostic marker for synovial sarcoma, and transcript subtype should be confirmed as an independent prognostic factor.

Ewing's sarcomas are characterized by a translocation involving chromosomes 22 and 11: t(11;22)(q24;q12).[85] Recent studies have evaluated the prognostic significance of transcripts produced by the fusion of the EWS and FL11 genes from chromosomes 22 and 11. The most common EWS-FL11 fusion, designated as type 1, is found in 65% of Ewing's sarcomas.[166,167] Two groups have demonstrated that type 1 EWS-FL11 fusion transcripts are associated with a more favorable prognosis.[90,91] De Alava and colleagues[91] have demonstrated that the prognostic significance of type 1 EWS-FL11 fusion transcripts is independent of tumor site, stage, and size. However, these observations were made with a short follow-up (median: 26 months, range: 1 to 140 months); therefore, additional studies and longer follow-up are needed to further substantiate these interesting observations. The biologic basis for these observations is unknown. Additional studies that examine the relationship between EWS-FL11 transcript subtype and proliferative rate, apoptosis, and response to treatment are warranted.

With the increasing use of cDNA expression profiling, it is possible that expression profile-based stratification may be possible within specific histologies, in a manner analogous to current use of this technique to stratify breast cancer.[168] Additionally, these profiles have recently been applied to determining metastatic potential of primary tumors, and this approach could clearly be applicable to STSs, in which the presence or absence of metastases remains the most important prognostic factor.[169] Most recently, phosphoprotein profiling has been employed to stratify patients with stage III rhabdomyosarcoma and predict outcome.[170] This approach also holds future promise for both prognostic and therapeutic approaches (see later discussion).

Although specific cellular and molecular parameters have been identified as having independent prognostic significance, there is currently no consensus on how specific molecular prognostic factors should be utilized in clinical practice. Until more data are available, molecular prognostic factors that have proven to be of prognostic significance (e.g., Ki-67) should be considered for inclusion as stratification criteria in clinical trials.

Prognostic Factors as Therapeutic Targets

The prognosis of GISTs is poor when they are treated by surgery alone,[171] and these tumors rarely respond to conventional systemic chemotherapy. The most exciting discovery in GIST research in recent years is targeted molecular therapy, which will be discussed later in the chapter. The proto-oncogene c-Kit is the cellular homolog of the oncogene v-Kit (a feline sarcoma virus). c-Kit encodes a transmembrane tyrosine kinase receptor, KIT (CD117), that is structurally similar to platelet-derived growth factor and provides selective targets of key aberrations in the molecular signaling implicated in the pathogenesis of GISTs and other tumors (e.g., DFSP). An interesting additional feature of c-Kit expression in GIST is that different types and locations of mutations in c-Kit appear to be independently significant for predicting disease-free survival irrespective of treatment with kinase receptor inhibitors.[172] CD117 expression was uniformly evident in a recent study of GIST cases not treated with imatinib.[74,172] Of interest, c-Kit was highly phosphorylated in all cases, even in those few that lacked demonstrable sequence mutations.[74] Mutations were found in specific regions of the c-Kit gene, and specific mutations appear to be associated with differing prognosis (see following discussion). The subset of patients with exon 11 mutations resulting in single amino acid substitutions (i.e., missense codon mutations) fared much better than did patients with deletion/insertion mutations of exon 11 (5-year recurrence-free survival rate of 89% ± 11% versus 37% ± 10%, respectively). A potential explanation for this finding is that exon 11 missense mutations are detected in lower-grade, favorable outcome GISTs.[172] Against this explanation is the fact that the vast majority of metastatic GISTs have exon 11 mutations. While it is conceivable that the type of mutation is a surrogate for the behavior of a GIST, however, it is also plausible that the type of mutation represents the initial pathogenetic mechanism, making it a true prognostic marker and target. Finally, in vitro studies suggest that GISTs with regulatory region KIT mutations are more likely to respond to imatinib than are GISTs with enzymatic region mutations.[173]

Molecular Therapeutic Targets in Sarcomas

We have just now begun to see the implications and success of targeting genetic alterations in sarcomas that drive oncogenesis. GIST tumors were previously thought to be gastrointestinal leiomyosarcomas that were particularly resistant to cytotoxic chemotherapy. It was subsequently demonstrated that these tumors were derived from interstitial cells of Cajal and were frequently characterized by point mutations in the c-Kit receptor tyrosine kinase and were clearly distinct from leiomyosarcomas.[174,175] Subsequently, the tumors were treated with imatinib mesylate that targets the c-Kit kinase with dramatic results.[176] The c-Kit mutations that were seen were located in exon 11 (juxtamembrane domain, seen in 71% of tumors), exon 9 (the extracellular region, 13%), exon 13 (first lobe of the split-kinase domain, 4%), and exon 17 (phosphotransferase domain, 4%). The subset of patients with exon 11 mutations resulting in point single amino acid substitutions (i.e., missense codon mutations) fared much better than did patients with deletion/insertion mutations of exon 11 (5-year recurrence free survival rate of 89% ± 11% versus 37% ± 10%, respectively).[172] In addition, tumors that lack c-Kit mutations appear to have mutations in PDGF-α receptor, and these mutations appear to be mutually exclusive of c-Kit mutations.[177] Finally, the type of mutation that is identified appears not only to predict response to imatinib mesylate, but also to suggest whether other kinase inhibitors such as sunitinib may have beneficial effects.[178] While it is unlikely that most sarcomas will be driven by mutations in a kinase that is amenable to target inhibition, it is likely that as more information is acquired regarding activation of specific signaling pathways in STSs, most will have treatment options that are not currently available.

Predicting Individual Prognosis

Kattan and colleagues have observed that information that is appropriate for researchers is not as helpful for patients with cancer who must plan in a different way for the future.[179] Patients' main preoccupation is to obtain a predicted probability of individual (i.e., personal) survival unencumbered by specific knowledge of prognostic factors, relative risk, or the risk group in which the person may belong. Kattan and colleagues have constructed and validated a nomogram to predict the probability of 12-year sarcoma-specific death based on a prospective series of patients (Fig. 97-8).[179] This tool is useful for individual patient counseling, follow-up scheduling, and clinical trial eligibility assessment and is further facilitated by being also available for personal handheld computer devices. This sarcoma-specific computer application is available at www.nomograms.org.

TREATMENT OF LOCALIZED PRIMARY SOFT-TISSUE SARCOMA

Surgery

Limb-Sparing Surgery versus Amputation

Surgical resection remains the cornerstone of therapy for localized STS, and the prototypical situations concern the management of lesions arising in the extremity, the most common anatomic site. Over the past 20 years, there has been a marked decline in the rate of amputation as the primary therapy for extremity STS. With the widespread application of multimodality treatment strategies, fewer than 10% of patients currently undergo amputation.[180,181] The current use of limb-sparing multimodality treatment approaches for patients with extremity sarcoma is largely based on a randomized prospective study from the U.S. NCI in which patients with extremity sarcomas that were amenable to limb-sparing surgery were randomized to receive amputation or limb-sparing surgery with postoperative radiotherapy.[182,183] Both arms of this trial included postoperative chemotherapy with doxorubicin, cyclophosphamide, and methotrexate. With more than 9 years of follow-up evaluation, 5 (19%) of 27 patients randomly assigned to receive limb-sparing surgery and postoperative radiation with chemotherapy had local recurrences, as compared to 1 (6%) of 17 patients in the amputation plus chemotherapy arm (P = 0.22; Fig. 97-9).[183] The disease-free survival rate was 63% for limb-sparing surgery versus 71% for amputation (P = 0.52; Fig. 97-10), and the overall survival rate was 70% for limb-sparing surgery versus 71% for amputation (P = 0.97). This study established that for patients for whom limb-sparing surgery is an option, a multimodality approach employing limb-sparing surgery combined with postoperative radiotherapy yields disease-related survival rates comparable to those for amputation while simultaneously preserving a functional extremity.

Currently, at least 90% of patients with localized extremity sarcomas can undergo limb-sparing procedures.[180,184] Most surgeons consider definite major vascular, bony, or nerve involvement to be relative indications for amputation. Complex en bloc bone, vascular, and nerve resections with interposition grafting can be undertaken, but the associated morbidity is high. Therefore, for a few patients with critical involvement of major bony or neurovascular structures, amputation remains the only surgical option but offers the prospect of prompt rehabilitation with excellent local control and survival.[183]

Completeness of Resection

Satisfactory local resection involves resection of the primary tumor with a margin of normal tissue around the lesion. The width of the margin should differ depending on whether or not adjuvant radiotherapy is used. It is clear that dissection along the tumor pseudo-

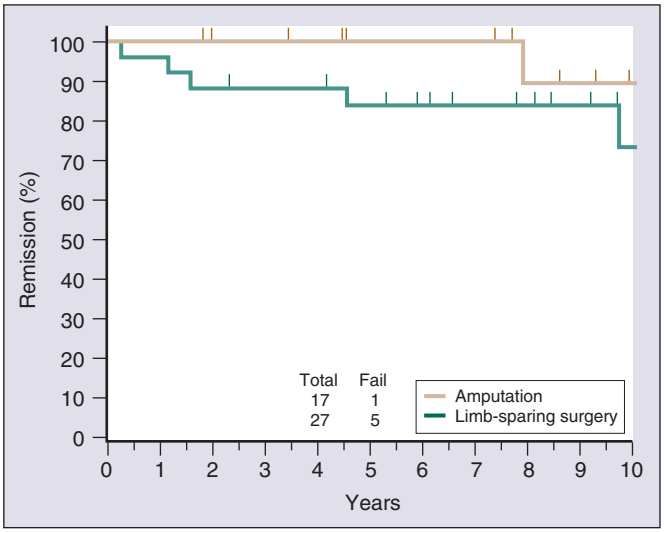

Figure 97-9 • Local recurrence rates in patients with high-grade extremity sarcomas randomized to receive amputation or limb-sparing surgery. capsule (enucleation) is associated with local recurrence rates ranging between 33% and 63%.[185–187] Wide local excision with a margin of normal tissue around the lesion is associated with local recurrence rates in the range of 10% to 31%, as was noted in the control arms (surgery alone) of the randomized trials evaluating postoperative radiotherapy.[188,189] In contrast to malignant melanoma, a disease for which there are randomized data to address adequate margin size, no comparable data are available to define what constitutes a satisfactory gross resection margin for a sarcoma. In general, every effort should be made to achieve a wide margin (2 cm is a frequently cited arbitrary choice) around the tumor mass, except in the immediate vicinity of

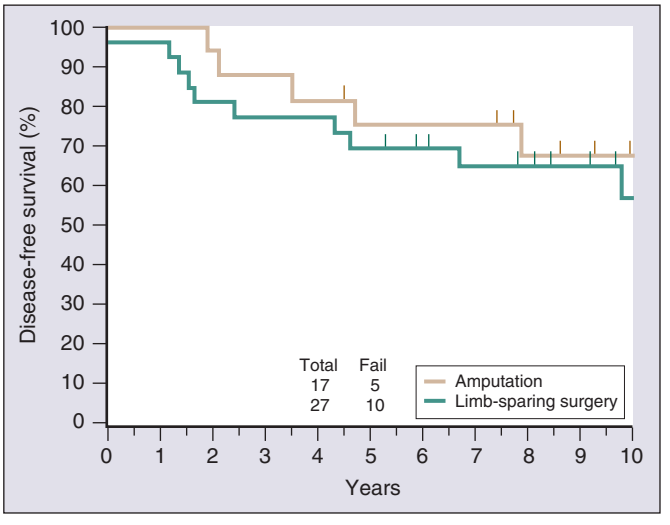

Figure 97-10 • Disease-free survival rates for patients with high-grade extremity sarcomas randomized to receive amputation or limb-sparing surgery. All patients were treated with adjuvant chemotherapy using doxorubicin, cyclophosphamide, and methotrexate. Median follow-up: >9 years (P = 0.52). functionally important neurovascular structures, where, in the absence of frank neoplastic involvement, dissection is performed in the immediate perineural or perivascular tissue planes. The 2-cm choice is unnecessary if radiotherapy is also used, since substantial modification of the surgical approach with much closer margins of resection (e.g., 1 to 2 mm) is made possible, and even large lesions can be managed conservatively in that setting. Technical details of the surgical approach to extremity sarcomas are beyond the scope of this chapter but are comprehensively reviewed in a surgical atlas.[190] At the same time, it is also important to bear in mind that involved (i.e., positive) resection margins remain an adverse finding even when adjuvant radiotherapy is used, notwithstanding the amelioration of risk that radiation treatment provides. Data from Memorial Sloan-Kettering Hospital, Princess Margaret Hospital, and Massachusetts General Hospital suggest an additional absolute reduction of local control of approximately 10% to 15% for patients with positive margins compared to those with microscopically negative surgical margins.[190–193]

In considering the existing outcome data, it is important to bear in mind that these data consider the rubric "positive margins" in a uniform way, although in reality, this is unlikely to be the case. In fact, positive resection margins have different causes. One is oncologically inadequate surgery in which positive resection margins might have been avoidable in another surgeon's hands. When this is the case, microscopically positive surgical margins can be considered a technical failure. Alternatively, positive resection margins may arise in anatomically adverse presentations in which locally advanced disease challenges the goals of conservative resection from the outset. In another study from the Princess Margaret Hospital, Gerrand and colleagues evaluated the type of microscopically positive margin as a prognostic factor and defined four groups in this setting.[194] Patients with low-grade liposarcomas and microscopically positive surgical margins (group 1) have a low risk of local failure (4.2%), as do those in whom a positive margin is anticipated before surgery to preserve critical structures and radiotherapy is given to sterilize the minimal residual disease (group 2). However, two categories of positive margins are associated with a higher risk of local recurrence: (1) patients who present after prereferral unplanned excision and who have a positive margin on subsequent reexcision (group 3) and (2) patients with unanticipated positive margins occurring during primary sarcoma resection (group 4; Fig. 97-11). For group 3, an "unplanned excision" is defined as an excisional biopsy or resection that is carried out without adequate preoperative staging or consideration of the need to remove normal tissue around tumor, an adverse feature reported by the same authors previously.[195] These data appear to support the premise that, provided that adjuvant radiotherapy is administered, a very small amount of residual disease resulting from a "planned" positive margin at the site of a critical anatomic structure (group 2, local recurrence rate of 3.6% and 95% confidence interval 0 to 10.4) is not associated with the same deleterious risk that occurs with a positive margin that follows major contamination due to "shell out" intralesional surgery (group 3, local recurrence rate of 31.6%, 95% confidence interval: 10.7 to 52.5) or inadvertent contamination of the wound (group 4, local recurrence rate of 37.5%, 95% confidence interval: 13.8 to 61.2).[194] These data seem particularly relevant to anatomic sites where achievement of adequate resection margins is a perennial problem, such as the head and neck, as evidenced by recent results from a prospective series where the outcome approaches that of extremity and body wall sarcomas.[196] We would caution, however, that such results are probably not attainable without a defined management protocol and joint multidisciplinary assessment before treatment is undertaken, since there exist issues that merit discussion at the individual case level (e.g., the complex relationship between tissues to be resected and reconstructed and the radiotherapy volumes and doses, all of which can influence each other in the decision algorithm).

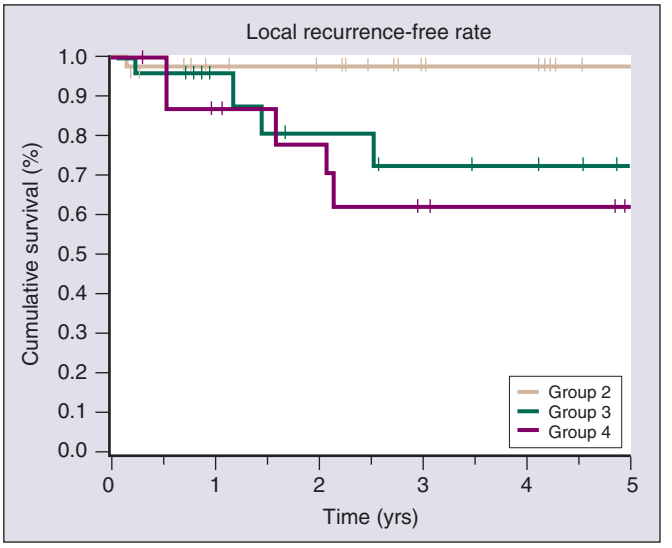

Figure 97-11 • Kaplan-Meier estimate for local recurrence-free rate for three different groups of positive margin categories (see text for details). Group 1 (low-grade liposarcoma with positive resection margins) is not shown. Tick marks represent censored cases. J Bone Joint Surg Br 2001;83:1149.)

Lymph Node Dissection

Given the low (2% to 3%) prevalence of lymph node metastasis in adults with sarcomas,[102,103] there is no role for routine regional lymph node dissection. Patients with angiosarcoma, embryonal rhabdomyosarcoma, and epithelioid histiotypes have an increased incidence of lymph node metastasis and should be carefully examined for adenopathy. Therapeutic lymph node dissection (curative) results in a 34% actuarial survival rate;[105] therefore, the rare patients with regional nodal involvement who have no evidence of extranodal disease should undergo therapeutic lymphadenectomy. Patients with adverse features at the time of dissection (i.e., extracapsular extension beyond the lymph nodes into perinodal fat or positive or doubtful margins on the neurovascular bundle) or in whom treatment into the next grossly uninvolved lymph node echelon is not feasible with surgery should also be considered for additional adjuvant nodal irradiation. The principles underlying this approach have recently been outlined.[197]

Surgery Alone

Although the majority of patients with extremity STS should be treated with preoperative or postoperative radiotherapy, recent reports suggest that concomitant radiotherapy might not be required for selected patients with completely resected, small, primary STSs (Table 97-8).[198–201] Rydholm and colleagues have reported their experience with 70 patients with subcutaneous or intramuscular extremity sarcomas treated with wide surgical resection and microscopic assessment of surgical margins.[200] Negative histologic margins were obtained for 32 of 40 subcutaneous and 24 of 30 intramuscular tumors. The 56 patients with microscopically negative margins received no postoperative radiotherapy, yet only 4 (7%) developed local recurrence. A study from Brigham and Women's Hospital reported similar results for a selected group of 74 patients with primary extremity STS treated by surgery without radiotherapy.[201] The 10-year actuarial local control rate was 93% plus or minus 4%. The absolute gross margin was a significant predictor of local recurrence; patients with a close gross margin of less than 1 cm had a 10-year local control rate of 87% ± 6% compared to 100% for patients with a closest gross margin of 1 cm or greater ($P = 0.04$). The generally favorable local control rates with surgery alone that these and other[198,202] investigators reported in these series of highly selected patients are comparable to local recurrence rates observed for more heterogeneous patient populations treated with conventional multimodality therapy incorporating preoperative or postoperative radiotherapy (Table 97-9).[66,188,203–209] These data support the hypothesis that selected patients with small, primary STSs can be treated with surgical resection alone without preoperative or postoperative radiotherapy.

It is difficult to define the precise selection criteria that should be used to identify patients with primary sarcoma who can safely undergo treatment by surgery without radiotherapy. Most investigators have limited this approach to patients with carefully selected T1 tumors that can be resected with clear margins (see Table 97-8). In contrast, Karakousis and colleagues did not consider absolute tumor size but instead utilized surgical resection alone for all patients in whom a minimum intracompartmental margin of 2 cm could be maintained circumferentially, irrespective of tumor size.[198] Karakousis and colleagues recently updated the results for high-grade STS of the policy of limiting the use of postoperative radiation treatment for tumors resected with positive or "narrow" (less than 2 cm) resection margins.[210] This approach has yielded useful data because the consistent application of this treatment approach resulted in a local recurrence rate of 19% with "wide" margin surgery alone compared to 24% after "narrow" margin surgery and adjuvant radiotherapy.[210] Although the results provide some clarity about the 2 cm or greater margin benchmark, it would be useful to also have similar data from other groups for a variety of margin widths to draw conclusions about when it is safe to withhold radiotherapy. Moreover, the authors acknowledge the potential to treat a greater proportion of cases with radiotherapy and lower the 19% local recurrence rate in some of those "favorable cases" that are currently treated with surgery alone by widening the indication for adjuvant radiotherapy in a proportion of these patients.[210] This view would certainly be consistent with

contemporary observations such as the local recurrence rate of 7% in patients who are undergoing combined modality treatment such as those in the recent Canadian randomized trial (see section on Preoperative or Postoperative Radiotherapy).[211]

Factors other than anatomic location, tumor size, and the feasibility of achieving an R0 resection (macroscopically and microscopically complete) should be considered in selecting patients for treatment by surgery alone. For example, the issue of whether the patient has had a prior "unplanned" excision (referred to earlier) is important. At the Princess Margaret Hospital, a significantly higher rate of local recurrence was apparent in patients who were treated after unplanned excision on the outside than in patients who received their treatment at their institution (22% versus 7%, $P = 0.03$).[195] It is important to remember that unplanned excision is very common in the community setting, where small soft-tissue lesions are often excised without image guidance under the presumption that they are benign. Therefore, while it is reasonable to attempt a reexcision if it is considered feasible, patients who have undergone unplanned excision should also be strongly considered for adjuvant radiation.

Preoperative or Postoperative Radiotherapy

Conservative (limb-sparing) surgery and radiotherapy have been combined to optimize local control for patients with localized STS. Radiotherapy can be administered preoperatively,[203–205,212,213] postoperatively,[207,214,215] or by interstitial techniques (brachytherapy).[66,206,216–220]

Local Control

Data from two randomized controlled trials (RCTs)[71,188] have confirmed earlier retrospective reports suggesting that surgery combined with radiotherapy results in superior local control compared to surgery alone.[204,207,209] Yang and colleagues from the NCI recently reported on a RCT of postoperative external beam radiotherapy (EBRT).[188] In this trial, 141 patients with localized extremity STSs amenable to limb-sparing resection were randomly assigned to receive postoperative EBRT or no radiotherapy. All patients with high-grade lesions received postoperative chemotherapy. In the subset of 91 patients with high-grade lesions, no local recurrences have been noted in the 44 patients who received postoperative radiotherapy (with chemotherapy) versus 9 local recurrences (19%) in the 47 patients who received postoperative chemotherapy alone ($P = 0.0003$). In the 50 patients with low-grade sarcomas, 1 (4%) of 26 patients who received adjuvant radiotherapy has had a local recurrence versus 8 (33%) of 24 patients treated by surgical resection alone ($P = 0.016$). However, no improvement in survival was noted with adjuvant radiotherapy in the entire cohort of patients or in any subgroup.

The second RCT of postoperative radiotherapy was conducted at Memorial Sloan-Kettering Cancer Center, where investigators studied adjuvant brachytherapy for patients with extremity and superficial trunk STSs.[193] One hundred sixty-four patients with extremity or superficial trunk STSs were randomly assigned to receive adjuvant brachytherapy (42 to 45 Gy with an iridium-192 implant) or no postoperative radiotherapy after complete resection of their sarcomas. Randomization took place in the operating room after gross total resection, thereby limiting the potential bias that might influence the extent of surgical resection in a comparative trial. Sixty-eight of 119 patients with high-grade tumors also received chemotherapy. With a median follow-up of 76 months, 5-year actuarial local control rates were significantly better in the group treated with adjuvant brachytherapy (82%) than in those who received surgery alone (69%). Subset analysis demonstrated that the local control advantage of brachytherapy was confined to patients with high-grade lesions, for whom the 5-year local control rate was 89% (versus 66% in the surgery-only group; Fig. 97-12). Patients with low-grade STSs did not appear to experience the same local control benefit with adjuvant brachytherapy.[193,220] As was noted in the NCI RCT,[177] the improvement in local control did not translate into any detectable survival difference between the brachytherapy and no-brachytherapy arms of the trial.

Local failure rates with combined-modality regimens incorporating surgery and radiotherapy are generally less than 15% (see Table 97-9). Despite theoretical advantages that may favor preoperative radiation, brachytherapy, or postoperative radiation, there does not appear to be a major difference in local control rates among these radiation techniques, although at present, data comparing the approaches are sparse.

Relationship Between Local Control and Survival

Whether local control affects overall survival for patients with STS remains unclear and highly controversial.[221–225] Only an adequately powered prospective randomized trial can assess the precise nature of any relationship between local control and overall survival. Three RCTs have evaluated local control and survival in the context of defining treatment approaches for STS. In a randomized trial of

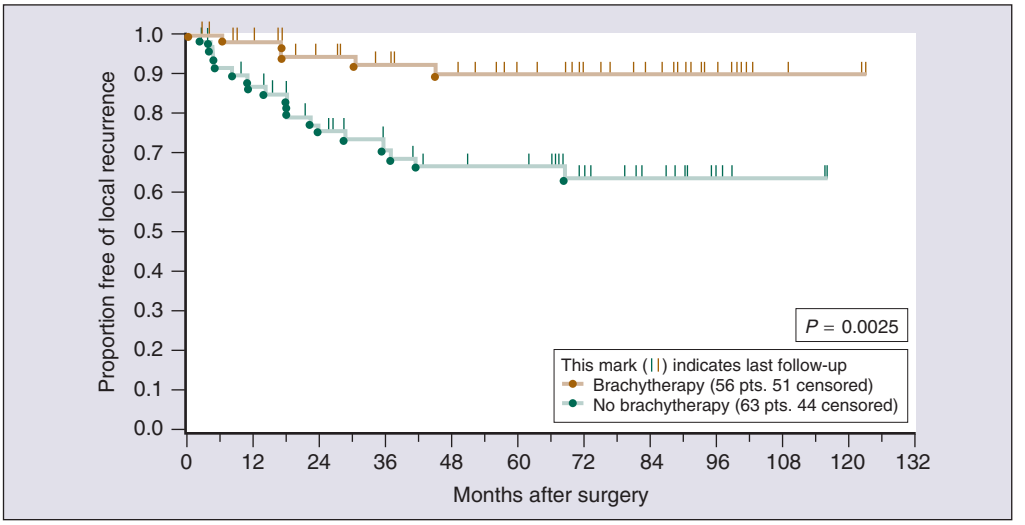

Figure 97-12 • Local recurrence-free survival in patients with high-grade sarcoma treated in the Memorial Sloan-Kettering Cancer Center randomized trial of postoperative brachytherapy versus surgery alone. A statistically significant difference was noted in local recurrence-free survival with brachytherapy ($P = 0.0025$). (Reprinted with permission from Pisters PW, Harrison LB, Leung DH, et al: Long-term results of a prospective randomized trial of adjuvant brachytherapy in soft tissue sarcoma. J Clin Oncol 1996;14:859.)

amputation versus conservative surgery plus radiation from the NCI, local recurrence rates were 19% in the limb-sparing arm versus 6% in the amputation arm ($P = 0.022$).[182,183] Despite this, overall survival rates were equivalent at 70% for limb-sparing surgery and 71% for amputation ($P = 0.97$). In the randomized trials of postoperative radiotherapy,[188,193] the improvement in local control that was noted in patients who were treated with surgery plus radiotherapy did not translate into any detectable survival advantage. Thus, none of the currently available data from prospective RCTs support the hypothesis that better local control enhances survival in patients with sarcoma. Methodologically, the available trials are problematic for this issue because the outcome of interest (i.e., a difference in survival consequent on a differential in local control) would require a prohibitively large sample size. Thus, it is most improbable for these trials to be capable of demonstrating an effect with their modest sample sizes that were intended for evaluation of different outcomes. Indeed, it is most unlikely if even a meta-analysis of the trials could demonstrate this. Furthermore, data from nonrandomized studies support the concept that there is little, if any, relationship between local control and survival. In a recent series from Sweden, the outcome of patients who were treated with an inadequate excision was compared with that of patients who had an adequate operation.[224] Local recurrence was 3.5 times more common after inadequate excision, but there was no difference in the incidence or timing of distant metastases. The power of the RCTs that have been reported so far to detect a difference in survival is relatively small, and a large number of patients may be required to demonstrate that prevention of local recurrence affects survival.[222] Stotter and colleagues have argued that local recurrence is a time-dependent variable and should be considered as such in multivariate studies.[221] Analysis in this fashion of the data from a nonrandomized study demonstrates a statistically significant relationship between local control and survival. Other retrospective analyses have yielded similar conclusions.[226,227]

For a more detailed description of the methodologic problems associated with time-dependent variables and the use of surrogate endpoints that emerge after the initial sarcoma treatment, the reader is referred elsewhere.[228] In this context, it is clearly important to distinguish between the well-defined adverse prognostic impact of subsequent local recurrence on survival[109,225,229] and the unproven positive effect of improved local control (i.e., prevention of local recurrence with improved local therapy) on survival. The former phenomenon might be a manifestation of more aggressive tumor biology; that is, biologically more aggressive lesions might recur locally and metastasize more frequently.

Treatment Sequencing: Preoperative versus Postoperative Treatment

Of further interest, an improvement in overall survival (a crude rate of 85% versus 72% in favor of postoperative radiotherapy, $P = 0.0481$) has emerged and is only partially explained by increased deaths in the postoperative arm unrelated to sarcoma (Fig. 97-13).[211] This observation is of obvious oncologic interest. Longer follow-up is clearly required, and a 5-year analysis is currently under way. In summary, the final results of the SR2 trial are expected to provide insight into the comparative efficacy, functional outcome, economic costs, and complication rates of these two options for EBRT and potentially on survival outcome if the preliminary results are sustained.

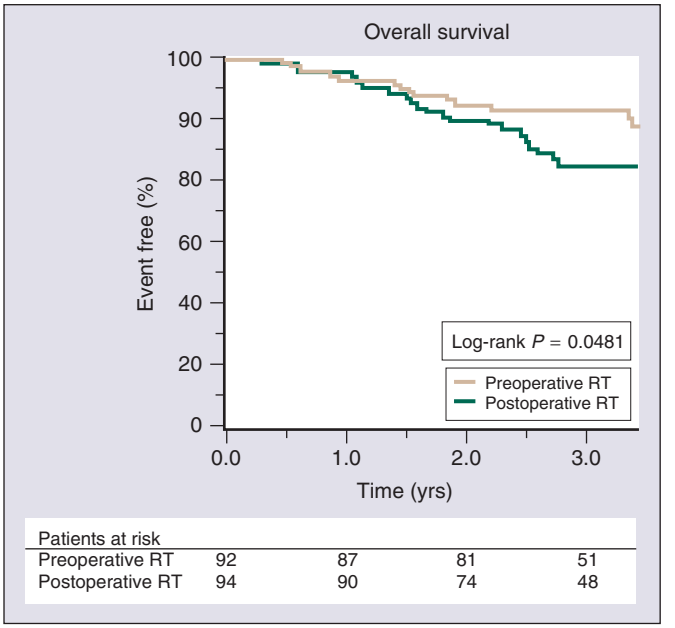

Figure 97-13 • Actuarial probability of overall survival for preoperative versus postoperative radiotherapy in extremity soft-tissue sarcoma. (Reproduced with permission from O'Sullivan B, Davis AM, Turcotte R, et al: Preoperative versus postoperative radiotherapy in soft-tissue sarcoma of the limbs: a randomised trial. Lancet 2002;359:2235.)

Until the mature data from the Canadian Sarcoma Group RCT are available, it appears reasonable to treat patients with postoperative EBRT, since local control rates are comparable to preoperative techniques but major wound complication rates are significantly lower. On the other hand, the maturing data on late tissue effects for these respective approaches in the Canadian trial are salutary, and the emerging potential influence on survival, pending 5-year analysis, is awaited with interest. Also, in anatomic sites where wound complications are rarely seen (e.g., the upper extremity), the rationale for wound complication avoidance as a reason to favor the use of postoperative radiotherapy is not as sound. In particular, the obvious advantage to preoperative radiotherapy in the proximal arm and shoulder is apparent where avoidance of large volume and higher dose irradiation that may treat the lung or brachial plexus can be achieved. These principles are also reasonable in the head and neck based on the recent Princess Margaret Hospital data.[196]

On the other hand, with brachytherapy, the patient's entire local treatment (surgery plus radiation) can be completed in 10 to 14 days. This has significant cost advantages[230] and also has significant implications in terms of overall patient convenience. In the absence of comparative data addressing the efficacy of these techniques in achieving local control, these additional considerations assume increased importance. Where the necessary expertise is available for brachytherapy, this technique provides an excellent, cost-effective alternative for patients with high-grade lesions. Brachytherapy should not be used for patients with low-grade sarcomas.[220]

Recently, an RCT of EBRT for patients with localized extremity STS was reported by the National Cancer Institute of Canada Clinical Trials Group/Canadian Sarcoma Group in which 190 patients with extremity STS were randomized to preoperative versus postoperative radiation.[211] The radiotherapy parameters for this protocol required a field margin of 5 cm around the gross tumor volume for the initial phase of treatment (i.e., treatment to 50 Gy in 25 fractions), and this generally included any peritumoral edema that was seen on MRI, irrespective of the grade or size of the tumor. Subsequently, a reduced-volume field was treated to a total combined dose of 66 Gy in all postoperative cases and in those preoperative patients in whom the resection margins were involved.

The results of this trial are complex because the primary endpoint that powered the trial, and hence its sample size, was the cumulative incidence of acute wound complications 120 days after protocol surgery in both arms of the study. Nevertheless, the local control rates after 3.3 years of median follow-up are identical in both arms of the study (7%).

Wound Complication Rates and Post-Treatment Function

The results of the Canadian RCT may provide insight into the comparative efficacy, functional outcome, economic costs, and complication rates of preoperative and postoperative treatment sequencing for EBRT. In the absence of a clear local control advantage to any specific radiation technique, clinicians have considered other factors in formulating standards of care. Such factors have included wound complication rates, financial costs, patient convenience, health-related quality of life and physical function, radiotherapy toxicity, and perhaps even overall survival.

It is clear that while field size and radiation dose may be minimized with preoperative radiotherapy,[231] major wound complications after preoperative radiotherapy and surgery have been reported to be in the 20% to 35% range.[232,233] In the Canadian Sarcoma Group RCT, wound complications were defined as secondary wound surgery, hospital admission for wound care, deep packing, or prolonged dressings within 120 days after tumor resection. By these criteria, preoperative radiation had a significantly higher rate (35% versus 17%, $P = 0.01$) of wound complications than did postoperative EBRT. Of note, the risk was confined to the lower extremity.[211]

Taken in isolation, the wound complication fact alone can be expected to cause some groups to continue to favor postoperative radiotherapy, though this could change, as data have now emerged from the Canadian RCT that late tissue outcomes strongly favor the preoperative approach and a putative survival advantage needs to await mature follow-up.[234] Thus, the radiotherapy toxicity rates after 2 years differed between the arms of the study. The rates of grade 2 or greater fibrosis and edema were significantly higher in the postoperative arm compared to preoperative radiotherapy and were independently associated with the larger irradiation volumes and doses used in postoperative radiotherapy.[234] Short-term functional outcome in the SR2 trial has also been reported and continues to be collected prospectively.[235] Two validated instruments—the Toronto Extremity Salvage Score (TESS) and the Short Form-36 quality of life instrument (SF-36)—were applied, as was the observer-based Musculoskeletal Tumor Society Rating Scale (MSTS).[235] Patients who were treated with postoperative radiotherapy had better function with higher MSTS, TESS, and SF-36 bodily pain scores at 6 weeks after surgery than did those who were treated with preoperative radiation, but there were no differences at later time points up to 1 year. Thus, the timing of radiotherapy has minimal impact on the function of STS patients in the first year after surgery, but thereafter, significant factors likely come into play. These include the apparently deteriorating late tissue sequelae caused by larger doses and volumes. Of interest, patients who experience wound complications appear to continue to suffer some impaired function. Further follow-up will be required to assess the ongoing evolution of these competing risks.

Conformal Radiotherapy and Intensity-Modulated Radiotherapy

STSs present in virtually any anatomic site, and the capacity for unusual presentation is almost limitless. This can result in circumstances in which conventionally delivered radiotherapy is impossible owing to the magnitude of the volume to be treated, uncertainty in defining the target for radiotherapy, or, more usually, because of the proximity of normal tissues to the intended target volume. While some presentations are extremely problematic (e.g., uncertain targets due to organ mobility or imprecise anatomic issues resulting from poor definition of tumor location related to imaging limitations or inadequate surgical and/or pathologic description), others can be addressed by novel methods of radiotherapy delivery. Leading the advances in this field is intensity-modulated radiotherapy, an advanced form of three-dimensional conformal radiotherapy in which radiation beams are not only shaped at their perimeters, but also include variable intensity across the profiles of the beams. This permits the creation of exquisite conformation of dose to targets of irregular shape while generating high-dose gradients between tumor and normal tissues. A full discussion of the potential uses of intensity-modulated radiotherapy in STS is beyond the scope of this chapter but is discussed in detail elsewhere.[236] It may be administered preoperatively, postoperatively, or as a sole modality with specific indications. Some applications include its use in lesions adjacent to the spine or critical anatomic structures of the head and neck and in the retroperitoneum to permit liver avoidance (as well as to permit spinal cord, kidney, and intestinal dose limitation), especially in lesions involving the right upper abdominal quadrant. Avoidance of late toxicity to anatomic structures such as weight-bearing bone that are at risk for fracture after treatment of extremity sarcomas seems also to be feasible.[237] Although these approaches are promising, their precise contribution and role need to be evaluated.[238]

Conventional Radiotherapy Without Surgery

Radiotherapy alone has been employed as primary therapy for patients with locally advanced, inoperable STS and patients who present with stage IV disease. Efforts to use radiation as the primary treatment have demonstrated that high doses (more than 65 Gy) are required to achieve local control rates between 30% and 60%[239,240] and that

there appears to be an inverse relationship between tumor size and local control rates. In a series of 35 patients treated with high-dose (>65 Gy) primary radiotherapy for tumor sizes less than 5 cm, 5 to 10 cm, and larger than 10 cm, the local control rates were 88%, 53%, and 33%, respectively.[241] In general, local control rates with radiation alone are inferior to those after surgery; therefore, primary radiation should be reserved for patients who are medically unfit for surgery, have technically unresectable tumors, or refuse surgery as initial therapy. However, some caution is necessary in interpreting such results in a scientifically valid manner. Encumbered with such adverse selection factors, the outcome of radiotherapy would never be comparable to that of surgery. Moreover, surgery has the added advantage over radiotherapy alone because its use for locally advanced cases is ordinarily also combined with adjuvant radiotherapy.

Neutron Radiotherapy

Neutron radiotherapy has been emphasized by certain groups because of the lower oxygen enhancement ratio compared to x-rays and the consequent attractive possibility of overcoming the biologic phenomenon that hypoxic cells generally limit the curability of malignancy with x-rays. Additional differences from x-rays are the reduced repair of sublethal and potentially lethal damage. These neutron effects are less vulnerable to the differential radiosensitivities associated with different phases of the cell cycle. It should be apparent that some of these repair phenomena also negatively affect the tolerance of normal tissues. Neutrons have been employed in a number of pilot studies, primarily in patients with locally advanced disease, with 60% to 70% local control rates.[242–244] In a recent large series, 220 patients with locally advanced sarcomas were treated with neutron radiotherapy. Ninety-four patients with gross residual disease after resection were treated with neutron therapy alone; among these patients, 27% had major morbidity, 26% had 5-year survival, and 56% had local control. One hundred four patients with microscopically positive margins of resection received a neutron boost dose; they had 7% morbidity, 65% 5-year survival, and 78% local control rates. These results suggest that for patients with gross residual disease, neutron beam radiation may provide improved local control compared to conventional external beam treatment, but these data should continue to be interpreted with caution when one considers the late tissue sequelae that appear to result from neutron beam radiation use. Comparative studies are needed to define the precise role of neutron beam therapy in the treatment of STS. Apart from unresectable disease, it seems unclear where the benefit of neutron therapy might accrue when one considers the exceptionally favorable results of conventional x-ray treatment combined with surgery and the more adverse normal tissue tolerance to neutron therapy.

Adjuvant Chemotherapy

In the past 30 years, improvements in surgical and radiotherapy techniques have led to impressive rates of local control, particularly in extremity STS, with concomitant sparing of normal tissues and preservation of limb and/or organ function. Regrettably, in the same period, much less progress has been made in finding ways to eradicate the micrometastases that are the ultimate cause of death in many individuals who present with apparently localized STS. The discovery that doxorubicin had significant antitumor activity against adult STS prompted the initiation of multiple RCTs during the period 1973 to 1990 to evaluate the benefit of doxorubicin alone or in combination with other agents after the completion of local treatment. However, most of these trials were too small to detect moderate treatment effects reliably.

The statistical technique of meta-analysis may overcome the problem of inadequate power of small RCTs, and meta-analyses based on individual patient data (IPDMA) can minimize other potential biases (e.g., exclusion of unpublished trials, variable follow-up, postrandomization exclusions, and differing definition of endpoints) that are inherent in analyses that are limited to published results. In 1997, the Sarcoma Meta-Analysis Collaboration (SMAC) published an IPDMA of outcomes for 1568 STS patients included in 14 RCTs that completed accrual by December 1992.[245] As is outlined in Table 97-10, significant improvements were found in local and distant relapse-free intervals and recurrence-free survival for all patients, and these improvements did translate into a significant overall survival benefit in the prospectively defined subgroup—almost 60% of the patients—with extremity sarcomas but not in all patients.

When interpreting the SMAC results, one should compare them with the IPDMAs that have provided conclusive evidence of the benefits of adjuvant chemotherapy and hormone therapy in early breast cancer.[246,247] In contrast with the approximately 1500 patients who were included in the SMAC IPDMA, the Early Breast Cancer Collaborative Trials Group identified 47 trials that recruited 18,000 patients for comparisons of adjuvant chemotherapy versus no adjuvant chemotherapy. The power of large numbers, even in the setting of meta-analysis, is self-evident. Compounding the problem of small numbers of STS cases, STSs as a group show marked heterogeneity in pathology and site of origin; this is much less evident in breast cancer. For example, it has been suggested that in the SMAC meta-analysis, chemotherapy benefits for extremity (57% of total) and high-grade STSs were obscured by inclusion of sarcomas at other locations (head and neck, trunk, and uterus) and those of low (5%) or unknown grade (28%). Another point of contrast with breast cancer is the relative paucity of drugs that are active against STS. At the time of the SMAC meta-analysis, only two agents (doxorubicin and ifosfamide) have reproducibly produced overall response rates exceeding 20% in patients with advanced disease. This provides limited opportunity to exploit the potential advantages of combination chemotherapy. Of the 14 trials that were included in the SMAC meta-analysis, 6 used doxorubicin alone, and the remaining 8 were trials of combination chemotherapy. Only one unpublished STS trial (29 patients) examined the combination of doxorubicin with ifosfamide.

Table 97-10 Adjuvant Doxorubicin-Based Chemotherapy for Localized Soft-Tissue Sarcoma: Sarcoma Meta-Analysis Collaboration Results

Survival Outcome	No. of Trials	No. of Patients	Hazard Ratio (95% CI)	*P* Value	10-Year Survival Benefit (%)
Overall, All patients	14	1544	0.89 (0.76–1.03)	0.12	4
Overall, Extremity only	12	886	0.80 (NA)	0.029	7
Recurrence-free	14	1366	0.75 (0.64–0.87)	0.0001	10
Local recurrence-free	13	1315	0.73 (0.56–0.94)	0.016	6
Metastasis-free	13	1315	0.70 (0.57–0.85)	0.0003	10

Table 97-11 Post-1992 Randomized Controlled Trials of Adjuvant Chemotherapy versus Observation in Soft-Tissue Sarcoma

Study	Chemotherapy Regimen	No. of Patients	Disease Sites	Follow-up	Survival	
					RFS	OS
Italian Cooperative*[249]	Epirubicin + Ifosfamide + G-GSF (×5)	53	Limb (grade III > 5 cm)	59 mos (median)	48 mos	75 mos
	Control	51			16 mos	46 mos
					$P = 0.04$	$P = 0.03$
Australian Cooperative†[250]	Ifosfamide + Doxorubicin + Dacarbazine (IFADIC) + G-CSF ×6	31	Limb 47, Trunk 12 (grade II/III)	41 mos (mean)	77%	NR
	Control	28			57%	NR
					$P = 0.1$	$P = 0.4$

G-CSF, granulocyte colony stimulating factor; mos, months; NR, not reported at defined follow-up time; OS, overall survival; RFS, recurrence-free survival.
Outcome data provided in original papers.
*Median recurrence-free plus overall survival.
†(1) comparison % recurrence-free plus overall survival after mean observation period 41 (8–84) mos. (2) overall survival plotted but actuarial results not reported at defined follow-up time(s).

Since the SMAC meta-analysis, full reports have been published on two additional RCTs (Table 97-11) examining high-dose anthracycline and ifosfamide-based regimens supported by granulocyte colony-stimulating factor (G-CSF). In the Italian Cooperative Group study,[248] accrual was terminated, based on an early stopping rule, after half the planned number of patients had been recruited. The median recurrence-free survival and overall survival (see Table 97-11) were significantly better for the chemotherapy group, but a high cumulative incidence of late distant relapses was noted (2 year: 28% versus 45%, $P = 0.08$; 4 year: 44% versus 45%, $P = 0.94$ for chemotherapy versus control groups, respectively), although 4-year overall survival remained better for the chemotherapy group (69% versus 50%, $P = 0.04$). At the last published analysis, after a median follow-up of 89.6 months (range: 56 to 119), the intention-to-treat analysis still reveals a difference in overall survival ($P = 0.07$).[249] The 5-year overall survival estimates, a reasonable endpoint for the survival analysis of adjuvant treatment in STSs, were 66.0% and 46.1% for the treatment and the control groups, respectively ($P = 0.04$).[249]

The authors of the second study, a prospective randomized feasibility trial, concluded that a regimen of six cycles of ifosfamide, doxorubicin, and dacarbazine given concurrently with postoperative hyperfractionated radiotherapy (during cycles 3 and 4 when doxorubicin was omitted from the regimen) was manageable and tolerable.[250] It did not translate into significant benefits in recurrence-free survival ($P = 0.1$ versus control arm), time to local failure ($P = 0.09$), or overall survival ($P = 0.4$), but the small number of patients (31 versus 28) precludes any meaningful conclusions regarding benefit. A third RCT, from another Italian center, has been published in abstract form.[251] Only 19 of 41 patients in the chemotherapy arm received an intensive epirubicin/ifosfamide combination (the remainder received single-agent epirubicin), and the study was underpowered for efficacy endpoints.

So can any definite recommendations be made regarding the use of adjuvant chemotherapy in adult STS? In an editorial[252] that accompanied the report of the Italian Cooperative Group Trial,[248] Bramwell concluded that a specific standard of care was not yet clear and that the situation would take some time to change. A Canadian practice guideline[253] on this topic has suggested: "It is reasonable to consider anthracycline-based adjuvant chemotherapy in patients who have had removal of a sarcoma with features predicting a high likelihood of relapse (deep location, size >5 cm, high histological grade)." With the current state of knowledge, we believe that this is a reasonable approach. One of the high-dose anthracycline and ifosfamide regimens used in recent RCTs seems a logical choice for adjuvant treatment but might not be suitable for the substantial minority of patients who are older than 70 years. (This group has been excluded from RCTs evaluating these regimens.) Ultimately, the decision of whether to administer adjuvant chemotherapy and the regimen that is chosen will depend on a number of considerations, including risk of relapse, physician preferences (which may also depend on patient age and comorbid conditions), referral practices, and available resources. While there are very strong opinions on whether or not chemotherapy has added sufficiently to local therapy for routine use in high-risk patients, all agree on two facts: (1) High-risk patients die far too often of metastatic disease, so effective systemic treatment is needed; and (2) there is no current regimen that is anywhere near good enough.

Neoadjuvant Chemotherapy

Given that the role of postoperative adjuvant chemotherapy for patients with adult STS remains controversial, it is hardly surprising that the advantages of chemotherapy given before surgery (neoadjuvant therapy) are even less clear, particularly as there have been no adequately powered RCTs addressing this issue. Nonetheless, neoadjuvant chemotherapy has theoretical benefits that include the following:

- Destruction of the primary tumor may reduce the risk of contamination at surgery and permit closer margins with less tissue loss and functional disability but improved local control.
- Extensive delays in initiating chemotherapy resulting from complex surgery and/or radiotherapy are avoided; for rapidly growing tumors, this earlier elimination of micrometastases may improve survival, although this has not been proven.
- Treating with an intact tumor allows the medical oncologist to assess the effects of preoperative therapy and thus judge whether the chosen chemotherapeutic regimen has activity against the specific tumor in the specific patient being treated. The importance of this opportunity to determine whether an empirically chosen regimen will or will not be beneficial cannot be underestimated, especially in dealing with marginally effective chemotherapy.

Numerous neoadjuvant treatment approaches and preoperative drug regimens have been explored. Intra-arterial (IA) administration of drugs such as doxorubicin or cisplatin has been evaluated, in some cases in conjunction with radiotherapy, isolated limb perfusion, and/or hyperthermia. The IA route delivers drugs more directly to the tumor but is more complex, expensive, and prone to complications

than is the intravenous (IV) route. In the one small RCT on route of administration, there were no differences in rates of local control or overall failure between neoadjuvant chemotherapy given IA or IV.[254,255] In a series of nonrandomized studies reflecting the evolution of neoadjuvant treatment at their center over a 20-year period, the University of California, Los Angeles (UCLA) group treated a total of 498 patients with neoadjuvant chemotherapy.[256] The combination of chemotherapy and 28 Gy of radiotherapy before surgery provided the best local control with the lowest complication rate. On the basis of results of the RCT described earlier, IA doxorubicin was replaced by IV doxorubicin, and cisplatin and ifosfamide were added to the most recent protocol.[256] In the whole group of 498 patients, the overall local recurrence rates were 11% at 5 years and 15% at 10 years, and corresponding overall survival rates were 71% and 66%. The local recurrence rate was lower and overall survival rate higher for patients who had no residual tumor (38%) or greater than 95% necrosis (14%) after neoadjuvant chemotherapy, compared with those who had less than 95% necrosis. In a multivariate analysis, pathologic necrosis was an independent predictor of local recurrence and overall survival. The percentage of patients with 95% or greater necrosis increased to 48% with the addition of ifosfamide, compared to 13% for patients in all other protocols combined.

Pisters and colleagues have reviewed the long-term results of neoadjuvant chemotherapy given at the University of Texas M.D. Anderson Cancer Center for stage IIIB extremity sarcomas between 1986 and 1990.[257] All patients received doxorubicin-based regimens; at that time, ifosfamide was rarely used (3 patients). In 75 patients, the overall clinical objective response rate (complete response plus partial response) was 27%. At a median follow-up of 85 months, the 5-year actuarial local recurrence-free survival, overall recurrence-free survival, and overall survival rates were 83%, 52%, and 59%, respectively. In contrast with the UCLA group's results[256] for pathologic response, there were no differences in any outcomes between responding and nonresponding patients, as defined at that time. In the M.D. Anderson experience, complete pathologic response was an infrequent event, occurring in only 8% of patients treated between 1984 and 1992, although patients receiving preoperative radiation were excluded.[258] Five of the six patients with pathologic complete response were long-term survivors after a median follow-up of 76 months, supporting the findings from UCLA.

In a separate analysis at M.D. Anderson, 65 patients (42 extremity sarcomas and 23 retroperitoneal sarcomas) were treated at the same center between 1991 and 1996 with doxorubicin- or ifosfamide-based neoadjuvant chemotherapy; 34% achieved a radiographic partial response and 9% a minor response.[259] Patients having partial response had higher rates of negative-margin resections, local recurrence-free survival, and overall survival than did nonresponders. Postoperative morbidity was also evaluated in a larger cohort of 105 patients (71 extremity and 34 retroperitoneal STS) treated at M.D. Anderson during the same period, of whom 50 received ifosfamide as well as doxorubicin.[260] The authors found no evidence that preoperative chemotherapy increased surgical complications (e.g., wound infections and other wound problems), length of hospital stay, rate of readmission, or rate of reoperation.

A number of other institutions have recently reported, mostly in abstract form, their experience with neoadjuvant chemotherapy using doxorubicin- and ifosfamide-based regimens that in many cases included cisplatin.[261–264] In most of these studies, radiotherapy followed chemotherapy and was given preoperatively or postoperatively.

The European Organization for the Research and Treatment of Cancer (EORTC) has performed the only RCT assessing preoperative chemotherapy for STS (three cycles of doxorubicin and ifosfamide plus G-CSF) versus no preoperative chemotherapy (control).[265] A total of 150 patients with high-risk STS (≥8 cm any grade, or grade II/III tumors <8 cm, or grade II/III local recurrence tumors/inadequate surgery) were randomized, of whom 134 were considered eligible for outcome assessment. Radiotherapy was indicated for tumors that were excised with close or microscopically positive margins and was given in 46% of patients in the chemotherapy arm and 54% of patients in the control arms. Limb salvage was possible in 89% of patients, and chemotherapy did not affect postoperative wound healing. Grade 4 toxicities were rare, although there was one death due to neutropenic fever. At a median follow-up of 7.3 years, the 5-year recurrence-free survival and overall survival rates were 56% versus 52% ($P = 0.36$) and 65% versus 64% ($P = 0.22$) for the chemotherapy and control arms, respectively. Although originally planned as a phase III trial with adequate numbers to detect a 15% difference in 5-year overall survival, the study was closed after completion of the phase II section because of slow accrual. Most groups have concluded that for large high-grade tumors, preoperative chemotherapy is feasible, does not increase postoperative morbidity, increases the rate of operability, and may enhance local control. The beneficial effects on distant metastases and overall survival, if any, are less clear.

It is impossible to determine from the results of the phase II retrospective or prospective series whether preoperative neoadjuvant chemotherapy reduces distant metastases and improves survival, and the EORTC RCT was too small to illuminate this issue. Preoperative chemotherapy, particularly in combination with preoperative radiotherapy, can induce substantial rates of pathologic necrosis, may increase operability in large high-grade tumors, and leads to impressive rates of local control. It is not clear, however, that these results are better than would be achieved with preoperative radiotherapy alone, particularly if radiation is delivered by using modern intensity-modulated techniques; and most neoadjuvant chemotherapy regimens are associated with substantial toxicity. The contribution of drugs such as cisplatin and dacarbazine (agents with poor activity in metastatic STS) other than increasing toxicity can be questioned. There is a clear need for an RCT comparing neoadjuvant chemoradiotherapy with preoperative radiotherapy alone in patients with large high-grade STS. Because this will require international collaboration and opinions regarding the value of chemotherapy are often entrenched, this may never occur. Preoperative chemoradiotherapy should be delivered only in centers experienced in these techniques, providing further rationale for referral of the majority of patients with STSs to centers that can provide multidisciplinary assessment and treatment. Alternative techniques to achieve local control in large high-grade extremity STS are discussed in the next section.

Combined Preoperative Chemotherapy and Radiotherapy

With the advances that have been made with combined-modality treatment of other solid tumors, there has been interest in combined-modality preoperative treatment (concurrent or sequential chemotherapy and radiation) for patients with localized STSs. Concurrent doxorubicin-based chemoradiation has been employed extensively by Eilber and colleagues at UCLA.[266,267] This treatment protocol involved intra-arterial doxorubicin with unusually high-dose-per-fraction radiotherapy (35 Gy of EBRT delivered in 10 daily fractions, which was reduced to 17.5 Gy in 5 daily fractions to minimize local toxicity). A subsequent prospective randomized trial compared preoperative IA doxorubicin to IV doxorubicin, both followed by 28 Gy of radiation delivered over 8 days followed by surgical resection.[268] No differences in local recurrence or survival were noted.

The combination of regional chemotherapy and concurrent radiotherapy that was originally pioneered by Eilber and colleagues has been modified and utilized by other groups.[269–271] Investigators from the University of Illinois treated 55 patients with a 10-day preoperative regimen of intra-arterial doxorubicin (10 mg/m^2/day) with concomitant radiotherapy (25 Gy: 2.5 Gy per fraction in 10 fractions).[271] With a mean follow-up of 94 months, local control was 85%. Complications related to the therapy occurred in 26% of patients and

required further operative management in 7% of patients. Temple and colleagues treated a group of 42 patients with a similar regimen of 60 to 90 mg of doxorubicin that was infused IA or IV over a 3-day period followed by sequential radiotherapy (30 Gy: 3 Gy per fraction in 10 fractions).[270] Resection of the residual post-treatment mass was performed 4 to 6 weeks later. At a median follow-up of 6 years, local control was achieved in 39 of 40 patients, although two patients were excluded from this analysis because clear margins were not obtained at the time of surgery. IA infusion-related complications occurred in 4 (11%) of 35 patients. Objective radiographic and pathologic response rates were not reported; therefore, the efficacy of concurrent chemoradiation therapy in achieving cytoreduction to an extent sufficient to convert lesions that are resectable by amputation only to lesions that are amenable to a limb-sparing approach remains largely anecdotal. Moreover, whether preoperative chemoradiation approaches offer local control advantages over conventional treatment approaches employing surgery with preoperative or postoperative radiotherapy is also not apparent. In fact, with current local control rates exceeding 90%, it is difficult to appreciate how this may be further improved by using preoperative chemotherapy unless the strategy involved a radiotherapy dose reduction to ameliorate normal tissue toxicity.

Alternative chemoradiation sequencing has been employed by investigators from Massachusetts General Hospital, who have recently reported mature data from a sequential chemoradiation strategy in the treatment of patients with large (>8 cm) localized, high-grade extremity STSs.[272] This treatment protocol involved interdigitating courses of chemotherapy and radiotherapy: three courses of doxorubicin, ifosfamide, mesna, and dacarbazine and two 22-Gy courses of radiation (11 fractions each) for a total preoperative radiation dose that is lower than is usually used (44 Gy). This was followed by surgical resection with microscopic assessment of surgical margins. An additional 16-Gy (8 fractions) boost dose was delivered for microscopically positive surgical margins. The strategy therefore usefully addresses the dual problems of local control and metastatic risk. The outcomes of 48 patients who were treated with this regimen between June 1989 and March 1999 have been compared to those of a matched series of historic controls (treated between January 1988 and March 1997).[272] The 5-year actuarial local control, distant metastasis-free survival, and overall survival rates for the sequential chemoradiation group are 92%, 75%, and 87%, respectively. For the matched historic controls, these rates are 86%, 47%, and 58%, respectively. The protocol was toxic, with 29% experiencing confluent moist skin desquamation, 25% requiring hospitalization at some time for febrile neutropenia, and G-CSF needed in 81%. Wound-healing complications evaluated using recently described criteria[211] were apparent in 29% of cases and confined to the lower extremities, as was also observed in the Canadian Sarcoma Group treatment sequencing RCT.[211] One patient died from late marrow dysfunction attributed to chemotherapy. Although the results are encouraging from a tumor standpoint (Fig. 97-14), they will require prospective comparative studies for confirmation and especially because of the local and systemic toxicity associated with this approach.[273] An ongoing Radiation Therapy Oncology Group protocol (RTOG-95–14) has also investigated this treatment approach (see the section on preoperative chemotherapy).[274] While the RTOG phase II results are similar in terms of tumor outcome to the data of DeLaney and colleagues,[272] they too are characterized by concerning features of significant toxicity, including marrow dysplasia and treatment-related death.

Hyperthermic Isolated Limb Perfusion and Whole-Body Hyperthermia with Chemotherapy

Hyperthermic isolated limb perfusion and whole-body hyperthermia are two investigational techniques that continue to receive considerable attention, particularly in Europe. Hyperthermic isolated limb perfusion (with tumor necrosis factor-α [TNF-α], interferon-α [IFN-α], and melphalan) has been used as an neoadjuvant therapy to render tumors resectable and as a primary therapy to avoid amputation for nonresectable extremity STS.[275–277] Overall response rates in three series, which recruited 55, 35, and 41 patients, respectively, ranged from 72% to 91%, and limb salvage surgery was possible in 84% to 91% of cases. Small numbers of patients experienced subsequent local recurrence, and some of these patients needed later amputations. Not surprisingly, many patients ultimately developed and died of distant metastases. Hyperthermic isolated limb perfusion has also been advocated to facilitate palliative limb salvage in patients with regional and/or distant metastases from unresectable stage IVA or IVB STS.[278]

Various techniques of regional or whole-body hyperthermia have been combined with a variety of chemotherapy regimens.[279–284] A group from Munich has evaluated preoperative chemotherapy (four cycles of doxorubicin, ifosfamide, and etoposide) combined with

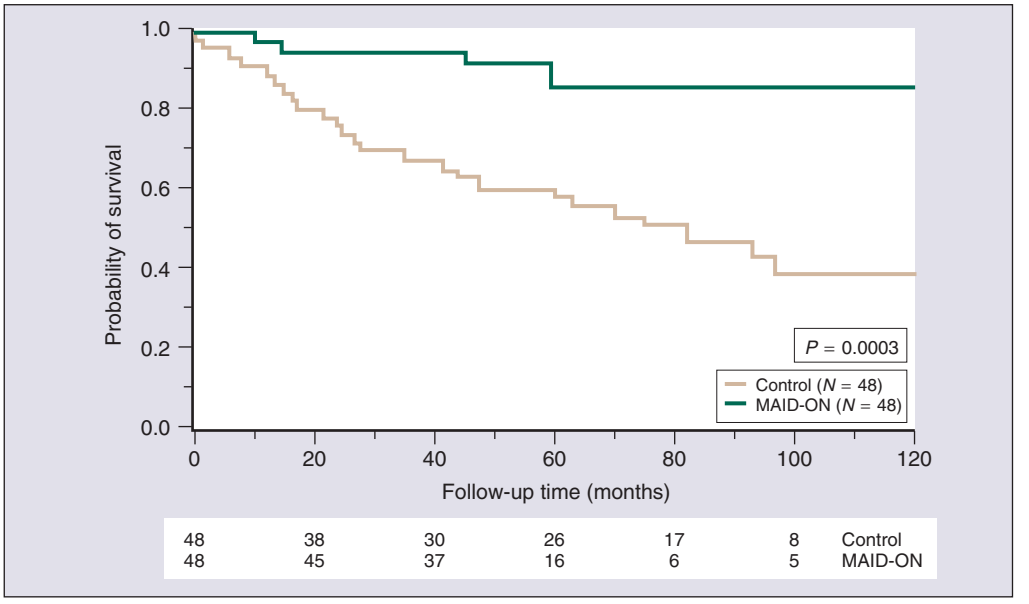

Figure 97-14 • Actuarial probability of overall survival for MAID-chemoradiotherapy and surgery versus control patients. The significant difference between the groups with respect to cause of death was distant metastasis (see text for details). Int J Radiat Oncol Biol Phys 2003;56: 1117.)

regional hyperthermia (RHT) followed by surgery and adjuvant treatment (same chemotherapy ± radiation). Median follow-up times were 58 months for the RHT-91 protocol (59 patients) and 30 months for the RHT-95 protocol.[283] All patients had grade II/III tumors 5 cm or larger with extracompartmental extension. Clinical response rates were 42% and 33% for the two protocols, with respective local progression-free survival rates of 58% and 57%. Corresponding overall survival rates were 42% and 48%, respectively. These results are now being evaluated in a phase III RCT (EORTC 62961/ESHO RHT-95). The assumption has been made that preoperative chemotherapy with doxorubicin, ifosfamide, and etoposide is effective for patients with high-risk localized disease in this setting, and patients are being randomized to receive preoperative etoposide, ifosfamide, and doxorubicin (EIA, four cycles) plus RHT (two fractions) versus EIA chemotherapy alone.

TREATMENT OF SARCOMA PATIENTS AT SPECIALTY CENTERS

Recent data on other tumor types have demonstrated improved outcomes for patients who required complex treatment and are treated at specialty centers.[285] The most comprehensive data addressing this issue in STS come from Sweden, where Gustafson and colleagues analyzed the quality of treatment in a population-based series of 375 patients with primary STSs arising in the extremities ($N = 329$) or the trunk ($N = 46$).[286] Comparisons were made between patients who were referred to a specialty soft-tissue tumor center before surgery ($N = 195$), those who were referred after surgery ($N = 102$), and those who were not referred for treatment of the primary tumor ($N = 78$). The total number of operations for the primary tumor was 1.4 times higher in the patients who were not referred and 1.7 times higher in the patients who were referred after surgery than in patients who were referred before surgery. Of greatest significance, however, was the finding that the local recurrence rate was 2.4 times higher in the patients who were not referred and 1.3 times higher in the patients who were referred after surgery than in patients who were referred to a specialty soft-tissue tumor center before any manipulation of their tumor. These findings support the principle of centralizing treatment of these rare tumors, which frequently require complex multimodality therapy.

TREATMENT OF LOCALLY RECURRENT SOFT-TISSUE SARCOMA

Incidence of Local Recurrence

Despite optimal multimodality therapy, at least 20% to 30% of STS patients will develop recurrent disease, with a median disease-free interval of 18 months.[109,287] Not surprisingly, local recurrence rates are a function of the primary tumor site and are highest for retroperitoneal and head and neck sarcomas. This is due in part to the fact that adequate surgical margins are technically more difficult to attain in these locations. Indeed, while acknowledging our earlier discussion relating the type of positive margin,[194] by multivariate analysis, an unqualified positive surgical margin is an adverse prognostic factor associated with local recurrence operation for recurrent disease.[109,110] In addition, employment of conventional standard-dose postoperative radiotherapy (60 to 65 Gy) is often limited in the retroperitoneum and the head and neck by the relative radiosensitivity of surrounding structures. These factors result in local recurrence rates of 38% for high-grade retroperitoneal sarcomas[133] and 48% for high-grade head and neck sarcomas,[288] compared to 5% to 25% for extremity lesions (see Table 97-9). It should also be acknowledged, however, that the rarity of nonextremity lesions probably results in a more varied approach to management, which may influence the ultimate outcome and may also have influenced the ability to design and execute clinical trials in the past. It would seem that properly applied principles of local management can achieve similar results even in sites with traditionally poor results, such as the head and neck, where disease access is limited by proximity to critical local anatomy.[196]

Surgery and Radiotherapy

Locally recurrent STS generally presents as a nodular mass or series of nodules arising in the surgical scar or radiation port. Patients with retroperitoneal recurrences usually present with nonspecific symptoms, often after the recurrence has reached a substantial size.

Treatment approaches for patients with locally recurrent STS need to be individualized on the basis of local anatomic constraints and the limitations on present treatment options imposed by prior therapies. In general all such patients should be evaluated for re-resection of their local recurrence. The results of such "salvage surgery" are good, two thirds of patients surviving long-term.[289,290]

If no prior radiotherapy was employed, adjuvant radiation should be utilized after surgery for locally recurrent disease. Occasionally, subtherapeutic or low-dose radiation was previously employed, and such patients might be candidates for additional adjuvant radiation by external beam or brachytherapy approaches. Patients who have had a full course of prior radiation should be managed on an individual basis.

In a recent series of 40 patients with recurrent extremity sarcoma, limb salvage was possible by combining limb-sparing re-resection with adjuvant brachytherapy.[291] A median dose of 45 Gy was possible with this technique, despite the fact that most patients had received prior external beam radiation. The 5-year actuarial local control rate was 68%, with satisfactory limb preservation. However, brachytherapy should be used with caution in patients who have locally recurrent low-grade sarcomas, since it appears to be ineffective against low-grade sarcomas.[193,220]

Catton and colleagues from the Princess Margaret Hospital also employed conservative surgery and reirradiation (external beam or brachytherapy) for treatment of local recurrences arising in a previous radiation field in a subset of 10 extremity sarcoma patients.[292] With a relatively short median follow-up of 24 months for the entire cohort, local control in the patients treated with further surgery and reirradiation was 100%.[292] Similarly, Nori and colleagues at Memorial Sloan-Kettering Cancer Center and Pearlstone and colleagues at the M.D. Anderson Cancer Center reported a local control rate of 82.5% (33 of 40) and 65% (17 of 26), respectively, when using conservative surgery and reirradiation with brachytherapy.[291,293] However, despite these encouraging findings, amputation or protocol-based hyperthermic isolated limb perfusion might be the only options for local control in some patients who were previously treated with radiation and have recurrent extremity sarcoma.

TREATMENT OF METASTATIC SOFT-TISSUE SARCOMA

The most common site of metastasis from STS of the extremity is the lung. Indeed, the lungs are the only site of recurrence in approximately 20% of all patients with primary extremity and trunk STSs.[287,284] Primary visceral and gastrointestinal sarcomas also commonly metastasize to the liver. Extrapulmonary metastases are uncommon forms of first metastasis and usually occur as a late manifestation of widely disseminated disease.[287] An obvious exception is in myxoid liposarcoma, in which unpredictable and aberrant recurrences to any area containing fat (the pelvis, retroperitoneum, mediastinum, paraspinal and subcutaneous soft tissue, and bone marrow) are a hallmark of disease behavior.[104,295] Evidence strongly suggests that apparently isolated soft-tissue masses that manifest in this disease are metastases, sharing the same molecular lineage with the original primary tumor.[296] For sarcomas in general, the median

survival from the time of development of metastatic disease is 8 to 12 months. An obvious exception is alveolar soft part sarcoma, in which metastatic disease may persist for more than 10 years. Optimal treatment of patients with metastatic STS requires an understanding of the natural history of the disease and individualized selection of treatment options based on specific patient factors, disease factors, and limitations imposed by prior treatment.

Surgical Resection

The current surgical approach for pulmonary metastases from STS is based on an extrapolation of the observations of Martini, Marcove, and colleagues in a series of patients with osteosarcoma treated at Memorial Sloan-Kettering Cancer Center in the 1960s. It had been observed that in a series of 184 patients undergoing amputation for osteosarcoma, 75% developed metastatic disease to the lungs within 18 months of amputation; and there were no 5-year survivors among this group.[297] In the absence of any effective systemic therapy for this disease, efforts were made to resect such metastatic lesions in later patients. Martini and colleagues reported successful complete resection in 22 of 28 patients, with a substantial 5-year overall disease-free survival rate of 32%.[298]

Multiple investigators have since reported their experience with pulmonary metastasectomy for metastatic STS in adults.[299–310] Three-year overall disease-free survival rates after thoracotomy for pulmonary metastasectomy have ranged from 23% to 54%, as outlined in the selected series summarized in Table 97-12.[299–303,310,311] With the exception of a study that evaluated the development and treatment of pulmonary metastases in patients with extremity sarcomas using a prospective sarcoma database (3-year survival rate of 23% after complete resection),[303] most studies have been retrospective analyses of the results of pulmonary resection in populations of carefully selected patients with metastatic sarcoma from heterogeneous primary sites. This could account for some of the variability in the reported survival rates.

Many investigators believe that repeated thoracotomies to render patients free of disease from pulmonary STS metastases are justified in the absence of effective systemic therapy. Several series of reoperative pulmonary metastasectomy have been published.[312,313] In an NCI series, 72% of 43 patients could be rendered free of disease at the second thoracotomy, with a median survival duration from the time of the second thoracotomy of 25 months.[312] In a report from the M.D. Anderson Cancer Center of a series of 34 patients undergoing reoperation for a second pulmonary metastasis after successful initial metastasectomy, factors predicting long-term survival included the presence of a solitary metastasis and the ability to perform a complete resection.[313] This study also illustrated the significant survival duration many of these patients enjoy: The median survival in the 19 patients who had unifocal recurrent metastatic disease was 65 months compared to 14 months in the 15 patients with complete resection of two or more sites of recurrent disease.

It remains difficult to predict which patients will benefit from pulmonary resection. A number of different clinical criteria have been evaluated by univariate analysis, including the disease-free interval,[299,301,311,314] number of metastatic nodules,[311,314–317] and tumor doubling time.[311,317,318] Multivariate analyses from both the NCI and Roswell Park Cancer Institute confirm that a short disease-free interval (as a surrogate endpoint of adverse behavior) and incomplete pulmonary resection are adverse prognostic factors for survival of patients with pulmonary metastases.[301,319] A multivariate analysis from the M.D. Anderson Cancer Center suggested that, in addition, the presence of more than three metastatic pulmonary nodules on preoperative chest CT is an adverse prognostic sign.[301]

The ability to completely resect all pulmonary disease is perhaps the most important prognostic factor affecting survival after pulmonary metastasectomy; patients with residual pulmonary disease have a median survival of 9 months versus 27 months ($P < 0.0001$) for patients who are rendered completely free of disease at thoracotomy.[301,303] In a series of 65 patients with metastatic pulmonary lesions from extremity sarcoma from the Memorial Sloan-Kettering Cancer Center, the median survival after complete resection was 19 months versus 10 months for patients who had incomplete resections and 8 months for patients who did not undergo surgery ($P = 0.005$).[303] The 3-year overall survival rate after complete resection was 23% compared to 2% in those who were treated nonsurgically ($P < 0.001$). The clinical criteria of disease-free interval, tumor doubling time, and number of nodules can serve as general prognostic indicators in patients who are being considered for pulmonary metastasectomy, but no single criterion should be used to exclude patients from surgery.

The ability to achieve complete resection and the number of pulmonary nodules that are present appear to best define the prognosis for patients postoperatively. Although carefully selected patients may benefit from surgical resection of pulmonary metastases, this treatment approach is feasible in only a small fraction of patients who develop pulmonary metastases. This is best illustrated by data from Memorial Sloan-Kettering, where a population of 716 patients with primary extremity sarcoma were followed for the subsequent development and treatment of pulmonary metastases (Fig. 97-15). Of the initial cohort, 148 patients (21%) developed pulmonary metastases. Isolated pulmonary metastases occurred in 135 (91%) of these 148 patients. Of the 135 patients with pulmonary-only metastases, 78

Table 97-12 Survival Following Complete Resection of Pulmonary Metastases from Soft-Tissue Sarcoma in Adults

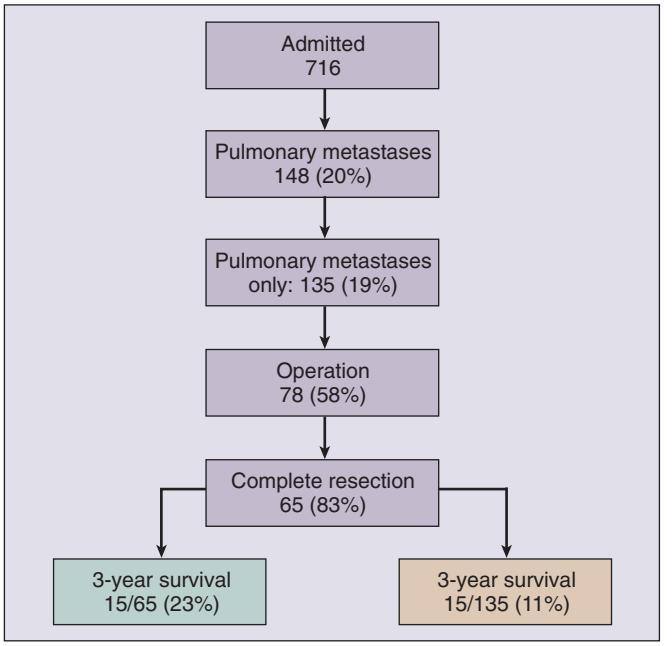

Figure 97-15 • Risk for and subsequent management of pulmonary metastases in 716 patients with primary or locally recurrent extremity soft-tissue sarcoma. (Reprinted with permission from Brennan MF: The surgeon as a leader in cancer care: lessons learned from the study of soft tissue sarcoma. J Am Coll Surg 1996;182:520.)

(58%) were considered to have operable disease, and 65 (83%) of those who were taken to thoracotomy were able to undergo complete resection of all their pulmonary metastatic disease. This group represents only 44% of patients with pulmonary metastases. Median survival from the time of complete resection was 19 months, and the 3-year overall survival rate was 23%. All patients who did not undergo thoracotomy died within 3 years. For the entire cohort of 135 patients who developed pulmonary-only metastases, the 3-year overall survival rate was only 11% (see Fig. 97-15).

The rather disappointing overall results of treatment for pulmonary metastases underscore the importance of careful patient selection for resection of pulmonary metastases. The following criteria are generally agreed upon: (1) the primary tumor is controlled or is controllable; (2) there is no extrathoracic disease; (3) the patient is a medical candidate for thoracotomy and pulmonary resection; and (4) complete resection of all disease appears possible.[320] With careful patient selection, the morbidity of thoracotomy can be limited to the subset of patients who are most likely to benefit from this aggressive treatment approach.

Wedge excision with negative margins is the procedure of choice for patients who undergo surgery for isolated pulmonary metastases. Formal segmentectomy, lobectomy, and mediastinal lymph node dissection are not necessary and do not contribute to improved local control. Occasionally, lobectomy or even pneumonectomy is required because of the proximity of the metastatic lesion to a pulmonary artery, vein, or major bronchus. Multiple ipsilateral lesions do not represent a contraindication, nor, in fact, do bilateral pulmonary metastases. Bilateral lesions can be approached by staged thoracotomies, median sternotomy, or simultaneous bilateral anterior thoracotomies, depending on the surgeon's preference and the number and location of the pulmonary metastases. In such cases, the preferred approach for most thoracic surgeons is simultaneous bilateral wedge resections via a sternotomy or "clamshell" anterior thoracotomy. Isolated unilateral lesions may be amenable to thoracoscopic resection.

Chemotherapy

First-Line Chemotherapy

SINGLE AGENTS. The single-agent activity of doxorubicin against metastatic STS is well established, with response rates usually reported as being in the range of 20% to 30%,[321–323] but response rates as low as 10%[324] and as high as 41%[325] have also been noted. The dose-response curve for doxorubicin in sarcomas was demonstrated to be steeper than that for any other tumor in the first RCT to address a dose-response question; the response rate increased from 18% at 45 mg/m^2 to 37% at 75 mg/m^2 (see later discussion).[326]

Epirubicin, which was developed as an active but minimally less cardiotoxic analog of doxorubicin, produced an objective response rate slightly lower than that of doxorubicin (18% versus 25%, $P = 0.33$) in an EORTC RCT of 167 patients receiving equimolar doses (75 mg/m^2) of the drugs.[327] There is some evidence of a dose-response relationship with epirubicin as with doxorubicin; a dose-escalation study showed response rates of 17%, 44%, and 100% for 140 mg/m^2, 160 mg/m^2, and 180 mg/m^2 of epirubicin, respectively.[328] Only three patients were entered at the maximum tolerated dose of 180 mg/m^2, and 160 mg/m^2 was recommended for routine clinical use. However, the EORTC group, in a three-arm RCT of 334 patients, was unable to demonstrate any benefit from either of two schedules of epirubicin (150 mg/m^2) compared with doxorubicin (75 mg/m^2); all regimens produced response rates of 14% to 15%.[329] Furthermore, there was considerably more myelosuppression in the two epirubicin arms, with two toxic deaths. Nevertheless, particularly in Europe, epirubicin has commonly been substituted for doxorubicin in high-dose regimens.

A number of studies of liposomal anthracyclines have suggested that these agents have lower rates of cardiotoxicity but variable activity.[330–334] An EORTC phase II RCT [324] demonstrated low activity for both doxorubicin and liposomal doxorubicin (Doxil)—9% versus 10%—but different spectrums of toxicity, with less myelosuppression but with palmar-plantar erythrodysthesia (grade 3: 20%) as the dose-limiting toxicity in the Doxil arm.

Lack of response rather than cardiotoxicity is the main limiting factor for anthracycline use in palliative chemotherapy of STS. Nonetheless, strategies to reduce anthracycline toxicity are of particular importance in the adjuvant setting.[335] Many American investigators routinely use continuous-infusion regimens with doxorubicin, which have been shown to be equally effective but less cardiotoxic. [336–338] Dexrazoxane is undoubtedly cardioprotective when given with doxorubicin.[339] Concerns about the possibility of tumor protection are theoretical and have not been noted in ongoing studies.

After the reports of several randomized studies documenting activity ranging from 24% to 67%,[340–342] Bramwell and colleagues performed an RCT comparing ifosfamide (5 g/m^2 by 24-hour infusion) with cyclophosphamide (1.5 g/m^2).[342] Respective response rates were 18% and 8%, but the difference was not statistically significant, owing to the inadequate power of the study ($P = 0.13$). Nonetheless, the authors correctly concluded that ifosfamide was the more active drug, and all sarcoma medical oncologists agree with that assessment.

Indirect data from several RCTs in which ifosfamide and/or cyclophosphamide were added to doxorubicin have provided additional evidence that ifosfamide is a more active analog than is cyclophosphamide.[321] Questions about the optimal scheduling of ifosfamide (multiple daily bolus doses versus continuous infusion) have never been satisfactorily resolved and are confounded by dose differences in many studies. Two consecutive phase II studies by investigators at M.D. Anderson evaluated ifosfamide (14 g/m^2) given as a 72-hour continuous infusion or a 2-hour infusion for 3 consecutive days. Respective response rates were 19% and 42%.[343] In an EORTC RCT comparing 5 g/m^2 ifosfamide over 24 hours with 3 g/m^2 ifosfamide over 4 hours on days 1 to 3, response rates were 3% and 17.5%, respectively. However, a subsequent EORTC study showed no dif-

ference in response rates for 9 g/m^2 ifosfamide by continuous infusion or intermittent bolus injection[344] (see the section on high-dose ifosfamide).

COMBINATION CHEMOTHERAPY. In the 1970s and early 1980s, before the widespread availability of ifosfamide, most combination chemotherapy regimens were based on doxorubicin and dacarbazine. The addition of cyclophosphamide and vincristine, which are active against childhood sarcomas, created a regimen called CyVADIC, for which the Southwest Oncology Group reported response rates as high as 59% in patients with metastatic disease.[345] Later investigators were unable to reproduce such high response rates with the same regimen, however, and summary data on variants of the CyVADIC regimen revealed an overall response rate of 35% in 2092 patients.[346] CyVADIC was the control for the three-arm EORTC study discussed later.[333] Despite the authors' conclusions that singe-agent doxorubicin should remain the standard, CyVADIC had the highest response rate (not statistically significant), with significantly lower toxicity than either of the other arms of the trial.

Most regimens now used for first-line chemotherapy are based on the combination of doxorubicin and ifosfamide. A recent systematic search of the literature[347] found 3 phase III RCTs and 16 phase II trials (excluding phase I studies and those recruiting fewer than 25 patients) in adult STS that used combination regimens including an anthracycline and ifosfamide. Although the response rate varied widely, from 25% to 56%, in the phase II studies, they were at the lower end of this range in the three RCTs.[348–350] In the Eastern Cooperative Oncology Group (ECOG) study[332] of 178 patients, the response rate was significantly higher for doxorubicin/ifosfamide than for doxorubicin alone (34% versus 20%, $P = 0.03$), although median survivals were similar. In an EORTC study of 471 patients, however, there were no significant differences in response rate (28% versus 23%) or median survival for doxorubicin/ifosfamide versus doxorubicin alone.[349] In an intergroup trial of 340 patients, the ifosfamide-containing regimen MAID was shown to produce a significantly higher response rate (32% versus 17%, $P < 0.002$) than doxorubicin/dacarbazine, but with no overall survival benefit.[350]

Bramwell and colleagues performed a meta-analysis of eight RCTs that compared doxorubicin-based combinations with single-agent doxorubicin.[322] In these eight studies with a total of 2281 patients, ten combination regimens were evaluated; five included ifosfamide (two) or dacarbazine (three), and the remaining five used other drugs with low known single-agent activity. There were no significant benefits in terms of response rate (odds ratio: 0.79, $P = 0.10$) or overall survival (odds ratio: 0.84, $P = 0.13$) for combination chemotherapy. Inclusion of a small RCT (106 patients)[351] that compared epirubicin (180 mg/m^2) with epirubicin (180 mg/m^2) plus cisplatin (120 mg/m^2) and reported respective response rates of 29% and 54% ($P = 0.025$) did not significantly alter the meta-analysis results. On the basis of single-agent doxorubicin's lower overall toxicity than that of combination regimens, Bramwell and colleagues suggested that for chemotherapy given with palliative intent, doxorubicin alone was a reasonable first-line option,[322] a conclusion that was also reached in a commentary by Santoro.[352] This leaves open the possibility of further second-line chemotherapy with ifosfamide in fit patients progressing on or relapsing after a response to doxorubicin therapy. Whether patients with advanced sarcomas should be treated with chemotherapy at all is also a topic of debate in Europe.[353] Interestingly, the European investigators who debate the issue place such patients on clinical trials, and the majority, if not all, of European experts who are members of the Connective Tissue Oncology Society treat patients both on trials and as standard practice.

One reason for the lack of convincing evidence that standard-dose combination chemotherapy improves outcomes compared with single-agent doxorubicin for metastatic STS might be that the doses of the drugs in combination regimens are often reduced below optimum levels to limit toxicity. In the first RCT of different doses of doxorubicin, a steep dose-response relationship was demonstrated for doxorubicin in sarcomas, with an increase in response rate from 18% at 45 mg/m^2 to 37% at 75 mg/m^2.[326] A similar dose-response relationship has been suggested for ifosfamide, the response rate increasing from 8 to 22% with an increase from 6 to 10 g/m^2 in consecutive series.[354] Myelosuppression, particularly neutropenia, limits the doses of these drugs that can be safely delivered in combination. Use of hematopoietic growth factors or autologous stem cell transplantation permits substantial dose escalation of these agents. In a systematic review, Verma and Bramwell identified seven phase I trials, five phase II trials, and two RCTs exploring dose-escalated regimens of doxorubicin and ifosfamide, with and without other agents for metastatic STS.[347] Most regimens included the growth factors G-CSF or GM-CSF, but in two trials, autologous stem cell transplantation was used in addition. In the phase I studies, the maximum tolerated doses were in the range of a twofold increase of the doxorubicin or epirubicin dose (over a standard dose of 75 mg/m^2) and a 2.4- to 2.8-fold increase of the ifosfamide dose (over a standard dose of 5 g/m^2). Significant toxicities included anemia, thrombocytopenia, nephrotoxicity, and neurotoxicity; severe neutropenia and febrile neutropenia were also seen at the higher doses. In a recently reported study,[355] De Pas and colleagues reported no nephrotoxicity or neurotoxicity with ifosfamide infused over 12 days at 15 g/m^2 (given with doxorubicin, 75 mg/m^2), although myelosuppression was dose limiting. Although not the primary objective, response rates were reported for all these phase I studies and were in the range of 28% to 58%. Additionally, for the five phase II studies of dose-escalated doxorubicin and ifosfamide (only studies with more than 20 evaluable patients were included), response rates were 31% to 65%. In a phase II study that was not included in the review, a response rate of 40% in 70 patients was documented.[356]

Patel and colleagues were the first to maximize the doses of each drug used in the combination.[338] In a series of small studies utilizing growth factors to support patients through the intense expected myelosuppression, they delivered doxorubicin at doses of 75 to 90 mg/m^2 together with ifosfamide at 10 g/m^2 divided as 2- to 3-hour infusions daily for 4 to 5 days. Of note, they identified that the regimen was suitable only for patients younger than 65 years old with two kidneys, normal renal function, and good performance status. Dose reductions were not employed for myelosuppressive toxicity unless it was accompanied by extreme morbidity. Patel reported a 62% response rate overall with a 57% response rate, a 10-month progression-free survival, and a 20-month survival in those with metastatic disease. The EORTC is attempting to confirm the results of the 75/10 regimen in a randomized study versus single-agent doxorubicin.

Patel and colleagues attributed their good results to the dose-intensive chemotherapy. In contrast, Worden and colleagues randomized patients to doxorubicin at 60 mg/m^2 plus either 6 or 12 g/m^2 of ifosfamide and showed no advantage for the higher dose.[357] Careful review of that study reveals that the careful selection criteria that Patel and colleagues used were not used in the latter study. Several older patients were entered, and in fact, the disadvantage of the higher dose regimen might have been due to unacceptable toxicity.

In contrast to these promising results in phase I/II studies, response data in the cooperative group RCTs have been disappointing. In an EORTC trial involving 314 patients with metastatic STS, standard-dose doxorubicin (50 mg/m^2) plus ifosfamide (5 g/m^2) was compared with higher-dose doxorubicin (75 mg/m^2) with the same dose of ifosfamide plus GM-CSF.[358] Respective response rates were 21% and 23%, with similar median overall survivals (56 versus 55 weeks); but median progression-free survival was significantly longer in the high-dose arm (19 versus 29 weeks, $P = 0.03$). In the other RCT that was included in Verma and Bramwell's review, as yet reported only in abstract form,[359] 162 patients were randomized to receive

standard-dose MAID or MAID with doses escalated 25% plus G-CSF support. Respective response rates were 37% versus 43% (P not significant), but no survival data were reported. There were five toxicity-related deaths, however, all in the dose-escalated MAID arm. In a third RCT, 180 mg/m^2 epirubicin and 150 mg/m^2 epirubicin, each combined with cisplatin but with no growth factor support, were compared in 151 patients.[351] There was a higher response rate (51% versus 28%, $P = 0.004$) and a marginal effect on overall survival ($P = 0.06$) with the higher-dose regimen. As all three RCTs were quite limited tests of dose escalation, more RCTs are needed before it can be concluded that such regimens are a more effective option than conventional-dose chemotherapy.

Verma and Bramwell discuss possible reasons for the lack of a clear benefit of dose-escalated therapy in the RCTs;[347] these include tumor heterogeneity, difficulties in eradicating large tumor burdens, and the appropriateness of the drugs, doses, and schedules used. It is interesting that even within the same group, results may differ between phase II and phase III trials. When the EORTC performed a pilot study of doxorubicin 75 mg/m^2 + ifosfamide 5 g/m^2 with GM-CSF support, the response rate was 45%.[360] When the group repeated the study as a phase III study, the response rate was 23%.[358] Why is there a discrepancy, and which value is closer to the truth? Phase III studies are supposed to be more representative of the overall population than are studies of highly selected patients from referral centers. Is it not possible, on the other hand, that the pilot study was conducted by a group that was more expert at treating sarcomas? Is it not possible that negative selection bias goes into the phase III trials, that is, investigators treat their younger, potentially curable patients with combination therapy off study and enter only those who are less likely to benefit into the randomized phase III studies? We know that referral to a specialty center improves outcomes of early-stage patients; why not those with metastatic disease? Furthermore, all of the randomized studies that have been reported occurred before there was effective treatment of GISTs. Many GIST patients were entered in front-line chemotherapy studies as having metastatic leiomyosarcoma without attention to its primary site. Inclusion of such patients, especially when they are rarely accounted for in the publications, dilutes the data and makes much of it uninterpretable.

Second-Line Chemotherapy

HIGH-DOSE IFOSFAMIDE. Although ifosfamide is often used as a first-line agent, it is clearly active as second-line therapy in patients who are progressing or relapsing after doxorubicin-based regimens. Early studies of ifosfamide suggested that there was a dose-response relationship,[354] and several groups have documented responses to high-dose ifosfamide in patients who had not responded to lower doses of the drug.[337,361–363] Nevertheless, dose-escalation studies of ifosfamide have produced conflicting results. Doses of 12 g/m^2 without and 14 to 18 g/m^2 with growth factor support seem achievable and have produced response rates of 33% to 45%, but nephrotoxicity and neurotoxicity are considerable.[343,359,363] Frustaci and colleagues found high-dose ifosfamide to be well tolerated when infused at 1 g/m^2/day over 21 days.[364] In 36 patients, they were able to administer up to three cycles with a median duration of 15 days, producing a response rate of 24%. Myelosuppression was dose limiting, but there was no significant nephrotoxicity or neurotoxicity. Pharmacokinetic data reported by Cerny and colleagues demonstrated that ifosfamide doses greater than 14 to 16 g/m^2 given over 5 days resulted in a relative decrease of the active metabolite iphosphoramide mustard, suggesting dose-dependent saturation or inhibition of ifosfamide metabolism.[365]

Despite encouraging phase II trial results, the advantages of increasing the dose of ifosfamide are far from clear on the basis of recent EORTC studies. The response rate rates for 9 g/m^2 (3 g/m^2 over 4 hours, days 1 to 3) and 5 g/m^2 (24-hour continuous IV) were 3% and 17.5%, respectively, in an RCT of 101 patients.[366] Escalation to 12 g/m^2 as a 3-day continuous IV infusion produced a response rate of 16% in a phase II study of 124 patients.[367] In the most recent EORTC RCT of first-line chemotherapy, the response rates were 11%, 6.5%, and 9.4% for 75 mg/m^2 doxorubicin, 3 g/m^2 ifosfamide over 4 hours on days 1 to 3, and 9 g/m^2 ifosfamide 24-hour continuous infusion, respectively. In addition to these disappointingly low and similar response rates, there were no differences in progression-free survival between the three arms.[344]

OTHER MARKETED DRUGS ALONE OR IN COMBINATION. Collected response rate data for many drugs that were studied in phase II trials for metastatic STS have been published in a number of reviews.[321,368,369] Dacarbazine has been used most extensively, either as a first-line agent in combination with doxorubicin and ifosfamide (MAID) or as a second-line salvage treatment. Demetri and colleagues found an overall 16% response rate for dacarbazine in 109 patients from collected phase II studies.[321] Although dacarbazine is commonly given in divided doses over 3 to 5 days, Buesa and colleagues showed that doses of 1.2 g/m^2 over 20 minutes are feasible and active, as well as more convenient, now that effective antiemetics are available.[370] The current availability of portable infusion pumps means that prolonged infusions are also feasible. Although Rosen and colleagues reported a response rate of 27% lasting 2 to 18 months or longer, Reichardt and colleagues were not able to confirm this high rate of activity when they gave 12- to 14-day infusions of 200 to 225 mg/m^2/day dacarbazine, observing only disease stabilization in 8 of 25 heavily pretreated patients.[371]

There is conflicting evidence on the activity of cisplatin and carboplatin against metastatic STS, although most reviews have reported response rates of less than 15%.[321,368,369] Low response rates are also seen for etoposide given as a single agent.[321,342,372] Promising early data on docetaxel[373] could not be reproduced in later studies,[352,374–377] and paclitaxel similarly has little activity.[378–380]

Objective response rates were also very low (3% to 5%) in three phase II studies of gemcitabine,[381–383] although the M.D. Anderson group described a response rate of 18% in 39 patients if GISTs were excluded[378] (they represented the majority of patients in some of the other studies). The M.D. Anderson study also confirmed the importance of timed delivery of gemcitabine, since it cannot be activated faster than 10 mg/m^2/min and the remainder of a more rapidly administered dose is simply excreted unchanged in the urine. Hensley and colleagues utilized timed infusion of gemcitabine at 900 mg/m^2 over 90 minutes on days 1 and 8 followed by docetaxel 100 mg/m^2 on day 8 with growth factor support and a 25% dose reduction for patients with prior pelvic radiation in a series of patients with leiomyosarcoma, almost exclusively of uterine origin, and observed a 53% response rate.[384] Leu and colleagues confirmed the activity of the regimen at the lower dose in patients with a variety of other sarcomas.[385] Since the response rate among patients with leiomyosarcoma in the M.D. Anderson study of gemcitabine was 4 out of 10, it was unclear whether the activity of the gemcitabine-docetaxel regimen was due to the timed infusion of gemcitabine, the large number of patients with uterine leiomyosarcoma, or the addition of docetaxel. To answer this question, SARC (the Sarcoma Alliance for Research through Collaboration) carried out a RCT comparing equimyelosuppressive doses of timed-infusion gemcitabine versus the combination of gemcitabine and docetaxel. The study employed a Bayesian adaptive randomization design with continuous feedback of data into the randomization model so that more patients were entered in the arm with greater efficacy.[386] Success was defined as a RECIST response at any time or freedom from progressive disease at 24 weeks, based on the assessment of the investigators that prolonged freedom from progression was more beneficial to patients than response. Results reported by Maki and colleagues at ASCO 2006 showed a statistically significant superiority of the combination regimen in terms of success rate, progression-free survival, and overall survival.[387]

Despite poor levels of activity as single agents, some of the preceding drugs have been incorporated into nonanthracycline-based salvage regimens. On the basis of encouraging data in pediatric sarcomas, etoposide has been combined with ifosfamide, although with variable results.[377,388–391] All but one such study produced response rate in the range of 38% to 46%; because ifosfamide given alone has produced up to 67% in phase II studies, however, these results are difficult to interpret. A combination of paclitaxel with gemcitabine and cisplatin was evaluated, with preliminary reports of encouraging synergistic activity.[392] Temozolomide,[393–395] raltitrexed,[396] irinotecan,[397] sargramostim,[398] topotecan,[399,400] and vinorelbine[401] seem to have minimal activity in STS, despite their proven value in other tumor types.

INVESTIGATIONAL NEW DRUGS. Of drugs that are currently in phase II development, trabectidin (ET743, ecteinascidin 743), a DNA guanine-specific minor groove-binding agent, seems to have clear-cut activity against sarcomas. Hints of activity in bone and STSs were observed in phase I trials[402,403] and appeared to be confirmed in phase II trials of this agent. Garcia-Carbonero and colleagues reported a response rate of 17.1% in 35 chemonaive sarcoma patients and 8% in 34 patients who had received prior chemotherapy.[405] George and colleagues reported a lower progression rate (5%) but a substantial proportion (19%) of patients with minor responses or stable disease.[406] Two European trials described response rates of 11% to 12% in previously treated sarcoma patients.[407,408] Occasional severe toxicities, sometimes lethal, seemed to be related to elevated baseline liver function tests; and with careful attention to alkaline phosphatase levels, toxicity other than myelosuppression and fatigue has not been a major problem. In the attempt to avoid the inconvenience of a continuous-infusion schedule, weekly administration has been evaluated. In a randomized study reported at ASCO 2004, the continuous infusion was more toxic, but it was significantly more effective in terms of time to progression and survival.[409] This study indicates that the drug is clearly active and that either the continuous-infusion schedule is superior or the dose that was chosen for the weekly schedule was too low.

Another interesting observation from the various studies of trabectidin is that it has high activity against a single subtype of sarcomas, myxoid liposarcoma, made by Grosso and colleagues at the Istituto Nazionale Tumori in Milan.[410] They noted a response rate of 43% by RECIST and an even higher response rate when changes in tumor density were considered—a so-called tissue response. We and others have verified their observation (unpublished observation), and it is clear that the responsiveness of myxoid liposarcoma to trabectidin is very high. It is a subtype that is rather responsive to doxorubicin plus ifosfamide as well, but the second-line (and sometimes fifth-line) activity of trabectidin is truly remarkable. Myxoid liposarcoma is characterized by a specific translocation putting either FUS or less commonly EWS with CHOP. It is possible that trabectidin specifically blocks transcription of the fusion DNA. It is also evident that trabectidin is more active against tumors with altered DNA repair mechanism. Tumors with low expression of BRCA1 and high expression of ERCC1 have substantially longer progression-free survival than do those with high expression of BRCA1 and low expression of ERCC1.[411] Whether the altered DNA repair is a specific feature of myxoid liposarcoma or other translocation-related sarcomas or whether the altered DNA repair is an independent predictor of response is to be determined.

Another class of drugs with activity against sarcomas are the mTOR inhibitors, the best studied of which is an investigational agent AP23573 from a small company, ARIAD. Data reported at ASCO by Chawla and colleagues showed an objective benefit rate, defined as RECIST response or stable disease at 16 weeks, of 28% in 193 patients.[412] At the same time, anecdotal responses to rapamycin were reported,[413] but a phase II study of an alternative mTOR inhibitor[414] showed no activity when the endpoint was only RECIST response. Note that if only RECIST response were counted for AP23573, it would have been declared inactive with a response rate of 2.6%.[412]

The observation that patients with growing tumor may benefit from therapy when the growth stops is not new, but its importance is becoming increasingly recognized. Initially described in a phase II study of doxorubicin as improvement[415] that included both responses that were inadequate to qualify by standard criteria and stabilization of previously progressive disease, improvement has traditionally been accepted as a "second-class" response at best. Trabectidin is the first modern drug for which the clinical observation seemed to take on added meaning. The EORTC has defined rates of time to progression at 3 and 6 months for active and inactive regimens.[416] Clinicians who treat osteosarcoma have known that standard responses might not exist despite a complete histologic response. The experience with GIST (see later discussion) has indicated that many patients who are clearly benefiting from therapy and have objectively measurable responses do not qualify as responders by RECIST or World Health Organization criteria. Therefore, the activity of gemcitabine-docetaxel that led to improved progression-free and overall survival, the activity of trabectidin, and the extent of the activity of imatinib in GIST were discovered by using modified response criteria. It make sense to look at new drugs such as the mTOR inhibitors using similar expanded criteria for drug activity and to pursue their study.

The identification of a specific molecular target (the tyrosine kinase receptor KIT) in a rare type of STS (GIST) and successful treatment with a drug (imatinib) that inhibits that target provide a model for future drug development in STS. Although it is unlikely that the pathogenesis of most STS will prove to be driven by a single genetic mutation, better molecular differentiation of STSs into categories with similar molecular characteristics could facilitate future studies of highly targeted drugs. At an NCI-sponsored "State of the Science" meeting on STS, Demetri pointed out that the ideal target would meet four conditions: (1) a single validated molecule that is critical to STS pathogenesis in humans, (2) expressed and active, (3) a target for which there are no alternative pathways to bypass the blockade, and (4) necessary and sufficient for sarcoma survival.[238] Other potential targets are discussed elsewhere in this chapter.

Complex sarcomas with diverse karyotypes and/or drug-resistance mutations are likely to require drugs used in combination to block multiple targets. Recent reviews have described signal transduction pathways in sarcoma as therapeutic targets,[417] the potential use of antiangiogenesis agents,[418] and new approaches to immunotherapy.[419] Early reports of antiangiogenesis therapies have shown limited benefit in STS,[420,421] but many agents remain to be evaluated.

Although the majority of patients with metastatic STS will not have access to phase II studies of investigational agents, where these are available, trial entry should be encouraged. Conventional wisdom suggests that use of an investigational agent as a first- or second-line therapy for metastatic disease should be considered, since investigational agents that are given as third- or fourth-line treatments could be doomed to failure because of acquired drug resistance. This concept has now been proven incorrect. Whenever there is an effective agent or regimen (gemcitabine-docetaxel, imatinib in GIST, ifosfamide in synovial sarcoma, trabectidin in myxoid liposarcomas), activity is obvious in multiply-treated patients.

UNIQUE ROUTES OF DELIVERY. Some experimental studies have evaluated intraperitoneal delivery of cytotoxic agents, usually doxorubicin and cisplatin, sometimes with hyperthermia, in sarcomas that are confined to the peritoneal cavity after resection of all visible abdominal disease.[368,422,423] Evaluation of any benefit is a major challenge in these studies, however, and this technique may be less suitable for sarcomas than for epithelial cancers.

Another novel approach is isolated lung perfusion with doxorubicin after resection of pulmonary metastases, in general a more common situation in STSs. To date, studies of isolated pulmonary perfusion have focused on feasibility rather than outcomes.[424]

SPECIAL SITES AND SUBTYPES OF SARCOMA

Retroperitoneal Sarcomas

Retroperitoneal sarcomas are relatively uncommon, accounting for approximately 15% of all sarcomas (see Fig. 97-1). The most common histologic subtypes are well-differentiated and dedifferentiated liposarcoma and leiomyosarcoma, found in 42% and 26% of cases, respectively (see Fig. 97-1). Nearly 80% of patients present with an abdominal mass, and 50% of patients report pain at the time of presentation.[189] Patients commonly describe nonspecific gastrointestinal symptoms. Other commonly noted symptoms include neurologic symptoms (primarily sensory) in 27% of patients and weight loss in 7%.[189,425] These tumors often grow to substantial size before a patient's nonspecific complaints are evaluated or an abdominal mass is noted on physical examination.

CT and MRI are the primary methods that are used to image retroperitoneal tumors (see Figs. 97-3, 97-5, and 97-6).[426–428] These modalities allow assessment of the consistency of the mass (fat, cystic or solid components, associated necrosis), the precise anatomic location of the mass, and the extent of any regional disease, and they confirm function of the contralateral kidney. CT of the abdomen and pelvis usually provide images that are satisfactory for treatment planning. Occasionally, MRI with gradient sequence imaging can be helpful in defining long-segment vascular anatomy for surgical planning. For patients with an abnormal chest radiograph, chest CT should be performed to exclude the possibility of metastatic disease.

The differential diagnosis for a retroperitoneal mass is relatively limited. Physical examination should include a testicular examination in men to evaluate the possibility of a primary testicular neoplasm. Laboratory tests should include the common serum markers for germ cell tumors, beta-human chorionic gonadotropin, and α-fetoprotein. If physical examination is suggestive of testicular malignancy or biochemical markers are elevated, testicular ultrasonography should be performed. This may obviate laparotomy for patients with metastatic testicular tumors and allow identification of primary retroperitoneal germ cell tumors.

In general, preoperative biopsy is not necessary when radiographic appearance makes the diagnosis of well-differentiated liposarcoma (atypical lipomatous tumor) and surgical resection is planned for a resectable primary retroperitoneal mass. If there is a question of diagnosis (lymphoma) or if preoperative chemotherapy or radiation is considered, a core-needle biopsy is essential.

Surgical resection with negative margins remains the standard primary treatment for patients with localized retroperitoneal sarcoma. Unfortunately, the data are extremely difficult to interpret because most series lump all patients, the majority or whom may have atypical lipomatous tumors (also called well-differentiated liposarcoma) with patients with true high-grade sarcomas. Patients should be thoroughly evaluated with multidisciplinary input before there is any attempt at surgery. If ifosfamide might be required at some point in the patient's management, for example, and if adequate surgery would remove a kidney, strong consideration should be given to preoperative chemotherapy. Similarly, if radiation will be required, it is preferably given preoperatively (see later discussion). If primary surgery is chosen for the patient, all patients should have preoperative bowel preparation and assessment of bilateral renal function by CT, because en bloc multiorgan resection might be required to achieve negative margins. Resectability rates in recent series combining patients with primary and recurrent lesions have ranged from 25% to 96% (Table 97-13).[189,425,429–434] Resectability rates at different institutions are difficult to compare and interpret because these rates are a function of the referral pattern, the criteria that are used to determine which patients will undergo surgical exploration, and the surgeons' skill and experience.[433,435,436] For patients with primary lesions, grossly complete resection is possible in up to 78% of cases.[133,433] The most common reasons for unresectability are the presence of major vascular involvement (aorta or vena cava), peritoneal implants, or distant metastases.[189] Resection of adjacent retroperitoneal or intra-abdominal organs, frequently the kidney, colon, or pancreas, is required in 50% to 80% of cases to permit complete resection.[189,431,437] Partial resections or debulking procedures have been performed, but there is no evidence that partial resection improves survival (Fig. 97-16).[189,437] Deliberate partial resection should be reserved for relief of bowel obstruction or palliation of other critical manifestations of advanced disease.

Results from published series demonstrate 5-year overall survival rates in the range of 54% to 64% for patients with completely resected retroperitoneal sarcoma.[133,189,431,433,434] Overall survival rates for patients with incompletely resected disease range from 10% to 36%. Adequate margins are often difficult to obtain in retroperitoneal sarcoma surgery because of the proximity of critical organs, vascular structures, and the spine. Consequently, recurrent disease remains a significant problem, recurrence developing alone or with systemic relapse in 46% to 59% of patients with completely resected tumors.[134,189,431,433,438]

A number of recent studies have evaluated prognostic factors for retroperitoneal sarcomas by univariate and multivariate analysis.[133,134,425,431,438] For patients who presented without metastatic disease, complete surgical resection and histologic grade were the primary determinants of survival in several multivariate analyses.[133,425,431,434,438] Some investigators have also found by multivariate analysis that large tumor size (>10 cm) and fixation to adjacent retroperitoneal structures other than neurovascular bundles or bone were significant adverse factors for survival.[431] Patients who undergo a grossly complete resection have a 60% 5-year overall survival rate and a median survival of 64 months (see Fig. 97-16). These results

Table 97-13 Resectability Rates for Retroperitoneal Sarcomas in Selected Series

First Author	Institution	Accrual Period (Yrs)	Total No. of Patients	No. Completely Resected	Restability Rate (%)

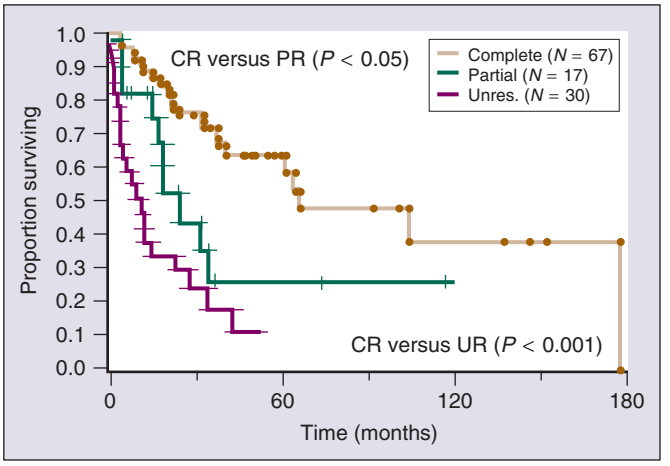

Figure 97-16 • Proportion of patients with retroperitoneal sarcoma who survive from the date of first operation at Memorial Sloan-Kettering Cancer Center for patients undergoing complete (gross negative margin), incomplete (gross positive margin), or no resection. (Reprinted with permission from Jaques DP, Coit DG, Hajdu SI, et al: Management of primary and recurrent soft-tissue sarcoma of the retroperitoneum. Ann Surg 1990;212:51.)

are significantly better than those of patients who have an incomplete resection (grossly positive margins) or unresectable disease. For patients with low-grade lesions, the median survival (80 months versus 20 months) and 5-year overall survival rate (70% versus 25%) are significantly better than those for with patients with high-grade lesions.[189]

The unfavorable results of outcome for retroperitoneal sarcoma logically points to the need to investigate adjuvant approaches. The obvious candidates include preoperative chemotherapy and preoperative radiotherapy. Detailed discussions of the pertinent issues in these approaches are available[439,440] and are summarized in the following section.

Surgery Plus Radiation Treatment

Postoperative EBRT has been shown to reduce local recurrence rates for extremity sarcomas and superficial trunk sarcomas. However, gastrointestinal toxicities or neurotoxicities often limit the delivery of sufficient radiation doses to the retroperitoneum. Several retrospective studies have suggested that postoperative EBRT might improve local control after grossly complete resection[189,219,430,438,441–445] while other small retrospective reports have not suggested any improvement in local control with postoperative radiotherapy.[189,219,430]

However, these series have included small numbers of patients (<30 to 40), no standard treatment protocol, and variable details on histopathology, extent of resection, and margin status. The largest study addressing this issue was reported by the French Cancer Federation Sarcoma Group with the suggestion that postoperative radiotherapy was associated with significantly reduced local recurrence compared to surgery alone.[446] In this report, 145 patients presented with localized nonmetastatic retroperitoneal sarcoma. As is typical for this disease, the tumors were large (median size: 15 cm, range: 2 to 70 cm), and only a minority (6%) were T1 lesions. As in others series, liposarcoma was unusually well represented (30%). Their patients may differ from those in other reports in that only 27 cases (19%) had grade 1 lesions. A significant number of patients (31%) had neurovascular or bone involvement. Complete resection took place in 94 of the 145 patients (65%), and 60 of these patients received radiotherapy to a median dose of 50 Gy. Of the 94 patients who underwent complete resection, the 5-year actuarial local recurrence-free interval was 60% for those who were treated with radiotherapy and 23% for those who did not receive postoperative radiotherapy ($P = 0.0021$). Clearly, the likely possibility of selection bias must be considered in interpreting these results, since patients with large and more complex (i.e., unusually located or infiltrating) lesions and patients who experienced postoperative morbidity are less likely to have been treated with radiotherapy.

Preoperative EBRT for retroperitoneal sarcoma offers certain theoretical and practical advantages: (1) High-dose treatment could minimize the risk of tumor implantation in the peritoneal cavity after a marginal resection by sterilizing a large number of tumor cells; (2) partial tumor regression could facilitate grossly complete resection; (3) there are favorable anatomic issues, including the tumor displacement of critical radiosensitive organs (bowel predominantly) away from the preoperative radiation field, thereby reducing toxicity and improving tolerance; and (4) an intact peritoneum offers a mechanical barrier to tumor seeding during the time radiotherapy is being administered before resection and division of these membranes. Moreover, postoperative radiotherapy is problematic if bowel is tethered in the radiotherapy target area, making it impossible to treat some patients, at least without unnecessary risk of complications.

Two recent series, the first from the Princess Margaret Hospital and the other from the University of Texas M.D. Anderson Cancer Center, are informative because acute toxicity resulting from preoperative radiotherapy was differentiated prospectively from the effects of other treatments.[447,448] In the Princess Margaret Hospital series, the median preoperative dose of radiotherapy comprised 45 Gy in 25 fractions. Although the median radiation volume exceeded 7 L, preoperative EBRT was associated with European Organization for the Research and Treatment of Cancer/Radiation Therapy Oncology Group (EORTC/RTOG) acute toxicity scores of ≤2 in all patients who underwent resection. Furthermore, no patient was hospitalized for acute toxicity, and there were no treatment interruptions or requirements for cessation of treatment because of acute toxicity. The remarkably low toxicity of the preoperative course with enormous radiotherapy volumes in the study has been attributed to the displacement of bowel outside the target volume. At the same time, brachytherapy used postoperatively in selected cases did appear to be associated with toxicity and also does not appear to have contributed to enhanced tumor outcome. Late toxicity resulted in death in 4.3% (2 of 46) and with life-threatening illness in 2.2% (1 of 46) of patients, all of whom had been treated with brachytherapy to the upper abdomen. The 2-year overall survival and disease-free survival for resected retroperitoneal sarcoma were 88% and 80%, respectively. Significantly better 2-year disease-free survival was achieved in patients with primary (in contrast to recurrent) disease and in those with low-grade tumors (93% and 95%, respectively).[447] Similarly, in the M.D. Anderson Cancer Center phase I trial ($N = 35$), the tolerance of preoperative radiotherapy is also reported. The M.D. Anderson Cancer Center trial differed from the Princess Margaret Hospital study in that it also evaluated outcome after preoperative doxorubicin in addition to concurrent allocation to one of six sequential 1.8-Gy-per-fraction escalating radiotherapy protocols (from 18 to 50.4 Gy) and used intraoperative electron beam as the boost technique in localized retroperitoneal tissue sarcoma.[448] At the highest radiation dose of 50.4 Gy, 2 (18%) of 11 patients had grade 3 or 4 nausea. Twenty-nine patients (83%) underwent laparotomy; 6 patients had interval disease progression and did not undergo surgery. Grossly complete resection (R0 or R1) was performed in 26 (90%) of 29 patients who had surgery. Intraoperative electron beam was feasible and successfully administered to 22 patients who had R0 or R1 resections. This trial demonstrates that preoperative external beam radiation can be safely administered to a total dose of 50.4 Gy with continuous-infusion doxorubicin.

The three papers with sufficient follow-up that describe the use of preoperative radiotherapy with a brachytherapy or electron boost reported improved outcomes compared to most other series, especially for primary (as opposed to recurrent) presentation cases,[447,449,450] and presumably, the M.D. Anderson Cancer Center trial will

demonstrate similar findings with maturation of the data.[448] However, we again caution against overinterpretation of results that could be explained by surgical technique at major referral sarcoma centers or by case selection; of note, none of the four studies provides a comparison control group from which to infer efficacy. Similarly, it remains unclear what contribution is being provided by the use of brachytherapy or intraoperative radiotherapy (as opposed to the preoperative EBRT, common to all four studies), which should probably remain protocol-based in expert hands or be reserved for individual nonstandard clinical use.

Intraoperative Radiation Treatment

Intraoperative radiotherapy (IORT) offers the advantage of a direct boost dose to the tumor bed, thereby allowing a reduction in the dose of relatively more toxic concomitant EBRT. However, critical evaluation of its role is especially problematic because of treatment selection factors (both medical and technical) along with the fact that any observations of efficacy are confounded by the frequent use of additional fractionated EBRT in the "adjuvant package." Therefore, a clear demonstration of the effectiveness of IORT is lacking, although its potential value should continue to be evaluated in appropriate investigational protocols. The same situation applies to the use of adjuvant brachytherapy approaches to dose augmentation in the retroperitoneum.

The efficacy of combined adjuvant IORT and EBRT has been evaluated in two recent series, one from Massachusetts General Hospital and the second from the Mayo Clinic,[449–451] and in a previous report from the NCI.[452] The NCI study was a prospective trial in which 30 patients with completely resected retroperitoneal sarcomas were randomly assigned to receive IORT (11- to 15-MeV electron beam to a dose of 20 Gy) with low-dose postoperative EBRT (35 to 40 Gy) or to receive high-dose postoperative EBRT (50 to 55 Gy) alone.[452] IORT with low-dose EBRT was associated with a significantly lower rate of gastrointestinal toxicity (7% versus 60%), but no differences were noted in local control, disease-free survival, or overall survival. The rates of 5-year disease-free (20%) and overall survival (40%) seen in this study were comparable to those observed with surgery alone.[219,431] The reports from Massachusetts General Hospital and the Mayo Clinic described preoperative high-dose EBRT (40 to 50 Gy), instead of postoperative administration, with IORT (using electron beam to a dose of 8.75 to 30 Gy, depending on the series).[422,423] Both papers report on overall toxicity without differentiation between the influence of preoperative external beam and the boost after resection. This likely arose because of retrospective toxicity data collection in the two studies, which is further confounded by the frequent use of IORT in each.[449,450] The inference from our analysis of the results of both studies is that much of the toxicity seems related to use of IORT and is not from preoperative EBRT.

In summary, in the management of retroperitoneal sarcoma, complete surgical resection remains the standard of care. In selected patients with advanced disease, some disabling symptoms may be palliated by low- to moderate-dose EBRT. As for extremity sarcomas, there are no currently available data to support the use of routine adjuvant chemotherapy for these patients. Given the relatively high complication rates of high-dose external beam radiation to the retroperitoneum and the lack of clear demonstrable clinical benefit, routine preoperative or postoperative EBRT is not recommended outside the setting of a clinical trial and clinicians should be encouraged to enter patients in ongoing trials at referral centers.[439,453,454]

Chemotherapy

Retrospective studies have not demonstrated any benefit for preoperative[455] or postoperative[133,189,430,456] doxorubicin-based chemotherapy for retroperitoneal sarcomas. In one study, six complete responses were seen in 23 patients who received high-dose doxorubicin/ifosfamide/DDP (cisplatin) with concurrent radiotherapy.[254] Neoadjuvant chemotherapy has been combined with hyperthermia[457] and preoperative radiotherapy[448] without excessive toxicity. Idoxuridine was used as a radiosensitizer in a small pilot study.[458] These techniques remain experimental, however, and need further assessment, eventually in RCTs, to evaluate their place in the management of retroperitoneal sarcomas.

Most of the studies indicated previously included retroperitoneal sarcomas as a single group without differentiating primary histologic type or grade. Because of the preponderance of patients with atypical lipomatous tumors who were included in such studies, assessment of the effects of chemotherapy needs reexamination. Clearly, for high-grade retroperitoneal sarcomas, the recurrence rate is unacceptably high, and even when the local disease is controlled, patients are at risk from metastatic disease. If an effective chemotherapeutic regimen could be identified early, with the primary tumor intact, and if some progression of disease under therapy would not render the patient unresectable, it would be beneficial. Thus, there is an indication for preoperative chemotherapy in appropriately selected patients. Proof of principle comes from the UCLA study mentioned previously where complete responses to chemotherapy and radiation were demonstrated. With newer regimens such as gemcitabine-docetaxel, which might be effective in leiomyosarcomas, individualized multidisciplinary therapy should be considered.

Gastrointestinal Stromal Tumors

GISTs represent about 80% of sarcomas that arise from the gastrointestinal tract. This group of soft-tissue tumors has become increasingly recognized as a separate subtype of sarcoma defined pathologically by expression of the receptor tyrosine kinase, c-Kit (CD117), in about 95% of cases. The management of these tumors has undergone significant recent change with the development and availability of imatinib mesylate, an agent with significant clinical benefit for patients with advanced GISTs. Details of the molecular pathology of GISTs are addressed in the sections on Potential Molecular Prognostic Factors and Prognostic Factors as Therapeutic Targets.

This section of the chapter will cover the evaluation and treatment of patients with GISTs. Consideration of these issues is often aided by subclassification by clinical staging into patients with localized, nonmetastatic (resectable) disease and patients with metastatic GIST.

Localized (Surgically Resectable) Gastrointestinal Stromal Tumors

Patients with localized GISTs are best treated with surgical resection of the primary tumor. Surgical resection generally requires segmental resection of the involved section of the gastrointestinal tract without local or regional lymphadenectomy. Since GISTs were only recently pathologically defined, there are few reports outlining the natural history of localized GISTs (excluding other forms of mural gastrointestinal neoplasms). Moreover, the natural history of patients with localized disease stratified by c-Kit mutation subclassification is not well characterized at this time.

Details of the natural history of patients with surgically treated gastrointestinal leiomyosarcoma, the vast majority of whom might have what we currently would classify as GISTs, are outlined in prior reports.[141,459,460] These reports emphasize the importance of macroscopically and microscopically complete surgical resection and the adverse prognostic significance of large tumor size and high tumor grade (as assessed by light microscopic criteria). Although surgical resection has been the mainstay of therapy for patients with localized GISTs, a recently published analysis of 200 patients by DeMatteo and colleagues noted only a 54% disease-specific 5-year survival rate for patients in whom a grossly complete resection of their primary GIST had been achieved, and there were additional deaths thereafter.[461] Furthermore, the median survival in patients with metastatic disease was only 20 months.[461]

The precise role of imatinib mesylate in the postoperative treatment of patients with localized GISTs is unknown. Current clinical trials address the issue, but unfortunately, none of the currently active clinical trials in the United States or Europe clearly address the issue of the appropriate duration of imatinib therapy. The first RCT, the Z9001 trial by the American College of Surgeons Cooperative Group, was closed early owing to a clear advantage of imatinib in decreasing the recurrence rate at one year (R. P. DeMatteo, personal communication). Although it is intuitively obvious that a therapy as effective in metastatic disease as imatinib will benefit patients when given early in their course, it is not clear that therapy before relapse is better than therapy afterward. Furthermore, since patients with advanced disease who relapse when imatinib is stopped respond again when it is reinstituted, it is not clear that a finite course of early therapy will have lasting benefit, especially if it is as short as 1 year. Therapy for as long as 3 years is explored in one European trial, but even that might not be long enough. Preoperative therapy is also being studied; however, most clinicians agree that whenever the likelihood of successful surgery would be increased or the extent of surgery would be substantially diminished by preoperative treatment, a trial of preoperative imatinib is warranted.

Metastatic Gastrointestinal Stromal Tumors

The primary sites of failure for most patients with recurrent GIST are the liver, the peritoneum, or sometimes both sites. It is very rare for this tumor to metastasize to the lungs.

CHEMOTHERAPY. GISTs are resistant to conventional cytotoxic chemotherapy agents, with response rates that are typically in the single-digit range or lower. In the era of imatinib mesylate, there is no defined role for conventional chemotherapy agents in this disease.

The identification of mutations of c-Kit, which cause constitutive activation of the KIT tyrosine kinase receptor pathway in GIST, prompted treatment in 1996 of a Finnish patient with imatinib,[462] a tyrosine kinase inhibitor that is highly effective against chronic myeloid leukemia. An impressive response led to rapid initiation of phase I[463] and randomized phase II studies of imatinib for GISTs.[464] In an EORTC study, 40 patients, of whom 36 had GISTs, were treated at dose levels ranging from 400 to 1000 mg/day orally. There were 19 patients who had partial responses (54%) and 13 with stable disease (37%). Four of five of non-GIST patients progressed. The most common side effects of imatinib were nausea, vomiting, edema, and rash. In a multicenter phase II study, 147 patients were randomly assigned to receive 400 or 600 mg of imatinib daily. Although no patient had a complete response during treatment, 79 (54%) had a partial response, and 41 (28%) had stable disease. The median duration of response had not been reached at a median follow-up of 24 weeks from the onset of response.[76] There were no significant differences in response rate or toxicities between the two doses, edema, diarrhea, and fatigue being the most common side effects. Gastrointestinal hemorrhage occurred in approximately 5% of patients.

Two RCTs of imatinib have been completed in North America[465,466] and in Europe and Australia,[467] accruing 746 and 946 patients, respectively, with locally advanced or metastatic GIST. They compared 400 and 800 mg of imatinib and assessed overall survival, progression-free survival, and toxicity. There is no significant survival advantage for the higher dose. Progression-free survival was significantly longer in the EORTC study.[467] A similar magnitude of improvement (4 months median and 5% increase in 2-year progression-free survival) in the North American study was not statistically significant ($P = 0.12$).[466] Most oncologists on both sides of the Atlantic prefer to start with the 400-mg dose, which is considerably less toxic, increasing only if patients do not respond or relapse after the initial response. There are data to suggest that the higher dose is more effective in the subset of patients with exon 9 mutations.[468,469] For patients with GISTs who are refractory to imatinib, sunitinib, a compound that targets multiple tyrosine kinases (KIT, PDGF-R, FLT3, and VEGF-R), can be effective.[470] Several other tyrosine kinase inhibitors are in clinical trial and have demonstrated some efficacy.

One observation from the early studies of imatinib in GIST was that traditional responses to treatment frequently underestimated the obvious clinical benefit that was observed. Van den Abbeele and colleagues noted that responses measured by PET at 1 month predicted for improved progression-free survival, while bidimensional responses according to SWOG criteria did not.[471] Choi and colleagues noted that response on CT often included decrease in size but that the degree of tumor shrinkage would have been classified as a minor response in a substantial fraction of the patients.[472] The tumors were also noted to have decreased in density after contrast enhancement.[471] Dr. Choi and her colleagues defined the CT changes that correlated with PET response and showed that they predicted for progression-free survival.[473] These changes, a 10% or greater decrease in maximum tumor diameter or a 15% or greater decrease in tumor density, the "Choi criteria," were confirmed to have prognostic importance in an independent group of patients with GIST.[474] There is increasing evidence that similar findings are seen in other tumors and after other treatments, suggesting that major therapeutic effects are missed when patients are evaluated only by RECIST.[475]

Singer and colleagues reported that c-Kit mutation type affects outcome.[172] They found a 5-year recurrence-free survival rate of 89% for patients with GISTs expressing missense exon 11 mutations compared with 40% ($P = 0.03$) for GISTs with other mutation types. Heinrich and colleagues reported a higher PR rate to imatinib (72% versus 32%, $P = 0.0033$) for patients with exon 11 versus exon 9 mutations in the initial phase II study[475] with similar findings in the North American study.[469] Debiec-Rychter and colleagues have published details of similar findings from the EORTC study.[468]

A unique aspect in the treatment of GIST with imatinib or another tyrosine kinase inhibitor is that therapy should be continued even in the face of documented disease progression, a practice that is endorsed by NCCN guidelines. In almost all cases, the progression occurs in only a portion of the tumor, while the majority of the tumor continues to be controlled by imatinib. Stopping all c-Kit inhibition leads to more rapid, diffuse tumor progression and shortened survival.

Other soft-tissue tumors that express activated tyrosine kinase receptors include DFSP (PDGF-β). Case reports of patients with DFSP have documented responses to imatinib.[94,476]

SURGERY. The role of surgery in patients with metastatic GIST is becoming better defined. There is no role for surgical resection in patients with multifocal recurrence. The advantage of adding surgical resection to imatinib in responding patients in whom all disease can be resected is unknown but is thought probably to be beneficial. Surgery in the setting of focal resistance, that is, a single progressive metastatic site while other disease appears to be controlled, is of less value, but most consider it a reasonable treatment strategy. It is clear that imatinib must be continued in the postoperative setting.[459,477,478]

Head and Neck Sarcomas

Head and neck sarcomas are uncommon, accounting for only 4% of all sarcomas and fewer than 1% of head and neck malignancies in adults. (A detailed discussion of the current state of knowledge for adult and pediatric head and neck sarcoma is available elsewhere.[479]) The most common histologic subtypes in adults are fibrosarcoma (18%), malignant fibrous histiocytoma (16%), and rhabdomyosarcoma (15%).[288,480] In recent large series of 176,[288] 188,[481] and 254[482] patients with head and neck sarcomas, the most common anatomic sites were the neck (23% to 38%) and paranasal sinuses (14% to 30%).

In the pediatric population, 40% of all STSs occur in the head and neck, where the most common histologies are neuroblastoma and embryonal rhabdomyosarcoma. The treatment of these lesions in the pediatric population is beyond the scope of this chapter and is reviewed in Chapter 99.

Methods of diagnosis, imaging, and biopsy for head and neck sarcomas do not differ substantially from those for other head and neck tumors. Wide surgical excision with negative margins is the therapeutic mainstay for head and neck sarcomas. Regional lymph node metastases are rare, occurring in only 4% to 6% of patients in large series.[481,482] Thus, in the absence of clinically positive lymph nodes, regional lymphadenectomy is not routinely required.

Recent series have identified prognostic factors for head and neck sarcomas.[135–138,288,481,482] Multivariate analyses of patients with head and neck sarcomas identified high histologic grade and positive surgical margins as independent adverse prognostic factors for survival.[137,138] Age greater than 60 years at diagnosis was also found to be an independent adverse prognostic factor in one multivariate analysis.[138] Additional data from the Mayo Clinic confirm that the presence of metastases is associated with a poor (25%) 5-year overall survival rate and that certain histologic subtypes (angiosarcoma and nonorbital rhabdomyosarcoma) may have an adverse prognosis.[482]

Patterns of failure for head and neck sarcomas reflect the difficulty in obtaining adequate surgical margins in the head and neck region. Local recurrence remains a significant problem, with overall rates of local recurrence ranging from 14% to 48%,[288,481,483] making it important to consider appropriately applied principles of sarcoma management with combined modality approaches where appropriate. As with sarcomas elsewhere in the body, biologic behavior is a function of histologic grade, with local recurrence rates ranging from 22% for low-grade head and neck sarcomas to 48% for high-grade lesions.[288] Systemic recurrence develops in 12% to 31% of patients despite complete resection.[288,483] Overall 5-year survival rates are 45% to 68%.[288,481,482,484]

Radiation Treatment

On the basis of experience gained in treating extremity sarcomas, adjuvant radiotherapy should be considered whenever there is doubt as to the adequacy of surgical margins or the location of the tumor precludes complete excision. Evidence for the benefit of adjuvant radiotherapy is less plentiful than in extremity lesions and probably relates to the rarity of these lesions and the absence of randomized trials addressing the specific issues for these lesions. However, Tran and colleagues from the University of California, Los Angeles have shown that local control was 52% with surgery alone versus 90% in head and neck patients who were treated with combined radiotherapy and surgery.[135] Additional evidence from Princess Margaret Hospital reveals that head and neck STS patients with clear surgical margins or microscopic residuum had similar local failure rates (26% and 30% failure, respectively), provided that radiotherapy was administered.[485] Indeed, these outcomes for radiotherapy after R0/R1 resections approach those achieved in extremity sarcoma.

One strategy to improve outcome in head and neck sarcomas is through the use of preoperative radiotherapy. This approach may have particular advantages in this site because of the smaller volumes of radiotherapy and the lower doses that can be used compared to the postoperative treatment in difficult surgical access locations, especially in the base of skull. Obvious advantages that are provided relate to the ability to spare critical anatomy such as the optic structures (globes, optic nerves, and the optic chiasm) as well as the brain stem and spinal cord. If for no other reason, the preoperative approach promotes collaboration between the surgical and radiation oncologist, facilitates a complete management plan to be fashioned before any surgical intervention, and maximizes the opportunity to achieve control even when disease may be resected with a small but planned positive margin against critical unexpendable anatomy, as was discussed earlier.[194]

In a prospective series of 40 patients (excluding rhabdomyosarcoma) with adverse selection criteria managed with preoperative radiotherapy between 1989 and 1999 at the Princess Margaret Hospital, 7 local relapses manifested (overall control rate of 82.5%).[196] This population of head and neck patients included five patients with intracranial extension and one with spinal cord compression; more than half of the lesions were greater than 5 cm in size (a formidable problem for lesions in this anatomic location), and 85% were deep to the investing fascia. The series also contained four angiosarcoma patients, a group of patients with sinister local control probability (see the later discussion of Vascular Sarcomas). In fact, three of the seven local failures occurred in the angiosarcoma patients. If the series is confined to more usual STS, the local control rate is 33 out of 36 (92%). The metastatic relapse-free rate also exceeded 80% in this series, potentially related in part to the smaller overall dimension of sarcomas in this location compared to sarcomas elsewhere. The improved local control compared to a previous series of patients treated at the same institution might also have contributed to this amelioration because the local control rate in the earlier series was substantially lower and death from concurrent local and metastatic disease was evident.[485]

Wound complications, assessed by the Canadian trial criteria,[211] were also seen with less frequency in this prospective study of head and neck lesions (overall rate: 8 of 40, or 20%)[196] than were noted earlier with preoperative radiotherapy in extremity lesions. This may relate to the greater use of flaps for head and neck reconstruction.

At present, useful guidelines for using preoperative radiotherapy in the head and neck are (1) the need to maximally restrict radiotherapy volumes in some anatomic sites (e.g., close to critical anatomy); (2) the desire to minimize radiation dose in some situations (e.g., where critical neurologic tissues are in close proximity, as in the optic structures); and (3) a desire not to irradiate new tissues, especially vascular reconstructions that are vulnerable to the effects of high-dose postoperative radiotherapy.

Genitourinary Sarcomas

Although STSs of the genitourinary tract are uncommon in adults, they account for up to 8% of all malignant disease in children younger than 15 years.[486] The management of genitourinary sarcomas in children has been more successful than that in adults and is discussed in detail elsewhere in this book. In the Memorial Sloan-Kettering Cancer Center adult sarcoma database, only 43 sarcomas (2.7%) were of genitourinary origin. The paratesticular region (33%) and prostate/seminal vesicles (28%) are the most frequent sites of genitorurinary sarcomas, followed by the bladder (23%) and kidneys (16%). The most common histologic subtypes in adults are leiomyosarcoma (44%) and rhabdomyosarcoma (33%), although a spectrum of other histologic subtypes has been reported.[487]

A feature of genitourinary sarcomas that distinguishes them from other sarcomas is the fact that the vast majority of these lesions are of high histologic grade. In a recent report from the Memorial Sloan-Kettering Cancer Center, fully 86% of genitourinary sarcomas were high grade, and 56% were larger than 5 cm.[487] Similar findings have recently been reported from the M.D. Anderson Cancer Center, where 15 (88%) of 17 primary sarcomas of the kidney met pathologic criteria for high-grade classification and tumor size ranged from 5.5 to 23 cm.[488] These findings have obvious prognostic implications, and recent series report relatively poor 5-year overall survival rates for patients with high-grade histology (48% versus 100% for low-grade lesions) or large tumor size (30% for lesions 5 cm or larger versus 83% for lesions less than 5 cm).

The primary treatment for genitourinary sarcomas, as with sarcomas elsewhere in the body, is complete resection with histologically negative margins. There are no comparative trials specifically evaluating adjuvant therapy in this subgroup of sarcomas, but most investigators have extrapolated from the lessons that have been learned

with extremity STS and employ adjuvant therapy for patients with high-risk lesions, including those with high histologic grade, large tumor size, microscopically positive margins, gross residual disease, or unfavorable anatomic site (prostate or kidney). Using preoperative chemoradiation and surgery for patients with nonbulky sarcomas of the bladder and prostate and postoperative chemoradiation after radical surgery for patients with bulky disease, investigators at UCLA and at the City of Hope have reported encouraging results, with 9 of 11 patients with leiomyosarcomas alive with no evidence of disease at a mean follow-up of 61 months.[489] These promising results are similar to those reported from the Mayo Clinic for a subset of seven patients with bladder sarcomas who were treated with preoperative radiotherapy and cystectomy[490] and are superior to those observed in a small series of patients who were treated with surgery alone.[491]

Paratesticular and spermatic cord sarcomas, if managed appropriately, can provide satisfactory outcome, as was reported in recent small series from the Princess Margaret Hospital[492] and the M.D. Anderson Cancer Center.[493] Simple excision proved to be inadequate treatment for sarcomas in the spermatic cord and paratesticular region. In the Princess Margaret Hospital report, wide repeat excision revealed microscopic residual disease in 27% of completely excised cases. These series suggest that adjuvant radiation should be considered for these patients as well as for those with narrow repeat resection margins. Definitive conclusions on multimodality therapy for genitourinary sarcomas await further experience with larger numbers of patients.

The comparative infrequency of these lesions and the lack of a uniform staging system lead to difficulties in comparison of series and identification of prognostic factors. Prognostic factors for survival were analyzed in the series from the Memorial Sloan-Kettering Cancer Center, and, by univariate analysis, favorable prognostic variables included tumor diameter less than 5 cm, low histologic grade, paratesticular or bladder (versus kidney or prostate) tumor site, and complete surgical resection.[487] No significant differences in survival were noted on the basis of patient age, sex, or histologic subtype. A poor prognosis for patients with primary renal sarcomas has also been observed at M.D. Anderson, with 13 of 15 evaluable patients dead of disease after a mean of 23 months.[488] Complete tumor resection was possible in 72% of patients in the series of 43 adult genitourinary sarcomas from Memorial Sloan-Kettering. The 5-year overall survival rate was 64% for this group of patients. No patient with an incomplete resection survived 5 years.

Unfortunately, as with head and neck rhabdomyosarcomas, the favorable results that are observed in pediatric patients with genitourinary rhabdomyosarcoma treated with a multimodality approach (58% to 74% 5-year overall survival rate)[494,495] have not been observed in adults in one study; only 5 (36%) of 14 adults were alive at the time of analysis (median follow-up: 32 months) despite aggressive multimodality therapy.[487]

Uterine Sarcomas

Uterine sarcomas are uncommon neoplasms that make up between 2% and 4% of uterine malignancies.[496,497] The three main histologic subtypes in a recent series of 66 uterine sarcomas were as follows: mixed mesodermal (müllerian) tumors, 48%; leiomyosarcomas, 36%; and endometrial stromal tumors, 15%.[498] As with patients who have adenocarcinomas of the uterus, most patients with uterine sarcomas present with vaginal bleeding (77% to 99%) or pelvic pain (30%).[499–502] A palpable pelvic mass is present in 20% to 50% of patients.[502,503] The diagnostic workup is similar to that for the common uterine neoplasms and involves an outpatient biopsy or fractional dilation and curettage. Imaging studies, including CT and MRI, are employed preoperatively in patients with positive preoperative biopsy findings or those with clinically apparent masses on examination.

The standard treatment approach for patients with localized disease is total abdominal hysterectomy with bilateral salpingoophorectomy. Complete abdominal exploration is important from the standpoint of prognosis, but since there are virtually no survivors among patients in whom extrauterine disease is found at the time of exploration, therapeutic extrapelvic dissection has no role. In a review of 423 patients from the West Midlands Cancer Registry, 5-year survival rates for patients with stage I, II, III, and IV (International Federation of Gynecology and Obstetrics staging system), uterine sarcomas were 51%, 13%, 10%, and 3%, respectively.[142]

A number of investigators have evaluated adjuvant radiation. To date, no completed RCT has evaluated the impact of adjuvant radiotherapy on disease-free survival or local recurrence using surgery alone as a control. A Gynecologic Oncology Group trial evaluating the role of postoperative radiotherapy closed because of poor patient accrual. Retrospective comparison of treatment results obtained with surgery alone versus surgery and postoperative radiotherapy has not demonstrated any significant difference in overall survival or disease-free survival rates.[498,504–509] However, multiple retrospective evaluations have suggested that patients who are treated with adjuvant radiotherapy have significantly improved local control with significantly improved freedom from local (pelvic) recurrence compared with patients who are treated with surgery alone.[500,505–508] These results parallel the findings that have been noted for patients with extremity sarcomas: demonstrable improvement in local control with adjuvant radiation but no impact on survival, although the same concerns exist pertaining to the small sample size to detect an effect of this kind.[188,193]

Several investigators have recently identified prognostic factors for survival in uterine sarcoma.[142,510] Multivariate analysis of 423 cases of uterine sarcoma demonstrated that advanced tumor stage, poor histologic grade, increased age, and leiomyosarcoma histologic subtype (versus mixed müllerian tumors) are characteristics that adversely affect survival.[142] A similar multivariate analysis by the Gynecologic Oncology Group of prognostic factors in 453 patients with uterine sarcomas demonstrated that factors related to progression-free interval were histologic grade, histologic type (homologous versus heterologous mixed müllerian tumors), adnexal spread, and lymph node metastasis.[510] These prognostic factors are of importance for selecting adjuvant therapy for individual patients and in designing future clinical trials in uterine sarcoma.

Chemotherapy

There is some evidence that mixed müllerian sarcomas (MMS) respond well to DDP chemotherapy alone[511] or in combination with other drugs.[512] Ifosfamide also seems to be active in MMS,[513] but doxorubicin might be of more limited value.[513] In a Gynecologic Oncology Group study[514] in which 76 patients with completely resected MMS were given three cycles of adjuvant ifosfamide/DDP, 2-year recurrence-free survival (63%) and overall survival (74%) rates were better than those for historical controls, but clearly, an RCT is needed to establish any true benefit for this regimen.

Paclitaxel combined with topotecan produced a 29% response rate in 45 patients with MMS,[515] and a retrospective analysis of MMS of the ovary found a very high response rate (72%) for a combination of paclitaxel and DDP.[516] Further exploration of agents active in epithelial ovarian cancer may be justified in MMS.

In contrast, uterine leiomyosarcoma, which often metastasizes to the lung rather than the liver, responds reasonably well to doxorubicin.[513] With respect to adjuvant chemotherapy, no significant differences in recurrence, progression-free survival, or overall survival rates were evident in a Gynecologic Oncology Group RCT of 156 patients comparing doxorubicin (60 mg/m^2) with no adjuvant chemotherapy after resection of stage I uterine sarcomas.[504] This trial was underpowered to detect small differences in outcome, however. The combination of gemcitabine, 900 mg/m^2 over 90 minutes on days 1 and 8, plus docetaxel 100 mg/m^2 on day 8 was initially studied in uterine

leiomyosarcoma at Memorial Sloan-Kettering Cancer Center.[384] There was a 53% response rate, and median progression-free survival was 5.6 months.

Desmoid Tumors (Aggressive Fibromatoses)

Desmoid tumor is an uncommon malignancy. It is estimated that approximately 700 to 900 new cases (three to four cases per million) occur annually in the United States.[514,517] The tumor arises principally from the connective tissue of muscle and the overlying fascia or muscular aponeurosis. Clinically, the tumor presents as a poorly circumscribed, painless mass and is commonly located in the muscles of the shoulder and pelvic girdle and frequently in the thigh. It is most common in patients between the ages of 20 and 40 years with a peak incidence of 25 to 35 years. *Aggressive fibromatosis*, *extra-abdominal desmoid*, *well-differentiated nonmetastasizing fibrosarcoma*, and *grade I fibrosarcoma* are terms that have also been used to describe this lesion.

Surgery and Radiation

Surgical resection remains the mainstay of therapy for desmoid tumors. Wide local resection with negative microscopic margins (R0) is the optimal surgical therapy. When resection is performed with positive microscopic surgical margins, local recurrence rates are substantially higher. Unfortunately, there are relatively few large series that outline actuarial local recurrence-free survival rates stratified by microscopic margin status for patients treated by surgery alone. Series from the M.D. Anderson Cancer Center, Massachusetts General Hospital, and Memorial Sloan-Kettering Cancer Center with margin-specific local recurrence-free rates are summarized in Table 97-14.[518–520] The experience of these institutions suggests that the local control rates for patients who are treated by surgery alone is on the order of 50% when microscopic surgical margins are positive (R1 resection), compared to approximately 75% when microscopic surgical margins are negative (R0 resection). As a consequence of the propensity for local recurrence, many groups have utilized postoperative EBRT for patients undergoing local excision (R0 or R1).[518,519] Postoperative EBRT is usually given to patients who are thought to be at higher risk for local recurrence. However, some groups employ external beam radiation for patients who have undergone an R0 resection (because of the generally high local recurrence rates associated with surgical treatment alone) and for most patients who have undergone an R1 resection. The criteria for selecting patients for postoperative radiation vary widely and are often subjective.

Interpretation of the limited literature on the use of EBRT in the management of localized desmoid tumors is hampered by the rarity of the lesion and the absence of margin-specific actuarial local recurrence rates for large series of consecutively treated patients. Retrospective comparisons stratified by margin status suggest that local recurrence rates might be reduced for patients treated with combined-modality therapy. The data substantiating this are all retrospective, nonrandomized, single-institution experiences; therefore, there is no clearly defined consensus on the role of radiation therapy in the management of patients with desmoid tumors.

Chemotherapy

Patients with desmoid tumors usually present to a medical oncologist only if the tumors have progressed after surgery and radiotherapy and are considered inoperable or are located at sites that are not amenable to full-dose radiotherapy. These tumors are rarely life threatening, although some tumors, especially the intra-abdominal desmoids that are seen in Gardner's syndrome, may become so owing to pressure on or invasion of vital organs. Rare responses have been reported to nonsteroidal anti-inflammatory drugs or anti-estrogens.[521–523] Weiss and Lackman were the first to report responses of desmoids to low-dose chemotherapy with methotrexate (50 mg/week) and vinblastine (10 mg/week).[523] Regressions are often slow, and toxicity usually requires dosing to be extended to 2-week intervals. Data on efficacy are clouded by the concomitant use of radiation therapy in some of the patients. Several groups have since confirmed the activity of this combination, however.[524–526] A much more aggressive regimen of continuous-infusion doxorubicin and dacarbazine[527,528] has produced substantial regressions in desmoids secondary to Gardner's syndrome. This regimen produces substantial toxicity, however, and should be reserved for patients with aggressive symptomatic disease. A case report documented a response of a desmoid to single-agent doxorubicin,[529] and this may be a less toxic alternative.

Breast Sarcomas

Primary sarcomas of the breast account for fewer than 1% of all primary breast neoplasms.[530] They should be distinguished from cystosarcoma phylloides and sarcomatoid carcinoma of the breast (carcinosarcoma), which are distinct clinical conditions. The most common histologic subtypes of breast sarcomas are malignant fibrous histiocytoma, liposarcoma, and fibrosarcoma.[531,532] A disproportionate number of angiosarcomas appear to arise in the breast either de novo[533] or after breast conservation surgery with adjuvant radiation.[534–536] In general, however, the etiology of most breast sarcomas is unknown. An association between augmentation mammoplasty with silicone prostheses and development of breast sarcoma had been postulated, but analysis of the NCI's Surveillance, Epidemiology and End Results Program database failed to demonstrate any relationship.[537]

On physical examination, breast sarcomas are usually well circumscribed, firm, mobile, and painless. Mammography frequently demonstrates a well-circumscribed lesion, in contrast to the irregular, stellate appearance of most mammary carcinomas. With the advent of fine-needle aspiration biopsy, an increasing number of these lesions are diagnosed preoperatively. This is important in planning an operative approach for these patients. Because breast sarcomas rarely spread to regional lymph nodes,[538–540] axillary lymph node dissection is not indicated for patients with a clinically negative axilla. The treatment of choice for breast sarcomas is wide local excision with

Table 97-14 Local Recurrence-Free Rates Following Surgery for Patients with Desmoid Tumors

				Local Recurrence-Free Surival

†Using 10-year actuarial analysis.

histologically negative margins. Depending on the relative proportions of the tumor and the breast, this sometimes necessitates total mastectomy.

Adverse prognostic factors for survival include high histologic grade and an infiltrative histologic pattern.[532,538,540,541] A recent retrospective review of 83 patients with primary breast sarcomas treated predominantly with surgery and selective use of adjuvant chemotherapy and/or radiation revealed 10-year overall and disease-free survival rates of 62% and 50%, respectively.[534] On the basis of this report and early reports,[538–540] it appears that patients with primary breast sarcomas have a natural history, prognostic factors, and outcome after combined-modality treatment similar to those of patients with extremity sarcomas.

Adjuvant radiotherapy has no clearly defined role in this disease, although it would appear prudent to offer radiation to patients who are at high risk for local recurrence (microscopically positive margins or presentation with recurrent breast sarcoma). In addition, in a report of a mixed group of breast sarcomas and phylloides tumors at the Princess Margaret Hospital, breast conservation seemed to be attainable by using conservative margin-negative excision and adjuvant radiotherapy in an organ-preserving approach that is consistent with contemporary management for both breast cancer and STS.[542]

Vascular Sarcomas

The collective term *vascular sarcomas* includes the histologic subtypes of angiosarcoma, hemangiosarcoma, and lymphangiosarcoma. Together, these lesions account for approximately 4% of all STSs.[543] A minority of these lesions are associated with well-known environmental factors, as is noted in Table 97-1. In a national review of 99 Japanese patients with angiosarcoma, angiosarcoma was most commonly located on the head or face (29 patients) and was found to be associated with several predisposing conditions, including chronic pyothorax (6 patients), use of Thorotrast in the liver (5 patients), previous radiotherapy (4 patients), and chronic lymphedema (1 patient).[544] Virtually all of the literature on these rare neoplasms focuses on individual histologic and site-specific subtypes and includes pediatric patients. These facts, and the relative infrequency of these lesions, make general estimates of survival difficult for adult patients with vascular STSs.

In a review of 69 patients with vascular sarcomas and malignant hemangiopericytoma (not truly a vascular tumor) from Memorial Sloan-Kettering Cancer Center, 35 patients (51%) had angiosarcoma, 28 (41%) had malignant hemangiopericytoma, and 6 (9%) had lymphangiosarcoma.[543] No anatomic site was spared from involvement. The most common sites of involvement for angiosarcomas and malignant hemangiopericytomas were similar: visceral, retroperitoneum, head and neck, and extremities. The six lymphangiosarcomas in this series all occurred in an edematous extremity.

Cutaneous angiosarcoma is a variant of angiosarcoma that often arises in the head and neck and frequently diffusely infiltrates the dermis of the scalp or tissues of the face.[545] In the head and neck, cutaneous angiosarcoma can be difficult to treat by surgery because of the infiltrating nature of the disease and the anatomic constraints of the head and neck that make wide surgical margins difficult to achieve. Primary chemotherapy with the possible addition of radiation is preferable.

Overall survival rates for patients with localized disease who undergo curative resection are similar for angiosarcomas and malignant hemangiopericytomas (68% to 72%). A clear survival advantage for patients with low-grade lesions was not demonstrable in this study, although other investigators have reported such a relationship for cutaneous angiosarcomas.[546] Several investigators have suggested that tumor size might be an important prognostic factor for survival in patients with malignant hemangiopericytomas[547,548] and angiosarcomas of the face and scalp,[549,550] although no relationship was noted in the study from Memorial Sloan-Kettering.

Surgery

By definition, these lesions are vascular, and this should be borne in mind in planning preoperative biopsy and surgery. In the study from Memorial Sloan-Kettering, perioperative bleeding was noted in 33% of patients, with 18 of 69 patients experiencing extensive blood loss (>1000 cc) and two deaths related to hemorrhage.[543] Frozen section control of microscopic surgical margins is advisable, given the locally infiltrative nature of many angiosarcomas, particularly those that arise on the scalp.

Adjuvant Therapy

There is no clearly defined role for adjuvant radiation or chemotherapy for vascular sarcomas, although it seems reasonable to extrapolate from data derived from extremity lesions and offer adjuvant radiotherapy for patients with high-risk lesions. Unfortunately, aggressive surgical approaches might prove disappointing, owing to the unusual capability of this disease to exhibit edge recurrence and manifest disease relatively remote from the initial site of presentation (Fig. 97-17). Alternative radiotherapy techniques such as modulated electron radiotherapy are promising and could be applied in the future to the treatment of wide field areas that require only superficial penetration at depth, as is the case in craniofacial angiosarcoma. Considering the proximity of the brain and eyes in these lesions, limiting the depth of penetration and consequent reduction in dose to tissues that are deeper to tumor is the attractive aspect of this technology.[551]

There have been anecdotal reports that paclitaxel could be specifically active in angiosarcomas, especially those arising in the scalp or the skin of the breast.[380,552] A complete remission in a patient with metastatic angiosarcoma was seen in the phase II study of gemcitabine at M.D. Anderson,[378] so the combination of gemcitabine and docetaxel is particularly appealing for these tumors. Interferon-α is active against benign capillary hemangiomas of infancy and malignant vascular lesions such as HIV-related Kaposi's sarcoma. Burgess and colleagues reported sporadic responses in a variety of angiomatous tumors to a combination of interferon-α and 13-*cis*-retinoic acid.[553] Angiosarcomas are quite sensitive to standard doxorubicin ifosfamide therapy as well, but responses tend to be of short duration. Such therapy should be considered initially for visceral lesions such as those arising from the heart.

Chemotherapy Considerations for Specific Histologic Subtypes

Synovial Sarcomas

Rosen and colleagues[554] were the first to suggest that synovial sarcomas were particularly responsive to ifosfamide. They documented 3 complete responses and 9 partial responses in 13 patients (9 of whom had received prior doxorubicin-based chemotherapy) with metastatic synovial sarcomas. These investigators also reported on 14 patients with localized synovial sarcomas who received adjuvant doxorubicin/ifosfamide/DDP chemotherapy.[555] There was one patient with local recurrence, but the remaining 13 patients (93%) remained disease free at a median follow-up period of 37 (6 to 85) months. In a large EORTC phase II trial of 124 patients with advanced STS receiving ifosfamide (12 g/m^2), the overall response rate for all histologic subtypes was 16%,[367] but 8 (44%) of 18 patients with synovial sarcoma responded. Edmonson and colleagues described a higher response rate in synovial sarcomas for doxorubicin/ifosfamide than for doxorubicin alone (88% versus 20%, $P = 0.02$) in the setting of an RCT of multiple histologic subtypes of STS.[348] A subsequent ECOG phase II study of doxorubicin/ifosfamide in synovial sarcomas showed 5 partial responses (42%) in 12 patients; however, the median survival for the whole group was only 11 months, and the trial was closed because of poor accrual.[556] In many studies evaluating ifosfamide, including some of the RCTs, the question of response by histologic subtype has not been addressed, and most of the data on histologic

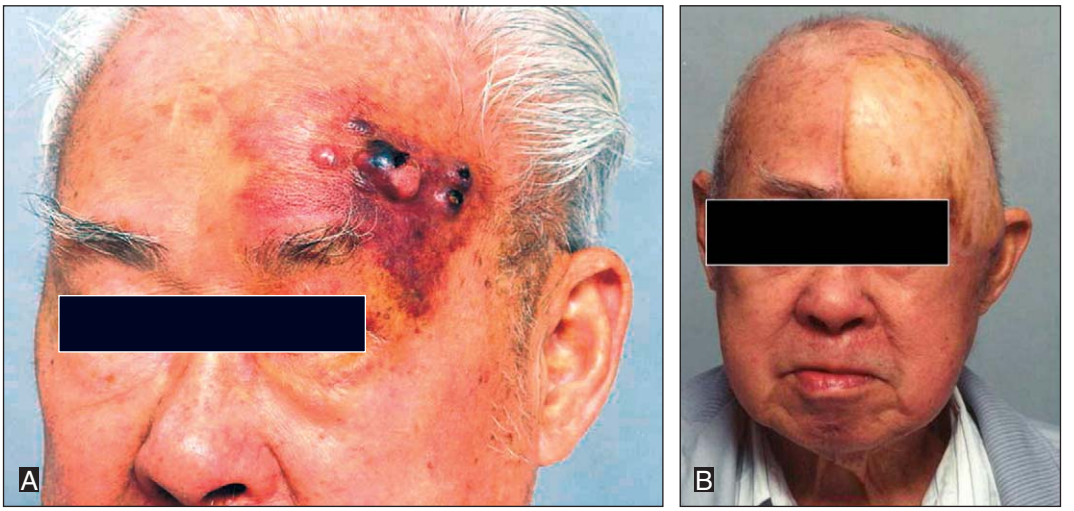

Figure 97-17 • **A,** Angiosarcoma of the scalp and facial areas in an older male. Note the infiltrative and multinodular nature of this process characterized by mottled discoloration and ecchymosis in the upper eyelid and facial tissues adjacent to the lesion. These lesions pose a formidable challenge in achieving local control owing to their propensity to manifest out-of-field recurrences after wide-field surgical and radiotherapy interventions **(B),** as well as a high predilection to fail in regional lymph nodes and distant sites. **B,** The same patient as in **(A)** showing the irradiated skin and the flap and reconstructed tissues at the site of wide field radiotherapy and surgery to the scalp for angiosarcoma. Unfortunately, this patient continued to manifest disease in other areas of the scalp remote from the treated areas that were managed with small field radiotherapy fields. This pattern of disease, including the ability to control disease locally but with relentless failure beyond the surgical and radiotherapy fields, is characteristic of angiosarcoma.

variations in response come from subset analyses of larger trials. Because many of the patients with synovial sarcoma are young and fit, inclusion of ifosfamide in first-line chemotherapy for metastatic disease seems reasonable. If the circumstances merit adjuvant chemotherapy, an anthracycline/ifosfamide combination would be a logical choice.

Leiomyosarcomas

Hensley and colleagues[384] were the first to report the activity of the gemcitabine-docetaxel combination in patients with leiomyosarcomas. While clearly active in that subset, particularly in leiomyosarcomas arising from the uterus, this regimen is broadly active and should not be limited to leiomyosarcomas. In contrast to the increased activity of ifosfamide in synovial sarcomas, ifosfamide is less active against leiomyosarcomas than against other subtypes,[340,354] even when GISTs were excluded,[354] and high-dose ifosfamide had a similar lack of efficacy.[343,363,366]

Liposarcomas

Marked clinical activity of trabectidin (ET-743) was noted in patients with myxoid liposarcoma.[557] Among 51 patients who were treated at five institutions, a RECIST response rate of 51% was noted, with objective benefit characterized by decreased postcontrast tumor density in all of the responding patients and an additional 29% categorized as having minor response or stable disease by RECIST. Progression-free survival was 88% at 6 months. For comparison, in all STSs, including those with myxoid liposarcoma, the RECIST response rate to trabectidin is about 10%, and progression-free survival was 20% at 6 months. Thus, myxoid liposarcomas are uniquely sensitive to this agent.

Activation of the PPARγ nuclear receptor stimulates terminal differentiation in preadipocytes and in liposarcoma cell lines regardless of histologic subtype.[558] Troglitazone, previously used in the treatment of diabetes mellitus, is an activating ligand for PPARγ. Biopsies before and after troglitazone therapy were obtained in 34 of 49 patients with different types of liposarcomas entering a phase II trial.[559,560] Five of seven (71%) evaluable patients with myxoid/round cell disease exhibited histologic evidence of lineage-appropriate differentiation of liposarcoma cells, whereas only one of three (33%) patients with high-grade pleomorphic disease showed such changes. Although this study provides proof-of-concept data, the clinical significance is uncertain, and the limited clinical benefit of troglitazone was confined to myxoid liposarcoma.

Pediatric Sarcomas in Adults

Embryonal rhabdomyosarcomas and the PNETs, including extraskeletal Ewing's sarcoma, all seem to be chemosensitive when they occur in the adult age group. Adult patients with these tumors should receive aggressive combination chemotherapy similar to that offered to children with the same disease.[561,562] Nevertheless, the outcome is likely to be poorer for adults with "pediatric sarcomas" than for pediatric sarcoma patients.

98 Carcinoma of Unknown Primary

Katrina Y. Glover, Gauri R. Varadhachary, Renato Lenzi, Martin N. Raber, and James L. Abbruzzese

SUMMARY OF KEY POINTS

Incidence
- Carcinoma of unknown primary accounts for about 2% to 5% of all cancers.
- At M.D. Anderson Cancer Center from January 1987 to June 1995, carcinoma of unknown primary accounted for 1.5% of all cancer referrals.

Evaluation
- Controversy continues regarding the extent of evaluation needed to exclude a definable primary cancer.
- Biopsy of a metastatic site is recommended early to establish the diagnosis and help direct further workup.
- Basic evaluation includes the following:
  - History and physical examination (including breast and pelvic examinations in women and testis and prostate examinations in men)
  - SMA-12, complete blood cell count, prostate-specific antigen test in men, chest radiography, abdominal and pelvic computed tomographic scan, and mammography in women
  - Testing for immunohistochemical markers (including CK7, CK20, TTF-1)
- The diagnostic utility of positron emission tomography (PET) and its cost-effectiveness are controversial and currently being studied.
- The role of DNA microarray and gene profiling in this subset is evolving.

Differential Diagnosis
- Diagnosis is made in patients with a biopsy-proved malignancy, when the site of origin is not obvious after preceding evaluation.
- Careful consultation with a pathologist is critical to exclude highly treatable malignancies (e.g., lymphoma, breast cancer, germ cell cancers).
- Newer diagnostic tools, including new immunohistochemical stains, and molecular markers promise the ability to identify the site of origin in a greater proportion of cases.

Primary Therapy
- It is important to identify specific patients who may have clinical or pathologic features of six highly treatable carcinoma of unknown primary subsets (minority of patients):
  - Women with axillary adenopathy (adenocarcinoma or carcinoma)
  - Women with peritoneal carcinomatosis
  - Patients with poorly differentiated or undifferentiated carcinoma
  - Males with the extragonadal germ cell syndrome
  - Patients with neuroendocrine carcinoma
  - Patients with high cervical adenopathy (squamous carcinoma)
- For the majority of patients, who belong to no identifiable subset, primary therapy consists of the following:
  - Systemic therapy: adenocarcinoma: paclitaxel/carboplatin ± etoposide; CDDP/5-fluorouracil/leucovorin
  - Carcinoma: paclitaxel/carboplatin ± etoposide; CDDP/etoposide
  - Squamous carcinoma: CDDP/5-fluorouracil/leucovorin
  - Local therapy: resection ± radiation therapy; observation with best supportive care

Second- or Third-Line Therapy
- No highly effective salvage systemic regimens are in use.
- Gemcitabine has produced low objective response rates and symptomatic improvement as single-agent therapy in the second-line setting.
- The role of newer agents such as irinotecan is evolving; patients should be encouraged to participate in clinical trials for novel agents.

INTRODUCTION

Despite the increasing array of sophisticated diagnostic tools available to establish the diagnosis of human neoplasia, oncologists have struggled to understand a subset of patients with metastatic cancer in whom detailed investigations fail to identify a primary anatomic site. The reported incidence of carcinoma of unknown primary (CUP) varies with the practice setting and the definition used, but averages 2% to 5% of all patients who are diagnosed with cancer.[1] Because identification of the primary lesion largely forms the basis for predicting the expected behavior and assigning appropriate therapy of malignant diseases, the absence of a primary carcinoma poses a major challenge. The inability to identify a primary carcinoma also generates anxiety for the patient, who may feel that the physician's evaluation has been inadequate or that the prognosis would be improved if a primary site could be established.

As suggested by the foregoing variable incidence statistics, the definition of CUP has not been standardized, varying in published reports mainly with regard to the extent of evaluation required to accept this diagnosis. For the purpose of this chapter we define patients with CUP as having a biopsy-proved malignancy for which the anatomic origin remains unidentified after history and physical examination (including breast palpation and pelvic examination in women and testicular and prostate examination in men), laboratory studies including liver and renal function tests, hemogram, chest x-ray, computed tomography (CT) of abdomen and pelvis, mammography in women, and measurement of prostate-specific antigen (PSA) in men. All positive findings on this initial evaluation are then

investigated in detail.[2] Depending on the clinical situation, additional studies might include sputum cytologic test, CT of the chest, breast ultrasonography, or gastrointestinal (GI) endoscopy. To further define the patient population, most investigators have excluded from analysis rare instances in which soft tissue sarcoma or melanoma present without a definite primary site,[2] concentrating clinical research efforts on the vast majority of patients with common epithelial histologies such as adenocarcinoma, carcinoma, squamous carcinoma, and neuroendocrine carcinoma.

The approach to patients with CUP is based on the generally held belief that this group of patients is heterogeneous and may have any one of numerous underlying primary cancers that remain occult during the lifetime of the patient. This concept is supported by studies showing that a detailed postmortem anatomic investigation will establish a primary cancer in many, if not the majority, of these patients.[3,4] However, clinically these small primary tumors usually remain undiagnosed during the course of the patient's disease. Although heterogeneous in their origins, detailed clinical and biochemical study of CUP cells may represent a valuable resource with which to delineate the metastatic phenotype.[5,6] More recent approaches involve simultaneous determination of a large number of molecular markers with tools such as DNA microarrays and reverse transcriptase-polymerase chain reaction (RT-PCR). Such approaches promise to identify the site of origin in a larger proportion of patients with CUP,[7,8] although poorly differentiated tumors still may elude accurate classification.[9] Also, the heterogeneity of this population may make them the natural population in which to evaluate experimental approaches such as immunotherapy and antiangiogenesis. As with the specific well-defined primary neoplasms discussed elsewhere in this text, it is the phenomenon of metastasis, as purely exemplified by the patient with CUP, that causes the great majority of cancer deaths.

ETIOLOGY AND EPIDEMIOLOGY

Whether specific etiologic factors are relevant to CUP is not known. Although a history of cigarette smoking often can be elicited (Table 98-1), the heterogeneity of CUP makes it unlikely that specific etiologic agents will be associated with this disease. The fact that numerous occult anatomic sites can give rise to carcinomas that present with only metastatic disease supports the possibility that specific interactions of genetic and environmental insults could give rise to genomic and biochemical changes that lead to the early development of the metastatic phenotype without the associated changes supporting local growth in the organ of origin. Although this concept must be considered highly speculative, it is a hypothesis that can be tested through analysis of available biomarkers such as oncogenes and tumor suppressor genes that have been characterized for cancers with known anatomic origins, such as lung, pancreatic, breast, and colorectal carcinomas. Either the absence of genetic changes typical for malignancies with established primary cancers or the presence of unusual variants of known genetic alterations would support this hypothesis. It is likely that as the genomic and proteomic characterization of malignancies is refined, fewer and fewer malignancies may be assigned to the CUP designation.

The epidemiologic characteristics of 1109 consecutive patients with CUP referred to the M.D. Anderson Cancer Center from January 1987 to June 1995 are presented in Table 98-1. These data are juxtaposed with the overall referral population during the same time period. Although the family history often identifies additional cancers with established origins in other family members, no clearly familial instances of CUP have been identified or reported.

HISTOLOGIC PRESENTATIONS

The frequency with which specific histologic diagnoses are established in CUP depends to some extent on the patient population chosen for study. For example, most recent investigators have excluded the well-characterized group of patients with metastatic squamous carcinomas to cervical lymph nodes.[10–12] The specific histologic diagnoses identified in a series of 1109 consecutive patients with CUP are outlined in Table 98-2 and are contrasted with another reported series.[13] The low frequency of squamous carcinoma reflects the direct referral of patients with squamous cell carcinoma involving high or mid-cervical lymph nodes to head and neck oncologists for management.

BIOLOGIC CHARACTERISTICS

The biology of CUP has been partially characterized through the evaluation of patient subsets using as primary endpoints responsiveness to therapy and survival. When all patients are considered, CUP is a highly aggressive neoplasm with an overall median survival time of 3 to 4 months in older series.[14] More recent studies have documented median survival times of 9 to 12 months.[15–18] In our series of 1109 consecutive patients, the median survival period was 11 months. The survival curve for these patients is presented in Figure 98-1.

The survival times for the four most commonly encountered pathologic subtypes are presented in Figure 98-2. The median survival times were as follows:

- For patients with squamous carcinoma (exclusive of patients with mid-high cervical adenopathy), 24 months
- For patients with adenocarcinoma, 9 months
- For patients with carcinoma, 12 months
- For patients with neuroendocrine carcinoma, 33 months.

The state of differentiation or mucin production did not appear to have a significant influence on the poor survival of patients with

adenocarcinoma (Fig. 98-3). Using univariate and multivariate analyses, various groups have assessed the influence of other clinicopathologic features of CUP on survival (Table 98-3). Culine and associates[19] also developed and validated a prognostic model to predict the length of survival in patients with CUP. Univariate and multivariate prognostic factor analyses were conducted in a population of 150 unselected patients and led to the construction of two successive classification schemes. When studying the clinical variables only, poor performance status and presence of liver metastases were retained in the multivariate analysis. The first classification scheme consisted of three groups of patients with median survival times of 10.8, 6.0, and 2.4 months, according to the number of adverse prognostic factors. When serum lactate dehydrogenase (LDH) was introduced in a further step, liver metastases were no longer of significance. The second classification scheme, therefore, included performance status and elevated serum LDH. Good- and poor-risk patients were identified, with median survival times of 11.7 months and 3.9 months and 1-year survival rates of 45% and 11%, respectively. Validation of the second classification was obtained using an external data set; and the median survival times of patients assigned

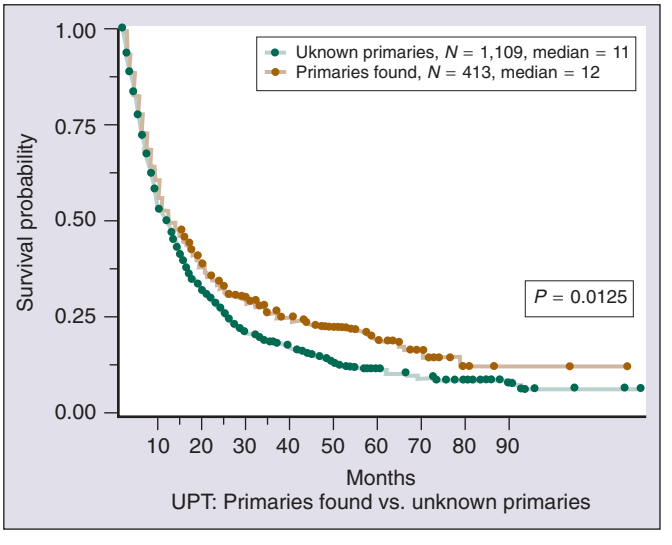

Figure 98-1 • Survival curves for 1109 patients with carcinoma of unknown primary (CUP) versus 413 patients referred with CUP in whom the primary cancer site was found.

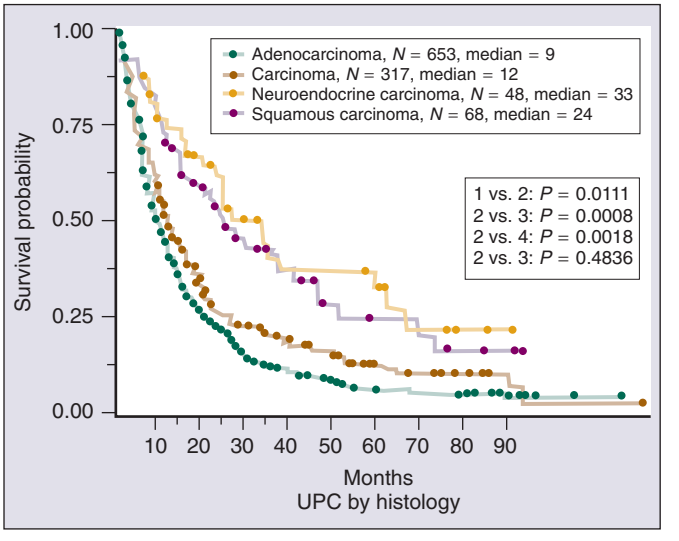

Figure 98-2 • Survival curves of the major histologic subtypes of carcinoma of unknown primary.

to the good-risk group and poor-risk group were 12 months and 7 months with 1-year survival rates of 53% and 23%, respectively. This simple prognostic model using performance status and serum LDH allows assignment of patients into two subgroups with divergent outcomes. Additional prospective trials will be designed using this prognostic model.

To assess the impact of disease extent on survival, the number of organ sites involved in the metastatic process was assessed at presentation in our series to provide a crude quantitation of tumor burden. For this analysis, involvement of an organ, even when there were multiple individual metastases within the site, was counted as involvement of one organ site. Using this definition, 133 patients (37.5%) had a single involved site and 122 patients (34.5%) had two sites involved. The remaining 99 (28.0%) patients had three or more sites involved in the metastatic process. The survival curves for patients with one, two, and three or more organ sites involved are displayed in Figure 98-4. The median survival time for patients with one site of involvement was 10 months, with two sites of involvement 8.0 months, and with three or more sites of involvement 6.0 months. These survival curves are statistically different by the Cox-Mantel log-rank test ($P = 0.028$). Other studies have documented similar results.[18]

The question of whether the biology of CUP is fundamentally different from known primary carcinoma with systemic metastases remains controversial.[20] Nystrom and associates[21] have argued that

the distribution of metastatic sites in patients with CUP where the primary cancer is subsequently found is sufficiently different from known primary carcinoma to support the hypothesis that CUP is biologically unique. However, analysis of our series shows few significant differences in the pattern of metastases (Table 98-4) or in overall survival for true CUP versus patients in whom the primary lesion was found (see Fig. 98-1). Continued study of CUP is necessary to resolve this controversy.

Why the primary organ site cannot be diagnosed remains unknown. Previous investigators have speculated that the tumor may remain below the limits of clinical or radiographic detection or that it spontaneously regressed.[22] Another possibility would be that a clinically detectable primary cancer never develops due to the development of specific genetic changes that support metastatic but not local growth. Continued investigation has resulted in greater understanding of the biologic features of unknown primary carcinomas, characterized by aneuploidy, chromosomal abnormalities, oncogenes, tumor suppressor genes, and microvessel density.

Aneuploidy, a well-recognized phenomenon occurring in 70% to 90% of solid tumors,[23–25] is defined as a chromosome complement that is not a simple multiple of the haploid set. Increasing evidence indicates that for many carcinomas, such as breast, prostate, and colorectal cancers, a diploid DNA content is associated with a more favorable prognosis.[26] Hedley and associates[27] measured the cellular DNA content of tumor biopsy specimens of 152 patients with metastatic adenocarcinoma or undifferentiated carcinoma of unknown primary site to determine favorable subgroups. Aneuploidy was found in the specimens of 70% of the patients. There were no significant

differences between men and women, and there was no obvious relationship to the various patterns of metastatic involvement. The median survival of patients with diploid tumors was 4.2 months, versus 4.8 months for patients with aneuploid tumors. Of the 46 patients with diploid tumors, 9 (18%) survived for more than 2 years, compared with 10 (9%) of 106 patients with aneuploid tumors. These results indicate that the incidence of aneuploidy in this heterogeneous group of patients is similar to that reported for carcinomas with known primary tumors. However, in contrast to many of these tumor types, in this single study conducted by Hedley and associates, metastatic adenocarcinomas of unknown primary origin that are diploid are not associated with a more favorable prognosis than are those of known primary origin.[27]

Chromosome Abnormalities

Evaluation of chromosomal abnormalities in CUP is an emerging area of investigation, and thus far relatively few studies have been performed. Abbruzzese and colleagues[5] and Bell and coworkers[28] developed a research program aimed at identifying common karyotypic changes in CUP. The karyotypes of 13 of 20 patients with CUP were determined, and in 12 of the analyzed cell lines abnormalities were identified in the short arm of chromosome 1. The abnormalities detected included deletion of 1p, translocations, isochromosome 1q, and gene amplification. These findings were consistent with earlier descriptions of chromosome 1p abnormalities in advanced malignancy as described by Atkin[29] and Mertens and associates.[30]

Motzer and associates[31,32] used karyotyping to determine the frequency of specific abnormalities of chromosome 12 in patients with CUP. It was hypothesized that patients with undifferentiated carcinoma of unknown primary origin responding to cisplatin-based chemotherapy had unrecognized germ cell tumors and that isochromosome 12p, i(12p), a specific chromosomal marker characterizing germ cell tumors, could be used to identify such patients. Thirty percent of patients had an increased 12p copy number or deletion of the long arm of chromosome 12, which proved predictive of response, thereby validating the hypothesis. Complete response to cisplatin-based therapy was achieved in patients with specific chromosomal aberrations associated with germ cell tumors, and objective responses were achieved in 75% of these patients, compared with 17% of patients without these aberrations. Summersgill and associates[33] and Ilson and associates[34] found similar associations for CUP patients with undifferentiated carcinoma. Thus, for patients with undifferentiated carcinoma, i(12p) correlated with a good response to platinum-based chemotherapy, although lack of i(12p) may not exclude a small percentage of responses; i(12p) occurs in more than 80% of the germ cell tumors and only sparsely in a few other lesions (e.g., acute leukemia, embryonal rhabdomyosarcoma, and neuroepithelioma), and, therefore, determination of the presence or absence of i(12p) can help diagnose extragonadal germ cell tumors in patients with CUP.[35]

Oncogenes

The oncogenes ras, c-myc, bcl-2, and her-2/neu are overexpressed in a variety of solid tumors. The levels of these genes are thought to be useful prognostic factors, though reports on c-myc and bcl-2 often are conflicting. Pavlidis and associates[36] found a high rate of overexpression of c-myc (96%), ras (92%), and c-erbB_2 (65%). Investigators found that the overexpression did not have a further relationship with histologic or clinical parameters or a diagnostic or prognostic value, however.

Briasoulis and associates[37] studied levels of bcl-2 expression in 40 patients with CUP (8% squamous, 36% adenocarcinoma, and 55.5% poorly differentiated carcinoma). Staining was evaluated based on intensity (+1 to +3) and the percentage of positive cells (1% to 100%). Expression of bcl-2 was seen in almost half of the tumors. This finding was not expected, because in most studies, bcl-2 had been found to be upregulated in premalignant lesions rather than advanced malignancies and also had been associated with a less aggressive phenotype.[38,39] In this study, the level of bcl-2 expression, by itself, had no prognostic value. When combined with a high level of expression of p53, however, high expression of bcl-2 showed a trend toward a higher response to platinum-based chemotherapy.

Hainsworth and associates[40] stained 100 tumor specimens of poorly differentiated adenocarcinoma (PDA) or poorly differentiated carcinoma (PDC) of unknown primary site for Her-2 protein. The samples of 10 patients (11%) overexpressed Her-2. These investigators did not observe any major difference in the overall response rate to chemotherapy between the patients whose cancer overexpressed Her-2 and those who did not. Evaluation of the efficacy of trastuzumab in selected patients with CUP with Her-2 overexpression is warranted.

Rashid and associates[41] retrospectively evaluated 100 serial formalin-fixed, paraffin-embedded sections from patients with CUP with biopsies or resections done at UTMDACC. Seventy-six samples with adequate tissue were stained by immunohistochemistry for epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF)-A, Cox-2, c-erbB2, and c-kit. Seventy-five percent of tumors stained for EGFR and 49% for VEGF-A. EGFR often was present with other markers, and was seen along with VEGF, c-erbB2, or Cox-2 in at least 30% of patients. Three triple-staining patterns of EGFR/c-erbB2/VEGF, EGFR/c-erbB2/Cox-2, and c-erbB2/Cox-2/VEGF were observed. Kaplan-Meier survival by intensity of staining failed to show significance. Further evaluation is warranted, because

this information may translate to therapeutic benefit regarding combination targeted therapies for patients with CUP.

Tumor Suppressor Genes

It is now known that a large number of gene deletions or allelic inactivation occur in most human cancers. Many of these genetic alterations result in the activation of oncogenes or in the loss of tumor suppressor genes and have been localized to specific chromosomes. To date, p53 is the best-known and most widely studied tumor suppressor gene. p53 can control tumor development by arresting cell cycle or initiating apoptosis of damaged cells. p53 mutations are common and occur in about 55% of all human cancers.[42–44]

Briasoulis and associates[37] evaluated p53 expression using immunohistochemistry in 47 cases of CUP (4 squamous carcinoma, 17 adenocarcinoma, 26 PDC). Staining was evaluated based on intensity (+1 to +3) and percentage of positive cells (1% to 100%). More than 70% of the tumors expressed p53; 53% expressed a high level and 47% expressed a low level of immunohistochemical staining. In this study, p53 expression alone had no prognostic value.

Bar-Eli and associates[45] also investigated the frequency of p53 mutations in a series of 15 CUP biopsies and 8 cell lines established from CUP. Mutations in the conserved regions of p53 gene were analyzed by single-strand conformation polymorphism analysis of exons 5 to 9 and were verified by direct DNA sequencing of PCR products. The p53 gene was mutated in 6 of 23 (26%) patients with CUP. Therefore, despite the fact that CUP represents bad-prognostic tumors that often are aneuploid, the frequency of p53 mutation was relatively low in this study. This finding suggests that p53 mutations may not play a major role in the development and progression of CUP. The discrepancy between the results of these two studies may be due to discordance between the results of immunohistochemical and genetic molecular methods in detecting the p53 abnormalities, which may occur in 25% of tumors.

No research is available on metastasis-suppressor genes in CUP, which seem to play an important role in regulating the growth of disseminated cancer cells at secondary sites.

Microvessel Density

Compelling evidence indicates that angiogenesis, as measured by microvessel density (MVD), correlates with the incidence of metastases in several solid tumors. Hillen and associates[46] aimed to identify a specific biologic role for angiogenesis in the metastatic phenotype of CUP by comparing MVD in liver metastasis of CUP with MVD in liver metastasis of colon and breast tumors. No difference was found between MVD in liver metastasis of CUP and known primary tumors. In CUP, as in other solid tumors, high MVD correlated with short survival in univariate and multivariate analyses.

Karavasilis and associates[47] investigated angiogenesis by assessing MVD and the tissue expression of VEGF and thrombospondin-1 (TSP-1). VEGF is the major stimulator of angiogenesis, and TSP-1 is an intrinsic angiogenic inhibitor. Paraffin-embedded archival material was evaluated from 81 patients diagnosed with CUP. Adenocarcinoma was the predominant histology found in 77% of cases, followed by undifferentiated carcinoma in 18% of cases and squamous cell carcinoma in 5% of cases evaluated. Tissue expression of CD34, VEGF, and TSP-1 were accessed immunohistochemically using specific monoclonal antibodies and were analyzed against clinicopathological data.

VEGF expression was detected in all cases and demonstrated a strong staining pattern in 83%. Stromal expression of TSP-1 was seen in 80% of cases, with only 20% of the 80% demonstrating a strong staining pattern. There was no evidence to suggest that expression of both proteins was associated with any clinical or pathological variables. A positive association was observed between VEGF expression and MVD and a negative association between VEGF expression and TSP-1. MVD also was found to be statistically higher in unfavorable CUP patient subsets, specifically adenocarcinoma metastatic to liver, multiple visceral involvement, and extensive metastatic bone disease. This study supports the activity of angiogenesis and almost universal expression of VEGF in CUP and prompts the need for further clinical investigation evaluating VEGF targeted therapy.

EVALUATION OF THE PATIENT

Considerable controversy surrounds the optimal evaluation of patients with CUP. It is clear that this diagnosis creates a serious dilemma for the clinician, because treatment planning is based on both the anatomic origin and the histologic type of the malignancy. Often there is the perception that the physician's efforts to locate a primary cancer have been somehow inadequate and that the prognosis and treatment of the malignancy would be radically altered if the primary tumor could be found.

An effective strategy would take into account the projected natural history and duration of survival and provide a reasonable probability of locating the primary anatomic site without compromising quality of life with difficult and time-consuming diagnostic studies. The overall goal is to rapidly identify the treatable patient subsets or occult primary lesions through a rational, calculated approach.

History and Physical Examination

The history and physical examination is one of the most important aspects of the evaluation of the patient with suspected CUP and often is overlooked. The history is critical, because it can define areas of concern that will require more detailed evaluation, such as the respiratory system in a smoker who presents with a supraclavicular node, cough, and hemoptysis. A detailed review of systems is mandatory, because it may elicit symptoms that were not immediately brought to the physician's attention. Attention also should be paid to history of previous biopsies or removed lesions, as well as spontaneously regressing lesions. The family history occasionally can be helpful, especially if the patient belongs to a specific ethnic group that is known to be at high risk for malignancies at specific sites (e.g., gastric cancer in Japanese populations or hepatocellular carcinoma or nasopharyngeal carcinoma in patients of Chinese ancestry) or belongs to a family that is known to be genetically predisposed to malignancies at specific sites (e.g., families with hereditary nonpolyposis colon cancer or hereditary breast malignancies).

The physical examination should be rigorous and should, in all cases, include careful palpation of the thyroid, breasts, lymph nodes, liver, and prostate. All patients should have a digital rectal examination with stool tested for occult blood. Genital examination, including a pelvic examination in women and careful palpation of the testes in men, is mandatory. Although these recommendations are routine, in our experience these aspects of the evaluation of the patient with CUP often are overlooked. When carefully performed, these examinations sometimes provide the probable diagnosis or, at a minimum, allow the clinician to formulate a directed laboratory and radiographic evaluation.

Laboratory Studies and Serum

Tumor Markers

The laboratory evaluation of patients with suspected CUP should begin with a complete blood cell count to screen for anemia (particularly to look for iron deficiency, which would suggest chronic GI blood loss and immediately focus attention on the GI tract as a potential primary site), urinalysis (to check for microscopic hematuria or proteinuria), and liver function studies, in some cases including studies for hepatitis B surface antigen or prior exposure to hepatitis C virus, which would suggest a risk for hepatocellular carcinoma or cholangiocarcinoma. Because many of these examinations often are

part of the routine evaluation of any new patient, only rarely would they be overlooked.

Tumor markers, especially the more recently described markers, and their potential role in the evaluation and management of patients with CUP have been reviewed.[48] As part of the routine evaluation of patients with CUP, five markers deserve special recognition. The beta subunit of human chorionic gonadotropin (β-hCG) has been classically associated with nonseminomatous germ cell tumors, and is useful both for diagnosis and during follow-up, often confirming the adequacy of therapy.[49] Alpha-fetoprotein (AFP) also is useful for the evaluation of nonseminomatous germ cell tumors as well as hepatocellular carcinoma.[49] Although many previous publications suggested that the presence of elevated β-hCG or AFP identified patients with marked chemotherapy responsiveness and good survival (see following section on Poorly Differentiated and Undifferentiated Carcinoma), in one study the presence of abnormal plasma levels of AFP or β-hCG did not identify patients with better overall survival.[50] In fact, for the subset of patients diagnosed with poorly differentiated carcinoma or poorly differentiated adenocarcinoma for whom both markers were available, those with AFP levels below 2.8 ng/mL or β-hCG levels below 3.4 mIU/mL survived longer. Thus, reliance on the use of these tumor markers to identify treatment-responsive patients with CUP does not appear to be justified.

Measurement of prostate-specific antigen (PSA) is very useful in men with adenocarcinoma and predominantly skeletal metastases. Elevation of PSA can provide a confirmation of metastatic prostate cancer, but the physician should be wary of the occasional coexistence of early prostate cancer with a more aggressive synchronous neoplasm. Serum measurements of PSA commonly should be coupled with immunohistochemical staining for PSA in tumor tissue, because rare patients have been reported with metastatic cancer and clinical features atypical for metastatic prostate cancer.[51,52]

The extensively used tumor marker carcinoembryonic antigen (CEA) also has been suggested as having a role in the evaluation of patients with CUP. The diagnostic utility of CEA was analyzed in a group of 32 patients initially diagnosed with CUP with the adenocarcinoma histologic type.[53] In this study 10 patients had a CEA of greater than 10 ng/mL, and of these patients the anatomic site of primary tumor was established as lung (5 patients), pancreas (2 patients), ovary (2 patients), and bile duct (1 patient). However, although the CEA appeared to be useful in this study, in our analysis of 147 patients with CUP who had a panel of tumor markers analyzed, 41 had a value over 10 ng/mL, and this finding did not appear to have a significant impact on the probability of establishing a primary tumor site (Abbruzzese and associates, unpublished data).

Another marker, which often is ordered during the evaluation and management of patients with CUP, is CA125. This marker initially was derived from a human ovarian carcinoma cell line, and its elevation in women with CUP is frequently suggested as a marker for chemotherapy sensitivity to agents that are used in the management of ovarian cancer. However, preliminary studies failed to validate this hypothesis, suggesting that the clinical presentation and histology were more predictive.[54] The exact role of other tumor markers such as CA19-9 and CA15-3 remains unclear, but they appear to be limited in their ability to establish a specific primary site or identify patients who respond to chemotherapy.

Pathologic Evaluation

General Considerations

An accurate pathologic assessment of biopsy material is essential in the initial evaluation of the patient with suspected CUP. In this context the pathologist usually is able to confirm that the lesion is neoplastic and often is able to judge whether the lesion is primary or metastatic.[2] However, in some situations it may be impossible to determine if the tumor has arisen from the biopsied organ site. This problem often complicates the cytologic evaluation of fine-needle aspirate specimens and emphasizes the need for close communication between the clinician and pathologist. Frequently, exchange of available clinical information may lead to additional tissue procurement for analysis using one or more of the more detailed diagnostic studies that follow. The pathologist typically puts the tissue specimen through one to four different steps, depending on what is needed. These studies include light microscopy, immunohistochemical stains, electron microscopy, and chromosomal studies, including cytogenetics.

Light Microscopy

The initial pathologic assessment of the biopsy specimen is by light microscopic examination of paraffin sections stained with hematoxylin and eosin. Based on established cytologic criteria, the pathologist usually can classify the tumor into broad groups such as carcinoma, sarcoma, or lymphoma.[55] Additionally, many carcinomas will be immediately recognized as manifesting at least some glandular differentiation (adenocarcinoma). When glandular differentiation is absent, patients with CUP often are diagnosed with poorly differentiated carcinoma or undifferentiated carcinoma. Other specimens will lack any cytologic distinguishing features, in which case a diagnosis of an undifferentiated malignancy is reported. In those groups with poorly differentiated carcinoma, undifferentiated carcinoma, or undifferentiated malignancy, additional pathologic studies, including histochemistry, immunohistochemistry, and electron microscopy, are most frequently and productively employed.[56] On light microscopy about 60% of the cases are reported as adenocarcinoma and 5% as squamous carcinoma; in 35% of cases light microscopy is not very helpful, and poorly differentiated adenocarcinoma, poorly differentiated carcinoma, or poorly differentiated neoplasm is then reported.

Immunohistochemistry

Immunohistochemical markers play a significant role in the diagnosis and workup of CUP. They help define tumor lineage by using peroxidase-labeled antibody against specific tumor antigens. Direct discussions between the pathologist and clinician are critical to ensure the most accurate pathologic characterization possible. Random use of large numbers of tissue markers is rarely helpful for establishing a diagnosis or planning therapy. The role of antibodies against AFP, β-hCG, PSA, and some other markers is well established (Table 98-5). More recently, cytokeratins and thyroid transcription factor (TTF-1) are gaining more importance as markers for the identification of the origin of the carcinoma.[57–62]

Cytokeratin 20 (CK20) is a low-molecular-weight cytokeratin, which is expressed in the normal glands as well as the tumors of the GI epithelium, urothelium, and Merkel cell.[57–59] Cytokeratin 7 (CK7) is found in tumors of the lung, ovary, endometrium, and breast but not in the GI tract. TTF-1 is a 38-kd homeodomain-containing nuclear protein that plays a role in transcriptional activation during embryogenesis in the thyroid, diencephalon, and respiratory epithelium.[57–59] TTF-1 staining is typically positive for lung and thyroid cancers. In 2002, Roh and associates[57] described the utility of TTF-1 and CK20 in identifying the origin of metastatic carcinomas of cervical lymph nodes. They stained 68 specimens with TTF-1 and CK20. The primary sites were lung (29 cases), stomach (13 cases), colorectum (3 cases), and other sites (23 cases). TTF-1 expression was detected in 69% of metastatic lung carcinomas and in none of the GI carcinomas. CK20 expression was detected in 68.8% of GI tumors and in none of the metastatic lung carcinomas. Jang and associates[58] looked at the utility of these markers in identifying the origin of malignant effusions. The primary sites of the tumors examined were lung (16 cases), ovary (15 cases), stomach (9 cases), colon (8 cases), and breast (8 cases). The lung adenocarcinomas showed TTF-1 positivity in 81% of the cases (13 of 16), but all of the nonpulmonary adenocarcinomas lacked TTF-1 staining. The CK7-/CK20+ immunophenotype was seen in 63% of colonic adenocarcinomas and in none of the lung, breast, or ovary tumors. The CK7+/

Table 98-5 Tumors Markers Useful in the Diagnosis of Carcinoma of Unknown Primary

Histologic Diagnosis Application	Tissue Marker	Diagnostic
Poorly differentiated carcinoma or undifferentiated carcinoma	1. Leukocyte common antigen (LCA)	Lymphoma
	2. Ki 1 (CD30)	Ki 1 lymphoma
	3. Human chorionic gonadotropin (β-hCG)	Germ cell neoplasm
	4. Alpha-fetoprotein (AFP)	Germ cell neoplasm
	5. Chromogranin	Neuroendocrine carcinoma
	6. S-100	Melanoma
	7. HMB-45	Melanoma
Adnocarcinoma	1. Estrogen receptor (ER)	Breast cancer
	2. Progesterone receptor (PR)	Breast cancer
	3. Prostate-specific antigen (PSA)	Prostate cancer
	4. Alpha-fetoprotein (AFP)	Hepatoma
	5. Thyroglobulin	Thyroid cancer

CK20- staining was seen in 100% of lung, 88% of breast, and 87% of cancers that originated from the ovary. They concluded that TTF-1 immunostaining was useful in differentiating between pulmonary and nonpulmonary origin of adenocarcinoma in malignant effusions. The combination of CK7-/CK20+ staining is useful in identifying colon adenocarcinoma. In 2000, Rubin and associates[59] looked at the role of CK7 and CK20 in determining the origin of metastatic carcinoma of unknown primary site. The nuclear CDX-2 transcription factor, which is the product of a homeobox gene necessary for intestinal organogenesis, is expressed in normal colonic epithelia and most colorectal adenocarcinomas, and often used to aid with the diagnosis of GI adenocarcinomas.[60] Some data suggest the role of cytokeratin 5/6 as a marker for squamous cell carcinoma in poorly differentiated tumors if mesothelioma is ruled out.[61–63] Based on Rubin's data[59] and other studies with these recent markers, we describe a simple algorithm (Fig. 98-5) for providing clinicians some guidance on using these immunohistochemical markers to identify the site of origin.

Electron Microscopy

Electron microscopy offers the option of looking at the ultrastructural features of a given cell. Patients with adenocarcinoma will typically show microvilli and mucin, neuroendocrine tumors may show secretory granules, and a melanoma will usually show premelanosomes. Electron microscopy is used infrequently today because of the improvement in immunohistochemical markers. Also, it requires pathologists who are experienced in the technique; it can be time-consuming and rarely offers information that changes the overall management. It may, however, be useful in some cases of poorly differentiated neoplasm.

Chromosomal Studies

Chromosomal aberrations in CUP and the significance of isochromosome (12p) have been discussed earlier (see Biologic Characteristics).

Radiographic Studies

Chest Radiographs and Plain Films

Given the large numbers of patients with CUP who eventually will be diagnosed with lung cancer, the chest x-ray should be part of the routine evaluation of these patients irrespective of whether there are respiratory symptoms. However, in this setting, Nystrom and associates[3] have pointed out that the chest x-ray must be interpreted with caution. Their study demonstrated that the chest x-ray often could not distinguish primary lung cancer from metastatic disease to the lungs conclusively. This problem is further complicated by the fact that some malignancies (notably breast, renal, and colorectal cancers) can metastasize to endobronchial sites and thus mimic primary bronchogenic carcinoma. In this situation a bronchoscopic biopsy with detailed histologic or cytologic analysis of the neoplastic tissue sometimes helps to clarify the situation.

Other routine radiographic films usually are reserved for evaluation of symptomatic sites, such as painful bone lesions. These films also must be interpreted with caution, because the degree of bony destruction needed to visualize an abnormality initially may not be present.[64] Radionuclide bone scan often resolves this issue.

Contrast Radiographic Studies

Contrast radiographic studies (e.g., upper GI series, barium enema, intravenous pyelogram) have a low diagnostic yield and generally should be reserved for patients with symptoms or signs referable to the organ system in question. Two studies have looked at the diagnostic accuracy of these examinations.[3,65] In over 200 examinations, only 7.4%, 11%, and 8% of upper GI series, barium enemas, or intravenous pyelograms, respectively, were positive. In addition, biopsy confirmation of the abnormalities identified radiographically was made in only half of the cases. Thus the false-positive rates from these studies were significant and could easily lead to inappropriate management based on faulty information.

Radionuclide Imaging

With the advent of CT, radionuclide imaging of the liver is performed very infrequently in the evaluation of patients with CUP. Bone scanning remains a useful diagnostic adjunct to stage patients with CUP (especially those complaining of bone pain) but is unlikely to provide information as to the site of the primary lesion. Using this modality in conjunction with routine x-rays, sites of significant destruction in major weight-bearing bones can be anticipated before devastating pathologic fractures develop. Radionuclide thyroid scanning often is performed for the evaluation of patients who present with papillary adenocarcinomas in cervical nodes, but it rarely is positive.[66] Thus, at this time radionuclide imaging cannot be recommended as a routine diagnostic study in patients with CUP. It can, however, be helpful with assessment of disease extent.

Mammography

Bilateral mammography should be a part of the routine evaluation of all women with CUP.[2] Despite the relatively low numbers of occult breast cancer accounting for CUP (4% to 8%), at least one study documented a 7.5% rate of positive examinations.[67] Even with

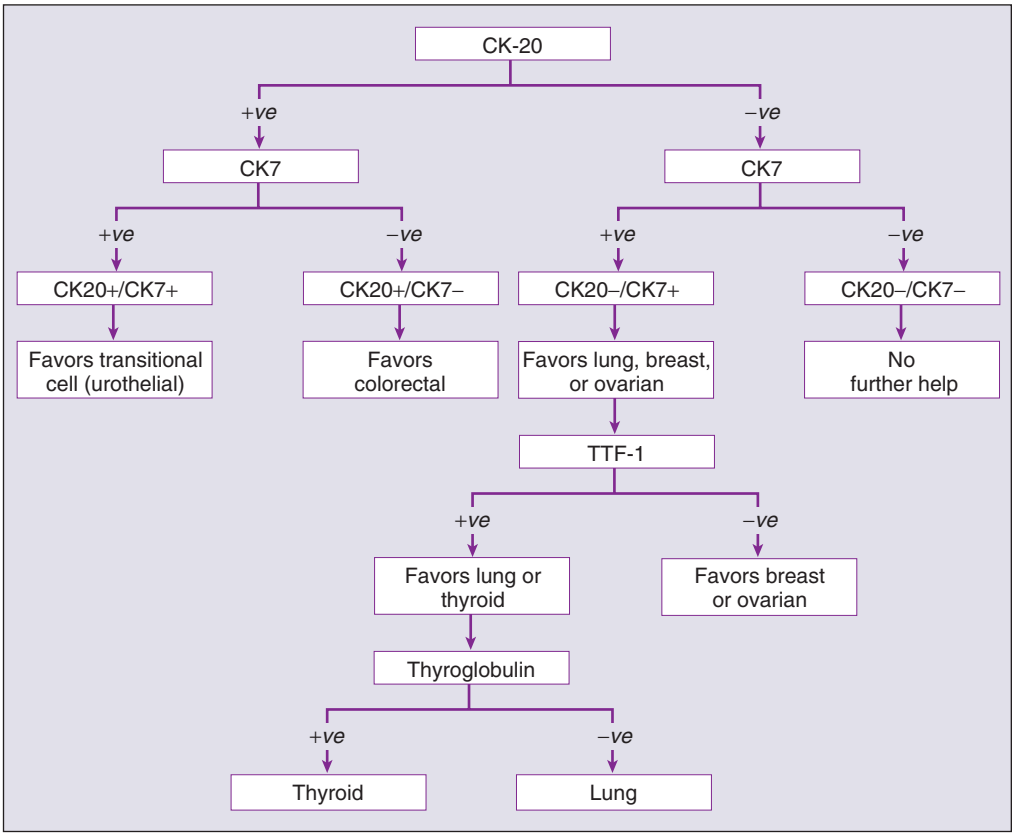

Figure 98-5 • Preliminary cytokeratin algorithm.

the apparent low yield from this evaluation, the good response of breast cancer to local and systemic therapy justifies the procedure in this patient population.

Computed Tomography

The role of CT of the chest in the evaluation of patients with CUP currently is unclear. Although chest CT can accurately document mediastinal adenopathy,[68] it often overestimates the amount of metastatic parenchymal pulmonary involvement. The additional lesions visualized by chest CT (as compared to chest x-ray and whole-lung tomography) in many cases are not malignant.[69,70] Until more evidence is available, routine use of the chest CT cannot be recommended. However, this study should be obtained to follow up an abnormal but nondiagnostic chest x-ray or positive sputum cytologic test.

The role for CT of the abdomen is much better defined and appears particularly useful in the detection of occult pancreatic primaries. Two relatively recent studies have addressed this issue. In one study, CT of the abdomen detected the primary site in 16 of 46 patients.[71] The primary sites documented included pancreas (6 patients), ovary (2 patients), hepatoma (2 patients), kidney (2 patients), lung (1 patient), adrenal gland (1 patient), gallbladder (1 patient), and stomach (1 patient). The second series, from the Mayo Clinic, identified the primary site in one third (31 of 98) of patients with clinically occult tumor.[71] In addition, this study pointed out that tissue confirmation could be obtained from the suspected primary site through the use of CT-directed needle aspiration biopsies. Thus, although it appears that CT of the abdomen should be considered a standard procedure in the evaluation of patients with CUP, the primary cancers identified often are difficult to treat, causing at least one group to question the cost-to-benefit relationship in this patient population.[2]

In the pelvis a combination of CT and pelvic ultrasound may be justified. In one prospective study of 24 women with pelvic masses palpable by gynecologic examination, additional clinical information was provided by ultrasound in 71% and by CT scan in 63% of these patients.[72] However, in three patients both modalities failed to detect tumor recurrence. More problematic, however, is the usefulness of pelvic ultrasound or pelvic CT for patients without palpable abnormalities by gynecologic examination. There is no prospective study analyzing these diagnostic examinations in this group of patients. The most efficient evaluation includes pelvic CT, which is performed with CT of the abdomen.[2]

Magnetic Resonance Imaging

Enthusiasm for magnetic resonance imaging (MRI) is high. As the technical capabilities of this diagnostic modality evolve it may be increasingly indicated in the diagnosis and management of patients with CUP. Currently, however, few prospective or retrospective studies are available to suggest a broad role for MRI in evaluating CUP. One application that appears promising is in the evaluation of female patients with isolated axillary lymph node metastases and suspected occult primary breast carcinoma. In a recently reported series of 12 female patients presenting with isolated axillary lymphadenopathy pathologically confirmed to contain metastatic adenocarcinoma, 9 had a primary malignancy localized to the breast identified by MRI.[73] Thus, at this time MRI should be limited to clinical situations in which it appears that the additional information to be gained will significantly alter the therapeutic approach recommended to an individual patient.

Positron Emission Tomographic Imaging

Positron emission tomography with ^{18}fluoro-2-deoxy-D-glucose (^{18}F-FDG-PET) is a noninvasive nuclear imaging technique that has been proved to be a valuable diagnostic tool in identifying primary malignant tumors, assessing the extent of metastatic disease, and localizing carcinoma of unknown primary origin. Several studies have been conducted to determine the value of FDG-PET imaging in detecting

occult primary tumors after unsuccessful conventional diagnostic evaluation in patients with metastatic disease from a carcinoma of unknown primary. Most of the studies consist of a small number of evaluable patients[74–77] and focus primarily on patients with cervical lymphadenopathy (mostly squamous cell pathology; Table 98-6). In 1998, Kole and associates[74] evaluated the role of FDG-PET imaging in 29 patients with various histologic types of metastasis from CUP after unsuccessful conventional diagnostic workup. FDG-PET imaging identified the primary tumor in 7 patients (24%), but survival was not altered by discovery of the primary tumor. In 1999, Lassen and associates prospectively studied 20 patients who underwent a FDG-PET scan after standard evaluation, and the FDG-PET results were verified either histologically or by the clinical course of the disease.[75] All the metastatic lesions were visible with FDG-PET. In 13 patients, FDG-PET suggested the site for primary tumor, and this site was verified in 9 patients (45%) either histologically or by the clinical course of the disease. Eight of these patients had primary lung cancer and one had carcinoma of the base of the tongue. In most patients, FDG-PET had no treatment-related implications. In 2000, Jungehulsing and associates[76] evaluated the use of FDG-PET imaging in 27 patients with head and neck lymphadenopathy and presumed CUP after unsuccessful conventional diagnostic evaluation failed to reveal the primary tumor. FDG-PET imaging revealed a primary tumor in 7 patients (24%). In 2002 Johansen and associates[77] evaluated 42 patients with squamous cell or undifferentiated metastatic disease from a CUP. Potential focal pathologic uptake indicated a primary tumor in 20 of 42 cases (48%). After FDG-PET imaging, additional investigations confirmed the primary tumor in 10 patients (24%). Rusthoven and colleagues reviewed 16 FDG-PET studies published between 1994 and 2003 involving 302 patients with cervical metastases from unknown primary tumors. Conventional workup included either panendoscopy or CT/MRI, and in 10 of these 16 studies, both of the diagnostic techniques were performed before diagnosis. They reported the overall sensitivity, specificity, and accuracy rates of FDG-PET in detecting unknown primary tumors were 88.3%, 74.9%, and 78.8%, respectively. FDG-PET detected approximately 25% of tumors that were not apparent after conventional workup and was sensitive in the detection of previously undetected regional or distant metastases in 27% of patients. FDG-PET had a low specificity for tonsils, with a false-positive rate of 39% in the tonsils. False-positive rates were 21% for the base of the tongue, and only 8% for the hypopharynx. Sensitivity for the base of the tongue was 81.5%, and for other sites was 90.5%.[78]

Ambrosini and colleagues[79] report a 53% primary cancer detection rate in a small study of 38 patients with CUP. In a review of 10 FDG-PET studies (involving a total of 221 patients) published between 1998 and 2006, Seve and colleagues found that 94% of patients had a single site of metastasis. In 41% of patients, FDG-PET detected primary tumors that were not apparent after conventional workup. In this group of patients, the overall sensitivity, specificity, and accuracy rates of FDG-PET in detecting unknown primary tumors were 91.9%, 81.9%, and 80.5%, respectively. FDG-PET imaging also led to the detection of previously unrecognized metastases in 37% of patients. Lung cancers represented 59% of the detected tumors. FDG-PET had a notably high false-positive rate (58.3%) in tumors of the lower digestive tract, and altered the clinical management in 34.7% of patients. A large number of patients in these studies had a single site of metastasis, which may have influenced the study results.[80] Outside of cervical adenopathy with squamous cell cancer, the role of PET scans, especially PET-CT, is evolving, although given that these studies have been small, it is difficult to make firm recommendations. Larger studies to evaluate the utility and cost-effectiveness of PET in the CUP setting (other than cervical) may be useful.

Molecular Markers by Gene Expression

Although few individual markers can identify a tumor's site of origin with a high degree of confidence (PSA and mammoglobin are possible exceptions), metastatic tumors do appear to have distinguishable patterns of gene expression when a large number of markers are examined with tools such as DNA microarrays or RT-PCR assay.

Ramaswamy and associates[9] subjected 218 tumor tissues spanning 14 common tumor types (representing ~80% of the new cancer diagnoses in the United States) and 90 normal tissue samples to oligonucleotide microarray gene expression analysis. They used the relative levels of expression of 16,063 genes and expressed sequence tags to evolve a predictive support vector machine (SVM) algorithm. The algorithm then was tested on an independent group of 54 tumors, yielding an overall prediction accuracy of 78%. Although greatest accuracy required the use of all 16,063 genes, accuracy was still above 70% with fewer than 50 genes. Of the 54 independent tumors tested, 8 were metastatic tumors, of which 6 were accurately identified, suggesting that the cancers retain the markers of their tissue of origin throughout metastatic evolution, and that gene expression-based approaches to the diagnosis of CUP may be feasible. Most of the tumor types that could not be classified accurately were moderately or poorly differentiated (high-grade) carcinomas. It can be difficult to classify such tumors with traditional methods, because they often lack the characteristic morphologic hallmarks of the organ from which they arise. It has been assumed that these tumors are, nonetheless, fundamentally molecularly similar to their better-differentiated counterparts, apart from a few differences that might account for their clinically aggressive nature. However, Ramaswamy and associates[9] suggest that poorly differentiated tumors may not simply lack a few key markers of differentiation, but rather may have fundamentally distinct gene expression patterns, with a significant implication for the management of patients with these cancers.

Su and associates[81] used a set of 100 primary carcinomas from 10 common tumor types (prostate, breast, lung, ovary, colorectum, kidney, liver, pancreas, bladder/ureter, and gastroesophagus), which collectively account for 70% of all cancer-related deaths in the United States. They extracted mRNA from the tumors, and then used an Affymetrix (Affymetrix, Inc.) oligonucleotide microarray to identify genes that were differentially expressed. A predictive algorithm was developed using 110 genes of the 9198 genes that were minimally expressed in these tumors. The algorithm was then tested against an

additional 75 blinded samples and accurately predicted the tumor of origin in over 90% of the cases.

Dennis and associates[82] used a different approach to identify predictive markers, starting with published data on differential gene expression by tumor type. They identified 61 candidate tumor markers whose expression pattern was predicted to be characteristic of the site of origin and tested 11 of them against adenocarcinoma samples (breast, ovary, stomach, pancreas, lung). The actual expression patterns were consistent with those predicted in seven cases (64%), with three agreeing exactly. By extending this approach, it may be possible to identify a smaller subset (10 to 20 genes) of highly predictive markers that could be applicable to more commonly used laboratory techniques such as immunohistochemistry.

The foregoing work holds out the promise that in a large proportion of CUP, the site of origin can be identified using arrays of molecular markers, although with one caveat. The underlying assumption is that CUP is no different from other metastatic lesions, and that CUP lesions retain the molecular markers associated with their tissue of origin identity, an assumption that still must be tested.

CLINICAL MANIFESTATIONS AND MANAGEMENT

The clinical presentations of CUP are extremely varied. Historically, patients commonly have been characterized as to whether they have disease above or below the diaphragm.[83] However, given the heterogeneity and widespread metastases that characterize this disease, this arbitrary division is of doubtful value. Other investigators have used other approaches effectively to subclassify patients based largely on clinicopathologic criteria of histologic type, involved organ sites, and responsiveness to therapy (Box 98-1). This approach has led to the definition of clinically defined patient subsets, which will be discussed later in this chapter. Despite these efforts at subclassification, most patients present with solitary or multiple areas of involvement in a variety of visceral sites. Thus, in most cases, the presenting symptoms and physical signs simply reflect the neoplastic involvement of these organ sites. The most common organ sites encountered are listed in Table 98-7, with lung, bone, lymph nodes, and liver the most frequently encountered. Table 98-7 also shows the histologic spectrum of disease associated with each site, as well as the other frequently involved metastatic sites encountered. Of the sites listed, only isolated involvement of lymph nodes was associated with significantly superior survival relative to the CUP population as a whole.[84]

The treatment of CUP continues to evolve. Although most patients are treated with systemic chemotherapy, the careful integration of surgery, radiation therapy, and even periods of observation is important in the overall management of these patients.[85–87] Observation is particularly important for patients with single sites of disease who have received adequate local therapy.

The most common problem is treatment of the patient with progressive metastatic adenocarcinoma involving two or more organ sites. Treatment of these patients remains suboptimal and probably awaits discovery of novel strategies applicable to other highly resistant adenocarcinomas, such as those originating in the lung or GI tract. This situation is contrasted with the management of the favorable subsets described in the following section. These favorable patients have been grouped together primarily on the basis of their responsiveness to therapy. The numbers of patients who fall into these favorable groups are small, but they are important to recognize because specific treatment may significantly extend survival.

Box 98-1. M.D. ANDERSON APPROACH TO THE PATIENT WITH NEWLY DIAGNOSED CARCINOMA OF UNKNOWN PRIMARY SITE

Patients with physical or radiographic evidence of metastatic cancer should undergo biopsy early in their evaluation. This approach confirms the diagnosis and provides histologic or cytologic information that will help in the planning of additional evaluation and treatment.

The essential diagnostic evaluation includes history, physical examination, CB count, SMA-12, PSA in men, chest radiography, CT of abdomen and pelvis, and mammography in women. Further investigations are performed only on the basis of positive findings from these screening studies. Patients are then readily classified and treated as outlined here.

Important Treatable Subsets (Minority of Patients) and Their Management

Clinic Subset	Management
Women with adenopathy (adenocarcinoma and carcinoma)	Same as for stage II breast cancer
Women with peritoneal carcinomatosis (papillary adenocarcinoma)	Same as for stage III ovarian cancer
Poorly differentiated and undifferentiated carcinoma (controversial subset)	Platin-based combination chemotherapy (carboplatin/paclitaxel ± etoposide or cisplatin/etoposide)
Extragonadal germ cell syndrome	Same as for nonseminomatous germ cell tumor
Neuroendocrine carcinoma	Same as for carcinoid/ pancreatic islet cell carcinoma; cisplatin-based chemotherapy for poorly differentiated neuroendocrine tumors
High- and mid-cervical adenopathy (squamous cell carcinoma)	Surgical resection of palpable disease + curative radiation therapy to the neck

Favorable Clinical Subsets

Squamous Carcinoma Involving Mid-High Cervical Lymph Nodes

High cervical adenopathy with squamous cell carcinoma has been mentioned previously because of its well-defined natural history, high frequency of identification of the primary site, and responsiveness to therapy.[10–12] With appropriate evaluation, including direct visualization of the hypopharaynx, nasopharynx, larynx, and upper esophagus, an occult primary lesion often will be identified. When no primary site is found, aggressive local therapy is applied to the involved neck.[12,87] Five-year survival rates of 30% to 50% have been reported with radical neck surgery, high-dose radiotherapy, or a combination of both modalities. A potential advantage of radiation therapy is that the suspected primary anatomic sites (nasopharynx, oropharynx, and hypopharynx) can be included in the radiation port.[86] The role of chemotherapy in these patients is unclear. However, one randomized study suggested that chemotherapy with cisplatin and 5-fluorouracil improved the response rate and median survival when compared with radiation alone.[88]

Adenocarcinoma involving mid-high cervical nodes and lower cervical or supraclavicular adenopathy of all histologic types carry a much poorer prognosis.[89] These patients are managed with local measures (usually radiation therapy), or they may be candidates for systemic chemotherapy protocols.

Women with Isolated Axillary Adenopathy

Isolated axillary adenopathy secondary to metastatic adenocarcinoma usually occurs in women and has unique clinical features. Many of these women have occult primary breast cancers, which can be identified in 40% to 70% of these patients who undergo mastectomy.[90,91]

Table 98-7 Clinical Characteristics of Common Subsets of Carcinoma of Unknown Primary Sites

Involved Site (No. Patients)	No. Patients with One Site Only	No. Patients with Multiple Sites	Histologic Type (Site Only/Site + Other)				
			Adenocarcinoma	Carcinoma	Squamous	Neuroendocrine	Other
Bone (318)	73	245	45/139	21/80	2/13	2/10	3/3
Lung (296)	21	275	13/175	5/72	0/13	0/10	1/5

Skin	14	11	3	0	—	17	2	*	8

*Median not yet reached.

In this setting, repeat biopsy of involved axillary nodes for estrogen and progesterone levels should be considered in view of the influence of this information on diagnosis and management. Management is based on the treatment of stage II breast cancer and should include both local and systemic therapies. Prognosis following treatment is comparable to women with stage II breast cancer. Older series have advocated modified radical mastectomy and axillary dissection for primary treatment.[90–92] However, a reported series of 42 patients suggested that survival was superior in patients receiving systemic chemotherapy, and local control was improved by irradiating the breast and axilla.[67] The actuarial disease-free survival rate in this study was 71% at 5 years and 65% at 10 years. This nonoperative approach has been outlined in a study by Lenzi and colleagues.[93]

Patients with axillary adenopathy and involvement of additional sites (usually liver or bone) or with nonadenocarcinoma histologic type compose a much more heterogeneous group, including equal numbers of men and women as well as a broader histologic spectrum, with poorly differentiated carcinoma and neuroendocrine carcinomas represented in addition to adenocarcinoma.[94] Despite this heterogeneity, the survival of patients with axillary adenopathy and other involved organ sites is intermediate between that of the overall population of CUP and women with isolated axillary adenopathy (Fig. 98-6).

The management of patients with involvement of the axilla as well as other sites or nonadenocarcinoma histology is less certain. These patients usually are approached using a combination of local and systemic modalities and may again be good candidates for novel systemic chemotherapy protocols.

Women with Peritoneal Carcinomatosis

Women with diffuse peritoneal carcinomatosis with adenocarcinoma make up another recognized subset. These patients form a distinctive subset because of their clinical similarities to patients with ovarian carcinoma. Often papillary histologic type and elevations in CA125 are found, but exploratory laparotomy fails to document a primary.[95,96] Other workers also have recognized this patient subset, terming this syndrome *peritoneal papillary serous carcinoma* or *multifocal extraovarian serous carcinoma*. These patients often respond to platinum-based chemotherapy.[96–98] Many patients in these series also underwent exploratory laparotomy with surgical debulking followed by chemotherapy. Median survival times are reported to be 16 months to 2 years.

The natural histories of males with isolated peritoneal carcinomatosis or patients with histologic features inconsistent with ovarian carcinoma or additional metastatic sites are much more poorly characterized, but overall survival, even with therapy, is poor.[99]

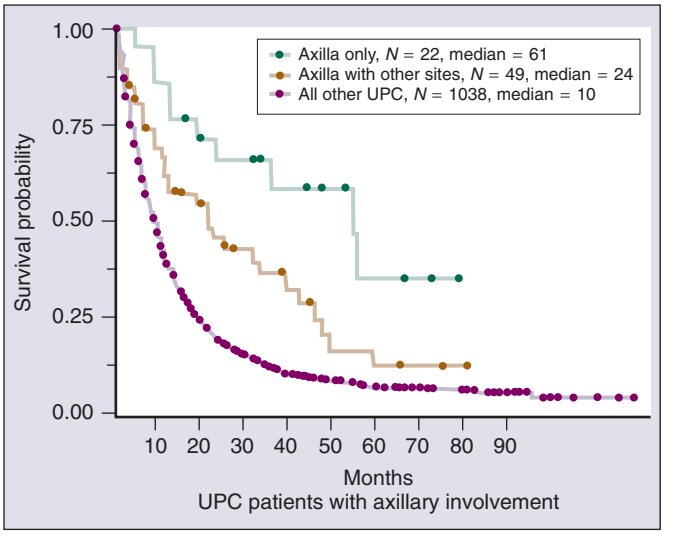

Figure 98-6 • Comparison of survival of patients with CUP in three groups: those with isolated axillary adenopathy; those with axillary adenopathy with other metastatic sites; and those without axillary nodal involvement.

Poorly Differentiated and Undifferentiated Carcinoma

Approximately one third of patients with CUP will be defined as having the histologic picture of poorly differentiated or undifferentiated carcinoma. In this subset, detailed histochemical or immunohistochemical studies are most likely to identify highly treatment-responsive patients with lymphoma (leukocyte common antigen), germ cell (β-hCG, AFP), or neuroendocrine (neuron-specific enolase, chromogranin) neoplasms (see Table 98-7). Additionally, Greco and Hainsworth[1] have identified a group of patients with PDC or PDA that are responsive to platinum-based chemotherapy. Most of these patients had clinical features (e.g., young age, mediastinal/retroperitoneal involvement, and rapid growth) of the extragonadal germ cell syndrome.[100] Many of these patients are male and have elevated β-hCG or AFP. Motzer and coworkers[31] identified abnormalities in chromosome 12 specific for germ cell neoplasms in a group of male patients with PDC involving midline structures, confirming the germ cell origin of these tumors.

Combination chemotherapy regimens specific for germ cell carcinoma of testicular origin usually have been employed in the treatment of these patients.[15,49,100–102] In selected patients, these regimens have produced documented complete responses and an actual 10-year disease-free survival rate of 16%.[13]

Despite these favorable results, one analysis of this "favorable" subset failed to confirm that patients with CUP who had PDC or PDA enjoyed prolonged survival.[50] The exact reasons for the failure of this newer study to confirm the earlier studies is unknown. However, insight into this question can be achieved by analyzing the patients reported in this analysis. From the population of 1400 patients referred with suspected CUP a primary tumor[2] was established in 365 patients. The primary tumors most commonly diagnosed included 70 patients considered to have highly treatable tumors: 28 patients with breast cancer, 20 patients with lymphoma, 11 patients with ovarian cancer, 6 patients with germ cell tumors, and 5 patients with other hematologic malignancies. This study also clearly showed that the survival of patients with CUP squamous or neuroendocrine features have survival times superior to those for patients with PDC or PDA. Thus, the PDC and PDA populations analyzed in this study reflect the biology of these patients' malignancies after patients with slower-growing tumors (e.g., neuroendocrine cancers) or chemotherapy-responsive tumors (e.g., lymphomas, other hematologic malignancies, germ cell tumors, breast cancer, ovarian cancer) had been excluded.

Increasingly frequent use of special pathologic studies, including immunohistochemistry, is likely to be responsible for the ease with which patients with lymphoma, neuroendocrine, germ cell, and other malignancies can be excluded from the PDC or PDA groups. Many of these patients often were included in earlier series of PDC and PDA patients, which may well have confounded data on chemotherapy responsiveness and survival.

Poorly Differentiated Neuroendocrine Carcinoma

Poorly differentiated neuroendocrine carcinoma is an emerging clinicopathologic entity recognized primarily for its responsiveness to therapy. There probably is considerable overlap with extrapulmonary small cell carcinomas, anaplastic carcinoid, anaplastic islet cell tumors, Merkel cell tumors, and paragangliomas. Histologically these tumors are very poorly differentiated, but histochemical stains are positive for chromogranin or neuron-specific enolase. These patients often present with diffuse hepatic or bone metastases but do not have the indolent histologic or clinical features of typical carcinoid tumors, islet cell tumors, or paragangliomas, and thus observation may not be appropriate. These tumors also often are responsive to cisplatin-based chemotherapy.[103,104]

Carcinoma of Unknown Primary in Unselected Patients

The good results for the patients with a favorable prognosis described earlier do not apply to the vast majority of patients with CUP. Two thirds of patients with CUP have metastatic adenocarcinoma with involvement of two or more visceral sites, usually some combination of liver, lung, lymph nodes, or bone. In addition, many men and women with poorly differentiated carcinoma have none of the clinical features outlined previously and respond poorly to therapy.[49] Even in series showing optimistic results for selected patients with poorly differentiated carcinoma or poorly differentiated adenocarcinoma, the overall median survival time remains poor, at 12 months.[13]

For unselected patients numerous empiric chemotherapy combinations have been reported[105–122] (Table 98-8). Many have been based on doxorubicin (Adriamycin), 5-fluorouracil, or cisplatin. Little information is available on the use of biologic agents, either alone or with chemotherapy. Response rates generally range from 20% to 30%, but most responses are partial and brief, resulting in little or no impact on median survival. The recent availability of new antineoplastic agents with broad-spectrum activity and potential efficacy in the treatment of CUP has renewed interest in empiric chemotherapy for these patients. The taxanes, gemcitabine, and the topoisomerase I inhibitors represent such agents with potential efficacy in the treatment of CUP.

Taxane-based regimens evaluated in phase II clinical trials have included the following combinations: (1) paclitaxel/carboplatin/etoposide; (2) paclitaxel/carboplatin; (3) docetaxel/platinum; and (4) paclitaxel/carboplatin/gemcitabine.[121–123] Overall response rates with taxane-based regimens have ranged between 24% and 47%. Longer median survival times also have been observed with taxane-based regimens, ranging from 9 to 11 months, as compared to a range of 5 to 8 months using older GI and breast cancer chemotherapy regimens. One report using carboplatin, paclitaxel, and etoposide reported that 25 of 53 patients (47%) had objective responses.[124] In this series seven patients (13%) experienced complete responses. However, the actuarial median survival time for the entire group was 13.4 months. The disappointing aspect of this survival statistic is that it is not substantially different from the 11-month median survival time reported in large consecutive series of patients with CUP.[77,125]

Gemcitabine is a pyrimidine analog antimetabolite with single-agent activity in several solid tumors, and also has been found to be useful as secondary therapy for some patients with CUP. Hainsworth and associates[126] conducted a phase II trial evaluating single-agent gemcitabine in the second-line therapy of patients with CUP. Thirty-five patients (90%) previously had received treatment with chemotherapy containing both a platinum agent and a taxane. This study showed an 8% partial response rate (3 of 36 evaluable patients), and 25% (9 patients) had minor responses or stable disease with reduced symptoms. The median time to progression was 5 months. These results show that as a second-line treatment for CUP, gemcitabine has a relatively low level of clinical activity in a refractory patient population, although a portion of patients experienced symptomatic improvement.

Because of the previously demonstrated activity of gemcitabine against a variety of advanced adenocarcinomas, gemcitabine was evaluated with combination chemotherapy as a front-line agent. Greco and associates[127] evaluated the efficacy and toxicity of gemcitabine, carboplatin, and paclitaxel in previously untreated patients with CUP. Twenty-eight (25%) of 113 assessable patients had a major objective response. The median progression-free survival time was 6 months, with a median survival time for the entire group of 9 months. Actuarial survival at 1 and 2 years was 42% and 23%, respectively. This study showed that combination chemotherapy with gemcitabine, carboplatin, and paclitaxel followed by weekly paclitaxel was well tolerated. However, the survival seen in this poor-prognosis group of patients is notable, and is similar to that seen in other

*Calculated from data presented.

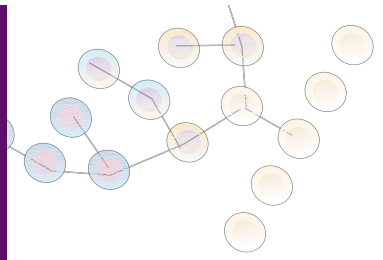
taxane-based regimens for these patients. Newer regimens continue to be tested, and some evidence suggests that even patients with a poor prognosis may benefit.

Culine and associates[128] evaluated the efficacy and toxicity of combination chemotherapy consisting of gemcitabine with cisplatin (GC) or irinotecan with cisplatin (IC) in patients with CUP in a phase II clinical trial. Eighty patients were assigned to receive either GC or IC. Seventy-eight patients were assessable for efficacy and toxicity. The median number of cycles was four in each arm of the study. Objective responses were observed in 55% of patients in the GC arm and 38% of patients in the IC arm. Treatment had to be discontinued in seven patients in the GC arm and eight patients in the IC arm. Median survival times were 8 and 6 months in the GC and IC arms, respectively, with a median follow-up of 22 months.

Greater knowledge regarding the molecular biology of CUP has translated to additional therapeutic options with targeted molecular agents. Hainsworth and associates[129] have evaluated the efficacy of combined targeted therapy with bevacizumab and erlotinib in 51 patients with CUP. Of these, 25% of patients were chemotherapy-naïve, with advanced bone or liver metastasis, and 75% of patients had received prior therapy with one or two chemotherapy regimens. Objective response occurred in 4 patients (8%), and 30 patients (59%) had stable disease or minor response. The median overall survival was 8.9 months, with a median follow-up of 13 months.

Median progression-free survival for the entire group was 6.2 months. Forty-two percent of patients were alive at 1 year. The 1-year survival for the previously treated versus untreated patients was 41% vs. 46%. These data clearly confirm the activity of targeted agents in the management of CUP, and additional prospective clinical trials are warranted to evaluate the use of these agents as part of front-line therapy.

FUTURE DIRECTIONS



Near-term research in CUP will continue to focus on the identification and treatment of patient subsets. This approach has been very successful in dealing with the inherent heterogeneity of CUP. Sophisticated data collection and computer-based analysis will foster these studies. The role of DNA microarray in this subset is evolving, as discussed earlier. Patients who do not fit a treatable subtype, as discussed in this chapter, should be encouraged to get involved in clinical trials for novel therapies. Looking further into the future, research into the metastatic phenotype through an analysis of CUP cells may identify specific molecular and biochemical targets, which could be therapeutically exploitable for patients with CUP. These targets may be applicable to other metastatic malignancies as well. We would anticipate that the molecular characterization of CUP not only will improve our understanding of metastases but also, through comparison with known primary carcinomas, eventually will resolve the question of anatomic origin.

99 Pediatric Solid Tumors

Jeffrey S. Dome, Carlos Rodriguez-Galindo, Sheri L. Spunt, and Victor M. Santana

SUMMARY OF KEY POINTS

Osteosarcoma

Incidence

- The incidence of osteosarcoma is 4 new cases per 1 million population per year among children younger than 15 years of age.
- Osteosarcoma is the most common bone tumor in children and adolescents.

Differential Diagnosis

- Other lytic bone lesions, including eosinophilic granuloma and giant cell tumor, must be excluded.
- At histopathologic examination, tumors must be differentiated from fibrosarcoma and chondrosarcoma.

Staging Evaluation

- Staging evaluation includes a complete history and physical examination, complete blood cell count (CBC), serum chemistry analysis (including determination of alkaline phosphatase level), and imaging studies of the primary tumor and chest.

Primary Therapy

- The primary tumor is managed surgically with a limb-sparing operation or amputation.
- Adjuvant chemotherapy incorporating high-dose methotrexate is used preoperatively for presumed micrometastatic disease; response will guide further therapy.
- Methotrexate responders have a more than an 80% chance of cure.
- Primary pulmonary metastatic disease is managed surgically, although adjuvant chemotherapy may reduce the extent of resection.

Effective Second-Line Therapy

- Pulmonary metastatic disease is managed surgically.
- Post-thoracotomy adjuvant chemotherapy is of unproven benefit.
- Local recurrence is managed surgically.
- Further adjuvant chemotherapy with non–cross-resistant agents is of uncertain benefit.

Ewing's Sarcoma Family Tumors

Incidence

- The incidence of Ewing's sarcoma family tumors is 2.8 new cases per 1 million population per year among children younger than 15 years of age.
- Ewing's sarcoma is the second most common bone tumor among children and adolescents.

Differential Diagnosis

- Osteomyelitis must be ruled out, especially when the patient has a fever.
- Lesions to be excluded include benign tumors of bone that manifest as lytic lesions (e.g., eosinophilic granuloma, giant cell tumor), malignant tumors (e.g., osteosarcoma, primary lymphoma of bone), and metastatic lesions from a nonosseous tumor (e.g., neuroblastoma).

Staging Evaluation

- Staging evaluation includes a complete history and physical examination, CBC, serum chemistry analysis (including determination of lactate dehydrogenase level), bone marrow biopsy, and imaging studies of the primary tumor, bones, and chest.

Primary Therapy

- The primary tumor should always be treated with multimodality therapy consisting of chemotherapy, radiation therapy, surgery, or a combination of these treatments.
- Specific local treatment depends on the primary site. Surgical extirpation may be considered with tumors in expendable bones (proximal part of the fibula, rib, clavicle, iliac wing).
- Unresectable tumors generally necessitate a combined approach of chemotherapy, radiation therapy, and surgery.
- Localized disease is curable with combined therapy in more than 70% of cases. Metastatic disease is curable in 30% to 40% of cases.

Effective Second-Line Therapy

- Effective second-line therapy has not been established.
- Local recurrence may be amenable to surgical extirpation.

Neuroblastoma

Incidence

- Among white children younger than 15 years of age, 10.5 new cases occur per 1 million population per year. Among black children, the incidence is 8.8 new cases per 1 million population per year.
- Neuroblastoma is the most common extracranial solid tumor in children.

Differential Diagnosis

- Disseminated bone disease can resemble systemic infection, inflammatory disease, osteomyelitis, or rheumatoid arthritis.
- Paraneoplastic syndromes associated with neuroblastoma (vasoactive intestinal peptide syndrome, opsoclonus-myoclonus-ataxia syndrome) must be differentiated from primary inflammatory bowel disease and neurologic disease.
- Neuroblastoma must be differentiated from other small round blue cell neoplasms of childhood (e.g., Ewing's sarcoma, primitive neuroectodermal tumor, non-Hodgkin's lymphoma, undifferentiated soft-tissue sarcoma).
- In as many as 10% of tumors, catecholamines are not produced. In 1%, the absence of an obvious primary lesion confounds the diagnosis.

Staging Evaluation

- Staging evaluation includes a complete history and physical examination, CBC,

serum chemistry analysis (including determination of lactate dehydrogenase level), quantitative urine catecholamines, bone marrow examination, radionuclide scintigraphy, and imaging studies of the primary tumor and chest.

Primary Therapy
- Specific treatment depends on stage of disease, age of the patient, and biologic features of the tumor.
- With few exceptions (completely resected primary tumor, infants with stable stage 4S disease), multiple-agent chemotherapy is the backbone of multimodality treatment.
- Survival depends on stage and biologic features of the tumor (e.g., histopathologic subtype, *MYCN* gene amplification).
- The overall survival rate for patients with stage I tumors is 90%; for those with stage 2A tumors, the survival rate is greater than 80%.
- Overall survival among patients with advanced-stage disease is poor. Sixty percent of children with stage 2B and 3 tumors live, and fewer than 15% with metastatic disease are long-term survivors.

Effective Second-Line Therapy
- No second-line therapy has proved beneficial.

Wilms' Tumor

Incidence
- The incidence of Wilms' tumor is 8 cases per 1 million population per year among children younger than 15 years of age.

Etiology and Epidemiology
- Mean age at diagnosis is 44 months for unilateral tumors and 31 months for bilateral tumors.
- Familial cases account for 1.5% of cases of Wilms' tumor.
- Associated with Wilms' tumor are a syndrome comprising aniridia, genitourinary anomalies, and mental retardation (WAGR syndrome); Denys-Drash syndrome; and Beckwith-Wiedemann syndrome.
- No firmly established environmental factors have been identified.

Pathology and Tumor Biology
- The main histologic subtypes are favorable and anaplastic.
- Implicated genes and loci include *WT1* (11p13), *WT2* (11p15), *FWT1* (17q12-q21), *FWT2* (19p13), *BRCA2*, and chromosomes 1p, 16q, and 7p.
- Mutations of the p53 gene (*TP53*) are associated with anaplastic tumors.

Clinical Features
- An asymptomatic abdominal mass is found in most patients.
- Other characteristic features include abdominal pain, hematuria, hypertension, and congenital anomalies (genitourinary malformations, aniridia, and hemihypertrophy).

Differential Diagnosis
- Neuroblastoma is the main consideration in the differential diagnosis.
- Other tumors to be excluded are renal neoplasms (clear cell sarcoma, rhabdoid tumor, congenital mesoblastic nephroma, renal cell carcinoma).
- Benign renal processes (nephrogenic rests, multicystic or polycystic kidneys, hydronephrosis, renal carbuncles, hemorrhage) also should be ruled out.

Staging Evaluation
- Evaluation begins with complete history and physical examination, with careful attention to blood pressure and assessment for associated congenital anomalies.
- Other components of the staging evaluation include CBC, serum chemistry analysis, urinalysis, abdominal ultrasonography or computed tomography (CT), and chest radiography with or without chest CT.

Primary Therapy
- *Surgery*: Surgical resection of the primary tumor usually precedes chemotherapy in North America.
- *Chemotherapy*: Agents used depend on disease stage and favorable versus unfavorable histology: stages I and II, favorable histology—vincristine, actinomycin D; stages III and IV, favorable histology, and stage I, anaplastic histology—vincristine, doxorubicin, actinomycin D; stage II through IV, anaplastic histology—vincristine, cyclophosphamide, doxorubicin, carboplatin, etoposide.
- *Radiation therapy*: Management for stages III and IV, favorable histology, and stages I through IV, anaplastic histology, consists of radiation therapy.
- Recurrent disease is effectively managed with radiation therapy and chemotherapy with agents not used for initial treatment.
- Patients who initially received aggressive treatment may respond to ifosfamide-, carboplatin-, and etoposide-based regimens.

Complications
- Renal failure (seen in less than 1%) and congestive heart failure may occur in patients who receive doxorubicin (in 4.4%).
- Pregnancy-related complications in adulthood have occurred in girls who receive flank irradiation.
- A second malignant neoplasm also may develop (1.6%).

Prognosis
- With *favorable* histology, outcomes include 85% 4-year relapse-free survival rate and 90% 4-year overall survival rate.
- With *anaplastic* histology, outcomes include 50% 4-year relapse-free survival rate and 50% 4-year overall survival rate.

Renal Cell Carcinoma

Incidence
- The incidence of renal cell carcinoma is 4 cases per 10 million population per year among children younger than 20 years of age.
- Mean age at diagnosis is 9 years.

Differential Diagnosis
- Other renal tumors of childhood, primarily Wilms' tumor, should be ruled out.

Staging Evaluation
- Staging evaluation includes a complete history and physical examination, CBC, serum chemistry analysis, and imaging studies of the abdomen, pelvis, and chest.

Primary Therapy
- Nephrectomy of the involved kidney constitutes definitive therapy for primary tumors.
- For metastatic disease, interleukin-2 or interferon-α-based therapy, or enrollment in clinical studies of investigational agents, is recommended.

Rhabdomyosarcoma

Incidence
- Among children younger than 20 years, the incidence of rhabdomyosarcoma is 4.3 new cases per 1 million population per year.
- Rhabdomyosarcoma is the most common soft-tissue sarcoma among children and adolescents.

Differential Diagnosis
- Other benign and malignant soft-tissue tumors must be excluded.
- At pathologic examination, rhabdomyosarcoma must be differentiated from the other small

round blue cell tumors of childhood (e.g., Ewing's sarcoma, neuroblastoma, non-Hodgkin's lymphoma).

Staging Evaluation
- Staging evaluation includes a thorough history and physical examination; CBC; serum chemistry analysis; imaging studies of the primary tumor, regional lymph nodes, lungs, and bones; and bone marrow examination.

Primary Therapy
- Primary therapy is chemotherapy with surgery, radiation therapy, or both. Specific treatment depends on age of the patient, tumor primary site and histologic subtype, and extent of disease.
- Mutilating surgery usually can be avoided because the tumor is sensitive to both chemotherapy and radiation therapy.
- The overall survival rate exceeds 70%, but survival will depend on extent of disease. More than 90% of patients with localized, resectable tumors survive, but less than 20% of patients with metastatic disease survive.

Effective Second-Line Therapy
- Cure rarely is possible except for patients with botryoid tumors and those with embryonal tumors whose tumor arose in a favorable site and was completely resected at initial diagnosis.

Nonrhabdomyosarcoma Soft-Tissue Sarcoma

Incidence
- Among persons younger than 20 years, 6.2 new cases occur per 1 million population per year.
- Peaks in incidence occur among infants and among children older than 10 years.

Differential Diagnosis
- Other tumors to be ruled out include benign soft-tissue tumors, rhabdomyosarcoma, and extraosseous Ewing's sarcoma.

Staging Evaluation
- Staging evaluation includes a thorough history and physical examination and imaging studies of the primary tumor and lungs.
- Imaging of regional lymph nodes, liver, bones, and brain is indicated in some clinical settings.

Primary Therapy
- Surgical excision with or without radiation therapy is indicated for patients with resectable tumors.
- Chemotherapy may provide some benefit for patients with high-grade tumors larger than 5 cm in diameter and for those with unresectable or metastatic tumors.
- Survival depends on the size and grade of the tumor and extent of disease. Patients with localized tumors 5 cm or smaller or localized low-grade tumors larger than 5 cm in diameter have a survival rate exceeding 85%. Approximately 50% of patients with high-grade tumors larger than 5 cm or with unresectable disease survive. The survival rate is less than 10% among patients with metastatic disease.

Effective Second-Line Therapy
- Cure generally is possible only for patients with local recurrence amenable to surgical extirpation and for those with distant recurrence of low-grade tumor that proves to be surgically resectable.

Retinoblastoma

Incidence and Clinical Forms
- Among children younger than 5 years of age, 11 new cases occur per 1 million population per year.
- The two clinical forms of retinoblastoma are as follows:
  1. *Hereditary, bilateral or multifocal* (40% of cases)—This form, characterized by germline mutations of *RB1*, may be inherited from an affected survivor or a silent carrier parent or may be the result of a new germline mutation.
  2. *Nonhereditary, unilateral or unifocal* (60% of cases)—15% of unilateral cases represent germline mutations.

Clinical Manifestations and Differential Diagnosis
- *Clinical manifestations*: Leukocoria is seen in more than 50% of cases, strabismus in 20% to 25%.
- *Differential diagnosis*: Coats' disease, retinopathy of prematurity, persistent hyperplastic primary vitreous, *Toxocara* uveitis, and toxoplasmosis need to be ruled out.

Staging Evaluation
- Approach to staging depends on tumor size and on the presence or absence of intraocular and extraocular extension.
- Indirect ophthalmoscopic examination of both eyes with the patient under general anesthesia is essential.
- Imaging studies helpful in staging include ultrasonography, orbital and cerebral CT, and magnetic resonance imaging (MRI).
- Bone marrow biopsy and cerebrospinal fluid examination are reserved for patients with extraocular disease, optic nerve involvement, or choroid invasion.

Treatment
- Treatment must be individualized and depends on laterality, potential for vision, and tumor extent.
- Enucleation is reserved for cases in which no potential for useful vision remains. Cryotherapy and photocoagulation are useful for management of small primary or recurrent tumors.
- Radiation therapy is the treatment modality of choice for controlling local disease and preserving vision with larger tumors.
- Use of chemotherapy is restricted to patients with advanced intraocular disease or with extraocular disease.

Hepatoblastoma

Incidence
- Among children younger than 15 years of age, 1.5 new cases occur per 1 million population per year.

Etiology and Epidemiology
- Mean age at diagnosis is 18 months.
- The tumor is associated with familial adenomatous polyposis and Beckwith-Wiedemann syndrome.
- An association with low birth weight has been found.

Pathology and Tumor Biology
- The major histologic subtypes are fetal, embryonal, macrotrabecular, and small cell (anaplastic).
- The tumor is associated with mutations of the *APC* and β-catenin genes and loss of heterozygosity at 11p15, the locus of the *IGF2* gene.

Clinical Features
- An asymptomatic abdominal mass is present in most patients.
- Other features may include anorexia, weight loss, vomiting, and precocious puberty (seen in 2% of cases).

Differential Diagnosis
- Other malignant tumors to be excluded include hepatocellular carcinoma, embryonal sarcoma, rhabdomyosarcoma, angiosarcoma, and teratoma.
- Benign tumors to be ruled out include hemangioma, hemangioendothelioma, hamartoma, and adenoma.

Staging Evaluation
- Staging evaluation includes a complete history and physical examination, with careful assessment for any congenital

abnormalities or signs of precocious puberty.
- Laboratory tests typically include CBC, serum chemical analysis and alpha-fetoprotein and α-human chorionic gonadotropin assays.
- Diagnostic imaging may include CT or MRI of the abdomen and chest CT.

Primary Therapy
- Cure is possible only when complete surgical excision is performed. If complete excision is not feasible, liver transplantation should be considered.
- Adjuvant chemotherapy (cisplatin-based, in conjunction with doxorubicin or 5-fluorouracil) is useful preoperatively for achieving resectability and postoperatively for preventing distant metastasis.
- Radiation therapy has a limited and ill-defined role.

Salvage Therapy
- Recurrent disease confers a poor prognosis, but repeated resection of local and metastatic recurrences has lengthened the survival period.

Complications
- Hearing loss and nephrotoxicity (related to cisplatin), cardiac toxicity (related to doxorubicin), and development of second malignant neoplasms may occur.

Prognosis
- With *localized disease*, outcomes include a 60% to 70% 5-year relapse-free survival rate and a 70% to 80% 5-year overall survival rate.
- With *metastatic disease*, outcomes include a 25% to 30% 5-year relapse-free survival rate and a 50% to 60% 5-year overall survival rate.

Adrenocortical Carcinoma

Incidence
- The incidence of adrenocortical carcinoma is 2 to 3 new cases per 10 million population per year in the United States.
- A 10- to 15-fold higher incidence has been observed in southern Brazil.

Etiology and Epidemiology
- Associated with germline *TP53* mutations and Li-Fraumeni syndrome.

Differential Diagnosis
- Other conditions associated with pathologic androgen or cortisol production, such as Cushing's syndrome or ovarian or testicular tumors, should be ruled out.

Staging Evaluation
- Evaluation for staging includes imaging studies of the abdomen, pelvis, and chest; skeletal scintigraphy; and measurement of blood and urine concentrations of adrenocortical hormones.

Primary Therapy
- Complete surgical removal of the tumor is indicated.
- Mitotane-based therapy or chemotherapy with cisplatin also is given.

Effective Second-Line Therapy
- Recurrent disease can be managed with further surgery, or experimental agents can be tried.

INTRODUCTION

Solid tumors account for 60% of all pediatric malignant neoplasms, approximately 3700 new cases being diagnosed each year in the United States. The spectrum of tumor types that occur in children is much different from that observed in adults. Included among the diverse types of pediatric neoplasms are tumors of the central nervous system (35%); neuroblastoma (15%); soft-tissue sarcoma, including rhabdomyosarcoma (7%); Wilms' tumor (6%); bone tumors, including osteosarcoma and Ewing's sarcoma (8%); retinoblastoma (5%); and miscellaneous tumors including hepatoblastoma, germ cell tumors, and melanoma (17%). Enormous progress has been made in the diagnosis and management of these tumors since the original demonstration of the chemosensitivity of Wilms' tumor to actinomycin D in 1966. Cure rates for most childhood solid tumors have increased by as much as 50% since the mid-1970s. The increase is attributable largely to improved understanding of prognostically important biologic and clinical features, enhanced precision of clinical staging systems, consistent use of supportive care, and development of more effective treatment, often incorporating a combination of chemotherapy, surgery, and radiation therapy.[1,2]

OSTEOSARCOMA

Epidemiology

Osteosarcoma, a malignant neoplasm derived from primitive mesenchymal cells and characterized by the presence of osteoid-producing spindle cell stroma, is the most common malignant bone tumor in the pediatric age group.[3] Osteosarcoma ranks tenth among all newly reported pediatric cancers in the United States, accounting for 2.6% of all neoplasms in children. The estimated annual incidence is 3.9 cases per 1 million population among white children and 4.5 per 1 million population among African-American children.[4] Most osteosarcomas occur during the first 2 decades of life, a period characterized by rapid skeletal growth. Boys are affected more commonly than girls. Several observations support the association between skeletal growth velocity and osteosarcoma. First, patients with osteosarcoma tend to be taller than their counterparts without this disease. Second, osteosarcoma develops at an earlier age in female patients than in male patients, perhaps because of differences in the timing of onset of puberty and the growth spurt.[5]

Tumor Biology

Unlike osteosarcoma in adults, in whom more than 25% of tumors are associated with pre-existing pathologic osseous conditions such as Paget's disease or fibrous dysplasia, most pediatric osteosarcomas arise spontaneously in areas of bone without any abnormality.[3] Irradiation is the best-characterized etiologic factor contributing to the development of secondary osteosarcoma. In a study involving 91 patients with second malignant bone sarcomas, osteosarcoma accounted for 72 cases, 52 (72%) of these tumors arising within previously irradiated fields.[6] The median time for development of the secondary tumor was 9.6 years after irradiation.

Children with hereditary retinoblastoma are at increased risk of development of secondary nonocular tumors irrespective of previous radiation to the primary site.[7,8] The estimated 50-year cumulative incidence of secondary neoplasms in children with retinoblastoma is 51% in hereditary cases and 5% in nonhereditary cases. Osteosarcoma is the most common second neoplasm in these children, accounting for as many as 44% of cases.[8]

Alterations in components of the cell cycle control system appear to characterize the ontogeny of osteosarcoma. Studies of the retinoblastoma gene (*RB1*) have shown that alterations affect the *RB1* gene in as many as 80% of cases[9] and that other events, such as *CDK4* alterations, also may result in *RB1* inactivation.[10] In experimental

models, introduction of the *RB1* gene into *RB1*-deleted osteosarcoma cell lines suppressed the tumorigenic potential of these cells.[11] The ontogeny of osteosarcoma is complex, however, and probably involves several genetic alterations other than loss of *RB1* function. Other genetic abnormalities have been reported, including allelic loss at chromosomal locus 17p, 25% to 50% of osteosarcomas having structural alterations at 17p13 of the p53 tumor suppressor gene.[12,13] Additional genetic abnormalities associated with osteosarcoma include amplification of the *MDM2* gene, whose protein product is important in regulation of p53 function. Tumors with *MDM2* amplification appear to display clinically aggressive behavior characterized by either local or distant metastasis.[14] Allelic loss at other chromosomal loci, including 3q, 13q, and 18q, have been observed in as many as 75% of karyotypically analyzed osteosarcomas. This finding suggests the presence of at least two other potential tumor suppressor genes involved in the multistep process of tumor development and progression in osteosarcoma.[15,16]

The peak incidence of osteosarcoma coincides with the adolescent growth spurt. This finding has led to the hypothesis that the altered hormonal milieu typical of adolescence may play a role in development of osteosarcoma. It is therefore possible that the insulin-like growth factor I (IGF-I)–insulin-like growth factor I receptor (IGF-IR) axis may be involved in the unregulated proliferation of osteoblasts that occurs in osteosarcoma. IGF-I functions as a mitogen in human and mouse osteosarcoma cells, and osteosarcoma cell lines depend on IGF-I for in vitro growth.[17] Although the levels of IGF-I and its binding protein (IGFBP-3) are not elevated in patients with osteosarcoma, other components of the IGF-I signaling pathway may be involved in the development and progression of osteosarcoma.[18]

Pathology

Osteosarcoma is characterized by the presence of spindle cell stroma that produces osteoid. Conventional osteosarcoma can be subdivided histologically into three major groups depending on the predominant cell type. Approximately 50% of tumors are categorized as *osteoblastic*, because the predominant extracellular element is osteoid, whereas 25% are *chondroblastic*, with a prominent cartilaginous component. Approximately 25% have a herringbone pattern similar to that observed in fibrosarcoma and are therefore called *fibroblastic*. No significant differences in overall outcome are apparent among these three histologic subtypes.[3] In one report, however, patients with fibroblastic histology showed better histologic response and better overall outcome than were observed for patients with osteoblastic or chondroblastic histology.[19]

Clinical Manifestations

Pain is the most common symptom in children and adolescents with osteosarcoma.[3] Onset of pain often is insidious, and the pain usually involves the area affected by tumor. Severe pain of sudden onset commonly is associated with pathologic fracture. Swelling around the affected bone is the second most common clinical finding. The tumor may be easily palpable when located in areas such as the anterior surface of the femur but may manifest only as leg edema when occurring in difficult-to-appreciate areas such as the popliteal fossa. A painful limp that increases with weight bearing is the third most common symptom. Systemic signs and symptoms such as fever and weight loss are uncommon.

Osteosarcoma most commonly involves the long bones, most tumors occurring around the knee. The most frequent sites of involvement are the distal part of the femur, the proximal portion of the tibia, and the proximal part of the humerus. The axial skeleton, including the pelvis, is rarely affected in children (fewer than 10% of cases) but more frequently is involved in patients older than 60 years.[3,20] Overt macroscopic metastatic disease occurs in 20% of cases and carries a grave prognosis.[21–23]

Laboratory and Radiologic Evaluation

Laboratory evaluation often is unrevealing. Elevations of serum lactate dehydrogenase (LDH) and alkaline phosphatase levels are the most common laboratory abnormalities. The latter appears to correlate with osteoblastic activity and has therefore proved useful in monitoring response to therapy.[24]

Radiologic evaluation of a patient with osteosarcoma must include assessment of the primary site as well as a search for distant metastatic lesions. Plain radiography is the most effective method of detection of bone tumors.[25,26] The main limitation of plain radiography is accurate delineation of local tumor extent. Characteristic radiologic findings in osteosarcoma commonly include a metaphyseal permeative lesion with periosteal new bone formation and destruction of pre-existing cortical bone. A soft-tissue mass is present in more than 90% of cases. Other radiologic signs commonly associated with osteosarcoma include cumulus cloud-like density and the presence of Codman's triangle (Fig. 99-1A). A baseline chest radiograph should be obtained to search for distant metastatic lesions. Angiography usually is reserved for patients who receive intra-arterial chemotherapy or for those who need optimal vessel visualization before limb salvage.[26]

Computed tomography (CT) of the primary tumor is accurate in assessment of degree of tumor calcification and ossification, which are important in assessment of response to therapy.[26] Chest CT always should be performed at the time of diagnosis for documentation of metastatic disease. Findings at magnetic resonance imaging (MRI) offer the best estimate of intramedullary tumor extension,

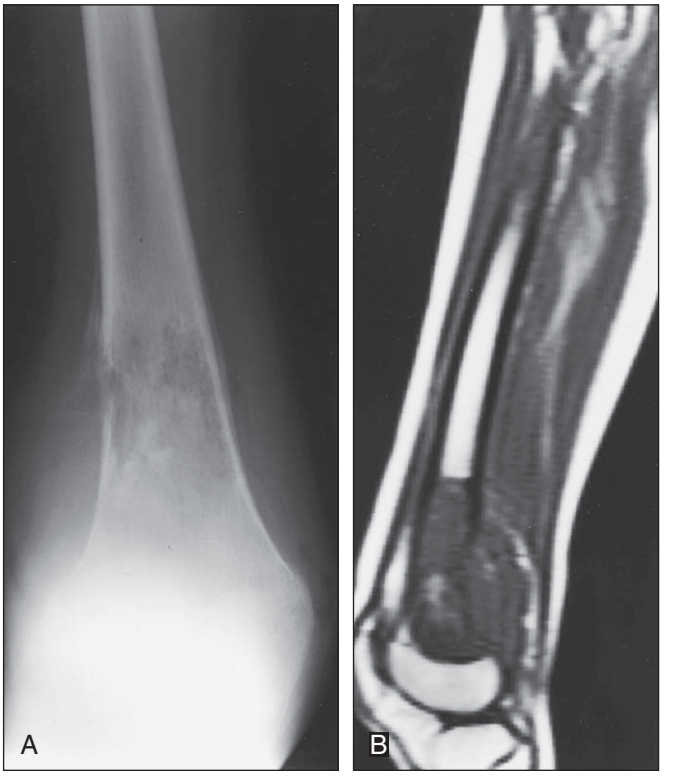

Figure 99-1 • Osteosarcoma involving the right distal femur. **A,** Plain radiograph shows a poorly defined, permeative destructive pattern; periosteal reaction; a Codman's triangle; and an associated soft-tissue mass. **B,** Sagittal T_2-weighted magnetic resonance image from the same patient shows abnormally dark area (representing increased signal intensity) in the intramedullary space consistent with tumor involvement by osteosarcoma. The associated posterior soft-tissue mass is evident. Areas of bright focal signal enhancement represent intramedullary hemorrhage.

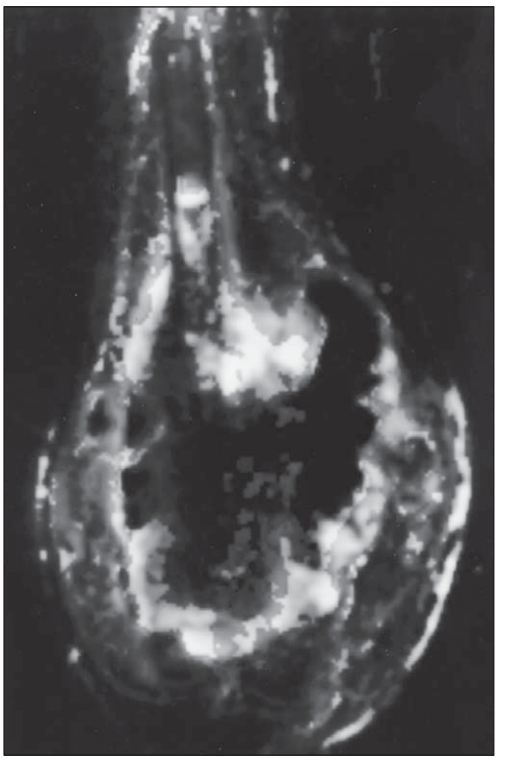

Figure 99-2 • Dynamic, paramagnetic, contrast-enhanced magnetic resonance image from a patient with an osteosarcoma of the distal right lower extremity. At subsequent pathologic examination, the focal areas of increased signal intensity were found to represent nests of viable tumor.

joint and vascular involvement, detection of "skip" metastatic lesions, and delineation of the soft-tissue component (see Fig. 99-1B). The blood supply and vascularity of the tumor can be better appreciated with administration of gadopentetate dimeglumine, or gadolinium-diethylenetriaminepenta-acetic acid (Gd-DTPA), a paramagnetic contrast material. MRI is helpful in assessing response to chemotherapy, as evidenced by changes in signal intensity on T_2-weighted images and alterations in the enhancement of tumor tissue after administration of Gd-DTPA (Fig. 99-2).[26] Dynamic contrast-enhanced MRI (DEMRI) is a valuable method for assessing microcirculation in osteosarcoma.[27] DEMRI can be used to evaluate changes in regional contrast access during chemotherapy. The findings appear to correlate accurately with histologic response and outcome, allowing early identification of patients at risk for recurrence.[28] Radionuclide bone scans with technetium 99m (^{99m}Tc)-labeled bone-seeking phosphate compounds are particularly useful in detection of metastatic bone lesions.[26] Thallium bone scintigraphy also is useful in the diagnosis of osteosarcoma; its primary role may be in assessing response to chemotherapy.[29]

Biopsy of the primary tumor should be done carefully, preferably by the surgeon who will ultimately perform the definitive operation. In performance of biopsy of a suspected bone tumor, the following basic principles should be observed: (1) avoidance of transverse incisions, which can make subsequent surgery difficult; (2) avoidance of contamination of multiple compartments and hematoma formation, because successful limb-sparing procedures can be jeopardized; and (3) if feasible, biopsy of the soft-tissue component only.

Osteosarcoma Subtypes

In addition to conventional osteosarcoma, a small proportion of patients present with clinical subtypes that are characterized by distinct clinical, radiologic, and histologic characteristics.

Telangiectatic Osteosarcoma

Telangiectatic osteosarcoma is characterized microscopically by blood-filled spaces divided by septa containing neoplastic sarcomatous cells. Both radiologically and histologically, it is difficult to differentiate from aneurysmal bone cyst. It accounts for less than 4% of cases of osteosarcoma. Age and anatomic distributions are similar to those in conventional osteosarcoma. On imaging studies, telangiectatic osteosarcoma manifests as a purely lytic lesion with a permeative destructive growth pattern; it usually disrupts the cortex, but with minimal or no periosteal new bone formation, which often is multilayered, in an onionskin pattern. Overall, the radiographic appearance is not that of a typical osteosarcoma, which usually has a mixture of blastic and lytic areas. Indeed, a purely lytic radiographic appearance is a diagnostic requirement for its diagnosis. This pattern can simulate aneurysmal bone cyst.[30,31] Histologically, telangiectatic osteosarcoma is very hemorrhagic, similar to the gross appearance of aneurysmal bone cysts. Microscopically, this tumor consists of cyst-like spaces divided by septa, which are composed of highly atypical sarcomatous tissue. Unlike aneurysmal bone cysts, these cystic spaces have no endothelial lining, and the tumor cells are in direct contact with areas of hemorrhage.[30] In the past, it was thought that telangiectatic osteosarcoma carried a worse prognosis than that for conventional osteosarcoma. With appropriate multimodality therapy, however, the outcome is similar to or better than that with conventional osteosarcoma.[19]

Low-Grade Intramedullary Osteosarcoma

Low-grade intramedullary osteosarcoma is a very rare variant of osteosarcoma, accounting for less than 1% of cases. Most cases are diagnosed during the third decade of life. Its anatomic distribution is similar to that of conventional osteosarcoma, with predilection for the distal femur and proximal tibia. In contrast with conventional osteosarcoma, symptoms typically develop over many months or even years before the patient comes to medical attention. Imaging studies usually show a variable pattern of lytic foci and dense areas, poorly demarcated. Periosteal new bone formation is minimal. Histologically, it shows a predominantly differentiated fibroblastic and osseous component, similar to what is seen in parosteal osteosarcoma (see later on). The differential diagnosis must distinguish this lesion from fibrous dysplasia. Treatment includes a complete resection of the lesion. Incomplete resection invariably results in local recurrence, and dedifferentiation increases with each recurrence.[3,32]

Surface Osteosarcomas

Osteosarcomas that originate and grow predominantly on the surface of the bone include the parosteal, periosteal, and high-grade surface osteosarcomas.

Parosteal osteosarcoma is a low-grade tumor that grows predominantly on the surface of long bones, in an exophytic pattern. Because it is derived from the outer layer of the periosteum, it grows without causing elevation of the periosteum or evidence of periosteal new bone formation. Parosteal osteosarcomas account for 3% of all osteosarcomas. They tend to occur in skeletally mature patients, with diagnosis during the third and fourth decades of life. More than 80% of these tumors are located in the distal portion of the femoral shaft, in its posterior aspect, within the superior popliteal area. Because of their slow growth, parosteal osteosarcomas usually manifest as a painless mass. Imaging shows a tumor growing on the surface of the bone, with a broad base, in a mushroom-like fashion. The mass typically is densely mineralized and has lobulated outlines. Microscopically, these tumors are characterized by the presence of a spindle-cell fibroblastic component, with variable osteoid production, low mitotic rate, and no atypical features.[33,34] The treatment is surgical, and a complete resection is mandatory. Incomplete resections invariably lead to local recurrences, and the risk of high-grade transformation increases with local recurrence.[33]

Periosteal osteosarcoma is a low- to intermediate-grade tumor that has a predominantly chondroblastic differentiation. It originates in the deep layer of the periosteum, so its growth is manifested by a separation and elevation of the periosteum from the cortex, causing a prominent periosteal new bone formation. It represents less than 2% of all osteosarcomas. Periosteal osteosarcoma is a tumor of childhood, with a peak incidence during the second decade of life, and it has a female predominance. The usual location is in the long bones of the lower extremity, most commonly the tibia, with an affinity for the diaphysis. The presentation is similar to that with conventional osteosarcoma, with pain and swelling of short duration. Imaging studies show a predominantly fusiform lesion on the surface of a long bone.

High-grade surface osteosarcoma is a very rare subtype of surface osteosarcoma, accounting for less than 1% of all osteosarcomas. The age distribution, anatomic location, and clinical presentation are similar to conventional osteosarcoma. By imaging, high-grade surface osteosarcoma simulates a periosteal osteosarcoma. Microscopically, however, it is indistinguishable from conventional osteosarcoma, showing anaplastic cellular features and osteoid and immature bone and cartilage formation. Medullary extension is minimal. Treatment should be the same as for a conventional osteosarcoma.

Prognostic Factors

The most important adverse prognostic factor in patients with osteosarcoma is the presence of metastatic disease.[21] In addition, primary tumor location is associated with outcome. Children with primary tumors of the tibia and distal femur appear to have a more favorable prognosis than those with axial primary tumors. This finding highlights the importance of complete surgical resection in the management of this malignant disease.[21,35] For patients with localized disease, factors associated with poor prognosis include measures of tumor burden, such as tumor size, and levels of alkaline phosphatase and LDH,[21,24,36] as well as more biologic measures, such as poor histologic response to preoperative chemotherapy,[35] hyperdiploidy,[37] and increased expression of P-glycoprotein[38] or Ki-67.[39] The percentage of tumor necrosis after preoperative chemotherapy is the most consistent and important factor associated with outcome in children and adolescents with localized osteosarcoma. A favorable response (more than 90% tumor necrosis) correlates with excellent overall survival. Patients who have less than 90% tumor necrosis are considered poor responders, for whom the prognosis usually is poor.[21,35,40] Because of this strong correlation between degree of histologic response to preoperative chemotherapy and outcome, noninvasive methods such as DEMRI, used for monitoring tumor response, can be used to evaluate changes in regional contrast access during chemotherapy.[31] Finally, a proportion of patients with extremity osteosarcoma present with a pathologic fracture, or a pathologic fracture develops after institution of therapy. This has been considered a poor prognostic factor and an indication for immediate amputation. It is possible, however, that with the use of preoperative chemotherapy and judicious use of limb-sparing techniques, a selected group of patients with pathologic fracture may still do well without amputation.

Treatment

Optimal management of osteosarcoma consists of multiple-agent chemotherapy and local control measures, including amputation or limb-sparing surgical procedures. Box 99-1 outlines the approach to management of osteosarcoma used at St. Jude Children's Research Hospital. Before the development of limb-sparing procedures, amputation was the standard surgical method used for curative treatment of osteosarcoma. Amputation now generally is reserved for primary tumors deemed unresectable. Limb function after below-the-knee amputation usually is excellent. Over the past several years, the role of limb-sparing procedures has increased dramatically. As a result of refinements in neoadjuvant chemotherapy, bioengineering, and imaging techniques, it is estimated that as many as 80% of patients with osteosarcoma will eventually be candidates for limb-sparing procedures.[41] The criteria for limb-sparing procedures include (1) absence of major neurovascular involvement by tumor, (2) feasibility of wide surgical excision to include a normal muscle cuff in all directions and en bloc removal of all biopsy sites, (3) resection of the adjacent joint and capsule, (4) adequate motor reconstruction with regional muscle transfer, and (5) adequate soft-tissue coverage.[42] In the past, immature skeletal age and primary tumor of the humerus were relative contraindications; however, new expandable prosthetic devices may help overcome this problem.[41,43] More recent improvements have been concentrated on achieving noninvasive extension of prostheses. One such method is the Phenix technology (Repiphysis). The basic principle involves storage of energy in a spring maintained in compressed form by a locking system. Prosthetic lengthening is performed through exposure to an external electromagnetic field that pilots the locking system and allows controlled release of the spring energy (Fig. 99-3). Prosthetic expansion of several millimeters can be achieved with each procedure, and the total duration of the procedure is less than 30 seconds[44] (Fig. 99-4). Thus, limb-sparing procedures are considered feasible in the care of most children and adolescents with osteosarcoma. When these procedures are appropriately performed, the risk of local recurrence is low (less than 5%).[45] Long-term functional outcome, however, must be carefully compared with that obtained with amputation alone. Complications of limb-sparing surgery include infection, nonunion, fracture, and unstable joints.

Before the introduction of adjuvant chemotherapy, fatal metastatic disease developed in more than 80% of patients with osteosarcoma.[46] Trials of single-agent chemotherapy began in the 1960s and early 1970s and established, in a nonrandomized manner, a role for the use of chemotherapy in the management of osteosarcoma. Responses with single-agent high-dose methotrexate or doxorubicin occurred in 20% to 40% of patients with metastatic disease.[46,47] Since then, different combinations of platinum compounds, doxorubicin,

Box 99-1. ST. JUDE CHILDREN'S RESEARCH HOSPITAL APPROACH TO MANAGEMENT OF OSTEOSARCOMA

At St. Jude Children's Research Hospital, the standard approach to the management of osteosarcoma entails the use of a platinum-based chemotherapy regimen followed by resection of the primary tumor. For patients with nonmetastatic disease, carboplatin may be substituted for cisplatin in a combination regimen that also includes high-dose methotrexate, doxorubicin, and ifosfamide. Resection for local control is performed after completion of three courses of chemotherapy, and postoperative chemotherapy is not modified on the basis of histologic response unless progression of the disease is documented. Most patients with extremity osteosarcoma are candidates for limb salvage surgery. Amputation is performed only in selected cases. For patients with immature skeleton and growth potential, the Phenix (Repiphysis) device, which allows noninvasive lengthening, is used.

In patients with metastatic and unresectable disease at diagnosis, cisplatin is used in combination with high-dose methotrexate, ifosfamide, etoposide, and doxorubicin. Aggressive resection of the primary tumor and all sites of metastasis is indicated. For patients with unresectable disease, radiation therapy is used, although the outcome for this group of patients is very poor.

The few patients with local recurrence after a limb-sparing procedure undergo amputation. Recurrent disease to the lungs is managed with aggressive surgery, and repeated thoracotomy usually is needed. Systemic chemotherapy with second-line regimens is added in cases of early recurrence or unresectable disease.

Figure 99-3 • Activation of Phenix (Repiphysis) device expansion in treatment for osteosarcoma involving the left lower extremity in a 13-year-old boy. The activating device is on the left. The electromagnetic coil is being held over the annular protuberance within the implant.

and high-dose methotrexate have formed the basis of standard chemotherapy regimens that lead to cure in 50% to 75% of patients with nonmetastatic disease (Table 99-1).

For more than two decades, therapy for nonmetastatic osteosarcoma has followed the basic guidelines of the T-10 protocol,[48] and most of the current treatment strategies have evolved from lessons learned with it. The T-10 protocol and its variants consist of a multiple-agent regimen of high-dose methotrexate, doxorubicin, cisplatin, and a combination of bleomycin, cyclophosphamide, and dactinomycin. When the T-10 protocol guidelines are used, the 5-year actuarial event-free survival (EFS) rate may approach 70%.[35,36] These results are not always reproducible, however, and multi-institutional U.S. and European studies conducted according to similar guidelines have shown lower EFS rates, usually 50% to 60%.[49–53] The lack of reproducibility of the results of the original study may be attributed in part to the complexity of the treatment. In a study performed by the European Osteosarcoma Intergroup, patients were randomized to receive the T-10 protocol or a much simpler treatment of six courses of a combination of cisplatin and doxorubicin.[49] Only one half of the patients in the T-10 protocol-like group completed all scheduled therapy, whereas 94% of the patients in the short-treatment group received the six courses of chemotherapy. The results for both treatment groups were identical, suggesting that a simple, two-drug regimen of cisplatin and doxorubicin can cure more than one half of patients with nonmetastatic osteosarcoma.[54]

One of the major contributions of the T-10 protocol and its predecessor T-7 is that the histologic response to neoadjuvant chemotherapy has been identified as the most important prognostic

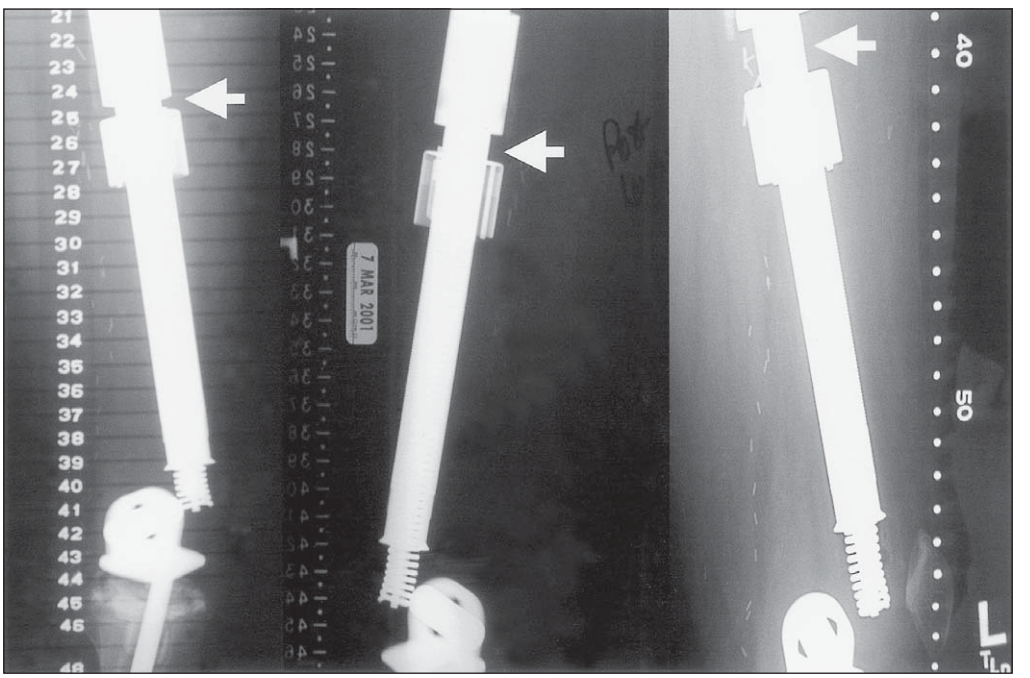

Figure 99-4 • Radiographs show the expandable portion of the Phenix (Repiphysis) device. The titanium tubular portion expands out of the polymeric tube. The increased distance between barrel and stem indicates the amount of expansion that occurred *(arrows)*.

Table 99-1 Summary of Most Relevant Chemotherapy Protocols for the Management of Osteosarcoma

		TREATMENT			
Protocol/Author	***N***	**Preoperative**	**Postoperative***	**Outcome**	**Comment(s)**
T-10/Meyers et al.[36]	31	MTX-BCD	*GR*: + DOX *PR*: + CDDP/DOX	5-yr EFS: 73%	*PR*: No advantage of intensified postoperative treatment
T-12/Meyers et al.[36]	36	MTX-BCD-DOX-CDDP	Same	5-yr EFS: 78%	No advantage of intensified neoadjuvant treatment
MIOS/Link et al.[52]	77	None	MTX-BCD-DOX-CDDP	2-yr DFS: 66%	Randomized study demonstrating need for chemotherapy
	36	Surgery alone		2-yr DFS: 17%	
CCG-782/Provisor et al.[51]	268	MTX-BCD	*GR*: + DOX *PR*: + DOX-CDDP	8-yr EFS: 53% *GR*: 81% *PR*: 46%	*PR*: No advantage of intensified postoperative treatment
COSS-82 arm A/ Winkler et al.[53]	59	MTX-BCD	*GR*: Same *PR*: + CDDP/DOX	4-yr EFS: 49%	
COSS-82 arm B/ Winkler et al.[53]	66	MTX-DOX-CDDP	*GR*: Same *PR*: + IFO	4-yr EFS: 68%	*PR*: IFO not advantageous
COSS-86 low risk/ Fuchs et al.[55]	41	MTX-DOX-CDDP	Same	10-yr EFS: 66%	No difference for IA vs. IV administration of CDDP
COSS-86 high risk/ Fuchs et al.[55]	128	MTX-DOX-CDDP-IFO	Same	10-yr EFS: 67%	Use of IFO for high-risk patients
EOI-1/Bramwell et al.[54]	142	CDDP-DOX × 3	CDDP-DOX × 3	5-yr DFS: 57%	Importance of a two-drug short regimen with CDDP-DOX
	140	CDDP-DOX-MTX × 2	CDDP-DOX-MTX × 2	5-yr DFS: 41%	
EOI-2/Souhami et al.[49]	192	MTX-DOX	+ BCD-CDDP	5-yr PFS: 44%	Two-drug short regimen may be better than longer; more complex protocols
	199	CDDP-DOX	Same	5-yr PFS: 44%

factor in the care of patients with nonmetastatic disease.[35] Intensification of postoperative[35,50,51] or preoperative[36] chemotherapy with cisplatin, doxorubicin, and ifosfamide, however, has not improved outcome. To increase the proportion of good histologic responders, some researchers have investigated intra-arterial administration of cisplatin. In the context of an aggressive, multiple-agent treatment, however, intra-arterial infusion of cisplatin does not offer any significant advantages.[55]

In recent years, ifosfamide has been incorporated into therapeutic regimens for osteosarcoma. After early reports showed that ifosfamide as a single agent achieved response rates of 10% to 60% in patients with advanced or treatment-refractory osteosarcoma,[56–58] some investigators began to use the agent in salvage therapy regimens for poor responders.[53,59] More recently, ifosfamide has been incorporated into front-line therapy in many regimens.[55,59–62] Whether incorporating the agent into standard treatment will improve the cure rate is unknown.[62] The Children's Oncology Group (COG) investigated the role of ifosfamide in a randomized study.[62A] Because giving an alkylating agent with etoposide has been shown to produce a synergistic antitumor effect,[63] several investigators have administered ifosfamide and etoposide together on a fractionated dosing schedule over 3 to 5 days. In patients with refractory osteosarcoma, some of whom had previously received ifosfamide, the combination of ifosfamide and etoposide achieved response rates of 15% to 48%.[64–67] Thus, this combination is being used increasingly to manage osteosarcoma.[59,68] Investigators in the Pediatric Oncology Group have reported response rates of 59% in patients with untreated metastatic osteosarcoma receiving this combination.[69] The combination of ifosfamide and etoposide appears to be more effective than ifosfamide alone in patients with untreated metastatic osteosarcoma.[58,69] These results support performance of additional studies of this combination in treatment for patients with nonmetastatic disease. The use of the combination of ifosfamide and etoposide is being increasingly used for the salvage of patients with poor histologic responses; however, evidence is lacking for improved outcome in this group of patients. The randomized European-American Osteoscarcoma (EUROS) trial will attempt to answer this question.

In the cooperative POG-CCG Intergroup INT0133 trial, patients with localized osteosarcoma received treatment with a standard methotrexate-cisplatin-doxorubicin regimen, and underwent a double randomization. The first randomization was to receive ifosfamide; the second randomization was to receive MTP, a derivative of the BCG cell wall that is known to stimulate the immune system, with the objective of decreasing pulmonary failures. Therefore, four regimens were compared. The addition of ifosfamide or MTP alone to the standard regimen did not seem to provide any benefit. However, the addition of both ifosfamide and MTP-PE resulted in a significantly better outcome when compared with the other three regimens. The significance of these findings is unclear.[62A]

Methotrexate is the classical antifolate, and blocks the action of dihydrofolate reductase. Methotrexate was among the first drugs reported to have an antitumor effect in osteosarcoma and it has been a major component of the osteosarcoma treatment ever since then.[46] Further, there is evidence that suggests that the pharmacokinetics of this agent may influence outcome, although this influence is minor in the context of more intensive multiagent protocols. However, the role of methotrexate appears to be limited to the administration of high doses (usually $12 g/m^2$), because the administration of lower doses appears to have a lesser therapeutic effect.[42] The administration of high-dose methotrexate requires close monitoring of serum levels, which cannot be performed in many institutions, particularly those of developing countries, and extensive supportive measures, including hyperhydration, urine alkalinization, and leucovorin rescue, which must be adjusted to the methotrexate serum levels. The development of acute renal failure, mediated by the perception of methotrexate and its metabolites in the renal tubules, is a potentially life-threatening complication. Even among patients receiving all available monitoring and supportive care, severe nephrotoxicity develops in 2% of them, and the mortality for those patients is 4.4%. Dialysis methods have limited effectiveness in removing methotrexate, compared with the rapid reductions in plasma concentrations that can be achieved with carboxypeptidase G2.

Cisplatin is one of the most active agents against osteosarcoma. The toxicity of this agent is substantial, however: Hearing loss and renal impairment can be permanent for some patients. Substitution of carboplatin for cisplatin was investigated at St. Jude Children's Research Hospital. In the context of a multiple-agent chemotherapeutic approach with high-dose methotrexate, ifosfamide, and doxorubicin, use of carboplatin resulted in a 3-year EFS rate of 72%, an outcome comparable with that obtained with cisplatin-based therapy but with less long-term toxicity.[61] Incorporation of carboplatin in future osteosarcoma trials needs further evaluation, however, because in some reports, carboplatin as a single agent has been found to have poor antitumor effect in the treatment of metastatic disease.[70]

Approximately 20% of patients with osteosarcoma have clinically detectable metastatic disease at diagnosis, and their outcome usually is very poor.[22,23] Optimal treatment for these patients entails a very aggressive multimodality approach that combines intensive preoperative and postoperative chemotherapy with resection of both the primary tumor and metastatic lesions. When these guidelines are followed, contemporary protocols that incorporate ifosfamide or the combination of ifosfamide and etoposide, along with high-dose methotrexate, doxorubicin, and cisplatin, result in 2- to 5-year progression-free survival rates of 25% to 45%.[58,69,71] For patients with recurrent osteosarcoma, a very aggressive surgical approach is recommended; the 5-year postrelapse survival rate for patients in whom a complete resection of all macroscopic disease can be achieved is close to 40%.[72]

In a small number of patients (3% to 5%), metachronous osteosarcoma can develop after primary treatment. This has been associated with the presence of germline *TP53* (Li-Fraumeni) or *RB1* gene mutations. These second primaries usually develop within 3 years from initial diagnosis, and with systemic chemotherapy and surgery, 30% to 40% of these patients can be cured.[73]

Lung metastasis develops in most patients in whom therapy fails. The ability to control pulmonary micrometastatic disease after completion of therapy would certainly result in a significant improvement in outcome. In an animal model, administration of liposome-encapsulated muramyl tripeptide phosphatidylethanolamine (L-MTP-PE) resulted in activation of pulmonary macrophages and eradication of pulmonary micrometastatic lesions.[74] Use of L-MTP-PE is an attractive strategy that deserves further clinical investigation. Other strategies under evaluation include use of new agents such as ecteinascidin-743 (ET-743), sequential administration of gemcitabine and docetaxel, administration of aerosolized granulocyte macrophage colony stimulating factor (GM-CSF) or 9-nitrocamptothecin, and use of various gene-modified interleukins.[75–77]

Some researchers have reported overexpression of HER2/erbB-2 (measured by immunohistochemistry studies) in approximately 40% of osteosarcoma tumor samples and correlation of this overexpression with more aggressive behavior and adverse outcome.[78] If this correlation holds true, the use of anti-HER2 monoclonal antibodies may be an attractive therapeutic strategy for this group of high-risk patients. Nevertheless, studies using either immunofluorescence[79] or fluorescence in situ hybridization[80] have not shown amplification of the HER2/neu gene in patients with osteosarcoma. Further complicating the issue is a more recent report showing that erbB-2 expression was associated with a better outcome.[81]

Finally, administration of high doses of the bone-seeking radiopharmaceutical samarium-153 ethylene diamine tetramethylene phosphonate (^{153}Sm-EDTMP) may provide good pain palliation with minimal nonhematologic toxicity for patients with local recurrences or bone metastasis of osteosarcoma, and its role may be expanding.[82]

EWING'S SARCOMA FAMILY TUMORS

Epidemiology

The term *Ewing's sarcoma family tumors* (ESFTs) defines a group of small round cell neoplasms of neuroectodermal origin that manifest as a continuum of neurogenic differentiation. On this continuum, Ewing's sarcoma of bone represents the least differentiated (most primitive) form of neuroectodermal tumors, and peripheral neuroepithelioma represents the most differentiated form. Ewing's sarcoma is the second most common malignant bone tumor in children and adolescents. The estimated incidence among white children younger than 15 years is 2.8 cases per 1 million population.[4] The tumor is rare in the nonwhite population, and boys are predominantly affected in most series. Most cases are diagnosed during the second decade of life.[84] The location of the tumor varies. Although most Ewing's sarcomas arise in bone, a significant proportion arise in soft tissue.[85] The most common locations for this tumor are the chest wall, pelvis, and extremities, but any bone can be involved.[84,86]

Tumor Biology

The histogenesis of Ewing's sarcoma has been a source of controversy since the first description of the tumor in 1921. Various hypotheses have been proposed in an attempt to identify the possible cell of origin in Ewing's sarcoma. Among these, cells of endothelial, pericytic, myeloid, mesenchymal, and neuroectodermal origin have been suggested.[87] The existence of either a mesenchymal stem cell or an early primitive neuroectodermal cell that has retained its ability for multilineage differentiation is the currently accepted hypothesis. It is now well accepted that ESFTs constitute a single group of neurally derived neoplasms that share unique immunocytochemical, cytogenetic, and molecular markers.[87,88]

Nearly all ESFTs have a reciprocal translocation that involves the *EWS* gene in chromosome 22q12.[89] The t(11;22) is the most commonly observed translocation (85% to 95% of cases) and juxtaposes the DNA-binding domain of the human homologue of the murine *Fli1* gene in chromosome 11 with the 5′ end of *EWS* in chromosome 22 (Fig. 99-5). The most common fusions occur between exon 7 of *EWS* and exon 6 of *FLI1* (type 1; 55% to 60% of cases) and between exon 7 of *EWS* and exon 5 of *FLI1* (type 2; 25% of cases).[89] The type of fusion transcript appears to be prognostically relevant, because type 1 fusion appears to be associated with a lower proliferative rate.[90] The t(11;22) appears to play a pivotal role in development of ESFTs because the *EWS-FLI1* fusion transcript can transform NIH 3T3 cells.[91] As many as 10% of ESFTs contain an alternative translocation between chromosomes 21 and 22. This translocation fuses the *ERG* gene on chromosome 21 and the *EWS* gene on chromosome 22, producing an *ERG-EWS* fusion transcript.[89] Finally, rare cases of ESFT contain a t(7;22)(p22;q12) that fuses the *ETV1* and *EWS* genes.[92] The mechanism by which these fusion transcripts become tumorigenic is poorly understood, although it has been postulated that this chimeric transcript can transcriptionally deregulate members of the manic fringe family of genes, which are instrumental in somatic development.[93] The IGF-I/IGF-IR pathway is actively involved in the cell transformation and inhibition of apoptosis induced by *EWS-FLI1*.[94–96]

Pathology

Microscopic examination shows that Ewing's sarcoma is the prototypical small round blue cell tumor of childhood. The ultrastructural and immunocytochemical characteristics of this and other small round cell tumors of childhood are shown in Table 99-2. Ewing's sarcoma is characterized by the presence of a dimorphic pattern of

densely packed cells with variable amounts of large clear cytoplasm. Individual cells have an ellipsoid nucleus without distinct cytoplasmic outlines. The cells are primitive, show a paucity of organelles, and often contain large amounts of intracellular glycogen. Various microscopic patterns, including the diffuse, lobular, organoid, and filigree patterns, have been described.[97] Immunocytochemical analysis shows vimentin and CD99 reactivity. The latter monoclonal antibody specifically recognizes the cell surface antigen $^{p30/p32}$MIC-2, which normally is expressed as a component of the T-cell receptor complex.[97,98] When overt neural differentiation is present, the term *peripheral neuroectodermal tumor* or *peripheral neuroepithelioma* is used (see Table 99-2). In such cases, the cells are round with more abundant cytoplasm but do not show mature neural elements, such as nerve bundles and mats of neuropile.[97] The term *extraosseous Ewing's sarcoma* has been reserved for neoplasms that cannot be differentiated from Ewing's sarcoma at light microscopic examination but arise exclusively in soft tissue.[87,97] Patients with this histologic variety accounted for 5% of all subjects in the Intergroup Rhabdomyosarcoma Study,[85] although extraosseous tumors are now managed in the same manner as for classic Ewing's sarcoma of bone. Despite these histologic distinctions, Ewing's sarcoma of bone, extraosseous Ewing's sarcoma, primitive neuroectodermal tumors, and peripheral neuroepithelioma are unified by the presence of the same oncogenic events and should therefore be considered the same neoplasm and managed in a similar manner. The advent of molecular diagnostic techniques has allowed development of sensitive tests, such as reverse transcriptase-polymerase chain reaction (RT-PCR) analysis, which is accurate in detection of *EWS-FLI1* and *EWS-ERG* fusion transcripts at levels well below those commonly found with routine cytogenetic studies.[99] RT-PCR assay is a useful adjunct in the diagnosis of Ewing's sarcoma, particularly in differentiation from other soft-tissue small round cell tumors, such as rhabdomyosarcoma.

Clinical Manifestations

Ewing's sarcoma commonly manifests during the second decade of life (median age, 13 years) with localized pain and a visible palpable mass.[84,100] Fewer than 3% of cases occur in children younger than 3 years.[101] Boys are more commonly affected than girls. Pathologic fractures may be present in as many as 15% of children and adolescents before diagnosis.[102] Back pain, extremity weakness, or altered sensation should raise suspicion for the presence of primary or metastatic disease. Systemic manifestations such as fever are more frequent than in osteosarcoma. Almost one half of patients have signs and symptoms referable to the primary tumor for more than 3 months before the diagnosis is made. Ewing's sarcoma has a tendency to involve the shaft of long tubular bones, pelvis, and ribs, but almost every bone can be affected. More than 50% of the tumors arise from axial bones, the pelvis being the most commonly involved (25%); one third of the tumors originate in the lower extremities, and less than 10% in the upper extremities. Chest wall Ewing's sarcoma is known as *Askin's tumor* (Fig. 99-6). Approximately 20% to 25% of patients with this tumor have metastatic disease when they present for evaluation. The most common sites of metastatic disease are in the lungs, followed by the bones and bone marrow. Metastatic disease appears to be associated with older age and with large tumor or pelvic primaries.

Laboratory and Radiologic Evaluation

Patients with suspected Ewing's sarcoma should be thoroughly evaluated to define the extent of local disease and the presence of metastatic lesions. Initial laboratory studies include complete blood cell count and erythrocyte sedimentation rate; measurement of serum electrolytes; LDH assay; renal and liver function tests; determination of alkaline phosphatase, calcium, phosphorus, and magnesium levels; and coagulation profile. In Ewing's sarcoma, elevation of erythrocyte sedimentation rate and of serum LDH is not uncommon. Bone marrow aspiration and biopsy should be performed, and evaluation with molecular techniques such as RT-PCR is recommended. Important imaging studies are chest radiography, plain radiography of primary and metastatic sites, bone scintigraphy, CT of the chest, and MRI of the primary site with T_1- and T_2-weighted sequences, as well as DEMRI.[26,103]

In Ewing's sarcoma, plain radiographs typically show a diaphyseal destructive lesion with a laminated periosteal reaction and large soft-

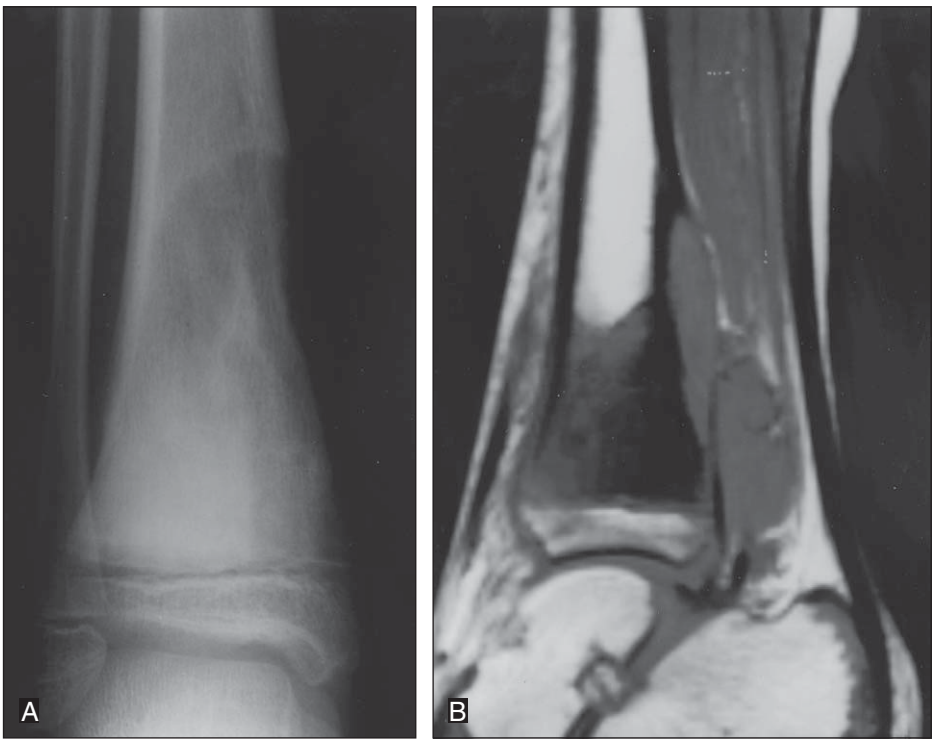

Figure 99-7 • Ewing's sarcoma of the right distal tibia. **A,** Plain radiograph shows a poorly marginated destructive lesion with associated periosteal reaction. **B,** Sagittal T_1-weighted magnetic resonance image of the same lesion shows a well-demarcated dark area of low signal intensity defining the intramedullary extent of the tumor contrasted against the bright appearance of the high signal intensity derived from intramedullary fat. The soft-tissue component of the tumor is evident in the posterior aspect.

tissue mass (Fig. 99-7A). We favor MRI over CT for defining the intramedullary component of the primary tumor and the extent of soft-tissue mass (see Fig. 99-7B). In contrast with the situation in osteosarcoma, DEMRI findings are not a reliable prognostic indicator.[104] Newer techniques such as positron emission tomography (PET) appear to be useful in noninvasive evaluation of response to chemotherapy.[105]

Prognostic Factors

A variety of initial clinical features have been correlated with outcome of therapy for Ewing's sarcoma. Two major European retrospective studies analyzed factors that are prognostically important in Ewing's sarcoma.[84,86] Both studies included patients who participated in different European protocols over a 25-year period. The results confirmed the classic clinical features associated with poor prognosis, such as metastatic disease, older age, large tumor size, and trunk and pelvic primary sites. Both studies, however, also showed that with refinement in the multidisciplinary approach to this disease that entails newer and more intensive chemotherapeutic regimens and superior local control measures, some of these classic prognostic factors are being redefined.

Although large tumor size classically has been associated with worse prognosis, this feature may be less important with more aggressive treatment. For example, in the early St. Jude studies, tumors larger than 8 cm in diameter were associated with worse prognosis.[106] However, tumor size disappeared as a prognostic factor in the more intensive St. Jude EW92 protocol.[99] In the first Cooperative Ewing's Sarcoma Study (CESS-81), tumors larger than 100 cm^3 were associated with worse outcome.[107] With treatment improvements, the tumor size associated with worse prognosis has increased to 200 cm^3.[108]

Tumor location also seems to be losing its prognostic significance with newer treatments: Although pelvic and axial tumor locations classically were associated with worse outcome in the early studies,[106,110,111] differences in outcome were minimal in subsequent studies.[109,112,113] The first Pediatric Oncology Group–Children's Cancer Group Ewing's sarcoma trial (POG-8850/CCG-7881), an investigation of the effect of addition of ifosfamide and etoposide to the standard VACD regimen (vincristine, actinomycin D, cyclophosphamide, and doxorubicin), showed that addition of the drug pair abrogated the negative prognostic implications of large tumor size (greater than 8 cm in diameter) and pelvic location. Of note, the benefit of addition of ifosfamide and etoposide was not seen in patients older than 18 years.

A newer prognostic factor is degree of histologic response to chemotherapy.[114,115] European studies consistently have shown the prognostic value of histologic response, the significance of which stands across protocols and appears to be independent of the drugs used. Patients with good histologic responses had a significantly better outcome than those with poor responses in the consecutive REN-1, -2, and -3 trials in Italy[86,115] and in the CESS-81[100] and CESS-86[116] trials in Germany. Thus degree of histologic response appears to be one of the most relevant prognostic factors. Type of fusion transcript also seems to influence the clinical behavior of ESFTs. Although the biologic behavior of tumors with fusion *EWS-FLI1* does not differ from the behavior of tumors with *EWS-ERG* fusion,[117] the type of *EWS-FLI1* fusion may significantly affect prognosis. The hybrid transcripts resulting from fusion of exons 7 and 6 of the *EWS* and *FLI1* genes, respectively (type 1 fusion), seem to result in sarcoma of a less aggressive behavior than that observed for other fusion types.[118,119] Because ESFTs manifest a continuum of neuroectodermal differentiation, the histologic diversity may reflect different biologic behaviors. Evidence is lacking, however, for correlation of degree of neuroectodermal differentiation with prognosis.[120] The most important prognostic factor is the presence of metastatic disease at diagnosis.[76] Advances in management of ESFTs have resulted in only very modest improvement in outcome among patients with metastatic lesions.[84,109,121] Even among patients with metastatic disease, heterogeneity is common. With an appropriately intensive treatment that includes bilateral lung irradiation, the European Intergroup Cooperative Ewing's Sarcoma Studies (EICESSs) have shown that patients with isolated metastatic lesions in the lung may have a better prognosis, albeit still inferior to that for patients with localized disease. Patients with extrapulmonary metastasis have a worse prognosis.[122,123]

With the use of molecular techniques in the staging of ESFTs, it is evident that a significant proportion of patients with localized disease (20% to 30%) have micrometastatic disease in the bone marrow detected by PCR assay.[124–126] In patients with lung metastasis and those with bone metastasis, this proportion is 40% and 90%, respectively.[125] The prognostic significance of this microstaging for patients with localized disease is still unclear. Although the presence of tumor cells in peripheral blood may lack significance, detection of tumor cells in bone marrow by molecular techniques may be predictive of unfavorable outcome.[125,126]

Treatment

Before the introduction of systemic chemotherapy, less than 20% of children with Ewing's sarcoma treated with either surgery or radiation therapy alone were expected to be long-term survivors.[127] In the past 3 decades, major advances have been made in the management of Ewing's sarcoma. These advances derive largely from cooperative trials (Table 99-3). The first studies conducted by the Intergroup Ewing Sarcoma Study (IESS) showed the importance of adjuvant chemotherapy that included a combination of alkylating agents and anthracyclines (IESS-I and -II).[112,128] Thereafter, conventional management of Ewing's sarcoma included local control measures in combination with administration of VACD.[106,109,111] More recently, incorporation of ifosfamide (VAID) has resulted in modest benefit for patients with high-risk features.[113,116] Preclinical and clinical evidence indicates that combined administration of etoposide and alkylators has a synergistic antitumor effect[63–65,129] and that with both types of agent, efficacy improves with fractionated administration.[130–133] Combined administration of ifosfamide and etoposide (IE) has been shown to be very active in patients with Ewing's sarcoma who have not received previous treatment.[134] Two randomized studies were conducted to investigate the effect of adding etoposide to VACD or VAID regimens.[135,136] In EICESS-92, patients with localized high-risk disease (tumor diameter greater than 200 cm^3) receiving VAID did not seem to benefit from the addition of etoposide.[136] The first Pediatric Oncology Group–Children's Cancer Group Ewing's sarcoma trial (POG-8850/CCG-7881) was an investigation of incorporation of the IE combination in frontline management of ESFTs. Patients were randomized to receive VACD with or without IE.[135] Patients receiving IE plus VACD appeared to have a more favorable outcome.[135,137]

Incorporation of granulocyte colony stimulating factor (G-CSF) into treatment regimens for many types of cancer has allowed modest dose intensification of multiple-agent chemotherapy by increasing the total dose per cycle[109,138,139] or shortening the time between treatments.[140] For ESFTs, this strategy is based on using high cumulative doses of alkylating agents and topoisomerase-II inhibitors.[109,140] When these general treatment guidelines are followed, the disease-free survival rate for patients with localized, low-risk disease approaches 70% to 75%, and the overall survival rate for this group of patients may be greater than 80%.[109]

The importance of dose intensification in the management of ESFT was evaluated in the second Pediatric Oncology Group–Children's Cancer Group Ewing's sarcoma trial (POG-9354/CCG-7942). In that trial, patients were randomized to receive alternating courses of vincristine, doxorubicin, and cyclophosphamide with ifosfamide and etoposide over either 48 or 30 weeks. The early results of that randomized trial demonstrated no difference in outcome between the standard and the dose-intensified treatment groups.[141] An alternative to increasing dose intensity is decreasing the intervals between cycles while maintaining the same dose per cycle with the use of G-CSF. In the United States, this is the approach taken by the COG in the recently completed AEWS-0031 study, in which patients were randomized to receive alternating cycles of VCD and IE every 3 weeks or two weeks, which results in 33% dose intensification.

Despite improvement, the prognosis for patients with metastatic disease continues to be very poor, and only 20% to 25% survive[121,122,142] (Table 99-4). Several institutions have used treatment intensification, by which very high doses of different agents are administered in a short time. In the case of ESFTs, this is a very attractive alternative, because ESFTs are highly sensitive to alkylating agents, which have a steep dose-response curve. Although most patients with ESFTs treated in this manner may exhibit good clinical and histologic responses, the final results are not better than those obtained with conventional therapy.[138,143,144]

Other protocols have been used to investigate the possibility of maintaining intensive treatments for more extended periods in an attempt to improve outcome for all patients with Ewing's sarcoma. At St. Jude Children's Research Hospital, the EW92 protocol was used to evaluate the feasibility of aggressive early induction with vincristine, cyclophosphamide, doxorubicin, ifosfamide, and etoposide (VCDIE), followed by prolonged maintenance therapy with intensification of alkylating agents and etoposide[109] (Box 99-2). The results were not better than less aggressive regimens for patients with localized disease, and no significant benefit was obtained for patients with metastatic disease. Important findings were that only 66% of patients completed therapy and that intensification was feasible in only 25% of the patients.

Use of protocols that include intensification of alkylators and topoisomerase-II inhibitors has resulted in a significant increase in the incidence of treatment-related leukemia—specifically, acute myelogenous leukemia (AML)—and myelodysplastic syndrome (t-AML/MDS). This therapeutic strategy appears to be strongly leukemogenic, and patients are at increased risk for development of both alkylator-related and etoposide-related t-AML/MDS.[143,145,146] With current therapies, the cumulative incidence of t-AML/MDS 5 years after treatment is 8% to 10%. This increased risk of t-AML/MDS appears to be related to both the increase in the total cumulative doses and dose intensification. The role of hematopoietic growth factors in this complication is unknown.

New drugs and new drug combinations continue to be investigated in the care of patients with Ewing's sarcoma. Although phase I and II studies of topotecan and irinotecan as single agents have shown little or no activity in patients with refractory disease, recent studies suggest that their combination with alkylating agents may be more promising. Phase II studies of the combination of topotecan (0.75 mg/m^2 per day for 5 days) and cyclophosphamide (250 mg/m^2 per day for 5 days) resulted in responses in 36% of patients with recurrent disease[147] and in 56% of patients with untreated metastatic disease.[148] The COG is currently investigating the incorporation of this combination in the frontline treatment of ESFTs, given in alternating cycles with VDC and IE. Also recently, the combination of irinotecan on a protracted schedule (10 to 20 mg/m^2 per day for 5 days in 2 consecutive weeks) with temozolomide (100 mg/m^2 per day for 5 days) has shown excellent response rates.[149]

Advances in management of ESFTs have resulted in only modest improvement in outcome among patients with metastatic disease.[84,109,121] With appropriately intensive treatment that includes bilateral lung irradiation, however, the prognosis for patients with isolated lung metastasis may be better than for patients with extrapulmonary metastasis.[122,123] For patients with bone and bone marrow metastasis, therefore, more intense therapies may have a role. ESFTs are very sensitive to alkylators, a group of agents with a very steep dose-response curve, which provides the basis for the use of consolidation with myeloablative therapy and autologous hematopoietic stem cell transplantation (HSCT). The results of treatment with megatherapy and HSCT for patients with high-risk ESFTs must be analyzed with caution because of the lack of randomized studies and the heterogeneity of patients and treatments. Results of most retrospective European and American studies do not seem to support the use of this approach.[122,150–152] In more recent results reported by the European Bone Marrow Transplant Registry, however, conditioning regimens that incorporate high doses of alkylating agents, generally busulfan and melphalan, confer an apparent survival advantage.[153,154]

Box 99-2. ST. JUDE CHILDREN'S RESEARCH HOSPITAL APPROACH TO MANAGEMENT OF EWING'S SARCOMA FAMILY TUMORS

At St. Jude Children's Research Hospital, for patients with nonmetastatic disease, regardless of the size and site of the tumor, intensive multiple-agent chemotherapy, with alternating courses of vincristine, cyclophosphamide, and doxorubicin with ifosfamide and etoposide, is used. Local control is undertaken after completion of approximately four courses of induction chemotherapy. If the disease is considered resectable, surgery is the treatment of choice for local control, and it is always performed with curative intent. Radiation therapy is used for unresectable disease and for close or microscopic surgical margins. The same approach is followed for patients with metastatic disease to the lungs, only with addition of radiation therapy to the lungs.

For patients with bone or bone marrow metastasis, the role of intensive chemotherapy and consolidation with high-dose chemotherapy and autologous hematopoietic stem cell rescue is under ongoing evaluation. In these patients, aggressive surgical resection for local control of the primary tumor and bone metastases is performed.

All patients with recurrent disease receive second-line systemic therapy. Patients with local recurrence undergo aggressive surgery when possible, and patients with metastatic disease to the lungs receive whole-lung irradiation.

Total-body irradiation does not seem to provide any additional benefit and only adds toxicity.[152,153] The European Cooperative Group is conducting a randomized study to evaluate the role of HSCT in the care of patients with metastatic Ewing's sarcoma.

Improvement in outcome among patients with ESFT also must be attributed to improvement in local control, which is largely related to advances in planning radiation therapy[107,108] and better surgical approaches. Advances in systemic therapy by means of incorporation of new drugs and treatment intensification also appear to contribute to better local control.[113,155–157] With current multimodality intensive protocols, rates of local recurrence have decreased significantly, and little difference in efficacy has been observed between surgery and radiation therapy for local control.[109,155,156,158] Surgery continues to offer slightly better results, but this observation is biased by the fact that small lesions are more likely to be managed surgically.[111,159–161] For unresectable tumors or in case of gross residual disease, recommended doses are 55 to 60 Gy. Doses of 40 to 45 Gy are used for microscopic disease. The risk of secondary sarcoma after radiation therapy is not negligible.[162] This risk is dose-dependent, but use of lower doses of radiation therapy has been associated with higher local recurrence rates.[163]

NEUROBLASTOMA

Epidemiology

Neuroblastoma is the most common extracranial solid tumor of childhood, accounting for 8% to 10% of all pediatric cancers.[164] In

the United States, the annual incidence is approximately 8 new cases per 1 million children per year with 550 newly diagnosed cases. The median age at diagnosis is 2 years. Most (85%) of the cases are diagnosed by the age of 5 years. Neuroblastoma is extremely rare in children older than 10 years. Familial cases occur. Neuroblastoma also has been found in patients with neurofibromatosis, Hirschsprung's disease, Beckwith-Wiedemann syndrome, and fetal hydantoin syndrome.[165–169] Microscopic neuroblast nodules are found in the adrenal glands of 2% to 3% of infants who die of nonmalignant causes before 3 months of age.[170] It is uncertain whether these nodules represent spontaneous regression of congenital neuroblastoma or maturation of the tumor into asymptomatic benign tumors.

Mass screening programs for detection of neuroblastoma in early infancy with assays for urinary catecholamine metabolites have been conducted in Japan, Germany, and the United States.[171–173] In general, patients with neuroblastoma detected in these programs have early-stage disease and enjoy otherwise excellent outcome.[174,175] Mass screening, however, has not resulted in a reduction in deaths from neuroblastoma. In addition, early detection has not changed outcome among patients with tumors that have biologic features associated with a poor prognosis.

Tumor Biology

Neuroblastoma originates in neural crest cells of the sympathetic nervous system and, not unexpectedly, secretes a variety of neurogenically derived substances, including catecholamines, neuron-specific enolase (NSE), and ferritin.[176–178] Urinary excretion of abnormally high levels of catecholamine metabolites occurs in 75% to 90% of patients and is related to the degree of tumor differentiation. The metabolites most often measured in evaluation of suspected neuroblastoma are urinary vanillylmandelic acid and homovanillic acid. Levels of these catecholamines are sensitive indicators of disease status. At diagnosis, other biologic markers, such as NSE, serum ferritin, and ganglioside G_{D2}, are present in high concentration in the serum of most patients with neuroblastoma.[179–182] None of these biologic markers is specific, but their presence at diagnosis may be associated with the extent of disease.

Cytogenetic studies of neuroblastoma have demonstrated chromosomal abnormalities in most cases. The most common cytogenetic abnormalities in neuroblastoma are double-minute chromatin bodies (DM), homogeneously staining regions (HSRs), and nonrandom deletion or loss of heterozygosity of the short arm of chromosome 1.[183–187] DMs and HSRs both represent cytogenetic manifestations of amplified sequences of the *MYCN* cellular oncogene.[188,189] Amplified *MYCN* (more than 10 copies per cell) is a feature in approximately 30% of neuroblastomas. It is associated with the presence of advanced disease at diagnosis and poor outcome, even in patients who have early-stage disease or who come to medical attention in infancy.[190,191] The DNA content of the tumor (ploidy) has been shown to correlate with therapeutic outcome and survival among infants with this tumor. Infants with hyperdiploid tumors (DNA index greater than 1.0) have a more favorable outcome than those with diploid tumors (DNA index, 1.0).[192–194] Results suggest that the presence of either *MYCN* amplification or diploid cellular DNA tumor content identifies whether an infant has a poor prognosis with current therapeutic regimens, independent of stage.[193,195,196] For children older than 24 months with disseminated disease, however, the DNA content of the tumor does not appear to have prognostic importance.[192,194] Recent studies suggest that additional cytogenetic imprints such as loss of heterozygosity at 1p36 and 11q23 confer an aggressive phenotype.[197]

Pathology

Neuroblastoma is one of the small round blue cell tumors of childhood. It originates from neural crest cells from within the sympathetic nervous system. Neuroblastoma can be classified pathologically into three broad histologic subgroups: neuroblastoma, ganglioneuroblastoma, and ganglioneuroma[198,199] (Fig. 99-8). These subgroups appear to recapitulate stages in the normal differentiation of neural crest stem cells. For example, neuroblastoma is the most primitive entity and is characterized by diffuse growth of undifferentiated neuroblastic cell nests irregularly separated by thin fibrovascular septa[200,201] (see Fig. 99-8A). By contrast, benign ganglioneuroma consists of mature ganglion cells embedded in bulky stroma composed of Schwann cell sheets enveloping neuritic processes and perineural and endoneural elements (see Fig. 99-8C). Between these two extremes is the transitional form known as ganglioneuroblastoma (see Fig. 99-8B). These transitional forms have been subclassified into intermixed and nodular diffuse ganglioneuroblastoma. Composite (nodular) tumor is a ganglioneuroma that contains one or more discrete nodules of pure neuroblastoma. Intermixed (diffuse) tumor contains a mixture of primitive and differentiating neuroblasts with bizarre, immature, and mature ganglion cells. Patients frequently have tumors with mixtures of these cell types, and evidence supports the clinical observation that neuroblastoma can sometimes mature into benign ganglioneuroma. Spontaneous regression and therapy-induced maturation can occur.[202]

In 1999, the International Neuroblastoma Pathology Classification was established to standarize the terminology and criteria for the prognostic evaluation of the morphologic features of neuroblastic tumors in an age-linked framework.[200]

Clinical Manifestations

The clinical manifestations of neuroblastoma are varied. Nonspecific constitutional signs and symptoms, such as fever, general malaise, and pain, are frequent initial features. The most common sites of primary tumors are the abdomen (adrenal gland or paraspinal ganglia) and the thorax (usually the posterior mediastinum). In infants, the distribution is slightly different in that a higher proportion of primary tumors occur in the thoracic cavity than is the case in older children. Common manifestations include a hard, painless mass in the neck, a localized intrathoracic mass found incidentally on a chest radiograph, and a palpable abdominal mass, according to the location of the tumor. A palpable abdominal mass can result from an enlarging primary adrenal or retroperitoneal tumor or from hepatomegaly secondary to tumor metastasis. Children may appear chronically ill and irritable and have periorbital ecchymosis, scalp nodules, and bone pain from widespread metastasis to the bone marrow or bone (Fig. 99-9; see also Fig. 99-8D). Lower limb paresis secondary to epidural extension of a primary paraspinal tumor growing through the intervertebral foramen can cause signs of spinal cord compression. Intermittent abdominal pain, malaise, failure to gain weight, and recurrent, unexplained fever may be present for prolonged periods before neuroblastoma is diagnosed.

Seventy-five percent of patients with neuroblastoma have metastatic disease at the time of diagnosis. The most common sites of metastasis are lymph nodes (local or distant), bone marrow, liver, skin, orbit, and bone (facial bones, skull, appendicular skeleton). Nearly one half of patients have widespread skeletal metastasis at diagnosis.[203,204] The bones of the skull and orbit frequently are affected, so proptosis, ecchymosis, and masses beneath the scalp are frequent findings (see Fig. 99-9). Lung metastatic lesions are extremely uncommon when the patient is first examined.[205] Horner's syndrome (ipsilateral miosis, ptosis, and anhydrosis) may be present in patients with lesions originating in the cervical or upper thoracic sympathetic ganglia. Less frequent is the syndrome of opsomyoclonus, manifested as acute cerebellar encephalopathy, truncal ataxia, and rapid and random eye movements (so-called dancing eyes, dancing feet).[206] The pathophysiologic mechanism of this syndrome is unknown, but metabolic and immunologic causes have been invoked. A syndrome of chronic watery diarrhea also may occur in patients with neuroblas-

toma. Increased serum levels of vasoactive intestinal peptide, which lead to increased intestinal motility and secretions, have been found in some cases.

Laboratory and Radiologic Evaluation

When neuroblastoma is suspected, evaluation should be performed to establish the diagnosis, determine the extent of disease, and obtain tumor material for molecular and genetic analyses. The physical examination should include special attention to look for blood pressure abnormalities, asymmetrical pupil size, facial sweating, lower limb weakness and other signs of spinal cord compression, and evidence of increased intracranial pressure. In addition, during the clinical examination, the size of palpable masses, enlarged lymph nodes, cutaneous lesions, and the liver should be carefully documented.

Laboratory studies include complete blood cell count, renal and liver function studies, coagulation screen, urinalysis, and urine catecholamine assay. Serum often is obtained for NSE, ferritin, and ganglioside G_{D2} determinations because the results may be helpful in prognosis.[177,207–209]

Staging of neuroblastoma requires radiologic studies and marrow aspiration and biopsy to determine the extent of local disease and distant spread. The minimal evaluation for metastatic disease includes radionuclide skeletal scintigraphy and bone marrow aspiration. CT generally has replaced intravenous pyelography, arteriography, and inferior vena cavography (Fig. 99-10). Ultrasonographic studies of the abdomen and pelvis may be useful in evaluation of mass lesions and the degree of compression of vital structures causing secondary complications. MRI may further improve the accuracy of determination of the anatomic extent of disease, especially in evaluation of tumors impinging on the spinal cord and assessment for the presence of hepatic metastasis.[210] CT- or MRI-based myelography is necessary in evaluation of all patients with neurologic evidence of cord involvement.[211] Scans performed with radionuclides such as ^{131}I-*m*-iodobenzylguanidine (MIBG) may be more accurate and sensitive for detection of nonosseous as well as osseous disease.[212] Newer modalities such as neural cell-specific monoclonal antibody conjugated to ^{131}I or ^{123}I currently are investigational. When tumor material is obtained, it should be submitted for determination of DNA content (tumor cell ploidy), detection of *MYCN* genomic amplification, and cytogenetic analysis.

The differential diagnosis suggested by the early manifestations of the tumor is broad because the initial signs and symptoms can be so vague. The presence of an abdominal mass may suggest Wilms' tumor, hydronephrotic kidney, enlarged spleen or liver, lymphoma, germ cell tumor, and mesenteric cyst. Compression of vital structures in the neck and mediastinum can cause superior vena cava syndrome indistinguishable from that caused by other tumors.[213] Persistent diarrhea suggests the presence of a malabsorptive state. Arterial hypertension may be attributed to intrinsic renal disease or pheochromocytoma.[214] Bone pain can simulate rheumatic fever, rheumatoid arthritis, osteomyelitis, and acute leukemia. When initial signs are attributable to widespread lymphatic metastasis, a broad range of possibilities in the differential diagnosis, including primary tumor of the lymphoreticular system, storage disease, acute infection, and primary hematologic disorder, must be considered.

The diagnosis of neuroblastoma is established by pathologic evaluation of tumor tissue obtained at biopsy or by documentation of bone marrow involvement at bone marrow trephine biopsy or aspiration with the presence of characteristic clumps or syncytia of tumor cells, together with increased urine or serum levels of catecholamines or metabolites.[215] If the histologic diagnosis is equivocal, genetic features characteristic of neuroblastoma, such as deletion of 1p or *MYCN* genomic amplification, support the diagnosis.

Several staging systems have been used to classify disease extent. The Evans and Pediatric Oncology Group staging systems historically were the most widely used in the United States. To facilitate comparison of clinical studies, the International Neuroblastoma Staging System (INSS; Table 99-5), which is based on clinical, radiographic, and surgical evaluation, was developed by consensus of major pediatric oncology groups in the United States, Europe, and Japan.[216–219] The INSS uses the most important components of the Evans (e.g., midline extension) and the Pediatric Oncology Group (e.g., histologically positive or negative lymph nodes) systems. The main differences between these systems relate to surgical-pathologic staging and definitions distinguishing grossly unresected localized tumors from regional disease.[219]

Prognostic Factors

Although many factors have been investigated and purported to have prognostic significance in neuroblastoma, the most significant in prediction of cure are patient age and stage at diagnosis.[220] Children with low-stage disease have a good prognosis, regardless of age. In general, extent of disease at diagnosis is inversely related to cure. In infants, the DNA content of tumor cells has been reported to be

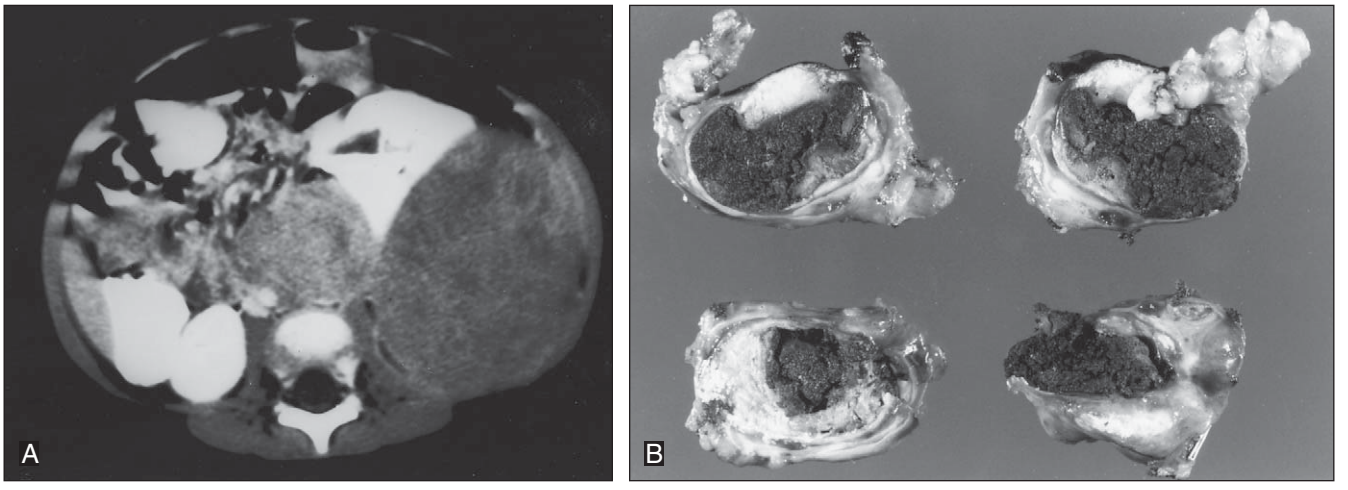

Figure 99-10 • **A,** Computed tomographic scan shows adrenal neuroblastoma at diagnosis. **B,** Serial sections through a resected adrenal neuroblastoma show large areas of diffuse hemorrhage and calcification.

Table 99-5 International Staging System for Neuroblastoma

Stage	Description
1	Localized tumor confined to area of origin; complete gross excision with or without microscopic residual disease; identifiable ipsilateral and contralateral lymph nodes microscopically negative
2A	Unilateral tumor with incomplete gross excision; identifiable ipsilateral and contralateral lymph nodes microscopically negative
2B	Unilateral tumor with complete or incomplete gross excision; positive ipsilateral lymph nodes; identifiable contralateral lymph nodes microscopically negative
3	Unresectable unilateral tumor infiltrating across the midline with or without regional lymph node involvement; or unilateral tumor with contralateral lymph node involvement; or midline tumor with bilateral lymph node involvement
4	Metastatic tumor involvement to distant lymph nodes, bone, bone marrow, liver, or other organs (except as defined in stage 4S)
4S	Localized primary tumors as defined in stage 1 or 2 with dissemination limited to liver, skin, or bone marrow involvement <10% (but not bone); limited to infants younger than 1 year of age

predictive of response to chemotherapy and ultimate outcome. Infants with hyperdiploid tumors fare better than do those with diploid tumors.[194] In children with metastatic disease, the most significant prognostic variable is age at diagnosis. Children younger than 12 months at diagnosis have a significantly greater chance of cure.[221,222] In older children with disseminated disease, the prognosis is dismal, although improvements in response and survival have been reported with modern treatment modalities.

A variety of biologic markers of neuroblastoma have been used to identify whether a patient is at prognostically low, intermediate, or high risk. These markers include tumor markers such as urinary catecholamine excretion and serum levels of ferritin, NSE, LDH, and ganglioside G_{D2}. Histologic subclassification based on degree of differentiation or presence or absence of stroma, mitoses, or karyorrhexis also has been used as a prognostic indicator (Shimada histopathologic classification). However, identification of various biologic and genetic features, such as the karyotype, DNA index determined by flow cytometry, *MYCN* copy number, deletion of chromosomal regions on 1p, P-glycoprotein expression, and expression of the nerve growth receptor TRK-A, has defined subsets of patients with different outcomes after therapy.[184,195,196,223,224] For example, *MYCN* amplification can be used as a marker of poor outcome independent of age, whereas TRK-A appears to be a marker of favorable outcome.[225,226] Clinical studies are being conducted in an attempt to correlate the most informative combination of biologic markers, age, and stage to develop appropriate risk-directed therapies (Table 99-6).

Treatment

A complete pathologic evaluation in conjunction with assessment of clinical features is important, because management of neuroblastoma is based on extent of disease. Accurate staging of the tumor at diagnosis is essential. Staging includes diagnostic imaging, pathologic

Table 99-6 Risk Categorization for Neuroblastoma on the Basis of Clinical and Biologic Features

INSS Stage	Age	*MYCN* Status	Shimada Features	DNA Ploidy*	Risk Group
1	0–21 yr	Any	Any	Any	Low
2A/2B	<365 d	Any	Any	Any	Low
	≥365 d–21 yr	Nonamplified	Any	—	Low
	≥365 d–21 yr	Amplified	Favorable	—	Low

	<365 d	Nonamplified	Any	1	Intermediate
	<365 d	Nonamplified	Unfavorable	Any	Intermediate
	<365 d	Amplified	Any	Any	High

INSS, International Neuroblastoma Staging System.

*DNA ploidy: DNA index (DI) >1 or 1. Hypodiploid tumors (DI <1, considered favorable ploidy) are treated as tumors with DI >1. *Note*: This risk categorization is current but will be modified as new clinical trials validate its use.

assessment of lymph node involvement in locoregional disease, liver biopsy in the case of primary abdominal disease in infants, and determination of the presence of hematogenous dissemination (usually to bone or to bone marrow).[227] Patients with tumors localized to one side of the midline or that cross the midline without encasement of major blood vessels are candidates for primary surgical resection.[228–230] With local disease, complete gross surgical resection gives an excellent chance of cure without additional therapy. If the patient has localized unresectable disease, surgical procedures that carry a high potential for morbidity should be avoided because of the excellent outcome with chemotherapy in this setting. If the tumor cannot be excised because it encases major blood vessels, surgery is performed for diagnostic purposes or for palliation if the tumor is compressing a vital organ. With dumbbell tumors with spinal cord compression, for example, rapid response to chemotherapy generally obviates laminectomy.[231] In patients who have disseminated disease when they come to medical attention, initial aggressive surgical approaches have been shown to be of no significant benefit. The potential benefit of resection of bulky primary tumors after reductive chemotherapy in disseminated disease (delayed or second-look resection) is currently under investigation.

Radiation therapy often is used for management of neuroblastoma and is particularly useful in the management of patients with tumors that are localized but unresectable, even after initial chemotherapy and second-look surgery. Because of the high frequency of metastatic disease, radiation therapy has a relatively limited role in initial overall treatment for a child with neuroblastoma. Indications for radiation therapy include control of local tumors unresponsive or resistant to chemotherapy and not amenable to surgical extirpation, palliative management of unresectable or metastatic disease, and management of 4S neuroblastoma (in selected cases). The last indication is based on the observation that infants with bona fide stage 4S disease sometimes respond to subtherapeutic doses of radiation (400 to 800 cGy) delivered to ports that do not encompass all known sites of disease.

Chemotherapy is the primary modality of treatment for most children with neuroblastoma, because the disease frequently is widespread at diagnosis.[232–234] Box 99-3 outlines the approach to management of neuroblastoma used at St. Jude Children's Research Hospital. A variety of single agents (cyclophosphamide, melphalan, doxorubicin, cisplatin, epipodophyllotoxin, vincristine) produce responses in patients with neuroblastoma, but significant and durable responses have been achieved only with combination chemotherapy.[235–237] In general, pairs of these drugs, such as cyclophosphamide plus doxorubicin or cisplatin plus etoposide, delivered in a cytokinetically rational manner, are more effective in producing responses than are single agents. Although improvement in survival of infants with advanced-stage disease and children with locally unresectable disease has resulted from implementation of various chemotherapeutic regimens, the outlook for older children with advanced disease has not changed dramatically. Only 20% to 25% of these patients are alive at 5 years from diagnosis.[238] Among older children, however, the complete response rate and disease-free interval have increased with more intensive combination chemotherapy, encouraging further development and refinement of this therapy. Recent studies report a subset of 12- to 18-month-old children with favorable tumor biologic features who have a much greater chance of survival with intensive therapy.[222]

Some current therapeutic regimens for neuroblastoma are so intensive that myelosuppression can be the dose-limiting toxicity. This problem can be overcome with hematopoietic stem cell transplantation. High-dose chemotherapy with bone marrow transplantation may be useful in the care of patients with a poor long-term prognosis who have achieved complete remission or at least substantial partial remission with chemotherapy.[239–243] The propensity of neuroblastoma to involve bone marrow has spurred development of various purging strategies, including tumor cell depletion with monoclonal antibodies and ex vivo chemotherapy, to facilitate autologous transplantation. Results with various transplantation protocols, both autologous and allogeneic, suggest a modest survival advantage for these aggressive regimens.[243,244]

Improvements in supportive care, including use of hematopoietic growth factors, may allow shortening of the intervals between treatment courses. They also may allow increases in the dose intensity of currently available chemotherapeutic agents in the treatment of patients with advanced-stage disease and decreases in toxicity among infants. In addition, parallel clinical studies of newer biologic therapies, such as those using differentiation agents and immunomodulators, in a setting of minimal residual disease or genetically engineered tumor vaccines are expected to form the basis for future therapeutic gains.[245,246]

Box 99-3. ST. JUDE CHILDREN'S RESEARCH HOSPITAL APPROACH TO MANAGEMENT OF NEUROBLASTOMA

At St. Jude Children's Research Hospital, a risk-categorization algorithm is used in which therapy for neuroblastoma is prescribed on the basis of clinical and biologic features. For patients with completely resected tumors independent of age or tumor biology, no additional treatment is indicated after surgery; recommended management consists of close monitoring and follow-up evaluation. In the event of disease recurrence, further surgical treatment with or without chemotherapy is instituted. Similarly, patients younger than 1 year of age with incomplete resection or limited nodal metastasis (in the absence of unfavorable biologic features) undergo no further therapy after surgery. Patients younger than 1 year with unresectable tumors (i.e., stage 3) and absence of the *MYCN* gene amplification receive a shortened course of chemotherapy comprising cyclophosphamide, doxorubicin, etoposide, and carboplatin. Chemotherapy is administered to patients with epidural tumor in an attempt to avoid laminectomy. All patients older than 1 year with metastatic disease or with unfavorable biologic features (e.g., *MYCN* gene amplification) or histologic findings are enrolled in research protocols that incorporate an induction phase with alkylating agents (e.g., cyclophosphamide), cisplatin, doxorubicin, and etoposide followed by surgery for removal of the primary lesion and a consolidation phase with high-dose chemotherapy, with or without irradiation and autologous hematopoietic stem cell transplantation, followed by 6 months of oral retinoic acid. Pilot studies incorporating new agents, such as topotecan and irinotecan, also are under investigation. When primary treatment fails, experimental therapies with biologic agents (anti-G_{D2} antibodies), metaiodobenzylguanidine (MIBG) therapy, or new cytotoxic agents usually are recommended.

WILMS' TUMOR

Epidemiology

Wilms' tumor, or nephroblastoma, is the most common primary malignant renal neoplasm of childhood. Although relatively rare, this disease has served as a paradigm for multimodality management of childhood solid tumors. Owing to refinements in surgery, chemotherapy, and radiation therapy, the overall cure rate for Wilms' tumor exceeds 85%. Studies of Wilms' tumor genetics have laid the foundation for our understanding of tumor suppressor genes and genomic imprinting.

The annual incidence of Wilms' tumor is 8 cases per 1 million children younger than 15 years, representing 6.3% of cases of childhood cancer.[247] In the United States, approximately 460 new cases are diagnosed each year, making Wilms' tumor the fourth most common pediatric cancer by specific histologic type.[247] The incidence

of Wilms' tumor varies with race and ethnic group. The range is 2.5 cases per 1 million Chinese children to 10.9 cases per 1 million African-American children.[248] Girls have a slightly increased risk for Wilms' tumor, with a male-to-female ratio of 0.92 to 1.00. The mean age at diagnosis is 44 months for unilateral disease and 31 months for bilateral disease. According to the Knudson two-hit model of tumorigenesis, the earlier age at onset of bilateral Wilms' tumor represents a genetic predisposition to the disease. Wilms' tumor in the adult population is rare, although numerous cases have been reported.[249,250] Although results of older studies indicate that the prognosis for adult Wilms' tumor is unfavorable, newer reports demonstrate cure of both localized and advanced disease with treatment regimens similar to those used for children.[251,252]

Familial Wilms' tumor is uncommon, occurring in only 1.5% of affected patients.[253] Most cases of familial Wilms' tumor occur in distant relatives, rather than in parents or siblings. Sixteen percent of cases of familial Wilms' tumor are bilateral, compared with 7% of sporadic cases. Unlike retinoblastoma, familial Wilms' tumor is bilateral in only a small number of cases. Conversely, only a small proportion (3%) of cases of bilateral Wilms' tumor is familial. The mean ages at diagnosis of familial unilateral and bilateral disease are 35 months and 16 months, respectively.

Tumor Biology

Although Wilms' tumor was one of the original paradigms of the Knudson two-hit model of cancer formation,[254] it has become apparent that several genetic events participate in tumorigenesis for this neoplasm. *WT1* was the first Wilms' tumor gene identified and is the most completely characterized Wilms' tumor gene to date. The discovery of *WT1* began with the observation that patients with a combination of aniridia, genitourinary anomalies, and mental retardation (WAGR syndrome) are at high (greater than 30%) risk for development of Wilms' tumor. Cytogenetic analysis in persons with WAGR syndrome has revealed large deletions at chromosomal band 11p13, which later was found to encompass a contiguous set of genes, including *PAX6*, the gene responsible for aniridia,[255] and *WT1*.[256–258] Patients with sporadic aniridia (*PAX6* defect with normal *WT1*) are not at increased risk for Wilms' tumor.[259] *WT1* encodes a transcription factor that is critical to normal kidney and gonadal development, but whose precise role in tumorigenesis is undefined. Although germinal deletions or mutations in *WT1* have been documented in almost all patients with WAGR syndrome and the related Denys-Drash syndrome, only a small number of patients with seemingly sporadic Wilms' tumor carry *WT1* mutations in the germline (5%) or in tumor tissue (6% to 18%).[260–263] Although *WT1* is a bona fide tumor suppressor gene, its role in sporadic Wilms' tumor development is limited.

A second Wilms' tumor-associated condition is Beckwith-Wiedemann syndrome, which is an overgrowth disorder that manifests as high birth weight, macroglossia, organomegaly, hemihypertrophy, neonatal hypoglycemia, abdominal wall defects, and ear pits and creases. Patients with this syndrome have a 5% to 10% risk for development of Wilms' tumor but also are predisposed to the development of other malignant tumors, such as hepatoblastoma, adrenocortical carcinoma, neuroblastoma, and rhabdomyosarcoma.[264] Beckwith-Wiedemann syndrome maps to chromosomal band 11p15, sometimes called *WT2*, because loss of heterozygosity at this locus has been detected in Wilms' tumor.[265,266] Although the precise *WT2* gene is undefined, molecular characterization of the *WT2* locus has revealed several genes that may play a role in tumorigenesis. These genes are imprinted, which means that they are preferentially expressed from one of the two parental alleles. Loss of imprinting, leading to aberrant messenger RNA and protein expression, has been postulated as a mechanism of tumor formation. Genes at the *WT2* locus that have been suggested to contribute to tumorigenesis for this neoplasm include *IGF2, H19*, and $p57^{Kip2}$ (*CDKN1C*).[267–273]

Genes and loci other than *WT1* and *WT2* have been implicated in the molecular pathogenesis of Wilms' tumor. In two studies, investigators found that approximately 15% of Wilms' tumors have activating mutations of β-catenin, a central effector of the Wnt signaling pathway.[274,275] Of interest, the β-catenin mutations were strongly associated with *WT1* mutations, indicating that these two genes operate in distinct pathways and may collaborate in the genesis of Wilms' tumor. Genetic linkage analysis has identified two familial Wilms' tumor loci, called *FWT1* and *FWT2*, on chromosomes 17 and 19, respectively.[276,277] Identifying the pertinent genes at these loci is an area of active investigation. It was recently recognized that some cases of familial Wilms tumor are associated with biallelic *BRCA2* mutations. Whereas monoallelic *BRCA2* mutations are associated with breast and ovarian cancers, individuals with biallelic mutations have the D1 type of Fanconi anemia and are predisposed to the development of Wilms' tumor and brain tumors.[278] Loss of heterozygosity at 1p and 16q has been found in 10% to 20% of Wilms' tumors. Loss at either or both loci is associated with adverse prognosis and is used for treatment stratification in the current COG studies.[279] Cytogenetic and loss of heterozygosity analyses have revealed recurrent abnormalities of 7p, but the clinical and biologic significance of these findings is unknown.[280,281] Finally, mutations in the *TP53* gene are observed in most cases of anaplastic histologic features of Wilms' tumor, implicating a role for this gene in progression from favorable to anaplastic histologic type.[282–284]

Pathology

Classic Wilms' tumor consists of blastemal, stromal, and epithelial elements, although tumors do not necessarily contain all three (Fig. 99-11). Because Wilms' tumor can be recognized with standard hematoxylin and eosin staining, the role of ultrastructural or immunohistochemical studies is limited. Other childhood renal neoplasms that must be considered in the differential diagnosis for Wilms' tumor are clear cell sarcoma of the kidney, rhabdoid tumor of the kidney, congenital mesoblastic nephroma, renal cell carcinoma, and soft-tissue sarcoma of the kidney.

An important advance in the care of patients with Wilms' tumor has been appreciation of the prognostic importance of histologic subtype. In 1978, Beckwith and Palmer published the results of a detailed histopathologic review of the cases of patients entered in the first National Wilms' Tumor Study (NWTS).[285] Approximately 6% of the Wilms' tumor specimens contained anaplasia, a term used to describe nuclear enlargement and atypia with irregular mitotic figures

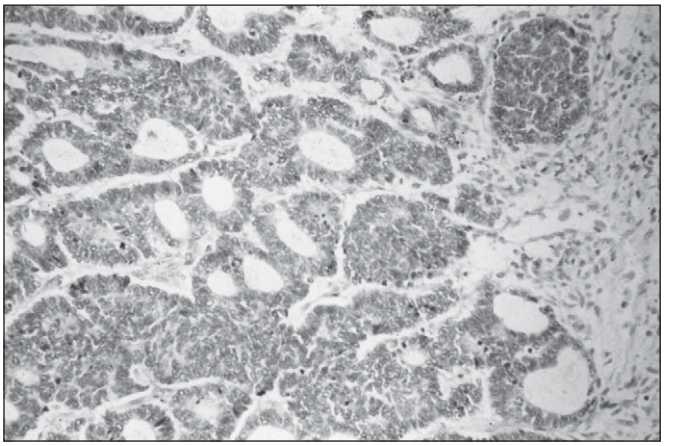

Figure 99-11 • Triphasic Wilms' tumor with well-defined tubules surrounded by dense clusters of blastemal cells and zones of pale-staining stromal differentiation (×20).

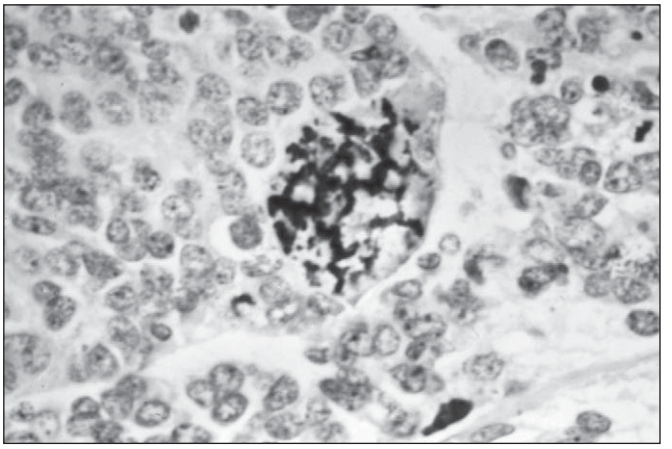

Figure 99-12 • Anaplastic Wilms' tumor with several enlarged, hyperchromatic, bizarre-appearing nuclei (×60).

(Fig. 99-12). The presence of anaplasia was prognostically significant: 11 (44%) of 25 patients with anaplasia died of tumor, whereas only 26 (7.1%) of 364 patients without anaplasia died of tumor. Results of subsequent studies by NWTS investigators, studies by the International Society of Pediatric Oncology (SIOP), and a United Kingdom Wilms' tumor study confirmed the adverse prognostic significance of anaplastic histologic features.[286,287]

Nephrogenic rests are foci of embryonal kidney cells that persist abnormally into postnatal life. They are present in approximately 1% of newborn kidneys and usually regress or differentiate by early childhood.[288] Because nephrogenic rests are present in the kidneys of approximately 40% of patients with Wilms' tumor, it is presumed that the rests represent Wilms' tumor precursors. Current models of tumorigenesis for this neoplasm propose that a mutation in a tumor suppressor gene, such as *WT1*, predisposes to nephrogenic rests, which may sustain additional mutations and transform into a Wilms' tumor.[289]

Clinical Manifestations and Patterns of Spread

Wilms' tumor typically manifests as an asymptomatic abdominal mass discovered by a parent or a health care practitioner. The mass is smooth and firm, is fixed in position, and often extends across the midline. Abdominal pain, fever, anemia, hematuria, and hypertension are other common signs and symptoms observed in 20% to 30% of children with Wilms' tumor.[290] Constitutional signs and symptoms (e.g., weight loss, cachexia, bone pain) are unusual manifestations of Wilms' tumor.

Wilms' tumor can spread both locally and hematogenously. Local spread typically occurs into the renal hilar structures and may penetrate the renal capsule. These tumors also have a propensity to invade the renal vein and form thrombi in the inferior vena cava, sometimes progressing as far as the right atrium. Local and distant lymph node involvement can occur. The most common sites of hematogenous metastasis are the lungs and liver.

Laboratory and Radiologic Evaluation

The goal of imaging before Wilms' tumor therapy is to define the extent of disease, assess the contralateral kidney, and determine whether tumor thrombus is present. Ultrasonography with Doppler technique is the recommended first-line study for Wilms' tumor because it allows panoramic examination of the abdomen, including the patency of the inferior vena cava, in a safe and painless manner (Fig. 99-13). CT can depict pelvic and abdominal structures as well as lymph nodes (Fig. 99-14). CT is especially useful in detection of

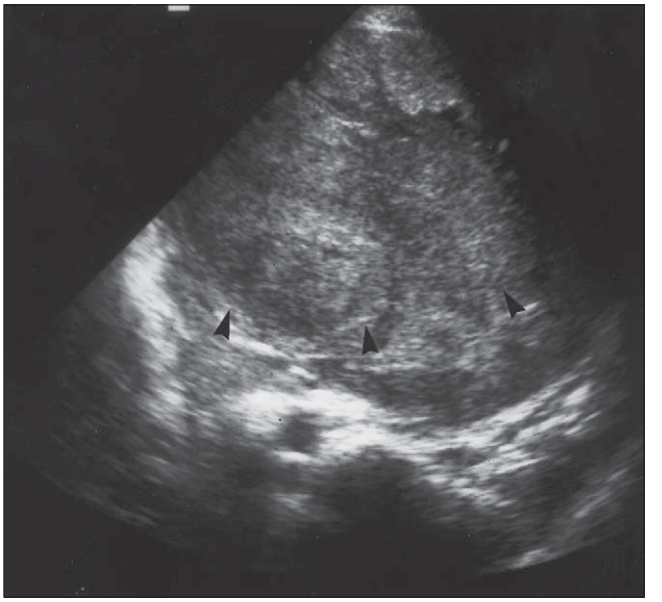

Figure 99-13 • Transverse sonogram shows large Wilms' tumor with almost no remaining normal renal parenchyma (*arrowheads*).

bilateral tumors. Intravenous pyelography and MRI typically are not necessary in the evaluation of Wilms' tumor, although MRI may facilitate differentiation between nephrogenic rests and Wilms' tumor.[291] Because Wilms' tumor metastasizes to the lungs, preoperative chest radiography is imperative. Plain radiographs of the chest are the traditional means of evaluation. Although chest CT is more sensitive than plain radiography in the detection of pulmonary metastasis, its role in initial evaluation for Wilms' tumor is controversial because CT is associated with false-positive findings and high interreader variability among radiologists.[292–294] Moreover, it is not clear whether the prognosis for patients with small pulmonary nodules detected only with chest CT is inferior to that for patients without radiologically detectable pulmonary metastasis.[295,296]

Treatment

The dramatic increase in cure rate of Wilms' tumor over the past 40 years is largely a testimony to the efforts of cooperative groups con-

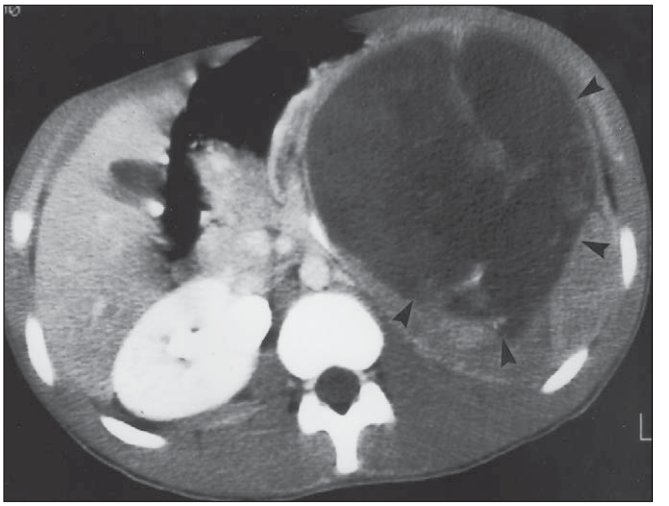

Figure 99-14 • Transverse computed tomographic image of the Wilms' tumor depicted in Figure 99-13 shows a large intrarenal mass (*arrowheads*).

sisting of oncologists, surgeons, radiation oncologists, pathologists, and statisticians. Nearly all patients undergo surgery as the primary method of achieving local control. The NWTS group advocates surgical resection at diagnosis, which yields the most accurate staging information. By contrast, SIOP recommends preoperative chemotherapy with the aim of decreasing tumor size and promoting fibrosis, thereby preventing intraoperative tumor spillage and decreasing surgical complications. Both approaches produce high rates of treatment success. The following discussion focuses on the results of the NWTS and COG, which assumed the responsibilities of the NWTS group in 2002.

Wilms' tumor surgery should be performed by an experienced pediatric surgeon through a transverse abdominal incision. The peritoneal surface, liver, and lymph nodes are inspected for tumor involvement. Biopsy is performed on suspicious lesions. A lymph node sample should be obtained whether or not the node appears involved. Although the NWTS group previously recommended inspection of the contralateral kidney, less than 0.3% of patients enrolled in NWTS-4 had lesions detected during surgery that were not detected on preoperative imaging studies.[297] With the availability of modern imaging techniques, routine exploration of the contralateral kidney is no longer recommended.

The tumor is removed en bloc with the kidney, hilar structures, and a generous segment of ureter. The adrenal gland is included in the resection if the tumor is adherent to the gland or if the tumor originates in the upper pole of the kidney. Caution should be exercised to avoid capsular rupture and tumor spillage, which could adversely influence staging and alter therapy. If a tumor is deemed inoperable owing to size or invasion of vital structures, biopsy is performed and adjuvant therapy is administered before definitive surgery. The COG staging system for Wilms' tumor is based on surgical and histopathologic findings[298] (Table 99-7).

Consecutive trials of the NWTS beginning in the late 1960s provided critical insights into the role of adjuvant therapy for Wilms' tumor. NWTS-1 and NWTS-2 revealed that the combination of vincristine and actinomycin D is superior to treatment with either drug alone and that irradiation is not necessary in the care of patients with stage I disease. NWTS-3 showed that patients with stage II tumors with favorable histologic features can be treated without abdominal irradiation if vincristine and actinomycin D are administered. This study also revealed that the addition of doxorubicin to the two-drug regimen improves outcome in stage III and IV disease with favorable histologic features. If doxorubicin is administered, radiation doses of 1000 cGy are sufficient to eliminate residual microscopic disease in the abdomen. NWTS-3 also showed that addition of cyclophosphamide to the vincristine-actinomycin D-doxorubicin regimen improved outcome for patients with stage II through IV tumors with anaplastic histologic features but not for those with tumors with favorable histologic features. NWTS-4 compared the use of single-dose pulse-intensive actinomycin D and doxorubicin with the traditional divided-dose method of administration. The investigators found that pulse-intensive dosing was equally efficacious, less toxic, and more cost-effective than the conventional regimen.[299,300] NWTS-4 also revealed that 6 months of therapy for stage II through IV tumors with favorable histologic features was equivalent to 15 months of therapy.

The NWTS-5 study sought to capitalize on previous successes. The aim was to curtail therapy in low-risk groups, improve cure rates for high-risk groups, and identify novel prognostic markers. The treatment algorithms used in NWTS-5 are shown in Table 99-8.[298] One of the primary objectives was to evaluate whether adjuvant chemotherapy provides benefit to children younger than 24 months who have small stage I tumors with favorable histologic features, a group with an outstanding prognosis. In 75 patients who met the eligibility criteria, the tumor was treated with surgical resection and close observation only. Eleven (14.7%) of these 75 patients experienced relapse or were found to have metachronous disease in the contralateral kidney, prompting early closure of this study arm.[301] Additional follow-up evaluation indicated that salvage therapy was very successful in this group. Only one patient had subsequent recurrence, and all patients were alive after a median follow-up period of 2.84 years. Future studies will reassess the need for adjuvant therapy in this group of patients.

A second primary objective of NWTS-5 was to test the hypothesis that tumor loss of heterozygosity (LOH) at chromosomal loci 1p and 16q is associated with unfavorable prognosis. More than 2000 patients on NWTS-5 had informative LOH results. LOH at 1p and 16q was prognostically significant for Wilms' tumor of favorable histology, but not for Wilms' tumor of anaplastic histology. The greatest effect on prognosis was seen in tumors that had LOH at both loci[302] (Table 99-9). The current COG Wilms' tumor study is evaluating the benefit of augmenting therapy for patients whose tumors harbor LOH at both 1p and 16q. The biologic mechanism for

Table 99-7 National Wilms' Tumor Study Clinicopathologic Staging

Stage	Description
I	Tumor limited to kidney and completely excised. No penetration of the renal capsule or involvement of renal sinus vessels.
II	Tumor extends beyond the kidney but is completely excised with negative margins and lymph nodes. At least one of the following has occurred: (a) penetration of the renal capsule, (b) invasion of the renal sinus vessels, (c) biopsy of the tumor before removal (except for fine needle aspirate, which may qualify as stage I).
III	Gross or microscopic residual tumor remains postoperatively, including inoperable tumor, positive surgical margins, tumor spillage occurring pre- or intraoperatively, regional lymph node metastasis, and transected tumor thrombus.
IV	Hematogenous metastasis (lung, liver, bone, brain) or lymph node metastasis outside the abdominal or pelvic cavities.
V	Bilateral renal tumors at diagnosis.

Table 99-8 National Wilms' Tumor Study 5 Treatment Algorithms

Stage	Treatment
Favorable histology	
I and II	AMD/VCR × 18 weeks, no XRT
III	AMD/VCR/DOX × 24 weeks, XRT to flank or abdomen
IV	AMD/VCR/DOX × 24 weeks, XRT to flank or abdomen for local stage III and to metastatic sites
Anaplastic histology	
I	AMD/VCR × 18 weeks, no XRT
II–IV	VCR/DOX/CPM/VP-16 × 24 weeks, XRT to flank or abdomen and to metastatic sites

AMD, dactinomycin; CPM, cyclophosphamide; DOX, doxorubicin; VCR, vincristine; VP-16, etoposide; XRT, radiation therapy.

Table 99-9 Results of National Wilms' Tumor Cancer Study 5

Stage	4-Year Relapse-Free Survival Rate (%)	4-Year Overall Survival Rate (%)
Favorable histologic features without LOH 1p		
I (<24 mo/tumor weight <550 g)	95.6	100
I (≥24 mo/tumor weight ≥550 g)	94.2	98.4

LOH, Loss of heterozygosity.

the association between LOH and unfavorable outcome is under investigation.

A third objective of NWTS-5 was to improve outcomes of patients with stage II to IV Wilms' tumor of diffuse anaplastic histology. Based on the finding that patients with diffuse anaplastic Wilms' tumor benefited from cyclophosphamide, a new treatment regimen consisting of chemotherapy with a vincristine, doxorubicin, cyclophosphamide, and etoposide and radiation therapy was developed. The outcomes for patients who received this regimen were improved compared with historical controls but still were clearly inferior to outcomes in patients with tumors of favorable histology[303] (see Table 99-9). Patients with stage I anaplastic Wilms' tumor received a two-drug regimen of vincristine plus actinomycin D, with the idea that completely resected tumors do not require intensive treatment. However, these patients did not fare as well as expected (see Table 99-9). The current COG study is augmenting therapy for patients with stage II to IV diffuse anaplastic Wilms' tumor by adding carboplatin to the treatment regimen. Patients with stage I anaplastic Wilms' tumor receive doxorubicin and flank irradiation in addition to vincristine/actinomycin D. Box 99-4 outlines the approach to management of Wilms' tumor used at St. Jude Children's Research Hospital.

Box 99-4. ST. JUDE CHILDREN'S RESEARCH HOSPITAL APPROACH TO MANAGEMENT OF WILMS' FAMILY TUMORS

At St. Jude Children's Research Hospital, patients with suspected Wilms' tumor undergo nephrectomy at diagnosis unless the disease is bilateral or unresectable. Patients with stage I and II Wilms' tumor with favorable histologic features receive 18 weeks of vincristine and actinomycin D without radiation therapy. Patients with stage III and IV Wilms' tumor with favorable histologic features receive 24 weeks of vincristine, actinomycin D, and doxorubicin with radiation to the involved sites. Management of bilateral (stage V) Wilms' tumor is complex, and each patient needs an individualized treatment plan. In general, biopsy of at least one tumor is performed to establish the diagnosis, and preoperative chemotherapy is given before definitive nephron-sparing surgery is attempted. Because patients with bilateral Wilms' tumor do not undergo lymph node sampling at diagnosis, a three-drug chemotherapy regimen—vincristine, actinomycin D, and doxorubicin—is used. If the tumor margins after nephron-sparing surgery are positive for viable tumor, flank radiation is administered to the side with residual disease. Diffuse anaplastic Wilms' tumor is a therapeutic challenge. Patients with this form of the tumor receive chemotherapy with ifosfamide, carboplatin, and etoposide alternated with vincristine, doxorubicin, cyclophosphamide, and radiation to the flank and sites of metastatic disease.

Bilateral Wilms' Tumor

Bilateral Wilms' tumor occurs in approximately 5% to 10% of patients with Wilms' tumor. These children pose a therapeutic challenge because of difficulty in obtaining local control while sparing renal parenchyma. The approach to patients with bilateral Wilms' tumor is to administer preoperative chemotherapy to elicit tumor shrinkage and then to perform partial nephrectomy, whenever possible, or complete nephrectomy. Patients with tumors that cannot be resected with clear margins receive localized radiation therapy. The 4-year overall survival rate among patients with bilateral Wilms' tumor treated in NWTS-4 was 81.7%.[304] Compared with patients with unilateral Wilms' tumor, patients with bilateral tumors have an increased rate of renal failure, estimated to be 3.8% in NWTS-4.[305] The most common cause of renal failure in this patient group is tumor progression or recurrence necessitating nephrectomy, not therapy-related effects.

Recurrent Wilms' Tumor

Despite excellent outcome among most patients with Wilms' tumor, approximately 10% to 15% of patients with disease with favorable histologic features and 50% of patients with anaplastic disease experience primary progression or tumor recurrence. The most common sites of recurrence are the lungs, liver, opposite kidney, and intra-abdominal sites, including the original tumor bed. Wilms' tumor occasionally recurs in the brain, bone, and distant lymph nodes. Most relapses are diagnosed within the first 2 years after the original diagnosis. Factors associated with favorable prognosis after recurrence include favorable histologic features, initial treatment with only vincristine and actinomycin D, recurrent disease involving the lungs only, recurrent disease arising in the abdomen of a patient who did not receive abdominal irradiation, and relapse more than 12 months after the original diagnosis.[306,307] With aggressive therapy, approxi-

mately 60% to 80% of patients with tumors with favorable prognostic features can be cured. Salvage regimens are not as successful for patients with tumors with at least one unfavorable prognostic feature. Salvage regimens include ifosfamide, cyclophosphamide, carboplatin, and etoposide.[307–309] The overall 4-year survival rate after relapse for patients whose initial treatment regimen consisted of vincristine and actinomycin D was 81% after treatment with a regimen containing vincristine, doxorubicin, cyclophosphamide, and etoposide and radiation therapy.[310] For patients whose initial treatment regimen included agents in addition to vincristine and actinomycin D, the 4-year overall survival rate was 48% after treatment with cyclophosphamide, carboplatin, etoposide, and irradiation.[311] Several groups of investigators have used high-dose chemotherapy followed by autologous stem cell rescue in patients with recurrent Wilms' tumor.[312–314] Results are promising, but it is unclear whether high-dose therapy is superior to conventional-dose chemotherapy with modern agents.

Late Effects of Therapy

The late effects of Wilms' tumor treatment have received considerable attention because Wilms' tumor usually is curable, and the number of long-term survivors is growing. Late complications can result from chemotherapy, radiation therapy, or the primary nephrectomy itself. Although most Wilms' tumor survivors have only one kidney, less than 1% of patients with unilateral Wilms' tumor treated in NWTS-1 through NWTS-4 were found to have renal failure.[305] The median interval from diagnosis to onset of renal failure was 21 months. Renal failure is most prevalent in patients with bilateral Wilms' tumor. Another recognized long-term effect of Wilms' tumor therapy is congestive heart failure (CHF), which was found to have a cumulative frequency of 4.4% 20 years after diagnosis of Wilms' tumor in patients whose initial treatment regimen included doxorubicin.[315] The frequency of CHF was higher among patients who received doxorubicin as part of a salvage chemotherapy regimen. Risk factors for CHF included increasing cumulative doxorubicin dose, female gender, and radiation to the lung and left hemiabdomen (but not right hemiabdomen). An analysis of pregnancy outcome among Wilms' tumor survivors revealed that women who received flank radiation therapy and their infants were at increased risk for fetal malposition, premature labor, low birth weight, and occurrence of congenital malformations.[316] Finally, the cumulative incidence of second malignant neoplasms in Wilms' tumor survivors was 1.6% 15 years after diagnosis of their initial tumor.[317]

RENAL CELL CARCINOMA

Renal cell carcinoma (RCC) is an uncommon malignant tumor of childhood. The latest Surveillance, Epidemiology and End Results (SEER) statistics indicated an incidence of 0.4 case per million persons younger than 20 years.[318] RCC accounts for 2% to 7% of primary renal malignant tumors of childhood.[319–321] The median age of children brought for evaluation of RCC is 9 years, considerably older than the age at manifestation of other pediatric renal malignant tumors. Unlike with Wilms' tumor, clear cell sarcoma of the kidney, and rhabdoid tumor of the kidney, which have been studied by the NWTS group and SIOP, no prospective clinical trials of therapy for pediatric RCC have been perfomed. Information about this entity is therefore limited to retrospective single-institutional case series.

Typical features of pediatric RCC include abdominal mass (24% to 55%), hematuria (42%), and pain (32%). Children also may exhibit the constitutional signs and symptoms of hypertension, fever, weight loss, and polycythemia.[322] Approximately 25% of children with RCC have distant metastatic disease when they arrive for evaluation, most commonly involving the lung, liver, and bone.

Tumors classified as childhood RCC compose a heterogeneous group of renal epithelial malignant neoplasms. Childhood RCC may resemble the adult clear cell and papillary subtypes.[323] Although some reviews indicate that the papillary subtype is prevalent in the pediatric population,[323] other reports indicate that the clear cell subtype is more common.[322,324] Genetic alterations at chromosomal locus 3p, the site of the von Hippel-Lindau gene, have not been described in pediatric RCC, although few cytogenetic and molecular studies have been performed. A distinctive variant of RCC that preferentially affects children and young adults is characterized by the translocation t(X;17)(p11.2;q25), which results in a fusion product between the *TFE3* and *ASPL* genes. This same translocation is observed in alveolar soft-part sarcoma, but it is balanced in RCC and unbalanced in alveolar soft-part sarcoma.[325–327] Another variant is associated with the translocation t(6;11)(p21.1;q12).[328] The prevalence and clinical behavior of these variants have not been characterized. Another renal epithelial malignant neoplasm of childhood is renal medullary carcinoma, which is a highly aggressive tumor associated with sickle cell trait.[329]

Categorization of pediatric RCC using the World Health Organization (WHO) classification system suggests that approximately one third of pediatric RCCs are translocation carcinomas.[330,331] These tumors have distinct histologic features and are associated with translocations involving the *TFE3* gene at chromosomal region Xp11.2. The first reported translocation was t(X;1)(p11.2;q21), which fuses the *PRCC* and *TFE3* genes. A more common translocation is t(X;17)(p11.2;q25), which results in the *TFE3-ASPL* fusion product. This translocation also is observed in alveolar soft-part sarcoma, but it is balanced in RCC and unbalanced in alveolar soft-part sarcoma.[325–327] Another observed translocation is t(6;11)(p21.1;q12), which results in fusion of the *TFEB* and alpha genes.[332,333] Because *TFE3* and *TFEB* translocation carcinomas have similar clinical and histologic features, it has been proposed that they be considered as a single category. In addition to translocation RCC, classic adult-type clear cell RCC, papillary RCC, chromophobe RCC, and oncocytic RCC associated with neuroblastoma have been described in children and young adults.[330,334] Another renal epithelial malignant neoplasm of childhood is renal medullary carcinoma, which is a highly aggressive tumor associated with sickle cell trait.[329]

Retrospective reviews have indicated that the survival rate of children and adolescents with RCC is approximately 50% to 60%.[335,336] Adult RCC and pediatric RCC have similar stage-for-stage outcomes: very good outcome for stage I and II disease, less favorable outcome for stage III disease, and poor outcome for stage IV disease (Table 99-10). An apparent difference between adult RCC and pediatric RCC is the prognostic significance of local lymph node involvement. Adults with RCC with lymph node involvement have a 5-year overall survival rate of approximately 20%. By contrast, a review of the published pediatric RCC experience showed that 58 (66%) of 72.4 patients with local lymph node involvement without distant metastatic lesions had durable survival.[336] This difference probably reflects

Table 99-10 Survival Rates by Stage for Pediatric Renal Cell Carcinoma

Stage*	No. of Patients (% by Stage)	Survival Rate (%)
I	79 (32.5)	92.4

From Geller J, Dome J: Local lymph node involvement does not predict poor outcome in pediatric renal cell carcinoma. Cancer 2004;1575–1583.

histologic and biologic differences between adult RCC and pediatric RCC.

The optimal therapy for pediatric RCC is unknown. Historically, treatment for children with RCC has been heterogeneous. Some patients received chemotherapy and radiation therapy (typical Wilms' tumor therapy), whereas others were managed with surgery alone. Among patients with lymph node-positive nonmetastatic RCC, no difference in survival was observed among patients who received adjuvant chemotherapy, immunotherapy, or radiation therapy.[336] Because most children with localized and completely resected RCC have a favorable outcome, and no agents with clear efficacy have been identified, adjuvant therapy is not routinely recommended for this patient group. On the other hand, the poor outcome associated with stage IV disease warrants the use of investigational agents. Although a few case reports describe children with metastatic RCC that was responsive to interleukin-2 or interferon-α,[337,338] only a minority of pediatric RCCs have clear cell histology, the histologic subtype that is most responsive to immunotherapy in adults. Likewise, the recent promising results observed with tyrosine kinase and mTOR inhibitors may not translate to pediatric RCC. Testing of these novel agents is warranted in children and young adults.

RHABDOMYOSARCOMA

Epidemiology

Rhabdomyosarcoma is the most common soft-tissue sarcoma of childhood. According to population-based data from the SEER program of the National Cancer Institute, rhabdomyosarcoma accounts for approximately 3% of pediatric malignant neoplasms.[339] The tumor is slightly more common in boys than in girls, and approximately two thirds of cases occur in children younger than 10 years.[339–342] Embryonal rhabdomyosarcoma is the most common histologic subtype at all ages; however, adolescents have a higher proportion of alveolar rhabdomyosarcoma than other age groups.[339–343] In many cases, histologic features and primary site can be correlated. For example, orbital and genitourinary sites are strongly associated with embryonal histologic features, whereas tumors of the extremities most commonly are of alveolar histologic type.[339,344–346]

Biology

Rhabdomyosarcoma arises from primitive mesenchymal cells that retain capacity for skeletal muscle differentiation. The two main histologic subtypes of rhabdomyosarcoma, embryonal and alveolar, differ in biologic characteristics. The reciprocal translocation t(2;13)(q35;q14) is characteristic of tumors of the alveolar histologic type.[347] This translocation juxtaposes the *PAX3* gene located on chromosome band 2q35 and the *FKHR* gene on 13q14 to form a novel chimeric gene that encodes an aberrant transcription factor. A less common translocation in alveolar rhabdomyosarcoma is t(1;13)(p36;q14), which fuses the *PAX7* gene located on chromosome 1p36 with the *FKHR* gene. The t(2;13) and t(1;13) translocations are found exclusively in alveolar rhabdomyosarcoma and are thus diagnostic of this histologic subtype. A recent study suggests that *PAX-FKHR* gene expression signatures may predict clinical outcome independent of other known risk factors.[348]

Unlike alveolar rhabdomyosarcoma, embryonal rhabdomyosarcoma is not characterized by recurring chromosomal translocations. The embryonal type, however, is consistently associated with loss of heterozygosity at chromosome band region 11p15.5. This association suggests the presence of a tumor suppressor gene at this location.[349] Children with Beckwith-Wiedemann syndrome, which is associated with cytogenetic alterations of chromosome band 11p15,[350] are at increased risk for development of rhabdomyosarcoma. This association is further evidence of a tumor suppressor gene at that locus.

A variety of other genetic alterations are associated with RMS. Li-Fraumeni syndrome, defined by germline mutation of the *TP53* tumor suppressor gene, is characterized by development of a variety of malignant neoplasms, including childhood rhabdomyosarcoma.[351] Sporadic mutation of the *TP53* gene has been identified in randomly selected tumor samples from children with rhabdomyosarcoma.[352] This finding suggests that acquired *TP53* alterations may play a role in development of this malignant disease. Other genetic abnormalities include amplification of the N-myc proto-oncogene in alveolar rhabdomyosarcoma[353] and point mutations in the N-ras and K-ras proto-oncogenes in embryonal rhabdomyosarcoma.[354]

Pathology

Although it can be difficult to establish the diagnosis and histologic subtype of rhabdomyosarcoma, diagnostic accuracy is crucial for appropriate assignment of therapy. Rhabdomyosarcoma is a small round blue cell neoplasm and must be differentiated from the other small round blue cell neoplasms of childhood, including neuroblastoma, ESFTs, and non-Hodgkin's lymphoma. The presence of malignant skeletal muscle differentiation, characterized by cross-striations in tumor cells at light microscopic examination, confirms the diagnosis of rhabdomyosarcoma.[355] Unfortunately, cross-striations often are difficult to identify. In the absence of this highly specific finding, immunohistochemical staining often is needed to establish the diagnosis. The presence of staining for myogenin, MyoD1, muscle-specific actin, myoglobin, or desmin supports the diagnosis.[356–358] The finding of sarcomeric differentiation of tumor cells at electron microscopic examination also confirms the diagnosis of rhabdomyosarcoma.

The International Classification of Rhabdomyosarcoma[359] divides these tumors into three prognostic categories on the basis of histologic features: favorable (botryoid and spindle cell rhabdomyosarcoma), intermediate (embryonal rhabdomyosarcoma), and unfavorable (alveolar rhabdomyosarcoma and undifferentiated sarcoma). In most cases, the histologic subtype can be determined with light microscopic examination. In the absence of characteristic histologic findings, however, the use of RT-PCR assay to detect the chimeric fusion transcripts resulting from the t(2;13) and t(1;13) translocations can be useful in confirming the diagnosis of alveolar rhabdomyosarcoma.[9] Immunohistochemical studies also may be useful in separating alveolar from embryonal tumors. AP2β and P-cadherin are specific for alveolar histology, whereas epithelial growth factor receptor (EGFR) and fibrillin-2 are markers of embryonal histology.[360]

Clinical Manifestations

The presenting signs and symptoms in patients with rhabdomyosarcoma depend on the site and size of the primary tumor and on the extent of metastatic disease. Because it is derived from primitive mesenchymal cells, rhabdomyosarcoma can arise in almost any tissue in the body. The most common sites are the head and neck (27% to 37%), genitourinary tract (19% to 26%), and extremities (17% to 20%).[340–344] Head and neck tumors are divided by primary site into three major groups: orbital, parameningeal, and nonparameningeal. Orbital tumors, which account for approximately one fourth of head and neck tumors, commonly manifest as proptosis and occasionally ophthalmoplegia (Fig. 99-15). Approximately one half of rhabdomyosarcomas of the head and neck arise in parameningeal sites, which include the nasopharynx and paranasal sinuses, middle ear and mastoid, and pterygoid and infratemporal fossae. Tumors at these sites may produce nasal, sinus, or aural obstruction, occasionally with purulent or bloody discharge. Parameningeal tumors may be associated with cranial base erosion, cranial nerve palsy, and intracranial tumor extension. Patients with intracranial tumor extension may exhibit signs of increased intracranial pressure and are at risk for leptomeningeal tumor spread.[361] The other one fourth of head and

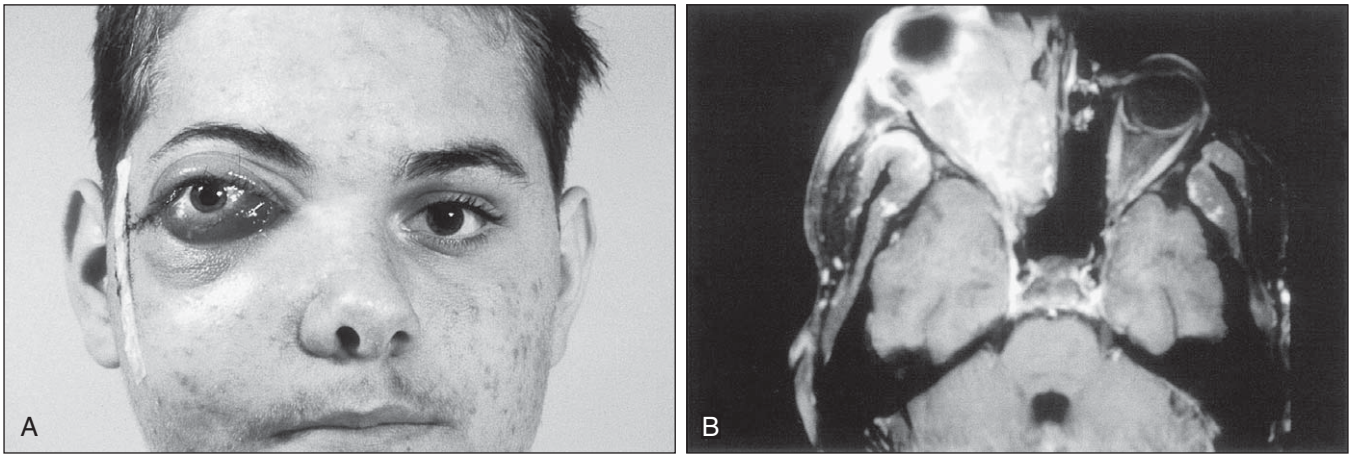

Figure 99-15 • A, Rhabdomyosarcoma of the right orbit invading the paranasal sinuses and soft tissues of the face. Tumor manifested as proptosis and facial swelling with accompanying vision loss. **B,** T_1-weighted contrast-enhanced axial magnetic resonance image shows a large right intraorbital mass displacing the globe anteriorly and extending into the subcutaneous tissues overlying the right maxilla.

neck tumors arise in nonparameningeal sites, such as the scalp, face, buccal mucosa, oropharynx, and neck. A visible or palpable mass often brings these tumors to medical attention.

Genitourinary primary sites account for approximately one fourth of all rhabdomyosarcomas and include the bladder, prostate, uterus, cervix, vagina, vulva, and paratesticular area. Bladder tumors often grow intraluminally and can cause hematuria or obstruct urinary outflow. Prostatic primary tumors can become large before causing appreciable clinical signs and symptoms. Urinary retention, constipation, and a palpable pelvic mass are characteristic. Rhabdomyosarcoma of the female genital tract is associated with protrusion of tumor tissue from the introitus accompanied by vaginal discharge or bleeding. Patients with paratesticular tumors characteristically have a painless unilateral scrotal mass with or without back or abdominal pain related to tumor involvement of retroperitoneal lymph nodes.

Rhabdomyosarcoma arises in an extremity in approximately 20% of the cases. Patients typically notice an enlarging, firm mass that often is painless. Extremity tumors frequently spread into the regional lymphatic system.[346] Thus, the presence of axillary or inguinal adenopathy may be the problem for which medical attention is sought.

Approximately 15% to 20% of patients with rhabdomyosarcoma have identifiable distant metastatic disease at initial diagnosis,[340–342] and an additional 10% to 15% have regional nodal involvement.[362] Lymphatic spread is most common in genitourinary and extremity tumors. Rhabdomyosarcoma is rare in orbital and other head and neck primary sites. The most common sites of distant metastasis are lung, bone marrow, and bone.[363]

Diagnostic Evaluation

The goals of the diagnostic evaluation of children with rhabdomyosarcoma are to establish a specific histologic diagnosis, assess the degree of local, regional, and distant tumor involvement, and collect baseline data against which to measure the response to treatment. A careful physical examination should be performed, with particular attention to regional lymph nodes. MRI or CT is used to determine the location, size, and invasiveness of the primary tumor and the anatomic relationships that will influence the choice of local therapy. Imaging assessment of regional lymph nodes should be performed for patients with genitourinary or extremity tumors, as well as for patients with palpable regional lymphadenopathy. Evaluation for distant metastatic disease includes CT of the chest, ^{99m}Tc bone scintigraphy, and bilateral bone marrow aspiration and biopsy. PET imaging also may be useful in evaluating patients with rhabdomyosarcoma, but its use has not yet become the standard of care.[364] For patients with parameningeal primary tumors, cerebrospinal fluid examination also is warranted to rule out meningeal involvement.

Open biopsy of the tumor usually is necessary to obtain adequate tissue for histologic and molecular characterization. Because of the high incidence of occult nodal involvement, regional lymph node sampling is necessary for patients with extremity tumors[346] and for those older than 10 years who have paratesticular tumors.[365]

Prognostic Factors

Assessment of prognostic variables is crucial for predicting the clinical behavior of rhabdomyosarcoma and for planning therapy. The most important predictors of outcome are histologic subtype, stage, and clinical group.[366] Patients with embryonal histology tumors fare significantly better than those with alveolar or undifferentiated histology (5-year failure-free survival rates 82% versus 65% in an analysis of Intergroup Rhabdomyosarcoma Studies III and IV).[366] The rhabdomyosarcoma staging system comprises primary site (favorable versus unfavorable), maximal tumor diameter (5 cm or less versus greater than 5 cm), and the presence or absence of nodal and distant metastases[367] (Table 99-11). Outcome for children with nonmetastatic tumors arising in favorable sites (orbit, nonparameningeal head and neck, genitourinary other than bladder or prostate, biliary tract) is superior to that for children with tumors at unfavorable sites. Among patients with nonmetastatic tumors arising at unfavorable sites, those with tumors that are larger than 5 cm in maximal diameter or that have spread to regional lymph nodes fare more poorly. Patients with metastatic disease have an unfavorable outcome. The clinical group classification[340] is based on the extent of residual disease after initial definitive surgery. For patients with localized tumor that is completely excised (clinical group I) or that is excised with microscopic residual disease (clinical group II), the prognosis is favorable. For those with gross residual disease (clinical group III), an intermediate prognosis is likely, and for patients with metastatic disease (clinical group IV), prognosis is poor.

Treatment

Because more than two thirds of children and adolescents with rhabdomyosarcoma can be cured, this goal should be the focus of treatment, which comprises the coordinated use of chemotherapy, radiation therapy, and surgery. Box 99-5 outlines the approach to management of rhabdomyosarcoma used at St. Jude Children's

Table 99-11 Intergroup Rhabdomyosarcoma Study Staging System

Stage	Primary Sites*	Maximal Tumor Diameter	Nodes	Metastases
1	Favorable	Any	Any	M0
2	Unfavorable	≤5 cm	N0 or Nx	M0
3	Unfavorable	≤5 cm	N1	M0
	Unfavorable	>5 cm	Any	M0
4	Any	Any	Any	M1

*Favorable sites: Orbit, head and neck (excluding parameningeal), genitourinary (not bladder/prostate), biliary tract.
Unfavorable sites: Head and neck parameningeal, bladder/prostate, extremity, other sites.

Research Hospital. All patients are presumed to have micrometastatic disease; therefore, systemic chemotherapy is administered universally. Agents shown to be active alone or in combination include vincristine, actinomycin D (dactinomycin), doxorubicin, cyclophosphamide, ifosfamide, melphalan, cisplatin, methotrexate, etoposide, topotecan, irinotecan, and vinorelbine [368–384] The standard of care in North America was established by the clinical trials of the Intergroup Rhabdomyosarcoma Study Group (IRSG) later named the Soft Tissue Sarcoma Committee (STSC) of the COG. The IRSG studies, which began in 1972, established vincristine and dactinomycin chemotherapy, with or without cyclophosphamide, as the therapeutic standard for rhabdomyosarcoma against which all other approaches are measured. In selected patients with favorable prognostic features, treatment is with only vincristine and dactinomycin; in patients with less favorable features, cyclophosphamide also is required. Efforts to further improve outcome with dose intensification of cyclophosphamide had proved ineffective.[385] Novel chemotherapeutic approaches recently under investigation by the STSC include the use of the camptothecin analogs topotecan and irinotecan. In Europe, vinorelbine-cyclophosphamide maintenance therapy is being studied.[386] To date, high-dose chemotherapy with autologous stem cell or bone marrow rescue has not been shown to improve outcome.[387,388]

In addition to systemic chemotherapy, local treatment with surgery, radiation therapy, or both is necessary for all sites of gross disease. Because complete surgical excision is associated with a better outcome, the goal of surgery is complete tumor removal without significant cosmetic or functional impairment. Less than 20% of tumors, however, are completely excised with negative microscopic margins.[340,341] Re-excision of tumors arising in the extremities and trunk to achieve negative margins before initiation of systemic therapy appears to confer a local control benefit and may favorably influence survival.[389,390] Therefore, the tumor bed should be re-excised before administration of chemotherapy when negative microscopic margins can be achieved. For patients with tumors not amenable to surgical excision at the time of initial diagnosis, administration of neoadjuvant chemotherapy may allow delayed surgical resection.

Radiation therapy is indicated for all patients with rhabdomyosarcoma except those who have embryonal tumors that have been completely resected with negative microscopic margins. Radiation therapy usually is delayed until after the initial response to chemotherapy is ascertained. In patients with tumors that erode the skull base, extend intracranially, or cause cranial nerve dysfunction or spinal cord compression, however, immediate initiation of radiation therapy is warranted.[361] The recommended dose of radiation therapy ranges from 36 to 50.4 Gy, depending on tumor site, extent of residual tumor, and response to chemotherapy. Current studies are evaluating radiotherapy dose reduction for particular patient subsets. In an effort to improve local control and decrease the late effects of conventional radiation therapy, an IRSG study evaluated a twice-daily hyperfractionation schedule. This schedule has shown no local control benefit, although the impact on late effects has not been evaluated.[391,392] Techniques such as brachytherapy, three-dimensional conformal radiation therapy, and intensity-modulated radiation therapy may be helpful in decreasing the late complications of radiation therapy.

Box 99-5. ST. JUDE CHILDREN'S RESEARCH HOSPITAL APPROACH TO MANAGEMENT OF RHABDOMYOSARCOMA

At St. Jude Children's Research Hospital, management of rhabdomyosarcoma begins with surgical removal of the tumor at initial diagnosis, when the operation can be accomplished without marked functional impairment or disfigurement. Primary re-excision is a consideration when gross or microscopic tumor can be removed with minimal morbidity. After initial surgery, systemic chemotherapy is administered according to available research protocols of the Children's Oncology Group. In the absence of an appropriate clinical trial, low-risk patients receive vincristine–actinomycin D chemotherapy, and intermediate- or high-risk patients receive vincristine–actinomycin D–cyclophosphamide chemotherapy. Local tumor control is addressed after completion of several cycles of chemotherapy. Surgical resection is performed if a gross total resection can be anticipated without producing excessive morbidity. All patients with alveolar histology tumors, as well as those with microscopic or gross residual embryonal tumors, receive radiation therapy after surgery during the completion of remaining chemotherapy. The radiation dose is dependent on the extent of residual disease after delayed tumor resection and ranges from 36 to 50.4 Gy. Local irradiation for treatment of metastatic disease is individualized and may be performed during local treatment of the primary tumor or at the end of therapy. In general, all metastatic sites (except bone marrow) are irradiated if feasible. Surgical removal of metastases is performed in limited circumstances.

Outcome and Late Sequelae

With contemporary therapy, the 5-year survival rate among children with rhabdomyosarcoma exceeds 70%. Beyond 5 years from diagnosis, approximately 9% of survivors experience tumor recurrence, secondary malignancy, or death from another cause. Long-term outcome varies according to risk factors: More than 90% of those with favorable disease features become long-term survivors, although fewer than 25% of those who present with metastatic disease survive. Patients who experience disease recurrence fare poorly. Fewer than 20% of children survive more than 5 years after recurrence, and almost all of these survivors experience local recurrence of botryoid or embryonal tumors.[393,394]

Although long-term survival is the norm for children with rhabdomyosarcoma, the late effects of the disease and its therapy can be

substantial.[395] Long-term sequelae are site-specific in many cases. More than one half of survivors of orbital rhabdomyosarcoma have dry eye, impaired vision, or cataracts.[396,397] Dental abnormalities, including root stunting, microdontia, and hypodontia, are common among survivors of head and neck rhabdomyosarcoma.[398] Other common problems in children who had head and neck tumors include short stature (due to growth hormone deficiency), hypothyroidism, and hearing loss.[340,399,400] Children who had rhabdomyosarcoma arising in the pelvis are at risk for impaired bladder and kidney function, gonadal failure, and sexual dysfunction,[401,402] whereas those who had paratesticular tumors may experience ejaculatory dysfunction and hypogonadism.[403] Other late effects may be caused by chemotherapy, radiation therapy, surgery, or all of these modalities. The most important of these effects include CHF,[395] infertility,[405,406] impaired bone and soft-tissue growth,[407–409] and second malignant neoplasms.[410,411]

NONRHABDOMYOSARCOMA SOFT-TISSUE SARCOMA

Epidemiology

Population-based data from the SEER program of the National Cancer Institute indicate that approximately 4% of pediatric malignant tumors are nonrhabdomyosarcoma soft-tissue sarcoms (NRSTS). As a group, these tumors occur more frequently than rhabdomyosarcoma.[339] Unlike rhabdomyosarcoma, which occurs most often in children younger than 10 years, NRSTS is found predominantly in older children and adolescents. NRSTS includes many histologically and biologically distinct entities, all of which are derived from primitive mesenchymal cells. Most tumors are named for the mature tissue that they resemble histologically. In pediatrics, the most common subtypes are synovial sarcoma, malignant fibrous histiocytoma, malignant peripheral nerve sheath tumor, and fibrosarcoma.[339,412–413] Certain subtypes that occur frequently in adults, such as leiomyosarcoma and liposarcoma, are rare in children.[414–418] Tumors unique to pediatric patients include infantile hemangiopericytoma and infantile fibrosarcoma, which behave in a more benign manner than that observed for their counterparts in adults.[419–421]

Tumor Biology

Most cases of NRSTS arise sporadically. Some of these tumors, however, have been found in patients with constitutional *TP53* gene mutations (Li-Fraumeni syndrome).[422] This finding suggests that aberrant *TP53* gene function may contribute to pathogenesis in some cases. Patients with neurofibromatosis type I, a genetic disorder of autosomal dominant inheritance caused by abnormalities on the long arm of chromosome 17, are at increased risk of malignant peripheral nerve sheath tumor (MPNST),[423] which often arises within a preexisting neurofibroma. MPNST also occurs sporadically in patients who do not have neurofibromatosis type I.[424] An unusually high incidence of leiomyosarcoma has been found among children with human immunodeficiency virus (HIV) infection.[425] Epstein-Barr virus (EBV) infection has been found in patients with HIV-associated leiomyosarcoma. This finding suggests that EBV has an etiologic role in the pathogenesis of leiomyosarcoma in HIV-infected patients.[426] Leiomyosarcoma in HIV-negative patients is not associated with EBV infection.[427]

A variety of forms of NRSTS have been reported as secondary malignant neoplasms arising after radiation therapy or chemotherapy for unrelated malignant disease.[162,428] Children with bilateral retinoblastoma are at high risk for secondary NRSTS, which can arise either within or outside of the radiation field used to manage retinoblastoma. This finding suggests that the *RB* gene locus may be important in the pathogenesis of some cases of NRSTS.[429]

Pathology

Because NRSTS is uncommon during childhood, these tumors can be diagnostically challenging. Procurement of an adequate tissue specimen during the initial evaluation is crucial to establishing an accurate diagnosis, and for determining the histologic grade, which is highly predictive of outcome[412–414] and may dictate treatment. Incisional biopsy is preferred, because fine needle aspiration and biopsy may yield inadequate tissue for thorough histologic and immunohistochemical evaluation and for molecular pathologic studies. Detection of chromosomal translocations specific to certain histologic subtypes may be helpful in confirming the precise diagnosis[429–440] (Table 99-12). Identification of specific tumor cell-gene fusions also may have prognostic importance. For example, synovial

Table 99-12 Chromosomal Translocations and Associated Fusion Proteins Described in Childhood Nonrhabdomyosarcoma Soft-Tissue Sarcoma

Tumor	Chromosomal Translocation	Fusion Protein
Alveolar soft-part sarcoma	der(17)t(X;17)(p11.2;q25)	ASPL-TFE3
Angiomatoid fibrous histiocytoma	t(12;16)(q13:p11)	FUS-ATF1

	t(12;22;20)(q13;q12;q11)	EWS-CHOP
Synovial sarcoma	t(X;18)(p11;q11)	SYT-SSX1 or SYT-SSX2

sarcoma with the *SYT-SSX1* fusion gene appears to have a less favorable outcome than that observed for synovial sarcoma with the *SYT-SSX2* fusion gene.[441]

Childhood NRSTS is divided into low-, intermediate-, and high-grade categories according to a grading schema formulated by the Pediatric Oncology Group.[442] This grading system includes elements of the system devised by Costa and colleagues[443] for adult NRSTS, in which metastatic potential and necrosis are assessed, as well as elements of the system developed by Enzinger and Weiss,[444] which is based primarily on histologic criteria. The system also includes the clinical variable of patient age to account for infantile tumors, which have a highly malignant histologic appearance but behave clinically in a benign manner.

Clinical Manifestations

The manifestations of NRSTS depend mainly on the site of the primary tumor. Because they are derived from primitive mesenchymal cells, these tumors can arise in almost any tissue. Extremity sites are most common, followed by trunk wall, head and neck, and visceral sites.[412,445,446] Extremity, trunk wall, and head and neck NRSTSs most commonly manifest as an enlarging, painless mass. Compression of nerves by the tumor can cause pain or disturbances in sensory or motor function. Tumors in the head and neck region can cause nasal, aural, or sinus obstruction and can impinge on the airway. Retroperitoneal and visceral tumors of the abdomen and pelvis often are large at initial evaluation. These tumors characteristically cause abdominal pain with or without symptoms of gastrointestinal or urinary tract obstruction.

Regional lymph node involvement is uncommon[446] and rarely is clinically evident when present. Children with synovial sarcoma, epithelioid sarcoma, angiosarcoma, and clear cell sarcoma are presumed to be at the highest risk for regional nodal disease, because these histologic subtypes are most commonly associated with regional spread in adults.[447] Approximately 15% of children and adolescents with NRSTS have distant metastatic lesions at initial diagnosis. The lung is the predominant site of metastatic disease,[445] but signs and symptoms of pulmonary metastasis are rare at initial diagnosis. Metastatic involvement of bone, skin, liver, and brain also has been reported. Pleural, peritoneal, and omental metastasis can occur in patients with tumors of the trunk wall, retroperitoneum, or viscera.

Diagnostic Evaluation

The goals of the diagnostic evaluation of children with suspected NRSTS are to establish a specific diagnosis and to assess the extent of disease to allow optimal treatment planning and measurement of response. The physical examination should be focused particularly on the local extent of the primary tumor and on the presence or absence of regional lymphadenopathy. MRI or CT aids in determining the location, size, and invasiveness of the primary tumor, as well as the anatomic relations that influence the surgical approach. Patients with epithelioid sarcoma and clear cell sarcoma require imaging assessment of regional lymph nodes, because regional tumor spread is most common in these subtypes of NRSTS in adults.[447] Any patient with enlarged regional lymph nodes also should undergo imaging of the nodal bed for definition of the extent of disease. The evaluation for distant metastatic disease should include either radiography or CT of the chest. CT is more sensitive and more expensive than radiography, but it is most cost-effective in patients with large, high-grade NRSTS.[448] Patients with tumors of the abdomen, pelvis, and retroperitoneum should undergo CT or MRI of the liver. Routine screening for bone, bone marrow, and brain metastasis is not warranted.[449]

The best approach to ensure adequate tissue for histologic and molecular tumor characterization is open biopsy. Core needle biopsies, however, have been shown to provide accurate diagnostic information when the specimen is reviewed by an experienced pathologist.[450] Fine needle aspiration is inadequate for establishing a specific diagnosis[451] but may be helpful in documentation of tumor recurrence.[452]

Prognostic Factors

Assessment of prognostic factors is important in selecting a therapeutic approach for patients with NRSTS. Few prospective studies of childhood NRSTS have been conducted, but the available results of prospective and retrospective studies suggest that the prognostic features of NRSTS are similar in children and in adults. Extent of disease and histologic grade and size of the tumor appear to be the most important prognostic variables. Patients with tumors that can be excised at initial diagnosis fare significantly better than those with unresectable or metastatic tumors.[412–414,445,446,453] Among patients with tumors that are surgically resected, high histologic grade is strongly associated with development of distant metastasis and with an inferior survival rate.[412–414] Tumor diameter greater than 5 cm is a risk factor for adverse outcome among patients with nonmetastatic NRSTS.[413,414,446] Other variables that have been associated with reduced probability of survival include age older than 10 years and intra-abdominal primary tumor site. Local recurrence is more likely in patients who have gross residual disease or tumor-positive microscopic margins after initial surgery.

Treatment

Only three prospective multi-institutional clinical trials of therapy for pediatric NRSTS have been conducted.[412,453,454] Therefore, the approach to management of childhood NRSTS depends largely on experience in managing adult NRSTS. In the pediatric population, however, the potential long-term effects of antineoplastic therapy on growth and development are additional factors that must be weighed.

NRSTS in children and adolescents can be assigned one of three risk categories for the purpose of determining optimal treatment. *Low-risk* disease includes resectable low-grade tumors and resectable high-grade tumors with a maximal diameter of 5 cm or less. Approximately 85% of patients with low-risk NRSTS become long-term survivors, and efforts should be made to limit the toxicity of treatment.[412–414] Wide local excision generally is adequate for cure.[412,413,455,456] When microscopic tumor remains after surgery, adjuvant radiation therapy (external-beam irradiation or brachytherapy) usually is indicated.[457] In selected patients with microscopic residual disease after resection of low-grade NRSTS, however, a period of observation may be appropriate, because only a small number of these patients experience local recurrence, and salvage therapy is almost always successful in these cases.[413,458]

The *intermediate-risk* category includes high-grade tumors larger than 5 cm in diameter and unresectable tumors. Patients at intermediate risk have an approximately 50% likelihood of long-term survival.[414,446] The optimal treatment in this subgroup is elusive. Patients with large, high-grade tumors are at substantial risk for distant disease recurrence,[413] but experience with treatment of these tumors in adults suggests that the available chemotherapy regimens are only modestly effective in preventing this usually fatal event.[459–461] The most active antineoplastic agents overall in soft tissue sarcomas are doxorubicin and ifosfamide; however, the rate of tumor response after neoadjuvant treatment with these agents is in the 25% to 40% range.[453,454,462,463] Dose intensification with these drugs may slightly improve the rate of response, although the effect of dose intensification on survival appears limited.[464] The late effects of high cumulative doses of doxorubicin and ifosfamide also must be considered.[465,466] For specific histologic subtypes, newer agents may be considered. Examples are

ecteinascidin-743 for liposarcoma and leiomyosarcoma[467] and imatinib for dermatofibrosarcoma protuberase.[468] Patients who have unresectable NRSTS are at risk not only for distant dissemination of disease but also for local tumor progression.[446] Local tumor growth can cause fatal complications when the tumor arises in the head and neck or intrathoracic and intra-abdominal regions. Neoadjuvant combined chemotherapy and radiation therapy may be a promising approach for improving local control in these patients.[469]

Metastatic NRSTS constitutes the *high-risk* category. For patients with metastatic disease, the prognosis is dismal. The median duration of survival is approximately 6 months, and less than 10% of these patients are alive 5 years after the initial diagnosis.[445,453] Novel treatment approaches are needed for these patients. In view of the poor outcome with standard chemotherapy, enrollment in phase I and II clinical trials of investigational agents should be considered.

Many aspects of the management of childhood NRSTS are controversial. Questions that have not been answered definitively include the following:

- Which children with resected NRSTS can be managed without adjuvant therapy?
- What minimum dose and field of radiation therapy provide adequate local control of resected NRSTS with positive microscopic margins?
- What is the optimal systemic therapy for patients at high risk for distant metastatic disease?
- What is the most effective local control therapy for unresectable NRSTS? Prospective clinical trials are warranted for investigation of these questions.

Box 99-6 outlines the approach to management of childhood NRSTS used at St. Jude Children's Research Hospital.

Box 99-6. ST. JUDE CHILDREN'S RESEARCH HOSPITAL APPROACH TO MANAGEMENT OF CHILDHOOD NONRHABDOMYOSARCOMA SOFT-TISSUE SARCOMA

At St. Jude Children's Research Hospital, the primary goal in managing childhood NRSTS is complete resection of all sites of disease. Whether radiation therapy or chemotherapy also is used depends on an assessment of risk factors for local and distant disease recurrence and on whether the tumor is resectable at the time of initial diagnosis.

For patients with localized, surgically resectable NRSTS that is of either low grade or high grade and 5 cm or less in diameter, the tumor is excised when it comes to medical attention. Although the goal of surgery is wide tumor-free margins, every effort is made to avoid functional impairment or disfigurement. Primary re-excision is performed in patients who have undergone unplanned resection and in those in whom negative microscopic margins can be achieved. External-beam radiation therapy or brachytherapy is administered to patients with high-grade tumors who have microscopic residual tumor after surgery. For patients with low-grade tumors who have microscopic residual tumor after surgery, radiation therapy generally is avoided because local recurrence is rare in these patients and is readily controlled by re-excision with or without radiation therapy. Adjuvant chemotherapy is not indicated for patients with localized low-grade NRSTS or for those with localized high-grade NRSTS 5 cm or less in diameter.

Neoadjuvant doxorubicin and ifosfamide chemotherapy is administered to patients with high-grade NRSTS larger than 5 cm in diameter, to those with unresectable NRSTS of any grade, and to those with metastatic NRSTS. After completion of two or three cycles of chemotherapy, surgery is performed with the aim of excising all tumors visible on diagnostic imaging, if possible. Resection of metastases may be delayed until the end of therapy if resection of both the primary tumor and metastases would produce excessive morbidity or treatment delay. Postoperatively, an additional two or three cycles of chemotherapy is given, provided that the response to neoadjuvant therapy is favorable. If microscopic tumor remains after surgery, external-beam radiation therapy or brachytherapy is given. In selected cases, radiation therapy is initiated concurrently with preoperative chemotherapy, and a postoperative radiation therapy boost is used only if microscopic tumor remains after surgery. For patients with NRSTS that continues to be unresectable after neoadjuvant chemotherapy and radiotherapy, different chemotherapeutic approaches are tried in an effort to permit tumor resection.

Outcome

The prognosis for children and adolescents with NRSTS depends on the histologic grade and size of the tumor, the resectability of the tumor, and the presence or absence of metastatic disease. Patients with nonmetastatic resectable low-grade and small high-grade tumors have a favorable outcome, with approximately 85% long-term survival.[415,416] For patients with nonmetastatic large, high-grade tumors or with nonmetastatic unresectable tumors of any grade, an intermediate prognosis is the rule. Approximately one half of these patients are alive 5 years after diagnosis.[446] For patients with metastatic disease at diagnosis, the prognosis is dismal; fewer than 10% become long-term survivors.[445,453]

The likelihood of cure of patients who experience tumor recurrence is difficult to ascertain because of the paucity of data on this subject. In patients with local recurrence, particularly if the tumor is of low histologic grade and is resectable, results usually are good.[413] Development of distant metastatic disease, particularly when the tumor is of high histologic grade, is a very unfavorable prognostic sign. A small number of patients with isolated pulmonary metastases may be cured surgically.[470]

Few reports have addressed the late effects of therapy for NRSTS in children and adolescents. Like pediatric patients who undergo intensive chemotherapy, surgery, and radiation therapy for other malignant diseases, those undergoing therapy for NRSTS are at risk for a number of long-term complications (Fig. 99-16). Surgical intervention can lead to permanent organ damage, disability, or disfigurement. Radiation therapy can cause disturbances of bone and soft-tissue growth,[405,406] restriction of soft-tissue mobility, neuroendocrine abnormalities,[399,471] and secondary malignant tumors.[410] Administration of anthracycline and alkylating agent chemotherapy has been associated with cardiotoxicity,[465] infertility,[404] nephrotoxicity,[466] and development of secondary malignant tumors.[410,472] These potential sequelae must be considered when treatment is selected for children and adolescents with NRSTS. Advances in the treatment of pediatric patients with NRSTS depend on further studies to identify more effective therapies that cause less long-term toxicity.

RETINOBLASTOMA

Epidemiology

Retinoblastoma is the most frequent neoplasm of the eye in childhood and the third most common intraocular malignant tumor in all ages, following malignant melanoma and metastatic carcinoma. Retinoblastoma represents 3% of all pediatric cancers. The average incidence of retinoblastoma in the United States is 1 in 14,000 to 1 in 18,000 live births. Thus, retinoblastoma develops in an estimated 200 to 300 children each year.[4] No sex or racial predilection has been

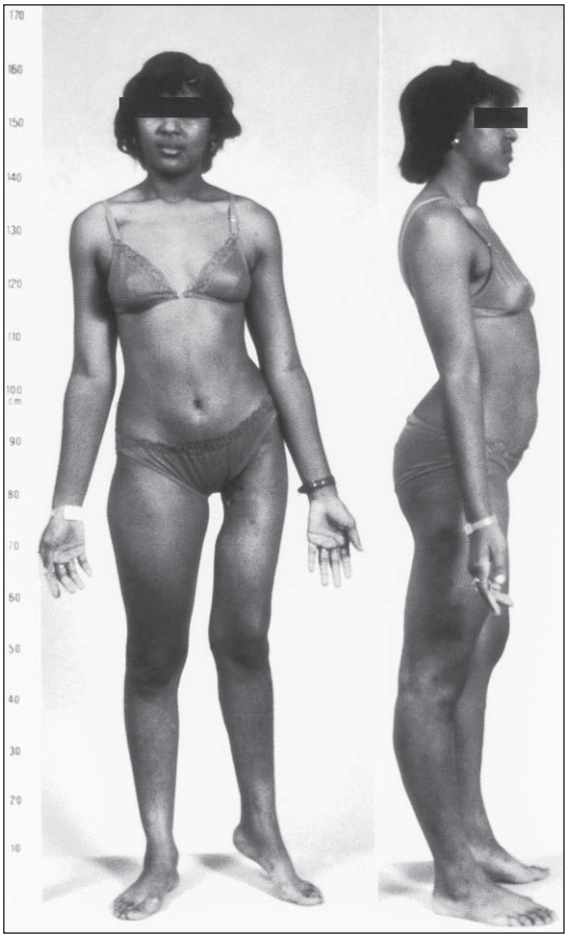

Figure 99-16 • This 19-year-old patient had undergone chemotherapy, surgical resection, and 64.8-Gy external-beam radiation therapy for synovial sarcoma of the left anterior thigh at 10 years of age. Marked soft-tissue atrophy of the left thigh and associated leg length discrepancy due to impaired skeletal growth are evident. Other late effects include avascular necrosis of the left femoral head and thoracolumbar scoliosis.

observed. The human retina is far from having completed its maturation at the completion of gestation, and it is not considered to be terminally differentiated until the age of 3 years. During this period, in which primitive photoreceptor cells are stimulated to differentiate into the mature retina, cells are at high risk of sustaining oncogenic events that result in development of a neoplasm. Retinoblastoma is therefore a cancer of the very young, and any therapeutic approach must take into consideration not only cure of the disease but also the need to preserve vision, with minimal long-term effects.

Clinical Forms and Tumor Biology

Retinoblastoma manifests in two distinct clinical forms. The first is bilateral or multifocal hereditary (accounting for 40% of cases), characterized by the presence of germline mutations of the *RB1* gene. Multifocal retinoblastoma can be inherited from an affected survivor (seen in 25% of the cases) or may be the result of a new germline mutation (in 75%). The second form is unilateral or unifocal and nonhereditary (accounting for 60% of cases).

Retinoblastoma is among the best understood of human neoplasms and has served as an important model for elucidating tumorigenesis. In 1971, on the basis of results of mathematical analysis of age at manifestation of hereditary and nonhereditary cases of retinoblastoma, Knudson[473] proposed the *two-hit hypothesis*, whereby two mutational events in a developing retinal cell lead to development of retinoblastoma. This hypothesis was extended to suggest that the two events could be mutations of both alleles of the *RB1* gene. The *RB1* gene, located in chromosomal band 13q14, was identified and cloned in 1986.[474,475] Its product, pRb, is a 110-kd nuclear phosphoprotein that acts by binding and inhibiting several proteins with growth-stimulatory activity. The pRb protein is a key substrate for G_1 cyclin-Cdk complexes, which phosphorylate target gene products required for transition of the cell through G_1. The active pRb is the unphosphorylated gene product, which binds to several cellular proteins, among which is transcription factor E2F, which activates transcription of genes whose products are required for entry into the S phase of the cell cycle. During the progression through G_1, pRb undergoes additional phosphorylation. The result is a hyperphosphorylated form that persists through the S, G_2, and M phases. The pRb protein appears to function as a tumor suppressor at least in part by inhibiting cell cycle progression past the G_1-S restriction point. Once cells traverse the G_1-S restriction point and enter S phase, they become irreversibly committed to cell division. Thus, pRb stands as the major gatekeeper to control this critical point in growth regulation. Lack of pRb or its inactivation removes the pRb constraint on cell cycle control. The consequence is deregulated cell proliferation.[476]

First Hit

RB1 is a large gene, containing 27 exons over approximately 200 kb of DNA, and mutations have been described in almost every exon. Nonsense and frameshift are the most common germline and somatic mutations, although deletions and duplications also are frequently encountered.[476] No mutational hot spots have been identified, although new germline mutations have an overwhelming preference for the paternal allele, a finding suggesting that deamination of methylated CpG pairs has an important role in mutagenesis.[477]

Second Hit

In both hereditary and nonhereditary retinoblastoma, the second tumorigenic event is chromosomal in nature, often occurring as a result of mitotic recombination errors.[478] This second hit occurs at a much higher frequency than is the case with the first hit, and it is more sensitive to environmental factors, such as ionizing radiation—hence the increased risk of radiation-induced malignant tumors in survivors of retinoblastoma.[479] After the second hit has occurred, retinoblastoma cells rapidly accumulate additional genetic damage. It is possible that an additional mutation ("third hit"), probably involving a gene of the apoptotic pathway, is necessary for final retinal tumor formation.[476] In contrast with the prevailing theories that suggest that *RB1* mutations bypass the p53 pathway, the Arf-Mdm2-p53 tumor surveillance pathway is activated after the Rb pathway is disrupted in the developing retina. *RB1*-deficient retinoblasts undergo p53-mediated apoptosis and cell cycle exit. Subsequent genetic amplification of the *MDMX* gene and increased expression of MDMX protein suppress the p53 response in *RB1*-deficient retinoblasts, leading to clonal expansion and tumor formation. This seems to be the mechanism by which the activation of the p53 pathway is disrupted in retinoblastoma: Close to two thirds of tumors have *MDMX* amplification.[480]

Genetic Counseling

Retinoblastoma is a unique neoplasm because the hereditary type has autosomal dominant inheritance with almost complete penetrance (85% to 95%).[481] Some families, however, have an inheritance pattern characterized by reduced penetrance and expressivity. These low-penetrance retinoblastoma mutations either cause a reduction in the amount of normal pRb produced or result in a partially functional mutant pRb.[482] The *RB1* gene mutation can occur at a late stage of embryogenesis, the result being variable expression depending on the

tissue and mosaicism in 10% to 15% of family members.[483] Genetic counseling is of utmost importance for determining the heritability of a given case and to estimate the risk among relatives. Because of the size of the *RB1* gene and the lack of mutational hot spots, however, exhaustive analysis of the *RB1* gene is required for clinical DNA testing.[484] With the refinement in methods of mutational analysis over the past decade, detection rates have increased to greater than 90% at present. Because of the heterogeneity in the site and type of gene defects, no single technology will be sensitive and effective, and a multistep approach must be taken.[485] In general, however, on the basis of inheritance pattern but in consideration of the existence of mosaicism, the following risk estimates can be made[481]:

- *Risk among offspring of survivors of retinoblastoma:* The risk of retinoblastoma in the offspring of survivors of bilateral (hereditary) disease is 45%. The risk is 2.5% among the offspring of survivors of unilateral retinoblastoma.
- *Risk among siblings of patients with retinoblastoma:* With a family history of retinoblastoma, siblings of patients with bilateral tumors have a 45% risk for development of retinoblastoma. The siblings of patients with unilateral tumors have a 30% risk. With a family history, the risk is 2% among siblings of patients with bilateral tumors and 1% among siblings of patients with unilateral tumors.

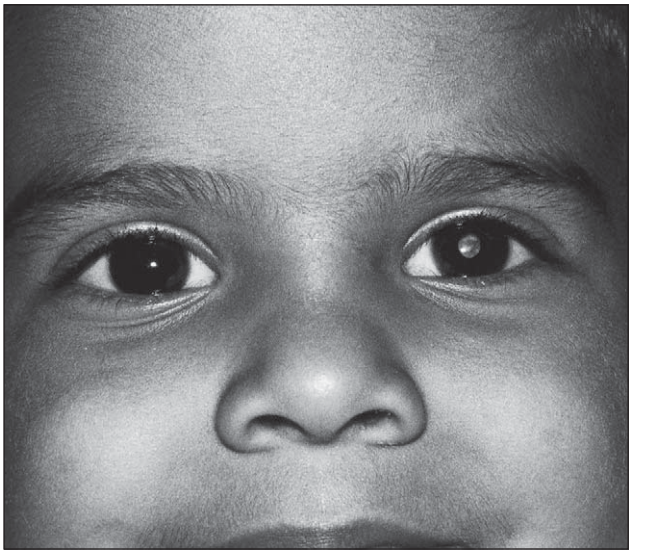

Figure 99-17 • Leukocoria of the left eye in a 3-year-old boy.

Pathology

Retinoblastoma arises from the photoreceptor elements of the inner layer of the retina,[486] usually extending into the vitreous cavity as a fleshy nodular mass (endophytic retinoblastoma). Less frequently, it extends externally, causing secondary retinal detachment; in such cases, no localized vitreous nodule (exophytic retinoblastoma) is visible. Macroscopically, retinoblastoma is soft and friable, and it tends to outgrow its blood supply; the result is necrosis and calcification. Because of the friability of the tumor, dissemination within the vitreous and retina in the form of small, white nodules (seeds) is common. In such cases, it may be difficult to differentiate multicentric primary tumor from disseminated tumor.[487]

The microscopic appearance of retinoblastoma depends on the degree of differentiation. Undifferentiated retinoblastoma is composed of small, round, densely packed cells with hypochromatic nuclei and scant cytoplasm. Several degrees of photosensory differentiation have been described and are characterized by distinctive arrangements of tumor cells. Homer Wright rosettes are composed of irregular circlets of tumor cells arranged around a tangle of fibrils with no lumen or internal limiting membrane. These rosettes are infrequent in retinoblastoma but are most common in other neuroblastic tumors, such as neuroblastoma and medulloblastoma. Flexner-Wintersteiner rosettes, on the other hand, are specific for retinoblastoma. These structures consist of a cluster of low columnar cells arranged around a central lumen bounded by an eosinophilic membrane analogous to the external membrane of the normal retina. The lumen contains an acid mucopolysaccharide similar to that around normal rods and cones. These rosettes are present in 70% of tumors. Fleurettes are less common. If rosettes are present, the cells exhibit even more ultrastructural characteristics of photoreceptor differentiation. The tumor is composed of larger cells with abundant eosinophilic cytoplasm arranged in a distinctive fleur-de-lis pattern. Especially well-differentiated tumors composed almost entirely of fleurettes have been called *retinoma* or *retinocytoma*. Ultrastructurally, retinoblastoma cells exhibit photoreceptor differentiation with the presence of the 9-0 microtubule doublet pattern, abundant cytoplasmic microtubules, synaptic ribbons, and neurosecretory granules.[487,488]

Dissemination of retinoblastoma occurs by several routes. Choroidal invasion provides access to a rich vascular network that serves as a potential route for distant metastatic lesions. In advanced cases, direct extension occurs through the sclera into the orbit. Retinoblastoma can invade the iris and the ciliary body and metastasize to regional lymph nodes. Finally, retinoblastoma can extend along the optic nerve, gaining access to the subarachnoid space and intracranial cavity.

Clinical Manifestations

Successful management of retinoblastoma depends on ability to detect the disease while it is still intraocular. Patients with bilateral retinoblastoma tend to come to medical attention at a younger age (14 to 16 months) than that typical for patients with unilateral disease (29 to 30 months).[481,489] In greater than half of the cases, the presenting sign is leukocoria, which occasionally is first noticed after a flash photograph (Fig. 99-17). Strabismus is the second most common sign and usually correlates with macular involvement. Very advanced intraocular tumors can become painful as a result of secondary glaucoma.[489] Considerations in the differential diagnosis include other childhood diseases that manifest as leukocoria, such as persistent hyperplastic primary vitreous, retrolental fibrodysplasia, Coats' disease, congenital cataracts, toxocariasis, and toxoplasmosis. In some series, these nonmalignant conditions account for a large proportion of enucleated eyes.[490]

Trilateral retinoblastoma is the association of bilateral retinoblastoma with an asynchronous intracranial neuroblastic tumor.[491] This association may be present in 3% to 9% of patients with hereditary disease, and the prognosis is almost uniformly fatal. Most of these tumors are pinealoblastoma, but suprasellar or parasellar tumors also occur. In most cases, the tumor resembles undifferentiated retinoblastoma with the more frequent formation of Homer Wright rosettes. The median interval between diagnosis of bilateral retinoblastoma and diagnosis of the brain tumor is 35 months. In recent years, with more widespread use of chemoreduction treatment for patients with bilateral retinoblastoma, the incidence of trilateral retinoblastoma has decreased dramatically.[492]

Evaluation

The diagnosis of intraocular retinoblastoma usually is made without histopathologic confirmation. Anesthesia and a maximally dilated pupil and scleral indentation are required to examine the entire retina. Retinoblastoma usually appears as a mass projecting into the vitreous, although the presence of retinal detachment or vitreous hemorrhage can make visualization difficult. Additional imaging studies that aid in the diagnosis include bidimensional ultrasonogra-

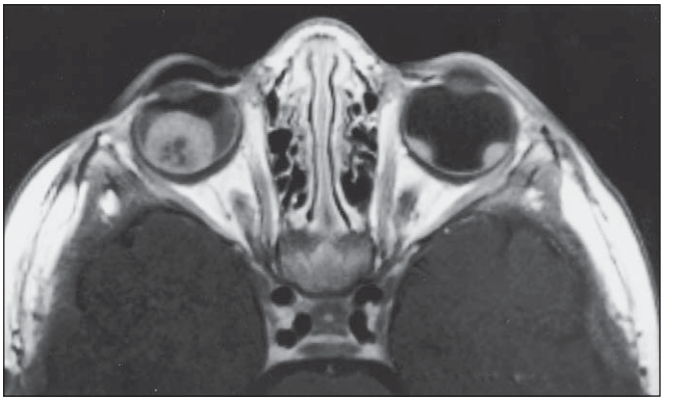

Figure 99-18 • T_1-weighted magnetic resonance image after contrast enhancement shows bilateral retinoblastoma with associated retinal detachment of the right globe.

phy, CT, and MRI (Fig. 99-18). These imaging studies are particularly important in evaluation of extraocular extension and in differentiating retinoblastoma from other causes of leukocoria. CT is helpful in detection of calcification, and MRI is helpful in the differential diagnosis for Coats' disease and other inflammatory conditions.[493] Evaluation for the presence of metastatic disease also must be considered in a subgroup of patients. Metastatic disease occurs in approximately 10% to 15% of patients, usually in association with distinct intraocular histologic features, such as deep choroidal and scleral invasion, or with involvement of the iris–ciliary body and optic nerve beyond the lamina cribrosa.[494] In such cases, additional staging procedures, including bone scintigraphy, bone marrow aspiration and biopsy, and lumbar puncture, must be performed.

Staging

The Reese-Ellsworth grouping system generally has been accepted as the standard for intraocular disease staging. This grouping system initially was designed for prediction of outcome after external-beam radiation therapy. In this system, eyes are divided into five groups on the basis of size, location, and number of lesions and presence of vitreous seeding[495]. The Reese-Ellsworth grouping system is gradually being replaced by a new classification system that has adapted to the changes in treatment approaches (Table 99-13). For patients undergoing enucleation, we use the St. Jude pathologic staging system, which incorporates other features known to influence modality of treatment and prognosis, such as choroidal involvement, optic nerve extension, and presence of metastatic disease[496] (Table 99-14).

Principles of Treatment

Management of retinoblastoma is aimed at saving life and preserving useful vision, so treatment must be individualized. Factors to be considered include unilaterality or bilaterality of disease, potential for vision, and intraocular and extraocular staging. Box 99-7 outlines the approach to management of retinoblastoma used at St. Jude Children's Research Hospital.

Surgery

Enucleation is indicated for large tumors filling the vitreous, for which little or no likelihood of restoring vision exists, and for tumor present in the anterior chamber or in association with neovascular glaucoma. For optimal staging, a long section (10 to 15 mm) of optic nerve has to be removed with the globe. A hydroxyapatite implant usually is fitted during the same procedure, and the extraocular muscles are attached to it. The size and type of implant are important for stimulating orbital growth.[497]

Table 99-13 International Classification for Intraocular Retinoblastoma

GROUP A

Small tumors away from foveola and disc

- Tumors ≤3 mm in greatest dimension confined to the retina, and
- Located at least 3 mm from the foveola and 1.5 mm from the optic disc

GROUP B

All remaining tumors confined to the retina

- All other tumors confined to the retina not in Group A
- Subretinal fluid (without subretinal seeding) ≤3 mm from the base of the tumor

GROUP C

Local subretinal fluid or seeding

- Local subretinal fluid alone >3 to ≤6 mm from the tumor
- Vitreous seeding or subretinal seeding ≤3 mm from the tumor

GROUP D

Diffuse subretinal fluid or seeding

- Subretinal fluid alone >6 mm from the tumor
- Vitreous seeding or subretinal seeding >3 mm from tumor

GROUP E

Presence of any of these poor-prognosis features:

- More than two thirds of globe filled with tumor
- Tumor in anterior segment
- Tumor in or on the ciliary body
- Iris neovascularization
- Neovascular glaucoma
- Opaque media from hemorrhage
- Tumor necrosis with aseptic orbital cellulitis
- Phthisis bulbi

Focal Therapy

Focal treatments are used for small tumors (less than 3 to 6 mm), usually in patients with bilateral disease, and in combination with chemoreduction. Photocoagulation with argon laser is used to manage tumors situated at or posterior to the equator and to manage retinal neovascularization due to radiation therapy.[498] Cryotherapy is used to manage small lesions situated in the anterior retina.[499] An important focal method is transpupillary thermotherapy, in which focused heat is applied at subphotocoagulation levels. Use of focal treatments is especially important in conjunction with chemotherapy, and use of both treatment modalities together appears to have a synergistic effect. Sequential administration of thermotherapy with carboplatin enhances the antitumor effect by increasing the platinum-DNA adducts. For this reason, thermochemotherapy is becoming a very important component of the management of intraocular retinoblastoma.[500,501] In addition to its effect on tumor control, cryotherapy increases intraocular penetration of carboplatin, presumably through disruption of the blood-vitreous barrier.[502,503] In general, local control rates of 70% to 80% can be achieved.[498–500]

Radiation Therapy

Retinoblastoma is a highly radiosensitive tumor. With increasing use of chemoreduction in conjunction with intensive focal therapy, however, external-beam megavoltage radiation therapy usually is reserved for cases in which more conservative approaches have failed, usually because of progression of vitreous and subretinal seeding, and for tumors adjacent to the optic nerve. Because most patients undergoing radiation therapy have multifocal disease, the entire retinal surface has to be irradiated to a uniform dose. Several techniques can be used, usually through lateral fields.[504–506] The recommended total dose is 40 to 60 cGy in 180- to 200-cGy fractions, although doses of 36 cGy can be effective in conjunction with other techniques.[507]

Three types of tumor regression after radiation therapy have been categorized. In type I, tumor shrinkage with calcium deposition produces a cottage cheese pattern. In type II, the tumor is a gray, homogeneous mass characterized by partial shrinkage and loss of the pink color of capillary injection. An annulus of atrophic pigment at the base of the tumor also is present. The regression pattern in type III has features of both type I and type II. The mass shows evidence of shrinkage, has lost the pink color, and has a nidus of calcium. Radiation therapy alone can cure 75% to 80% of patients. Addition of cryotherapy or photocoagulation can improve the results to 90%.[504–506]

Radioactive plaque technique is advantageous in the management of localized tumors, both because the procedure time is short and because a high dose of radiation is delivered to the area of interest while radiation effects on the extraocular structures are minimized. Indications for plaque therapy include solitary tumors with a diameter between 6 and 15 mm, tumor thickness of 10 mm or less, and location of the lesion more than 3 mm from the optic disc or fovea. Different radioactive episcleral plaques can be used, although iodine 125 (^{125}I) is the most widely used. A control rate of 85% to 90% can be achieved.[508]

Chemotherapy

Chemotherapy is indicated in the care of patients with extraocular disease, the subgroup of patients with intraocular disease with high-risk histologic features, and patients with bilateral disease in conjunc-

Table 99-14 St. Jude Children's Research Hospital Modified Staging System for Retinoblastoma

Stage	Description
Group I: Tumor confined to the retina	
IA	Solitary, smaller than 6 dd
IB	Multiple, all smaller than 6 dd
IC	Solitary or multiple tumors, involving less than 50% of retinal surface behind equator
ID	Solitary or multiple tumors, involving more than 50% of retinal surface behind equator
IE	Solitary or multiple tumors, involving more than 50% of retinal surface anterior to equator
Group II: Tumor confined to globe, extraretinal	
IIA	Extends to optic nerve head
IIB1	Extends to choroid
IIB2	Extends to choroid with replacement
IIC	Anterior chamber involvement
IID	Extends to choroid and optic nerve
Group III: Tumor with extrachoroidal extension (regional)	
IIIA	Extends to emissaries
IIIB	Extends beyond cut end of optic nerve (including subarachnoid)
IIIC	Extends through sclera into orbital contents
IIID	Extends to choroid and beyond cut end of optic nerve (includes subarachnoid)
IIIE	Extends through sclera and cut end of optic nerve
Group IV: Distant disease	
IVA	Extension through optic nerve into brain, including positive spinal fluid finding
IVB	Blood-borne metastasis to soft tissue, node, or bone
IVC	Bone marrow metastasis

dd, disk diameter (1.5 mm).

Box 99-7. ST. JUDE CHILDREN'S RESEARCH HOSPITAL APPROACH TO MANAGEMENT OF RETINOBLASTOMA

Most patients with unilateral, sporadic nonmetastatic retinoblastoma can be cured with enucleation alone. Careful histopathologic evaluation of the enucleated eye must be performed. At St. Jude Children's Research Hospital, risk factors for extraocular dissemination are considered to be extension of the tumor to the anterior chamber, ciliary body, or iris; massive choroidal involvement or extension into the sclera; and invasion of the optic nerve beyond the lamina cribrosa. In patients with any of these risk factors, adjuvant chemotherapy is recommended, with the addition of orbital irradiation for patients with transscleral involvement. Patients with metastasis to bone or bone marrow and those with tumor extension into the central nervous system (or in the optic nerve beyond the cut end) need more intensive chemotherapy and consolidation with high-dose chemotherapy and autologous hematopoietic stem cell rescue.

Patients with bilateral or multifocal disease present a therapeutic challenge. Cure of the disease is the priority, but preservation of the eye and vision also must be taken into consideration. The approach used at St. Jude Children's Research Hospital is highly conservative, and only eyes with very advanced disease at presentation are enucleated. Patients are given chemotherapy and intensive focal treatment. The aim is to delay or avoid external-beam radiation therapy and enucleation. For patients with low-stage intraocular disease, a combination of vincristine and carboplatin is used. For patients with advanced bilateral intraocular disease, the addition of the combination of vincristine and topotecan to the backbone regimen of vincristine and caraboplatin is under investigation. Because most treatment failures are caused by progression of vitreous seeds, subconjunctival carboplatin is added in cases of poor response of vitreous tumors. Patients are monitored closely with examinations performed using general anesthesia every 4 to 6 weeks, and focal treatment is applied during the procedure. Focal treatments include cryotherapy for small anterior tumors, thermotherapy and laser photocoagulation of small posterior tumors, and brachytherapy for larger tumors. Thermotherapy often is used immediately after administration of carboplatin (thermochemotherapy). For patients who need radiation therapy, conformal or intensity-modulated techniques are used to minimize radiation to orbital bones.

tion with aggressive focal therapy. Agents effective in the management of retinoblastoma include platinum compounds, etoposide, cyclophosphamide, doxorubicin, vincristine, and ifosfamide.[509]

Treatment in Specific Settings

UNILATERAL RETINOBLASTOMA. Patients with unilateral retinoblastoma usually have advanced tumors (Reese-Ellsworth groups IV and V) when they come to medical attention, and enucleation is the treatment of choice, being curative in more than 80% of cases. Patients with tumors with high-risk histologic features, such as deep choroidal invasion, or with involvement of the anterior chamber, iris, ciliary body, sclera or retrolaminar portion of the optic nerve, need adjuvant chemotherapy.[510,511] A small number of patients have extraocular or metastatic disease and need more intensive treatment, which usually includes high-dose chemotherapy, hematopoietic stem cell rescue, and radiation therapy to the orbit and areas of bulky disease.[512,513] Except for the small group of patients with metastatic disease, particularly those with central nervous system involvement, outcome among patients with unilateral disease in developed countries is excellent, with good functional results and minimal long-term effects.[514] Eye salvage techniques can be used in the rare patients with Reese-Ellsworth group I through III eyes. In these patients, the combination of chemoreduction with aggressive focal consolidation techniques, usually thermochemotherapy and brachytherapy, is necessary.

BILATERAL RETINOBLASTOMA. In patients with germline mutation of the *RB1* gene, multiple, bilateral retinoblastoma develops at an earlier age. These patients are at risk for development of new tumors until the completion of retinal differentiation. These patients also continue to be at risk for development of extraocular tumors throughout life.[7,8,433] In the past, treatment for patients with bilateral retinoblastoma was enucleation of eyes with advanced intraocular disease and no visual potential and use of external-beam radiation therapy for other eyes. A number of studies, however, have identified several complications associated with the use of radiation therapy. Irradiation of the orbit during a period of rapid growth results in a major decrease in orbital volume, which leads to midfacial deformities.[515,516] More important is increased risk of development of bone sarcoma in the radiation field. This risk appears to be age-related and decreases as radiation is delayed.[517] These concerns have resulted in development of new and more conservative approaches. Treatment of patients with bilateral retinoblastoma has thus evolved to incorporate the use of up-front chemotherapy, which is meant to achieve maximum chemoreduction of the intraocular tumor burden early in treatment, followed by aggressive focal therapy. The goals of this approach are to avoid or delay the use of external-beam radiation therapy and to increase the ocular salvage rate.

The use of systemic chemotherapy for cytoreduction, coupled with intensive use of sequential focal therapy (cryotherapy, laser photocoagulation, thermotherapy, and brachytherapy), has resulted in an increase in eye salvage rate and a decrease (and delay) in the use of radiation therapy. Different chemotherapy combinations are used. The best results are achieved with a combination of vincristine, carboplatin, and etoposide,[500,518–521] although a less intensive regimen with vincristine and carboplatin alone appears to be effective for early intraocular stages.[522] Salvage rates for Reese-Ellsworth group I through III eyes approach 100% when these techniques are used. For patients with advanced intraocular tumors (Reese-Ellsworth groups IV and V), ocular salvage rates are not better than 50% to 70%, and external-beam radiation therapy usually is needed.[518] However, radiation therapy usually is delayed for several months, which allows for better orbital growth and a decrease in the risk of second malignant tumors.

A large proportion of failures occur because of progression of tumor in the vitreous or as subretinal implants, two areas of difficult access for antineoplastic agents.[523] Carboplatin diffuses well into the vitreous.[524] Intraocular concentrations are 7 to 10 times higher when carboplatin is administered subconjunctivally. Results of animal studies have shown dose-dependent inhibition of intraocular tumor growth by subconjuctival carboplatin.[525] These encouraging preclinical data, however, have not been effectively translated into an improvement in the outcome of patients with advanced intraocular disease.[503,526] Radiation therapy appears to be the only valid alternative for these patients. With incorporation of external-beam radiation therapy early in treatment in the case of minimal disease before disease progression occurs, ocular salvage rates for Reese-Ellsworth group V eyes may improve.[522]

Long-Term Effects

Because their orbital growth is still in progress, children who have undergone treatment for retinoblastoma are at risk for the development of functionally and cosmetically significant bony orbital abnormalities. These sequelae become evident by early adolescence, when orbital growth is largely complete, and result in hourglass facial deformity.[515] Both enucleation, which causes orbital contraction, and radiation therapy, which induces arrest of bone growth, adversely affect orbital growth. In children who received treatment for bilateral retinoblastoma, the effect of enucleation on orbital development is not different from that of irradiation. However, final orbital volume after enucleation correlates with the size of the prosthetic implant.[516]

Patients with germline mutation of the *RB1* gene are at risk for development of second tumors.[433,515,516] These patients usually have multifocal, bilateral disease, which often is treated with radiation therapy, thereby further enhancing susceptibility to a second tumor. The cumulative incidence of second malignant tumors is 4% at 10 years, 18% at 35 years, and 51% at 50 years.[433,516] The tumors most commonly encountered are soft-tissue sarcoma, melanoma, and osteosarcoma. An apparent age effect on sarcoma risk has been identified. Patients who received radiation during the first year of life are at higher risk for development of sarcoma.[519] Patients with nonhereditary retinoblastoma are not at increased risk.[433,515]

HEPATOBLASTOMA

Epidemiology

Primary malignant tumors of the liver are rare in the pediatric population, constituting only 1.3% of malignant tumors in children younger than 15 years.[258] Of these, approximately 60% are hepatoblastomas. The median age at diagnosis of hepatoblastoma is 18 months.[527] Although more than 83% of cases occur during the first 5 years of life, the tumor occasionally is found in adolescents and adults. A male preponderance has been noted, with a male-to-female ratio of approximately 1.7 to 1. An intriguing association between extremely low birth weight and hepatoblastoma has been noted.[528–530] The explanation for this association is unresolved, but it has been suggested that environmental exposures in the neonatal intensive care unit, coupled with immature or genetically altered metabolic pathways, contribute to the genesis of hepatoblastoma.[529]

Tumor Biology

Insights into the genetic cause of hepatoblastoma have emerged over the past several years. In the 1980s, an association between hepatoblastoma and familial adenomatous polyposis (FAP) was found.[531] FAP is a disorder of autosomal dominant inheritance characterized by development of colorectal adenomas and nearly universal onset of colorectal carcinoma by the fifth decade of life.[532] Children of patients with FAP are at greatly increased risk for hepatoblastoma compared with the general population. In one study, investigators estimated an 847-fold risk; other investigators reported an overall risk of 0.4% to

0.6%.[533–535] Conversely, it is estimated that 1 in 20 cases (5% to 10%) of hepatoblastoma are associated with FAP.[535,536] In light of these data, colorectal screening should be considered in parents of patients with hepatoblastoma and adolescent survivors of the disease. FAP is caused by a mutation in the adenomatous polyposis coli (*APC*) gene, which encodes a member of the Wnt signaling pathway. A central effector of this pathway is β-catenin, which associates with members of the Tcf family of transcription factors to promote expression of growth-related genes such as MYCC the and the cyclin D1 gene.[537] In normal cells, the APC protein associates with and promotes degradation of β-catenin. Mutations of the $APC_{protein}$, β-catenin itself, and other members of the Wnt signaling pathway lead to accumulation of β-catenin in cell nuclei, activation of Tcf target genes, and tumorigenesis. Germline *APC* mutations in patients with hepatoblastoma without FAP have been reported.[538] A study of sporadic hepatoblastoma revealed loss of heterozygosity or mutations at the *APC* locus in 69% of tumor specimens.[539] Other studies have shown activating β-catenin mutations in 48% to 65% of sporadic cases of hepatoblastoma.[540,541]

Hepatoblastoma can be associated with Beckwith-Wiedemann syndrome, an overgrowth disorder that manifests as high birth weight, macroglossia, organomegaly, hemihypertrophy, neonatal hypoglycemia, abdominal wall defects, ear pits and creases, and a predisposition to development of Wilms' tumor and other malignant lesions. In a series of 183 children with Beckwith-Wiedemann syndrome followed through the first 4 years of life, hepatoblastoma developed in 5 (2.8%) of the patients.[274] The syndrome has been linked to chromosome region 11p15.5, the site of the *IGF2* gene (see earlier, "Wilms' Tumor"). Loss of heterozygosity at this locus has been found in hepatoblastoma samples, implicating *IGF2* or other proximal genes in the development of this disease. As observed in Wilms' tumor, the maternal 11p15 allele is preferentially lost, indicating the presence of genomic imprinting at this site. Loss or relaxation of imprinting of *IGF2*, resulting in a double dose of the gene, has been found in some cases of hepatoblastoma.[542–544]

Cytogenetic studies of hepatoblastoma specimens have revealed that trisomy of chromosomes 20, 2, and 8 are the most frequent chromosomal aberrations in this tumor type.[545–549] A recurrent translocation, t(1;4)(q12;q34), also has been reported.[550,551] Comparative genomic hybridization of 10 hepatoblastoma samples revealed that the most common abnormalities were gains of chromosomes 1q, 2, 17, and 20 and loss of chromosomes 4 and 11.[552] The biologic and clinical significance of these cytogenetic findings is unknown.

Pathology

Hepatoblastoma represents 60% of cases of childhood liver cancer, followed by hepatocellular carcinoma (32%) and extrahepatic biliary tree sarcoma (8%).[553] Other primary malignant tumors that arise in the liver include angiosarcoma, embryonal rhabdomyosarcoma, carcinoid tumor, leiomyosarcoma, teratoma, lymphoma, and neuroblastoma. Benign liver processes in children include vascular tumors (hemangioma and hemangioendothelioma), hamartoma, adenoma, and focal nodular hyperplasia.

Hepatoblastoma most often is unifocal, arising in the right lobe of the liver. Microscopic vascular spread may be found beyond the apparently encapsulated tumor. Hepatoblastoma is classified as either purely epithelial or mixed, consisting of both epithelial and mesenchymal elements. The epithelial type contains either fetal or embryonal cells or admixtures of the two. Rare histologic variants of the epithelial type include the macrotrabecular and small cell (anaplastic) patterns.

The prognostic significance of histologic subtype in patients with hepatoblastoma is unresolved. Data from the 1970s and early 1980s first suggested that completely resected hepatoblastoma of pure fetal histologic type with low mitotic activity is associated with an excellent prognosis.[553–555] On the basis of this observation, in the first Intergroup Hepatoma Study (INT-98), doxorubicin alone was used for chemotherapy in nine patients with completely resected pure fetal hepatoblastoma. All of these patients were alive without disease when the results were reported.[556] The current COG protocol for hepatoblastoma provides for surgical resection alone in patients with completely resected pure fetal hepatoblastoma. By contrast, SIOP does not incorporate histologic subtype into its treatment stratification schema because it is unclear whether completely excised hepatoblastoma of pure fetal histologic type behaves differently from completely excised hepatoblastoma of other subtypes.[557] Moreover, a standardized definition of pure fetal hepatoblastoma is lacking. A growing consensus is that the small cell variant of hepatoblastoma is associated with poor prognosis.[527,558] This variant is easily misdiagnosed because it often is associated with low alpha-fetoprotein (AFP) level and may be present only focally within a tumor.

Clinical Manifestations and Patterns of Spread

Hepatoblastoma most often manifests as an asymptomatic abdominal mass, but systemic signs and symptoms, such as anorexia, weight loss, vomiting, and abdominal pain, can be part of the clinical presentation. In rare instances, the first sign is acute abdominal crisis due to tumor rupture. At physical examination, liver enlargement is found, but jaundice is rare, occurring in fewer than 5% of cases. Other infrequent features include hemihypertrophy (seen in 2% of cases) and precocious puberty (in less than 3% of cases), which occurs in patients whose tumors secrete β-human chorionic gonadotropin. Distant metastatic spread occurs most commonly to the lungs, affecting 10% of patients when the disease manifests. Spread to bone and the central nervous system occurs but is unusual.

Laboratory and Radiologic Evaluation

Ultrasonography typically is the first-line imaging procedure in evaluation of a child with an abdominal mass. For liver tumors, this modality is particularly useful in establishing the presence of a discrete mass within an enlarged liver and in delineating cystic components. CT can be used to define local extent of tumor involvement and to determine important landmarks but is not always reliable in assessment of resectability.[559] MRI is more accurate in this regard and helps define vascular involvement. Although commonly used in the past, angiography plays no role in the diagnostic evaluation of childhood liver tumors. Investigation of metastatic spread includes chest CT. Bone scans typically are not recommended because skeletal metastasis is rare, and osteopenia, which is commonly associated with hepatoblastoma, can result in misleading findings.[560]

Routine blood counts frequently reveal mild normochromic normocytic anemia and marked thrombocytosis. Liver enzyme and bilirubin levels are infrequently elevated. The most valuable laboratory test for both diagnosis and monitoring of hepatoblastoma is determination of serum AFP. AFP levels are elevated in 80% to 90% of patients with hepatoblastoma, presumably reflecting recapitulation of fetal liver development by the tumor. After complete resection, an exponential decrease to normal range can be expected. Failure to achieve normal levels implies the presence of residual disease. Secondary elevation implies disease recurrence. Clinicians should note that AFP levels normally are elevated at birth and gradually decline to adult levels over the first year of life.

Staging

In North America, staging for hepatoblastoma is based on postsurgical findings. Low stage is assigned to completely resected tumors and high stage to unresectable tumors and those with distant metastatic

Table 99-15 Postsurgical Staging System for Hepatoblastoma

Stage	Description
I, favorable histologic features	Gross total resection with clear tumor margins. *Favorable histologic type* defined as pure fetal type with fewer than two mitoses per 10 high-power microscope fields
I, unfavorable histologic features	Gross total resection with clear tumor margins and absence of favorable histology
II	Gross total resection with microscopic residual disease at the tumor margins
III	Gross total resection with nodal involvement or tumor spill or incomplete resection with gross residual intrahepatic disease
IV	Distant metastatic disease

involvement[556] (Table 99-15). With the advent of preoperative chemotherapy, SIOP introduced a presurgical grouping system called PRETEXT (for *pret*reatment *ext*ent of disease).[561] In this system, the liver is divided into four sectors on the basis of anatomic distribution of the major veins and bile ducts. Group I denotes that three adjoining sectors are tumor-free; group II, that two adjoining sectors are tumor-free; group III, that one sector or two nonadjoining sectors are tumor-free; and group IV, that all sectors are involved (Fig. 99-19). Invasion of the hepatic and portal veins, extrahepatic extension, and distant metastatic lesions are designated separately in this system.

Treatment

The survival rate for hepatoblastoma has improved markedly, from only 30% in the 1970s to 60% to 70% today.[562] This improvement may be attributed to the advent of effective adjuvant chemotherapy and to the use of liver transplantation for patients with otherwise unresectable disease. The underlying principle of hepatoblastoma treatment is that complete surgical resection is necessary to achieve long-term cure. Although complete excision is possible at diagnosis in 40% to 60% of patients,[527] preoperative chemotherapy can render the tumor resectable in most cases.[563–574] Analogous to the international debate regarding the timing of Wilms' tumor resection, differing opinions have been presented regarding whether preoperative chemotherapy should be delivered to all patients with hepatoblastoma. The COG advocates initial resection of the primary tumor whenever possible, because this approach allows the most accurate histologic diagnosis.[567] By contrast, SIOP favors preoperative chemotherapy for all patients to render the tumors more amenable to resection.[568]

Management of hepatoblastoma unresectable after systemic neoadjuvant chemotherapy is a clinical challenge. Disease confined to the liver after primary chemotherapy has been managed with chemoembolization, which induces tumor responses and surgical resectability in some patients.[569,570] For patients with unresectable tumors, orthotopic liver transplantation seems to offer the best possibility of cure. A systematic literature review of the world experience with liver transplantation in patients with hepatoblastoma revealed 6-year overall survival rates after transplantation of 82% for patients who received a primary liver transplant and 30% for patients who underwent rescue transplantation for recurrent disease or complications of partial hepatectomy [575] among children with hepatoblastoma managed with liver transplantation with or without adjuvant chemotherapy.[571–576] Cure after liver transplantation has occurred even in children with a history of pulmonary metastasis. These results are much more favorable than those for the experience with hepatocellular carcinoma, perhaps because of the inherent chemosensitivity of hepatoblastoma.

Even if complete resection of the primary tumor is attained, adjuvant chemotherapy is recommended to eradicate micrometastatic disease.[577] Box 99-8 outlines the approach to management of hepatoblastoma used at St. Jude Children's Research Hospital. Current chemotherapy regimens for hepatoblastoma are based on several generations of clinical trials. The CCG-823F study showed that the combination of cisplatin and continuous infusion of doxorubicin led

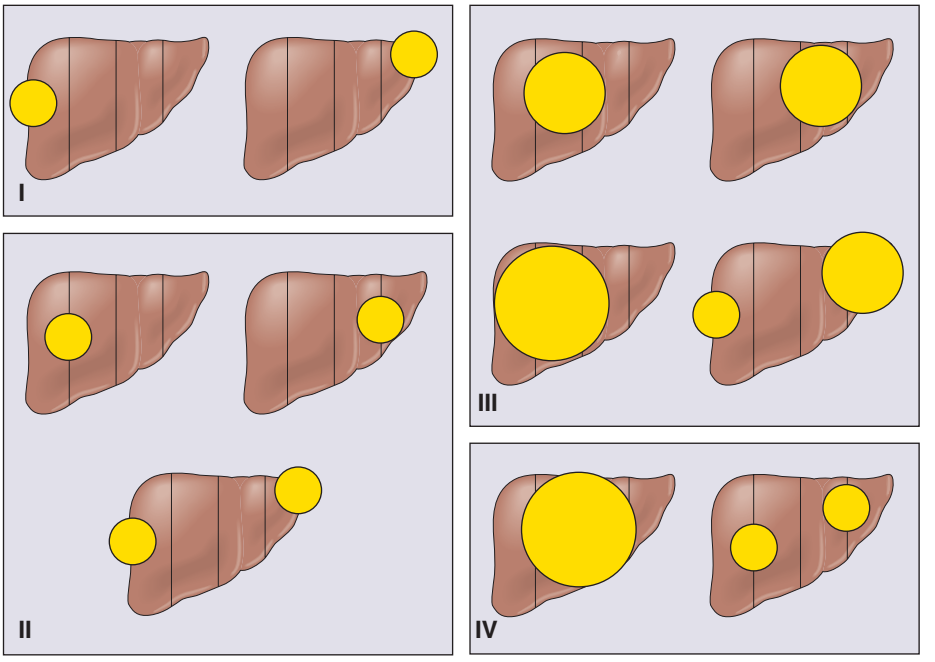

Figure 99-19 • Pretreatment staging system (Pretext) proposed by the International Society of Pediatric Oncology. The liver is divided into four sectors on the basis of the anatomy of the major vessels and bile ducts. Group I denotes one-sector involvement (three adjoining sectors are tumor free); group II, two-sector involvement (two adjoining sectors are tumor free); group III, three-sector involvement (one sector or two nonadjoining sectors are tumor free); and group IV, four-sector involvement (no sectors are free of tumor). Involvement can be either unifocal or multifocal, although hepatoblastoma usually is unifocal. Additional designations are given for metastasis, ingrowth into the vena cava or porta hepatis, and extrahepatic extension.

Box 99-8. ST. JUDE CHILDREN'S RESEARCH HOSPITAL APPROACH TO MANAGEMENT OF HEPATOBLASTOMA

Complete surgical resection is essential for achieving long-term cure in children with hepatoblastoma. At St. Jude Children's Research Hospital, surgical resection at diagnosis is attempted whenever feasible. If complete resection is achieved, patients receive four cycles of postoperative chemotherapy with cisplatin, 5-fluorouracil, and vincristine. Doxorubicin-containing regimens are reserved for patients with unresponsive or recurrent tumor. No standard of care has been established for patients with stage I hepatoblastoma of pure fetal histologic type with a low mitotic rate. In the current Children's Oncology Group hepatoblastoma study, such patients do not receive chemotherapy and are observed closely. If complete surgical resection is not feasible at diagnosis, four cycles of preoperative chemotherapy are administered, and resectability is reassessed. Once complete resection is achieved, patients receive two additional cycles of chemotherapy. Patients with tumors unresectable after chemotherapy are considered for liver transplantation or other local control measures, such as chemoembolization. The presence of distant metastatic disease that is resectable or resolves with chemotherapy does not preclude complete resection of the primary tumor or liver transplantation.

to a measurable tumor response in 75% of patients with initially unresectable disease and that 58% of these patients continued to be disease-free after treatment.[563] Contemporaneously, the POG-8697 study achieved similar results with a regimen of cisplatin, vincristine, and 5-fluorouracil.[565] The cisplatin-doxorubicin and cisplatin–vincristine–5-fluorouracil regimens were compared in a randomized trial (INT-98) that revealed 5-year EFS estimates of 69% for the doxorubicin-containing arm and 57% for the 5-fluorouracil–vincristine-containing arm ($P = 0.09$).[556] EFS rates were 100% for stage I favorable histologic type, 91% for stage I unfavorable histologic type, 100% for stage II, 64% for stage III, and 25% for stage IV. Because toxicity was more frequent with the doxorubicin-containing regimen, the combination of cisplatin–vincristine–5-fluorouracil emerged as the standard chemotherapy regimen in North America. The SIOPEL-1 study, in which a cisplatin-doxorubicin combination was used, yielded the subsequent COG 9645 study, which tested the hypothesis that intensification of platinum drugs would improve outcomes for patients with stage III or IV disease. Patients were randomized to receive cisplatin–vincristine–5-fluorouracil versus cisplatin alternating with carboplatin. The study was closed early after 3 years of enrollment because improvement with the cisplatin-carboplatin arm was statistically excluded. Three-year EFS rates were 60% for patients receiving cisplatin–vincristine–5-fluorouracil and 38% for patients receiving cisplatin plus carboplatin.[578] The COG 9645 study also evaluated whether the chemoprotectant amifostine prevents cisplatin-induced toxicity. At the dose and schedule used, amifostine was not protective.[579]

The European-based SIOPEL studies have taken a different approach. The SIOPEL-1 study used a cisplatin-doxorubicin combination (PLADO), which resulted in a 5-year EFS rate of 66% and a 5-year overall survival rate of 75%.[563] As in the INT-98 study, patients with metastatic disease had a 5-year EFS rate of only 28%.[580] The SIOPEL-2 study piloted a regimen of single-agent cisplatin for patients with localized hepatoblastoma confined to no more than three liver sectors (PRETEXT group III or lower).[568] Promising results were obtained using this regimen. Accordingly, the SIOPEL-3 study was designed to compare the effectiveness of cisplatin plus doxorubicin versus cisplatin alone in patients with localized hepatoblastoma. With this approach, the 3-year overall and progression-free survival rates were 91% and 89%, respectively.[581] Because of the success of single-agent cisplatin, the subsequent study, SIOPEL-3, was designed to compare the effectiveness of cisplatin plus doxorubicin with that of cisplatin alone in patients with tumors in PRETEXT group III or lower. Results have not yet been reported. Patients with high-risk disease (PRETEXT group IV tumors or distant metastases) received alternating courses of carboplatin plus doxorubicin and single-agent cisplatin on SIOPEL-2 and -3. This yielded 3-year overall and progression-free survival rates of 59% and 55%.[582] The German Pediatric Oncology Group used an ifosfamide-doxorubicin-cisplatin regimen, which resulted in a long-term disease-free survival rate of 75%.[583]

To summarize, modern cisplatin-containing chemotherapy regimens produce very good outcomes for patients with localized and completely resected hepatoblastoma. Novel agents and approaches are needed to improve outcome among patients with metastatic disease.

The role of radiation therapy in the management of hepatoblastoma is limited and undefined. Studies conducted with small series showed that in patients with microscopic or gross residual disease, local control can be achieved with radiation therapy and chemotherapy. These results suggest a possible role for irradiation in this setting.[565,584,585] Successful use of radiation therapy also has been reported for control of pulmonary metastatic lesions after wedge resection and chemotherapy.[584,585] In view of the effectiveness of surgery and chemotherapy, however, radiation therapy is not considered first-line therapy for hepatoblastoma.

Recurrence of hepatoblastoma usually confers a poor prognosis, especially if disease recurs locally or within 6 months after the initial manifestations. Long-term survival has been achieved, however, with aggressive surgical management, especially in the setting of isolated pulmonary metastatic disease.[586] The agent irinotecan has shown activity against recurrent hepatoblastoma.[587,588] The role of high-dose therapy followed by autologous stem cell rescue is unclear.

Although progress has been made in the management of hepatoblastoma, the goal of future studies will be to identify new agents with activity against this disease and to systematically define the role of orthotopic liver transplantation. Future trials will attempt to limit toxicity and the late effects of treatment without compromising care.

ADRENOCORTICAL CARCINOMA

Epidemiology

Adrenocortical carcinoma (ACC) is one of the rarest and most aggressive endocrine neoplasms. It follows a bimodal distribution, having peaks during the first and fourth decades of life.[589] Among children, 25 new cases are expected to occur annually in the United States, for an estimated annual incidence of 0.2 to 0.3 case per million population. Internationally, however, the incidence of ACC appears to vary substantially. The incidence of ACC is particularly high in southern Brazil, where it is approximately 10 to 15 times that in the United States. Most cases occur in the contiguous states of São Paulo and Paraná. Predisposing genetic factors have been implicated in 50% of cases in the United States and in 95% of cases in Brazil. In patients in both countries, germline *TP53* mutations are almost always the predisposing factor. In the United States, the incidence of cancer (Li-Fraumeni syndrome) often is high among relatives of children with ACC, and germline mutations occur in the *TP53* DNA-binding domains (exons 2 to 8). In Brazil, by contrast, patients' families do not have a high incidence of cancer, and a single mutation in axon 10 of the *TP53* gene is consistently observed in these children. This mutation occurs within the tetramerization domain of *TP53* (*TP53*-

R337H). This mutant tetramerization domain is less stable than the wild-type domain and is highly sensitive to pH in the physiologic range. This inherited unique *TP53* mutation represents a low-penetrance allele that contributes to development of ACC in a tissue-specific manner.[590,591] The incidence of *R337H* mutations in U.S. children with ACC is not known.

Clinical Manifestations

Typical clinical manifestations of ACC are the signs and symptoms of increased production of androgens (virilization) or cortisol (hypercortisolism or Cushing's syndrome). In rare instances, patients exhibit signs of hyperestrogenism (feminization) or aldosteronism (Conn's syndrome). Mixed syndromes are frequent. In general, 40% to 80% of patients have functioning tumors,[589–598] although as many as 50% of tumors may produce mainly hormonal precursors of low bioactivity.[596] An apparent correlation between the degree and type of endocrine disturbance and the age of the patient has been described.[589,594] Older patients are much more likely to have nonfunctioning tumors, whereas more than 90% of children have functioning neoplasms.[594,599–601] Adults usually have mixed virilization-hypercortisolism syndromes, whereas virilization syndromes constitute the most common manifestation in children. Most patients (50% to 60%) come to medical attention with large tumors and advanced regional or metastatic disease.[580–586,592–598,602] Distant metastatic lesions usually affect liver, lungs, and bone, in that order of frequency.[594]

Diagnosis

The diagnosis of ACC is straightforward. Because most affected children have an endocrine syndrome, an increased blood or urine concentration of adrenocortical hormones and a mass in the suprarenal region usually suggest a preoperative diagnosis of adrenocortical tumor. The distinction between benign (adenoma) and malignant (carcinoma) tumors, however, may not be easy. Several investigators have proposed histologic criteria that may help in discriminating between the two types of neoplasms.[603,604] Of note, the morphologic criteria used to differentiate benign from malignant pediatric adrenocortical tumors may not be reliable, especially in cases of carcinoma.

Prognostic Factors

In addition to stage at diagnosis, specific biologic and histopathologic characteristics within individual tumors appear to dictate outcome. Mitotic rate has been consistently reported as the most important determinant of aggressive behavior.[593,602,605,606] Tumor size, however, appears to have independent prognostic value.[602,606] Tumor size is especially important in children; with tumors smaller than 200 cm^3 or 100 g, the outcome is excellent with surgery alone.[599,607,608]

Treatment

Surgery is the mainstay of therapy for ACC. Curative, complete resection may be attempted in the 70% to 75% of patients with locoregional disease. Low stage and the ability to perform complete resection are the most important prognostic factors.[592,593,596,597,602,609] Despite efforts at curative surgery, however, the 5-year survival rate is not better than 30% to 40%.[593,594–598] As many as 70% to 80% of patients with a localized primary tumor experience recurrence.[602] Recurrences may be locoregional (15% to 25%), combined local and distant (25% to 30%), or distant alone (50%).[593,602,610] In childhood ACC, more than 90% of patients with stage I disease are long-term survivors, compared with 10% of those with stage IV disease. Despite presumed complete tumor resection, disease recurs in 50% of patients with stage II disease.[599] Because of tumor friability, rupture of the capsule leading to tumor spillage is frequent. Large ACC tends to adhere to adjacent structures (e.g., vena cava) and to have large necrotic and friable areas that make radical excision without capsule rupture very difficult.

For patients with advanced disease or with high risk of recurrence, systemic therapy with mitotane or chemotherapy is indicated, although the effect of this therapy on overall outcome is not well established. Mitotane (*o,p′*-DDD) both inhibits corticoid biosynthesis and destroys adrenocortical cells. At low doses (less than 3 g/day), mitotane suppresses secretion of adrenal steroids, providing symptomatic improvement and regression of some of the endocrine dysfunction. Higher doses (greater than 3 g/day) are required for an adrenolytic effect.[592,594] In patients with advanced disease, objective responses are obtained in approximately 20% to 30% of cases.[592,594,596,611] These responses are transient, however, and the effect on prolongation of survival is uncertain.[594,596,612] In children, the use of mitotane for advanced ACC has not been evaluated systematically. Complete responses in children with advanced or metastatic ACC have been described but appear to be rare events.[613–615] The pharmacokinetics of mitotane and the ability to maintain therapeutic levels for long periods appear to affect the antitumor effect. Serum levels plateau after 8 weeks of treatment,[594] and optimal antitumor responses occur when serum levels are maintained at more than 14 μg/mL for long periods.[609,611] A major problem, however, is the severe gastrointestinal and neurologic toxicity associated with administration of mitotane. The toxicity limits patient adherence to therapy, especially among children.[594,596,611] An alternative approach to use of high doses of mitotane is administration of low doses (2 to 3 g/day) for longer periods. With the appropriate monitoring, therapeutic levels can still be achieved after 3 to 5 months.[616,617] Chemotherapeutic agents other than mitotane have been less often evaluated in management of ACC. Cisplatin-based regimens induce responses in 20% to 40% of patients.[618–620] Preclinical studies have shown that mitotane reverts the multidrug resistance phenotype in vitro,[621] providing a rationale for the combination of mitotane with etoposide-containing regimens.[622,623] Responses have been observed in 53% of patients when the combination of mitotane with cisplatin, etoposide, and doxorubicin has been used.[623]

NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma (NPC) is very rare in children. Only 1% of all cases of NPC occur in patients younger than 19 years of age.[624] In the United States, the incidence of NPC in children is approximately 1 to 1.5 cases per million population per year. NPC represents approximately 1% of all pediatric malignant tumors, but it accounts for 35% to 50% of all nasopharyngeal malignant tumors.[625] In the United States, NPC appears to be more prevalent in the southern states and among African-American children.[626] The role of EBV in the development of NPC has been well established. EBV is harbored in almost every tumor, as shown by the presence of EBV DNA, RNA, and proteins in tumor tissue samples.[627–630] The role of EBV in neoplastic transformation is further supported by the presence of clonality. In nonendemic areas of the Western hemisphere, other causative factors, such as alcohol and tobacco use, may have an important role. Information on the clinical and biologic characteristics of childhood NPC is scarce, in particular that related to the role of EBV in its pathogenesis. Both histologic subtype and age at clinical manifestation of the tumor, however, suggest that pediatric NPC may be strongly associated with EBV infection. No studies have been aimed at characterizing or confirming the role of EBV in the pathogenesis of NPC in children.

Few studies have analyzed the clinical characteristics and outcome of NPC among children.[625,626,631–640] In almost all cases of NPC in this age group, type III histologic features are present, and clinical manifestation occurs at advanced stages. Most of these studies incor-

porated the use of cisplatin- or doxorubicin-based neoadjuvant and adjuvant chemotherapy.[625,631–638] With this combined approach, the survival rate among patients with advanced disease is 60% to 70%. The best results have been those reported by Douglass and collaborators at St. Jude Children's Research Hospital.[641] In their series of 21 patients, four courses of neoadjuvant chemotherapy with methotrexate, cisplatin, 5-fluorouracil, and leucovorin were given, followed by radiation therapy (in doses of 66 to 70 Gy). All 21 patients achieved complete remission, and 20 of them were long-term survivors. Because children are particularly sensitive to the toxicity related to therapy for NPC, alternatives aimed at decreasing toxic effects are of particular importance in this population. The alternatives include use of amifostine and investigation of carboplatin as an alternative to cisplatin.
