The most troublesome acute reaction for patients who are receiving radiation therapy to the oral cavity is radiation-induced mucositis. Acute mucositis results from the loss of squamous epithelial cells owing to the sterilization of mucosal stem cells and the inhibition of transit cell proliferation. This leads to a gradual linear decrease in epithelial cell numbers. As radiation therapy continues, a steady state between mucosal cell killing and mucosal cell regeneration may occur because of an increased cell production rate from the surviving cells. Usually, however, cell regeneration cannot keep up with cell killing, and partial or complete denudation develops. This presents as patchy or confluent pseudomembranous mucositis. Healing eventually occurs when cells regenerate from the surviving mucosal stem cells. The loss of the epithelial barrier exacerbates insults from physical, chemical, and microbial agents. It has been reported that the oropharyngeal flora may contribute to radiation therapy–induced mucositis. However, which flora is involved and which step in the mucositis process may be prevented by eliminating the offending flora remain unknown. One hypothesis is that endotoxins produced by gram-negative bacilli are potent mediators of the inflammatory process.

The oral cavity mucosa, having a relatively high turnover rate, change early during a course of fractionated external-beam radiation therapy. With 200-cGy fractions per day, 5 days per week, mucosal erythema is typically noted within the first week or two of treatment. By approximately 2 to 3 weeks, the erythematous mucosa develops small whitish yellow patches called patchy pseudomembranous mucositis. These pseudomembranes represent collections of dead

surface epithelial cells, fibrin, and polymorphonuclear leukocytes on a moist background. This acute reaction is typically accompanied by oral discomfort. In many patients, the patchy mucositis becomes confluent by the third or fourth week of radiation therapy and can be associated with significant pain.

The severity of mucositis is related to the daily dose of radiation therapy, the total cumulative dose, the volume of irradiated tissue, and the use of concurrent radiation-sensitizing and/or mucositis-inducing chemotherapeutic agents. At fractions of 170 to 180 cGy daily, 5 days per week, the maximal reaction is typically intense erythema with occasional patchy mucositis. In this situation, the cell killing and repopulation of epithelial stem cells are in near equilibrium. If the daily dose is increased to 200 cGy or more, as in the case of altered fractionation schedules such as hyperfractionation (110 to 150 cGy twice a day) or accelerated fractionation (160 cGy two or three times a day or concomitant boost with 180 cGy in the morning and 150 cGy in the afternoon), and the treatment volume is large (the entire oral cavity), cell killing will exceed the proliferative capacity of the epithelial stem cells, and almost all patients will have confluent mucositis by the third week of radiation therapy. Mucositis first appears and is often most severe on the mucosa of the soft palate, tonsillar pillars, buccal mucosa, lateral border of the tongue, and pharyngeal walls. In contrast, mucositis less frequently involves the hard palate, gingival ridges, and dorsum of the tongue during a course of radiation therapy or, alternatively, only after very high doses or when administered with concurrent radiation-sensitizing chemotherapy. In patients with metallic dental restorations, a prominent mucositis frequently develops on the adjacent buccal mucosa and/or the lateral border of the adjacent tongue or both as a result of backscattering of low-energy electrons.

Symptoms of oral discomfort are usually maximal 3 to 4 weeks into the course of radiation therapy. Thereafter, symptoms usually plateau and may even diminish in patients who are treated with radiation therapy alone, even though treatment is continued. After external-beam radiation therapy, the mucous membranes normally heal within 4 to 6 weeks, although an occasional patient might require up to 12 weeks or even several months. The latter is particularly true of patients treated with concurrent radiation-sensitizing chemotherapy.

The mucositis that is produced by an interstitial radioactive implant typically appears 7 to 10 days after removal and is maximal approximately 2 weeks after removal. The mucositis generally heals by 6 weeks unless the implanted volume was large, in which case complete healing may require several months.

Radiation-induced oral mucositis can result in intense pain, which may substantially limit adequate hydration and nutrition, prevent proper oral hygiene, serve as a portal for infection, and affect speech. All these effects can significantly interfere with the general well-being of the patient and might tempt the treating physician to interrupt the course of treatment to permit resolution of the acute symptoms. At times, the treatment might be discontinued altogether before delivery of a potentially curative dose of radiation therapy.

Clinical and radiobiologic evidence shows that the protraction of overall treatment time adversely influences the radiocurability of certain human tumors, particularly squamous cell carcinomas of the head and neck region. The additional dose that is needed to compensate for a protracted course of radiation therapy has been attributed to an accelerated tumor clonogenic growth rate. Randomized clinical trials have demonstrated improved local control and survival when altered fractionation schemes that deliver conventional or higher doses of radiation therapy are used over a shorter-than-conventional period.[69] Therefore, a break in radiation therapy because of mucositis may lead to treatment failure.

Prevention and Treatment

In light of the serious deleterious effects that radiation-induced oral mucositis may have on a patient's well-being and the potential loss of tumor control that may result from an interruption or prolongation of treatment because of mucositis, measures for preventing mucositis are being investigated. Benzydamine hydrochloride 0.15% oral rinse, a nonsteroidal drug, that has analgesic, anesthetic, anti-inflammatory, and antimicrobial properties, is effective, safe, and well tolerated for prophylactic treatment of radiation-induced oral mucositis.[49,70] Nonetheless, benzydamine is not approved for this use in the United States, as the data are not convincing regarding its benefit and as some of the studies looking at it used an alcohol-based control arm (which should cause toxicity in patients getting radiation therapy) instead of an inert placebo substance.

Several controlled clinical trials have evaluated the combination of relatively nonabsorbable antibiotics (tobramycin, polymyxin E, and amphotericin B or bacitracin, clotrimazole, and gentamicin or iseganan) for patients undergoing radiation therapy to the oral cavity.[49,71–79] In total, these trials do not provide convincing data of sufficient clinical magnitude to recommend use of antimicrobial mouthwashes (chlorhexidine or benzydamine), antibiotic lozenges, or paste as part of standard practice. For a critical review, the reader is referred to an article by Sutherland and Browman.[80]

The inability to control mucositis-related pain can be frustrating for both the patient and the treating physician. Viscous lidocaine with 1% cocaine; dyclonine hydrochloride 1.0%; a mixture of kaolin-pectin solution, diphenhydramine, and saline; morphine; tricyclic antidepressants; a mucosa-adhesive water-soluble polymer film containing topical anesthetics and antibiotics; oral aloe vera; capsaicin lozenges; and a sodium-sucrose octasulfate oral rinse have all been evaluated, with mixed results.[81–86] Janjan and colleagues[87] reported improved pain management in patients undergoing radiation therapy for head and neck cancer with daily nursing intervention consisting of instructions on the use of mouthwashes and a three-step analgesic protocol consisting of acetaminophen, acetaminophen with codeine suspension, and liquid morphine for relief of mild, moderate, and severe pain, respectively. The physician promptly changed the prescribed analgesic regimen when the patient's symptoms changed. Patients who had daily nursing intervention reported fewer days of moderate and severe pain; had less pain throughout the day; and noted less disturbance in sleep, eating, and energy level. Daily review of a symptom survey by a radiation oncology nurse combined with a well-defined strategy for mouth care and analgesics appeared to improve pain management of radiation-induced oropharyngeal mucositis because of prompt attention to patient needs. Many narcotic pain medications come in a liquid formulation that is relatively easy to swallow or can be administered through a feeding tube. Fentanyl patches are also very effective for patients who cannot swallow. A topical morphine mouthwash might be a more effective treatment for mucositis pain than a commonly utilized "magic mouthwash" (lidocaine, diphenhydramine, magnesium aluminum hydroxide).[88]

Additional interventions for preventing or minimizing radiation-induced mucositis have been evaluated. One such intervention involves the use of a sucralfate suspension, an agent that appears to provide a protective barrier and may also have a cytoprotective effect. The latter may be mediated through prostaglandin release, resulting in increased mucosal blood flow, increased mucus production, increased mitotic activity, and a surface migration of cells. However, results from small double-blind, placebo-controlled, randomized prospective trials are contradictory.[89–95] Thus, the randomized trials of sucralfate for therapy-induced mucositis do not establish a role for sucralfate in clinical practice.

In an evaluation of another intervention, Maciejewski and colleagues[96] reported that painting the buccal mucosa with a 2% silver nitrate solution for several days before radiation therapy stimulates normal mucosa repopulation during radiation therapy, producing a significantly less severe mucosal reaction and faster mucosal healing after completion of radiation therapy. Low-energy laser therapy might also activate epithelial healing. A phase III, randomized, placebo-controlled trial to evaluate the efficacy of low-energy

helium-neon laser in the prevention of radiation-induced mucositis demonstrated significant reductions in severity and duration of oral mucositis associated with radiation therapy, even when combined with chemotherapy.[97] A double-blind, placebo-controlled, randomized trial of treatment with 40 mg of prednisone, beginning on day 8 of an accelerated course of radiation therapy, did not show a reduction in the intensity or duration of mucositis. However, there was a trend favoring prednisone in terms of shorter treatment interruptions and a significant reduction in overall treatment time.[98] Zinc sulfate, α-tocopherol, and intravenous L-alanyl-L-glutamine have been found to be effective in decreasing the severity of radiation-induced mucositis and oral discomfort in placebo-controlled prospective trials.[48,99,100] In an uncontrolled evaluation, orgotein, a Cu-Zn superoxide dismutase, demonstrated reduced acute toxicity associated with radiation therapy.[101] These unique approaches to the problem of acute mucositis deserve further study.

Other preliminary studies have investigated the direct application of a prostaglandin E_2 gel,[102] the use of oral glutamine,[103] and daily use of subcutaneous GM-CSF.[104] Results of pilot studies suggested that GM-CSF might be quite effective in the prevention and treatment of radiation-induced oral mucositis.[105–108] However, prospective randomized clinical trials have revealed no definite evidence that subcutaneously administered GM-CSF reduce the severity of radiation-induced mucositis.[109,110] On the other hand, some early murine mucosal and human clinical data suggest that keratinocyte growth factor might be efficacious in the prevention and treatment of radiation-induced mucositis.[55,111–113] This was previously reviewed in the section on prevention of chemotherapy-induced oral mucositis. A multicenter study of intravenous palifermin to reduce mucositis in patients with head and neck cancer receiving chemoradiotherapy is being conducted by the Radiation Therapy Oncology Group.

The radioprotector amifostine has been evaluated as a means of preventing radiation-induced acute mucositis. One small randomized clinical trial reported that amifostine reduced the severity of acute mucositis.[114] Unfortunately, larger randomized trials evaluating intravenous or subcutaneous amifostine in patients receiving radiation therapy alone or combined with chemotherapy have revealed conflicting results.[115–119] Nausea, vomiting, hypotension, and allergic and injection site reactions are common side effects of this drug. These side effects may be reduced by rapid intravenous push, optimal hydration of the patient, premedication with antiemetics, and subcutaneous administration. The questionable efficacy and significant toxicity are associated with remarkably increased costs.[120] In total, present data are insufficient to recommend amifostine at the current dose and schedules to prevent mucositis associated with radiation therapy.[121]

One should not forget the role that sophisticated radiation therapy treatment planning can have in limiting the volume of normal tissues that are irradiated and thereby reducing the severity of normal tissue reactions. Normal tissue reactions can be reduced in a substantial number of patients with head and neck cancer by the use of computed tomography-based target delineation, intensity-modulated radiation therapy and simple, custom-made, intraoral devices that are designed to exclude uninvolved tissues from the treatment portals or to provide shielding of tissues within the treatment area.[118,122,123] Patients with primary cancers of the oral cavity, oropharynx, paranasal sinuses, and salivary glands are the best candidates for the use of such devices. These intraoral stents can be very useful in excluding the mucosa of the tongue and the floor of the mouth when hard palate, nasal cavity, and paranasal sinus malignancies are being treated. These same stents can be useful in excluding the palate mucosa during treatment of the tongue or floor of the mouth. Shielding stents made with a lead alloy were found to be useful in treatment of well-lateralized tumors of the oral cavity, parotid gland, lip, and skin of the cheek. These shielding stents can decrease the amount of radiation that is delivered to the contralateral mucosa. More frequent use of electron-beam and/or sophisticated three-dimensional conformal, multibeam, wedged-pair, or oblique treatment plans will also help to exclude or minimize the radiation dose to uninvolved mucosa. Packing gauze between metallic dental restorations and mucosa of the lateral tongue and buccal area appears to be very beneficial in minimizing the dose from scattered radiation.

Given these data, what measures should be taken to prevent and treat mucositis in patients receiving radiation to the oral cavity? Standard practice often includes aggressive, good oral hygiene consisting of brushing teeth after each meal, using a soft toothbrush and baking soda toothpaste, and rinsing the mouth every 2 hours throughout the day with a half-strength hydrogen peroxide or alkaline solution. Patients should be instructed to avoid the use of irritating or abrasive substances such as commercial toothpastes and mouthwashes; tobacco; alcoholic beverages; extremely hot or cold drinks or foods; very spicy foods; acidic foods such as citrus fruits and their juices; and foods that are hard and coarse, such as pretzels, raw vegetables, potato chips, crackers, and hard bread. When discomfort develops, topical anesthetic agents can be used. As the pain progresses, use of systemic analgesics, including acetaminophen with codeine suspension or oral morphine sulfate elixir, might become necessary. Suspensions are preferred over elixirs because suspensions are formulated without alcohol. As Janjan and colleagues suggest,[87] daily intervention by a radiation therapy nurse or physician with prompt increases in doses of systemic analgesics appears to result in improved pain control, improved sense of well-being, and less weight loss.

The mucosa of patients undergoing radiation therapy to the oral cavity should be examined at least once a week, and antibiotic or antifungal medications should be prescribed as infections are documented. Clotrimazole troches, one dissolved in the mouth five times a day for 14 days, generally work well for oral candidiasis. However, if significant mucositis, altered taste, or xerostomia has developed, the troches might not be tolerated. In this situation, nystatin oral suspension or fluconazole in tablet or liquid form is often effective. Fluconazole is more effective than nystatin and might need to be given at a higher dose and/or for an extended period of time in patients who are receiving combined chemotherapy and radiation therapy due to infections with resistant species.[124,125]

Xerostomia

Etiology

The major salivary glands (parotid, submandibular, and sublingual) produce most of the salivary secretion (up to 80%). The rest of the saliva is produced by minor glands scattered throughout the oral cavity. It is estimated that the sublingual glands contribute only 2% to 5% of the salivary flow rate. Submandibular glands seem to be as important as, or more important than, parotid glands in the resting state, although parotid glands become the main contributors under stimulation.

When radiation therapy treatment fields include the major salivary glands, many patients will experience dryness of the oral mucosa during the first 1 or 2 weeks of treatment. Not only is the quantity of saliva reduced, but its composition and physical properties are changed as well. Drastic reductions of baseline and reflex production of alkaline and watery secretions of serous acini often persist after the completion of radiation therapy. Without appropriate management, this problem can lead to progressive deterioration of the teeth, mucosa, gingiva, and mandible.

The acute radiation response of serous salivary glands has been shown to be due to interphase killing of serous cells. Chronic atrophy of these glands is attributed to the death of the reproductive stem cells and damage to the fibrovascular stroma. A progressive reduction in salivary flow rates, pH, and secretory immunoglobulin A (IgA) with increasing doses of radiation therapy has been demonstrated. In 90% of parotid glands that receive less than 1000 cGy, there will be continued secretion of measurable quantities of saliva after stimula-

tion. This is reduced to 50% after administration of 3000 cGy, 19% after 5000 cGy, and 0% after 7000 cGy. In 94% of patients receiving doses of less than 5200 cGy, there may be recovery of secretion beginning 2 months after treatment with continual improvement of the salivary flow for up to 18 months. Doses exceeding 6400 cGy cause irreversibly depressed parotid function in the majority of glands. Patients who receive doses of more than 6400 cGy to one gland might have only slight dryness; however, patients with both glands irradiated will have severe problems with salivary flow and discomfort of dryness. Exclusion of more than 50% of both parotid glands from the direct radiation beam can prevent severe dryness when the rest of the major salivary glands are included in the field. There is a linear correlation between postradiotherapy flow ratio and parotid gland dose (5% loss of function per 1 Gy of mean dose) and a strong parotid volume dependency.[126] There is no threshold dose. Therefore, in radiation treatment planning, attempts should be made to achieve as low a mean parotid dose as possible. A mean dose below 39 Gy has a complication probability of 50%. Recovery of parotid function can be demonstrated at 6 months, 12 months, and 5 years after radiation therapy.[127,128]

Eisbruch and colleagues[129] and Blanco and colleagues[126] suggested that a mean parotid gland dose of ≤26 Gy should be a planning goal if substantial sparing of the gland function is desired. Using the Normal Tissue Complication Probability model, they found that the dose/volume/function relationships in the parotid glands are characterized by dose and volume thresholds, steep dose/response/function relationships when the thresholds are reached, and a maximal volume dependence parameter. Chao and colleagues[130] observed a correlation between mean parotid dose and the fractional reduction of stimulated saliva output at 6 months after the completion of radiation therapy. They also noted that responses to quality-of-life questions on eating and speaking functions were significantly correlated with stimulated and unstimulated saliva flow at 6 months. Therefore, sparing of the parotid glands should translate into objective and subjective improvement of xerostomia and quality of life in patients with head and neck cancer receiving radiation therapy. Eisbruch and colleagues[129] found that the degree of xerostomia was related to the degree of preradiation therapy xerostomia, the time since radiation therapy, and the mean dose to the major salivary glands (most notably the submandibular gland) and to the oral cavity. This would suggest that sparing of the oral mucosa with its minor salivary glands is an important goal in treatment planning to reduce the severity of radiation-induced xerostomia.

Prevention and Treatment

Treatment of radiation-induced xerostomia includes the avoidance of any drugs that might also decrease the flow of saliva and contribute to the discomfort of xerostomia. These drugs may include anorectic agents, anticholinergics, antidepressants, antihistamines, antihypertensives, antipsychotics, antiparkinsonian agents, diuretics, caffeine, nicotine, hypnotics, and sedatives. Patients should be advised to take frequent sips of water and suck on ice chips. Because chewing stimulates the flow of saliva, patients with residual salivary function may be helped by eating foods such as carrots or celery or by chewing sugarless or xylitol-containing gum. Patients with xerostomia are highly susceptible to dental caries and should not use sugar-containing foods or acidic foods or beverages to stimulate salivary flow. Commercial nonprescription solutions that are used to lubricate the oral tissues might be the only effective treatment for patients without functioning salivary gland parenchyma or for those whose salivary glands do not respond to stimulation. Virtually all lubricants can provide some short-term relief for patients with xerostomia. Some studies have indicated that salivary substitutes that contain carboxymethylcellulose or hydroxymethyl cellulose are more effective in relieving dryness than are water- or glycerin-based solutions. Some patients prefer mucopolysaccharide solutions. Xialine, a xanthan gum–based saliva substitute, has been shown to be no better than placebo in decreasing the effects of xerostomia, although a trend was seen in favor of Xialine for improving problems with speech and senses.[131] Various reports have suggested that acupuncture can subjectively (patient-completed xerostomia inventories) and objectively (unstimulated and stimulated salivary flow rates) reduce symptoms of xerostomia and improve salivary flow rates.[132–134]

For the treatment of established radiation-induced xerostomia, the following are recommended (Box 40-3):

- Pilocarpine: 5.0 mg, given orally three to four times a day, up to 10 mg three times a day maximum
- Artificial saliva (Mouthkote, Xerolube, Moistir, Salivert, Sage)
- Biotene products (gum, toothpaste, mouthwash)

Xerostomia primarily affects mastication and oral manipulation of dry, absorbent food material. Initiation and duration of the pharyngeal swallow do not appear to be affected. Patients with severe xerostomia may be helped by eating soft, bland foods, especially cool or cold foods with a high liquid content, such as ice cream, Popsicles, puddings, watermelon, and grapes. Solid foods can be made easier to swallow by adding gravies, sauces, melted butter, broth, mayonnaise, yogurt, or salad dressing. Dunking bread and other baked foods in milk or other liquids will make them easier to swallow. Some patients may find a pureed diet or a full-liquid diet easier to swallow than solid foods. Addition of a liquid high-protein supplement will help to ensure that patients are getting enough protein and calories. Hot, spicy, or acidic foods may be irritating and should be eaten with caution. Some patients find that a vaporizer or humidifier in the room or at the bedside helps to alleviate the discomfort of xerostomia. Frequent oral rinses with an alkaline solution may help to refresh the taste, moisten the mouth, and promote better hygiene.

Two large randomized, double-blind, placebo-controlled, multicenter clinical trials have documented the efficacy of oral pilocarpine (5.0 mg given orally three times a day) in relieving oral dryness; improving salivary flow, mouth comfort, and ability to speak; and reducing the need for oral comfort agents after head and neck irradiation. Adverse reactions are minimal, the most common being mild to moderate sweating, which is dose-related. Best results may require continuous treatment for more than 8 weeks.[135–137] Most patients report significant relief of symptoms of xerostomia and improvement in quality of life that do not appear to be dependent on previous radiotherapy dose/volume parameters, suggesting that oral pilocarpine acts primarily by stimulating ectopic salivary glands and can be of benefit for a whole range of patients with xerostomia of varying severity. Topical pilocarpine administration has shown results similar to those achieved with systemic treatment but with improved patient tolerance.[138]

One small retrospective trial and two small double-blind, placebo-controlled, randomized trials suggested that pilocarpine (5.0 mg given orally four times a day), started the day before or on the same day as radiation therapy, given concurrently with radiation therapy

Box 40-3. PREVENTION AND THERAPY OF RADIATION-INDUCED XEROSTOMIA

Prevention of radiation-induced xerostomia has been actively studied in the recent past. Results from the use of pilocarpine in this situation have been mixed, the largest placebo-controlled trial being negative. However, on the basis of results of clinical trials, the FDA has approved amifostine in the adjuvant setting as an agent that can attenuate the development of xerostomia. Nonetheless, the inconvenience and toxicity of this drug therapy limit its use in some practices. Intensity-modulated radiation therapy has been shown in a phase III trial to preserve salivary flow and improve quality of life in patients with early stage nasopharyngeal carcinoma.

and for 3 months after radiation therapy, results in a lower frequency of oral symptoms and xerostomia during treatment and afterward. It might not be necessary to continue the use after 3 months to maintain the benefit.[139–141] Two large placebo-controlled clinical trials conducted by Princess Margaret Hospital and the Radiation Therapy Oncology Group nonetheless failed to confirm these initial findings and did not demonstrate any reduction in the incidence or severity of radiation-induced xerostomia with prophylactic use of pilocarpine 3 days before radiation therapy, during radiation therapy, and for 3 months after completion of radiation therapy.[142,143]

Amifostine appears to protect the salivary glands from the effects of radiation therapy and might prove to be helpful in preventing or minimizing the effects of xerostomia and loss of taste.[114–116,119,144,145] Buntzel and colleagues,[114] Brizel and colleagues,[116,] Wasserman and colleagues,[144] Antonadou and colleagues,[115] and Jellema and colleagues[145] have all reported significant reduction in the severity of acute and chronic radiation-induced xerostomia with prophylactic use of amifostine as determined by non-placebo-controlled clinical trials. There was no evidence that amifostine interfered with the antitumor effects of radiation therapy as measured by local or regional control and overall survival. Jellema and colleagues compared no amifostine to amifostine three times weekly and five times weekly amifostine. Grade 2 or greater late xerostomia differed significantly at 6 months (74% for no amifostine, 67% for three times weekly, and 52% for five times weekly) but not thereafter. Patient-rated xerostomia deteriorated more in the patients who received no amifostine. There was no difference between three times weekly and five times weekly administration of amifostine. Nausea and emesis were common side effects with 28% of patients discontinuing the amifostine before the end of radiotherapy.[145] Subcutaneous administration of amifostine may be as effective as intravenous administration with less severe nausea, vomiting, and hypotension but more frequent cutaneous toxicity.[146] It is of interest to note the continued reduction in the incidence of grade ≥2 xerostomia, and increased unstimulated and stimulated saliva production at 12, 18, and 24 months in the patients not receiving amifostine. In addition, while the mean overall scores for the patient benefit questionnaire are improved significantly by amifostine at 12 months, there are no significant differences at 18 or 24 months.[144] A placebo-controlled phase III trial failed to confirm the radioprotective benefit of amifostine on salivary function following chemoradiotherapy.[118] Patient self-reported xerostomia questionnaire scores are a more accurate reflection of the severity of xerostomia, since physician-assessed scores underestimate the severity of xerostomia.[147] A small randomized trial demonstrated that amifostine might prevent deterioration of dental health.[148] The use of amifostine may be considered to decrease the incidence of acute and late xerostomia in patients undergoing fractionated radiation therapy in the head and neck region that includes the salivary glands.[121] The Food and Drug Administration has approved amifostine for use in the postoperative adjuvant setting.

In selected patients with cancers in the oropharynx, hypopharynx, or larynx, it has been reported that surgical transfer of a submandibular gland into the submental space can be successfully accomplished.[149] If patients require postoperative radiation therapy, the submandibular gland can more readily be excluded from the irradiated volume, thus preserving some saliva production. This process requires validation by controlled clinical trials.

Three-dimensional conformal and intensity-modulated radiation therapy has been shown in prospective uncontrolled and controlled phase III clinical trials to preserve parotid salivary flow and improve quality of life by reducing the dose to the parotid glands.[117,129,130,150,151] Altered fractionation radiation therapy schedules may also help to preserve salivary function. Leslie and Dische[152] evaluated the function of parotid glands in patients treated with three different radiation therapy schedules 9 or more months after completion of treatment. Twelve parotid glands that had received conventionally fractionated radiotherapy to a dose of 60 to 66 Gy showed a mean percentage flow of 20% and a significant decrease in saliva pH. Six glands that had received continuous hyperfractionated accelerated radiation therapy showed mean percentage flows of 65% with only slight and nonsignificant decreases in saliva pH. These results were attributed to the lower dose per fraction used, with subsequent greater repair of sublethal damage between treatment fractions.

Dental Caries

Etiology

Patients undergoing radiation therapy to the oral cavity have an increased incidence of caries because of the lack of saliva to cleanse the teeth and changes in the quality of the saliva. This promotes oral cavity colonization with a more cariogenic flora. In addition, the discomfort associated with xerostomia and persistent mucositis may result in poor oral hygiene with infrequent brushing, flossing, and oral rinses. Some patients may also alter their diet to include sugar-containing drinks and soft foods to help alleviate the effects of xerostomia. Rampant caries can occur, involving all tooth surfaces (including the cervical portion) after just a few months of xerostomia.

Prevention and Treatment

To prevent the development of dental caries (which may result in the need for extraction, soft-tissue necrosis, bone exposure, and osteoradionecrosis) after a course of radiation therapy, all patients should undergo a thorough dental evaluation before treatment. Nonsalvageable teeth should be extracted, and an alveolotomy and primary wound closure should be performed, if indicated. A thorough dental prophylaxis should be performed, including scaling, root cleaning, curettage, and polishing. Restorative dental procedures, including surgical endodontics, should be performed for salvageable teeth. A preventive regimen should be initiated, including plaque removal with the use of dental floss and thorough instructions for correct toothbrushing. Custom-made fluoride carriers should be fabricated, and a neutral 1.1% sodium fluoride gel should be applied to the teeth after breakfast and before bedtime for a period of 2 weeks, beginning as soon as possible after the initiation of radiation therapy. This may be reduced to one bedtime application for 1 month and then twice-weekly fluoride applications indefinitely. Some patients may require twice-daily application throughout their lifetime. The dosage of the fluoride should be modified according to the patient's history of dental caries and oral hygiene performance. Patients should also use a calcium phosphate remineralizing rinse immediately after fluoride applications. Combined fluoride and calcium formulations are available.

Edentulous patients should have their dentures evaluated, and ill-fitting dentures should be corrected. Patients should be discouraged from wearing their dentures until the mucosa is completely healed from the acute effects of radiation therapy (usually about 3 months).

After radiation therapy, patients should be seen every 3 months for frequent dental checkups. There is no concern regarding the additional X-ray exposure of dental films, because the dose is insignificant in comparison with the therapeutic dose that is given for the cancer therapy. All routine dental procedures can be performed without unusual precautions after a course of radiation therapy except radical periodontal treatment and extractions, which may lead to osteoradionecrosis if not done with special care. When extractions are required after a course of radiation therapy, it is best to remove one tooth at a time with as little trauma to adjacent tissues as possible and to wait until healing is complete before proceeding to further extractions. Prophylactic antibiotic coverage should be started 1 day before extraction and be continued until the site is completely healed. Some institutions favor the use of hyperbaric oxygen before extraction.[153] Primary closure of the wound should be carried out

over a smooth, bony surface so that no sharp spicules or ridges are left beneath the mucosa. Postradiation therapy tooth extractions carried out in this manner have a good chance of complete healing without the development of necrosis. When extreme root sensitivity occurs after radiation therapy, brushing fluoride onto the exposed root surface and using specially formulated commercially available toothpaste appears to decrease the sensitivity to some extent.

Soft-Tissue and Bone Necrosis

Etiology

The soft-tissue necrosis of oral cavity mucosa that occurs after high doses of radiation therapy may be attributed to the obliteration of small blood vessels or severe mucositis with ulceration. Irradiated epithelium is thinner than normal and appears pale and atrophic. It also has telangiectatic vessels. The irradiated mucosa is more susceptible to mechanical injury and to the noxious effects of alcohol and tobacco. Soft-tissue necrosis usually begins with breakdown of damaged mucosa, resulting in a small ulcer. Most soft-tissue necroses will occur within 2 years after radiation therapy. Occurrence after 2 years is generally preceded by mucosal trauma. The risk of soft-tissue necrosis is increased with larger fraction sizes, higher total doses, large volumes of irradiated mucosa, and the use of an interstitial implant.

Treatment

If recurrent cancer is not clinically suspected, biopsy should be avoided, because this may enlarge the area of necrosis. Topical anesthetics can relieve the discomfort associated with soft-tissue necrosis and allow the patient to eat normally. Antibiotics often provide pain relief, particularly when the ulceration is deep and infected. It is essential that the patient discontinue the use of alcohol and tobacco. If the area of necrosis is traumatized by dentures, the dentures should not be worn until healing is complete.

More than 90% of soft-tissue necroses will heal with conservative treatment, although in some instances, it might take many months. A small trial (consisting of 12 patients with 15 sites of late radiation necrosis of the soft tissues) has been conducted to evaluate the effect of pentoxifylline on healing radiation necrosis. The average duration of nonhealing before treatment with pentoxifylline was 30.5 weeks. With the institution of pentoxifylline (400 mg given orally three times a day), 13 of 15 necroses healed completely, and one partially healed an average of 9 weeks after treatment was started. All patients had pain relief.[154] Additional case reports and small clinical trials have suggested that the combination of pentoxifylline, tocopherol, and clodronate may be beneficial in preventing and healing severe osteoradionecrosis, radiation-induced trismus, radiation-induced ulcerated fibrosis, soft-tissue necrosis, and mucosal necrosis.[155–162] These results support further study of pentoxifylline in patients in whom soft-tissue necrosis develops after a course of radiation therapy.

The mandible and maxilla will tolerate rather high doses of radiation therapy without serious problems, as long as the tissues overlying the bone remain intact. If soft-tissue necrosis develops in the mucosa overlying the mandible or maxilla, the underlying bone may become exposed. This can lead to serious injury, resulting in bone necrosis (osteoradionecrosis). Compared with the maxilla, the gingiva of the mandible has a rather tenuous blood supply, placing the mandible at greater risk of exposure and necrosis. Most bone exposures will heal spontaneously after conservative treatment. Small areas of bone exposure (<1 cm) generally heal spontaneously after a period of weeks to months. Larger areas of bone exposure may persist for a long period and may lead to bone necrosis, followed by sequestration. If exposed, necrotic bone may become infected. The necrotic process may then extend to involve adjacent bone for a considerable distance. Severe necrosis can then develop and lead to orocutaneous fistulae and pathologic fractures.

If the bone is rough or protrudes above the level of the gingiva, an oral surgeon may remove it to promote healing. Local debridement of moderate-size necrosis can be performed by an oral surgeon if indicated. If the patient wears a denture, it should be withheld from use or relieved over the site of exposure. Pain is not a common symptom; if present, it can usually be controlled with analgesics. A local anesthetic can be applied with a cotton-tipped applicator if needed for pain control. Antibiotics frequently reduce infection and discomfort within a few days but should be continued for 2 to 3 weeks. Hyperbaric oxygen along with antibiotic therapy and local debridement may help promote healing. Mandibular resection should be reserved as the last resort for the patient with intractable pain, recurrence of severe infections, fracture, or trismus.

Most bone problems develop within 3 to 12 months after radiation therapy, but some risk persists for many years, especially if the patient undergoes dental extractions. Necrosis is most likely to occur after extraction of mandibular teeth, although this is infrequent if special precautions are taken. The edentulous patient has a lower overall risk for bone necrosis compared with the dentulous patient.

Patients who are at highest risk for osteoradionecrosis appear to be those with tumors involving the gingiva or bone; those who continue to smoke or drink or both after radiation therapy; and those who receive high doses of radiation therapy, large treatment volumes, large fraction sizes, and/or interstitial implants.

Taste Alterations

Loss of taste occurs rapidly early in the course of radiation therapy to the oral cavity. Most patients report that the sense of taste is essentially nonexistent by the third or fourth week of treatment. After the completion of radiation therapy, most patients report some taste improvement within 1 to 2 months. Full recovery of taste usually requires 2 to 4 months. In some patients, taste never returns to normal, at least in part because of xerostomia. Although some studies have suggested that zinc therapy may be useful in improving taste acuity, a randomized clinical trial did not show any benefit for zinc over a placebo.[163] Amifostine may protect against taste loss caused by irradiation.[114,116]

Trismus

Etiology

Trismus may be caused by fibrosis of the muscles of mastication after high-dose radiation therapy to the oral cavity or oropharynx, surgical scarring, and/or advanced carcinomas involving the pterygoid and/or masseter musculature. The temporomandibular joint itself is relatively resistant to ankylosis caused by radiation therapy, but the risk of injury increases if the joint is invaded by tumor. The use of large daily treatment fractions also appears to increase the risk of trismus.

Prevention and Treatment

High-energy x-ray beams and sophisticated multiple-field techniques should be used whenever possible to reduce the dose of radiation therapy to the temporomandibular joint and to the muscles of mastication. Patients who are treated with both surgery and radiation therapy have a greater risk for trismus than do patients who are treated with either modality alone. Patients who are at high risk for trismus and those in whom trismus has developed before treatment should perform jaw-stretching exercises daily in an attempt to increase the interarch or interincisor distance. A number of techniques are used, including commercially available jaw-stretching tools and less expensive stacked tongue blades, tapered corks, or clothespins. These devices are inserted between the teeth to increase the interincisor distance until slight pain is encountered. The exercises should be done for about 30 seconds every 2 hours. Additional tongue blades can be added, or a thicker aspect of the cork can be placed between

the teeth every few days to increase the interincisor distance and stretch the muscles of mastication.

Malignancy

The carcinogenic effect of ionizing radiation has long been recognized. The latent interval between radiation therapy and the development of cancer varies from several to many years. Kogelnik and colleagues[164] reviewed charts of 1163 patients treated for head and neck cancer at the M.D. Anderson Cancer Center who had survived a minimum of 5 years after treatment without having recurrent cancer. Follow-up for these patients ranged from 7.5 to 25.5 years. Patients were treated with surgery alone (337 patients) or radiation therapy with or without surgery (826 patients). The incidence of new cancers in the primary tumor site (1.8% versus 2.7%), within the immediate vicinity of the primary tumor (4.2% versus 3.1%), or at sites remote from the primary tumor but still within the oral cavity or pharynx (4.7% versus 5.7%) was very similar for patients treated with surgery alone and patients treated with irradiation with or without surgery, respectively. It was concluded that moderate or high-dose radiation therapy did not produce any new squamous cell carcinomas of the mucous membranes. Similar findings were reported from the Fox Chase Cancer Center[165] and the University of California, Los Angeles.[166]

The rarity of radiation-induced sarcomas, the long latent period before their development, and the difficulty in obtaining reliable long-term follow-up data make the task of estimating the true risk of this problem difficult. However, most series include one or two cases of radiation-induced bone sarcoma per 1000 5-year survivors. If one were to assume malignant induction in 1 patient of every 500 long-term survivors, then with an estimated 5-year survival rate of 40% for all patients with head and neck cancer who received radiation therapy, it is calculated that 1 case would be induced per 1250 patients treated. A review of the Mayo Clinic experience showed no difference in survival between patients with radiation-induced sarcomas of the mandible or maxilla and non-radiation-induced sarcomas of the same site (45% 5-year overall survival).

Because some patients with radiation-induced osteogenic sarcomas of the mandible or maxilla can be cured, the risk of dying from a radiation-induced sarcoma after a course of radiation therapy is minimal and is very similar to the risk of death that a patient accepts when undergoing chemotherapy, general anesthesia, general surgery, or major head and neck cancer surgery.

An association has also been noted between radiation therapy and thyroid tumors. The latent period is usually 10 to 30 years. Almost all reported cases have followed low doses of radiation therapy (<6 to 1500 cGy), well below the doses that are used for squamous cell carcinomas of the head and neck.. Doses greater than 2000 to 3000 cGy are associated with a very low risk of induction of thyroid neoplasia compared with lower doses. This is likely because higher doses of radiation therapy either completely destroy follicular cells or at least render the surviving cells incapable of division. Not all thyroid neoplasms that develop after radiation therapy are malignant, and many of the malignant neoplasms that do develop (papillary and follicular carcinomas) are readily curable with surgery. Thus, the risk of radiation-induced carcinoma should not be a major factor in determining treatment approaches for the typical patient with head and neck cancer.

Implementation of Prevention and Treatment of Radiation-Induced Oral Complications

Jansma and colleagues[167] surveyed all Dutch radiation therapy centers in which irradiation of patients with head and neck cancer is performed to determine which prevention and treatment regimens are used for oral sequelae resulting from head and neck radiotherapy. Survey questions included queries about screening, care before irradiation, care during radiation therapy, care during postradiation therapy, and the composition of the dental team who evaluated and treated the patients undergoing radiation therapy. Unfortunately, these investigators found a great diversity in the preventive approach to treatment of patients with head and neck cancer at Dutch radiotherapy institutes. Disturbing findings included a lack of well-defined guidelines in many centers, absence of a dental team at some centers, absence of an oral hygienist on some dental teams, and the observation that many patients were not referred to the dental team in a timely manner. The investigators recommend the development of a general protocol for the prevention of oral complications applicable at all head and neck cancer radiation therapy centers.[168] Similar deficiencies are probably present at the head and neck cancer radiotherapy centers within the United States. It is strongly recommended that dedicated teams be assembled to administer aggressive care to patients receiving radiation therapy to the oral mucosa. These teams should institute preventive measures and treat symptoms early in their course.

41 Alopecia and Cutaneous Complications

Leslie Robinson-Bostom, John Kawaoka, Reena Rupani, and Charles J. McDonald

SUMMARY OF KEY POINTS

The human skin that serves as the interface between the living organism and the external environment is in fact the largest and most complex human organ. Its complexity is directly related to the myriad of specialized cells, tissue types, and structures that allow the skin to carry out many vital functions including maintenance of body temperature and protection against the ingress of infectious organisms and noxious chemicals, as well as the egress of vital tissue fluids. It is highly probable that the complex anatomy and physiology of the skin make it a major target of chemotherapy-induced toxicity.

Incidence

Cutaneous reactions are among the most common adverse drug reactions to occur in patients undergoing medical treatment for cancer. The incidence and severity of such reactions vary depending on the class of agent or agents, the route and frequency of administration, the dosage of drug or drugs given, and the specific tissue type involved. Some agents may cause toxicity only after the patient has been exposed to one more additional physical agent, such as ultraviolet light or x-ray emissions.

Etiology of Complication

Causes of adverse cutaneous reactions to cancer chemotherapeutic drugs are quite varied but tend to be characteristic and often unique to a particular agent or category of agents. Some reactions, such as those seen as a result of infiltration of drug during infusions, are caused by direct toxicity of the drug on any and all involved tissues. These reactions are often associated with regimens using the alkylating agents, the vinca alkaloids, and the antibiotics. Other reactions occur as a result of the specific tissue-targeted effect of an agent, such as alopecia associated with a variety of mitotic inhibitors, or the "pustular-like" eruption so commonly associated in epidermal growth factor receptor (EGFR)–targeted therapy. Cutaneous "hypersensitivity reactions" are also fairly common.

Evaluation of the Patient

Because the number and types of cutaneous reactions to cancer chemotherapy are large and quite variable, each having its own unique set of cutaneous and histopathologic findings, there are no well-established guidelines that may be commonly adhered to in patient evaluation. Patient skin signs and overall symptoms are one's best guides to evaluation and treatment. Histopathologic examination of skin specimens is often helpful as well.

Grading of the Complication

Unlike grading of complications in other organ systems, grading of cutaneous complications associated with cancer chemotherapeutic drugs has until recent years been poor, inconsistent, and often not addressed even in conjoint studies of a single agent. Interest in a more precise dermatologic examination and better grading of the severity of cutaneous eruptions has been stimulated by several recent reports that show a correlation between the extent and severity of the cutaneous eruption caused by a group of EGFR antagonists, and disease response and patient survival. It should be noted that at this point in time there is not universal acceptance of this concept (Table 41-1).

Treatment

Treatment approaches to the large variety of cutaneous responses to cancer chemotherapeutic drugs are as varied as there are reactions and teams of investigators addressing these reactions. To reduce patient morbidity and assure early initiation of the most appropriate treatment plan, it is most appropriate and beneficial to the patient to obtain dermatologic and surgical consultation, if needed, at the earliest stage of the reaction.

INTRODUCTION

As with other pharmacologic agents used in the treatment of human disease, the administration of most cytotoxic or cancer chemotherapeutic agents can result in toxic side effects. Moreover, as with other pharmacologic agents, toxicity is often manifested in the skin. Some toxic side effects occur at ordinary therapeutic drug dosages, whereas others occur as an extension of a therapeutic drug effect at higher dose levels. Toxic drug reactions in the skin may occur as idiosyncratic or allergic drug reactions.

Cancer chemotherapeutic drugs produce many common skin conditions, such as pruritus, urticaria, and angioedema. They also cause cutaneous reactions that are not shared by any other agent or class of agents—for example, the sclerotic effect that bleomycin can have on the skin.

A description of all the cutaneous reactions to cancer chemotherapeutic agents is beyond the scope of this book. Instead, we have elected to highlight a group of reactions that are fairly common and yet unique to cancer chemotherapy. Some reactions are associated with fairly severe sequelae and might direct the ultimate course of

Table 41-1 National Cancer Institute and Eastern Cooperative Oncology Group Grading System for Dermatologic Toxicities

Toxicity Grade	National Cancer Institute	Eastern Cooperative Oncology Group
1	Maculopapular rash or erythema and no associated symptoms	Maculopapular rash or erythema and no associated symptoms
2	Maculopapular eruption or erythema, associated pruritus, or other symptoms; <50% of body surface area coverage or localized desquamation or other lesions covering <50% of the body surface area	Scattered maculopapular eruption or erythema with pruritus or other associated symptoms
3	Symptomatic generalized erythroderma or macular, papular, or vesicular eruption or desquamation covering >50% of the body surface area	Generalized symptomatic macular, papular, or vesicular eruption
4	Generalized exfoliative dermatitis, ulcerative dermatitis	Exfoliative dermatitis or ulcerating dermatitis

chemotherapy; others might appear severe upon occurrence but can be treated symptomatically, with no effect on the outcome of the treatment regimen. For completeness, Table 41-2 lists the various categories of cancer treatment agents and the dermatologic conditions they may cause.

NONSPECIFIC REACTIONS

Alopecia

Of the myriad of drug-related cutaneous toxicities encountered by the cancer patient, alopecia is the most common.[1] Hair loss is an unfortunate side effect, because hair appearance often dictates a patient's self- and body image. Patients, especially females, receiving cancer chemotherapy often find alopecia psychologically and emotionally devastating. In fact, the occasional patient who is unable to cope with alopecia and the associated psychic trauma often opts to forgo potentially curative treatments.

Etiology

Systemic administration of a variety of cancer chemotherapeutic drugs can produce alopecia. Drug-induced inhibition of hair follicle stem cells within the hair matrix causes a reduction in the number and size of epithelial cells contained within the hair shaft. This results in a partially constricted and weakened hair shaft that is susceptible to breakage from trauma as minor as simple combing. Complete cessation of hair formation can also occur. Antineoplastic agents vary in their effects on hair matrix epithelium, hence their ability to induce alopecia. The degree of hair loss secondary to cancer chemotherapy is related to dosage, regimen, and route of administration. Drugs with a strong propensity to induce alopecia include doxorubicin, daunorubicin, cyclophosphamide, and etoposide.[2–5]

Some novel dosage formulations of standard chemotherapeutic agents may ameliorate the extent of alopecia; for example, liposomes coupled with doxorubicin and mitoxantrone have been shown to significantly decrease the extent of drug-induced alopecia.[6,7]

Clinical Manifestations

Chemically damaged and mechanically manipulated hair is more susceptible to the effects of chemotherapy.[8] Anagen effluvium (loss of hair during the proliferative or growth phase of its cycle) may begin 1 to 2 weeks after a single dose of chemotherapy but will be most noticeable after 1 to 2 months of continuous drug administration. It can also occur as late as 2 to 3 weeks after cessation of chemotherapy.[8] Alopecia associated with anagen effluvium is most pronounced and widespread on the scalp, because this site normally contains 60% to 85% of its hairs in the proliferating anagen phase. Repeated drug doses given over the course of 1 to 2 months ultimately synchronize with each follicle's matrix cells in anagen phase; total inhibition of cell replication follows, and alopecia results. The eyebrows, eyelashes, beard, groin, and axillary hairs have fewer hair follicles in the anagen phase at any one time; consequently, repeated doses over many more months are required to achieve significant alopecia in these areas. The onset of telogen effluvium (loss of hair during the resting phase of its cycle) occurs approximately 3 to 6 months after the start of chemotherapy.

Pathology

The normal scalp hair growth cycle consists of an anagen (growth) phase, a catagen (involution) phase, and a telogen (resting) phase. About 60% to 85% of scalp hairs are always in the anagen phase, 1% are in the catagen phase, and the remainder are in the telogen phase. Body hairs are not synchronized in such phases. During the anagen phase, germinative cells within the matrix of scalp hair have a cell replication time approximating 24 hours. Thus, scalp hair, by virtue of its content of highly proliferative matrix cells, is particularly susceptible to growth inhibition by chemotherapeutic drugs that inhibit cellular proliferation. Inhibition (anagen effluvium) ranges from partial to total. Patients with fewer anagen hairs are less sensitive to anagen effluvium induced by chemotherapy. Less commonly, certain drugs, such as recombinant interferon-α2b (IFN-α2b), can induce the anagen hair into the dormant telogen phase, which is followed by a period of total hair epilation.[9] Telogen effluvium can also occur in response to the emotional stress of chemotherapy or to an anemia associated with chemotherapy, principally iron deficiency anemia.

Differential Diagnosis

Most often, patients receiving cancer chemotherapy experience anagen effluvium; only a few experience telogen effluvium. Anagen effluvium alopecia usually persists throughout the period during which drug is given. Normally, hair returns shortly after drug administration ceases. There is always a temporal relationship to drug administration. Telogen effluvium results principally from psychic or bodily stress, high fever, nonmatrix toxic medication, or poor nutrition. Telogen effluvium is first noticeable about 3 to 6 months after insult and is temporary. Hair growth generally resumes, even as chemotherapy is continued.

Treatment and Outcome

It is important for the clinician to fully appreciate the negative emotional devastation that chemotherapy patients, particularly female, experience with rapid loss of hair. Strategies to ameliorate this experience include preparing patients mentally for such an event and constant reassurance that this effect is only temporary. Patients should receive early information on scalp hair care and on the availability and acceptable of wigs and other scalp covering.[10] In cooperation with the American Cancer Society, the Cosmetic Toiletries

Table 41-2 Chemotherapeutic Agents and Common Cutaneous Side Effects

Alkylating agents	Alopecia
	Neutrophilic eccrine hidradenitis
	Pigmentation reactions—depigmentation and hyperpigmentation
	Angioedema
	Extravasation necrosis
	Dysethesia and erythrodysesthesia (acral erythema)
	Radiation recall
	Reactivation erythema
Antimetabolites	Hyperpigmentation

	Radiation recall
	Alopecia
	Extravasation necrosis
	Cutaneous flare
Plant alkaloids	Alopecia
	Dysethesia and erythrodysesthesia (acral erythema)
	Radiation recall
	Cutaneous "flare" (must be differentiated from extravasation necrosis; excellent prognosis)
	Hair and nail dystrophy
Antitumor antibiotics	Xerosis/scaling
	Radiation recall dermatitis
	Rash/urticaria
	Reversible total alopecia
	Hyperpigmentation of nail beds
	Onycholysis
	Acral erythema
	Flagellate erythema (bleomycin)
	Cutaneous ulceration
	Pseudo-dermatomyositis (hydroxyurea)
Topoisomerase inhibitors	Reversible alopecia
	Dermatitis
	Facial edema
	Acral edema
	Paronychial inflammations
	Perianal dermatitis
	Anal fissures
Biologics	Acneiform rash
	Vasculitis-like eruption
	Paronychial inflammation
	Exfoliation/desquamation
	Xerosis
	Capillary leak syndrome
	Pruritus
	Urticaria/angioedema
	Alopecia
	Skin fissures
	Sweet's syndrome

and Fragrances Association and groups of local beauticians have developed a highly successful image-building program called "Look Good, Feel Good." This program is available free of charge to cancer patients with alopecia and other cosmetic defects.

Prognosis

Chemotherapy-associated alopecia is usually temporary. Regrowth can be apparent 3 to 10 months after withdrawal of the offending medication and may occur during prolonged cycles of therapy. Permanent alopecia has been reported infrequently with high-dose busulfan, bone marrow transplantation, and high-dose chemotherapy using cyclophosphamide, thiotepa, and carboplatin.[11,12] Most patients experience some changes in the character of their regrown hair. These changes, which include alterations in color, texture, and type of hair shaft, are often transient.[13]

Prevention

Several different maneuvers have been used in an attempt to protect patients from chemotherapy-induced alopecia. These include physical modalities that may temporarily decrease scalp blood flow and drug contact time with the hair follicle—that is, use of scalp-cooling devices, such as the MSC cold cap system (Medical Specialties of California, London, UK), cooling fluid ring turbans, and cold air hoods that deliver cooling temperatures below 22°C. Each works to decrease the metabolic rate of matrix stem cells and blood flow to the follicle matrix.[14] Results using hypothermic devices has been encouraging.[15] Efficacy is increased during use of a chemotherapeutic agent that has a short half-life (e.g., adriamycin) and is given in low dose. Also, patients treated with rapidly administered combinations seem to benefit from scalp hypothermia.[13] Tumor metastases to the scalp have been reported after use of this technique. Other side effects include headaches, dizziness, nausea, vomiting, aversion to ice, cold feeling, and heavy feeling on the head.[16] It has been suggested that hypothermia is contraindicated in patients with leukemia, lymphoma, or highly metastatic neoplasms and for patients who have a tendency to develop migraine headaches. Folic acid can prevent alopecia when given with methotrexate.[8]

Imuvert has been shown to protect against alopecia induced by ara-C (cytarabine) and doxorubicin but not by cyclophosphamide. This protective effect is presumed to be mediated by interleukin-1 (IL-1). AS101, a new immune modulator, has also been stated to prevent chemotherapy-induced alopecia.[8]

Electrotrichogenesis, or the use of specific pulsed electrostatic fields, has shown promising results in preventing chemotherapy-induced hair loss. A pilot study of 13 patients undergoing treatment with cyclophosphamide, methotrexate, and 5-fluorouracil (5-FU) showed good hair retention without attributable side effects.[17] M50054, 2,2.-methylenebis (1,3-cyclohexanedione), a novel inhibitor of apoptosis, might be an effective agent in the future for preventing or reducing chemotherapy-induced alopecia.[18]

Cellulitis, Phlebitis, Extravasation Necrosis, and Various Flare Reactions

It has been estimated that local skin toxicity, other than alopecia, accounts for 2% to 5% of all adverse reactions from antineoplastic drugs. The extravasation of vesicant cancer chemotherapeutic agents remains one of the single most distressing causes of this complication. Local tissue injury occurs as intravenously administered agents irritate the lining of access veins during drug administration (phlebitis), or when a cytotoxic drug escapes the confines of the cutaneous vasculature and spreads throughout the surrounding tissues. A local inflammatory reaction (chemical cellulitis), or local tissue necrosis (extravasation necrosis) then occurs. Cellulitis and necrosis can involve skin alone or can extend to subcutaneous tissue, muscle, fascia, and tendons. Extravasation frequently occurs during use of subcutaneous indwelling vascular access devices.

Etiology

Clarification of the mechanism of local tissue injury after insult by chemotherapeutic agents awaits further investigation. It has been postulated that agents that produce highly alkaline, or acidic, hypertonic solutions are probable causes. Drugs that bind to DNA are considered the most frequent causes. Necrotic tissue reactions can continue for weeks and months after withdrawal of the inciting agent. There is support for the concept of tissue binding as a probable cause of local necrotic reactions. Other possible contributors include local chemical irritant reactions and maturation arrest induced in proliferating cells.

The list of agents causing severe local tissue toxicity include the vinca alkaloids, vincristine and vinblastine; the alkylating agents, mechlorethamine and mitomycin C; the anthracyclines, doxorubicin and daunorubicin; and the antibiotic dactinomycin.[19–23] Other drugs less likely to cause severe local toxicity include 5-FU, etoposide, bleomycin, cisplatin, mitoxantrone, paclitaxel, streptozocin, oxaliplatin, docetaxel, and doxil.[24–31]

Delayed skin ulcers have been reported to appear within a prior mitomycin C infusion site after a second treatment is given into a site on the opposite extremity.

Doxorubicin local tissue reactivity includes, in addition to necrosis and radiation "recall effect," a "venous flare" reaction.[32,33] The "venous flare" that occurs is characterized by a linear eruption in the skin overlying access veins of the infusion site. Erythema, edema, induration, pruritus, and tenderness overlie the area (Fig. 41-1). Superficial blisters and vesicles can appear. This reaction subsides without residual tissue damage within 48 hours after discontinuation of the infusion. It has been estimated that venous flares occur in up to 3% of all adriamycin infusions.

Clinical Manifestations

During infusions that lead to necrosis, patients complain of acute burning pain and swelling. Within 7 days after the infusion, patients complain of pain, edema, erythema, and induration at the site. Severely involved untreated sites develop clusters of vesicles and large blisters, followed by ulceration or the development of a large plaque with a necrotic center, or both (Fig. 41-2). Underneath the plaque, or ulcer, extensive areas of necrosis may be found. A hard black eschar ultimately forms. Peripheral to the eschar, erythema and swelling persist for weeks. Simultaneously with involvement of subcuticular tissue, there is joint stiffness, limitation of motion, neuropathy, and causalgia in the affected parts.

Figure 41-1 • Venous flare reaction overlying access vein of the forearm.

Figure 41-2 • Extravasation injury, late-stage lesion with a central eschar, beneath which lies an extensive area of subcutaneous necrosis.

Pathology

Bhawan and colleagues among others reported early and late histologic changes in the skin of patients with doxorubicin extravasation.[34] In an early lesion, before eschar formation, marked epidermal hyperplasia is observed. Individual necrotic keratinocytes are abundant. All other cell types show similar reactive responses. In a late lesion, beneath the area of ulcer formation, panepidermal, dermal, and subcutaneous tissue necrosis is seen. Lateral to the ulcer, there is marked epidermal hyperplasia. Fibroblasts and endothelial cells show signs of extreme reactivity. Lobular panniculitis best describes lesions of the subcutaneous fatty layers. Curiously, signs of acute inflammation are not usually described in old or new lesions.

Differential Diagnosis

Local tissue extravasation must be differentiated from the doxorubicin "venous flare" reaction. Radiation recall phenomenon can occur with infusions of doxorubicin, mitomycin C, and 5-FU.This reaction tends to occur at remote sites of previous radiation dermatitis.

Treatment

Conservative, nonsurgical measures are very effective for treating small (500 mm^2 or less), and medium-size (2000 mm^2 or less) areas of extravasation. Phlebitis and cellulitis often cause mild injury, heal with minimum residual effects, and require minimum treatment. Because less than one-third of all local extravasations proceed to blister and ulcer formation, there is considerable disagreement about the correct approach to management of local tissue toxicity.[35–37] Termination of the infusion is mandatory and is almost always followed by complete healing without residual defect in areas of phlebitis and cellulitis. Elevation and intermittent cooling of the affected part can accelerate healing.

In more severe reactions the general use of a number of frequently recommended local antidotes is frowned upon. At most extravasation sites, antidotal treatments have often made necrosis and ulceration worse. There is general agreement that the infusion should be terminated immediately if the patient complains of pain, burning, or stinging at the infusion site or if local swelling is observed. If the original infusion needle or catheter is patent, aspiration of extravasated fluid may be attempted. If the line is not patent it should be removed immediately.

Elevation of the involved extremity is recommended for at least 48 hours. Local heat applications are recommended if the vesicant is one of the vinca alkaloids.[37] Cooling of the extremity may be benefi-

cial after other vesicant injury, except that caused by the alkylating agents mechlorethamine and mitomycin C.[38,39]

Although routine use of surgery is not indicated, timing and the ultimate use of surgical intervention are of utmost importance. Surgical consultation should be sought immediately on suspecting extravasation injury. Persistent pain, erythema, and swelling, even in the absence of ulceration and eschar formation, require surgical consultation and are indications for surgical intervention even in the absence of ulceration and eschar formation. Severe blistering, ulceration, and persistent pain make surgical intervention mandatory. Inordinate delay of surgery permits active drug to infiltrate and cause injury to tissues far beyond the original site of extravasation. In such cases, delay might ultimately cause the need for more extensive surgery ranging far beyond skin and subcutaneous tissues.

Outcome

Morbidity associated with extravasation injury is high, but mortality is nonexistent. The degree of discomfort experienced by some patients is severe enough to cause voluntary termination of treatment. Others become litigious, losing confidence in their therapist. The injury accompanying extravasation has no effect on disease status; thus there is no reason to stop further treatments with a given agent. Unless extravasation occurs again, retreatment of the patient with the same agent is not associated with recurrence of necrosis.

Prevention

In every patient considered for treatment with a known vesicant, prevention of local tissue injury is paramount. Prevention begins with selection of the infusion site. Sites to be avoided at all costs are the dorsal surfaces of the hands and the antecubital fossae, as well as extremities that have been sites of extensive ablative surgery. The preferred site of infusion is the proximal forearm that has not been surgically compromised, and where a large amount of subcutaneous tissue overlies vital structures. If tissue-poor areas such as the dorsal surface of the hand are used, a subcutaneous flexible indwelling catheter is preferred over the standard intravenous needle. When multiple infusions are anticipated over a prolonged period, placement of subcutaneous reservoirs with long indwelling lines should be considered. Nevertheless, even indwelling devices are not foolproof; an extravasation incidence of 6.4% has been reported using these devices.[40]

Drugs should always be administered through a free-flowing intravenous line. Any hint of obstruction within the line calls for immediate termination of the infusion and an attempt at correcting the problem. Every attempt should be made to administer a solution that is as dilute as possible over the shortest period of time, preventing injury from concentrated drug and eliminating lengthy exposure of tissues to a toxic agent.

Palmar-Plantar Dysesthesia and Erythrodysesthesia Syndrome (Acral Erythema)

The true incidence of this reaction is unknown. Yet, on the basis of personal experience, the number of cases reported in the literature, and a reported incidence of 39% in a group of patients treated for acute myeloid leukemia using the CHA regimen (lomustine, doxorubicin, cytosine arabinoside), one would suspect that erythrodysesthesia is fairly common and is among the most frequently encountered cutaneous reactions to cancer chemotherapeutic agents.[41–43]

Etiology

Early reports described this reaction in patients with hematologic malignancies. Subsequent reports described the reaction in patients receiving continuous infusions of 5-FU in solid tumors. Hence, 5-FU became widely recognized as the offending agent in nearly all cases of palmar-plantar erythrodysesthesia. A considerable variety of chemotherapeutic agents and treatment regimens have since been associated—for example, capecitabine, cytosine arabinoside, doxorubicin, methotrexate, 6-mercaptopurine, hydroxyurea, etoposide, 5-fluoro-2-deoxyuridine, and various combinations of agents. There appear to be no age, sex, or racial predilections for susceptibility to this phenomenon. There is no known mechanism for the reaction pattern other than that it seems to be dependent on drug dose.

Clinical Manifestations

Weeks to months after beginning high-dose intravenous chemotherapy, dysesthesia and paresthesia, expressed as a tingling sensation in the hands and feet, herald the onset of the syndrome. Increasing discomfort (consisting of burning sensations, pain, and tenderness while holding objects and while walking) signals progression of disease. Pain with swelling and erythema develop within 2 to 4 days of onset. Reddening begins over thenar and hypothenar eminences and spreads to involve the entire palm and sole (Fig. 41-3A and B). Blanching and erythema also occur on the interarticular spaces, and erythema appears in the periungual areas. Swelling and severe pain occur even at rest. Eventually, many of the blanching areas become bullous. This typical pattern is commonly seen with cytarabine therapy. Desquamation followed by healing of the palms and soles occurs within several weeks (Fig. 41-4). In a few patients, erythematous scaling dermatoses develop on other body areas, together with nail disturbances, including onycholysis. Recall-induced palmar-plantar erythrodysesthesia syndrome has been described with a variety of chemotherapy regimens.[44]

Pathology

Pathologic findings in a small number of patients have been described as nonspecific, showing mild focal spongiosis of the lower epidermis, mild to moderate epidermal atypia, mononuclear cell infiltration of the superficial dermis, and mild vasculitis of small vessels. Mild focal vacuolar degeneration of the basal cell layer has also been described.[43] Immunofluorescent studies are negative.

Differential Diagnosis

ACRAL ERYTHEMA ASSOCIATED WITH ACUTE GRAFT-VERSUS-HOST DISEASE. Dermatitis of the palms and soles may occur as the earliest and only sign of acute graft-versus-host disease (GVHD). Dermatoses of GVHD usually occur within a period varying from 4 to 47 days after allogeneic bone marrow transplantation, but the onset of palmar-plantar lesions may be delayed by as long as 100 days. Unlike the spotty erythema of erythrodysesthesia that begins on thenar and hypothenar areas, acute GVHD palmar-plantar erythema presents with reddening of the dorsal aspects of the fingers and within periungual skin. Diffuse erythema of the hands and feet soon follows. Pruritus and tenderness of the palms and soles characterize acute GVHD, as opposed to severe pain and swelling associated with the palmar-plantar dysesthesia syndrome. Other findings associated with acute GVHD and acral erythema include nausea, vomiting, intractable diarrhea, and a severe rise in serum bilirubin levels. Both diseases can occur concurrently.[45]

ACRAL ERYTHEMA OCCURRING IN SEVERE LIVER DISEASE. Acral erythema with severe liver disease is a chronic abnormality and is not generally accompanied by pain, blistering, or desquamation of the skin. Liver abnormalities are profound, with elevated serum enzymes and serum bilirubin.

Treatment

Treatment has been quite variable. In some patients complete cessation of chemotherapy is mandatory, followed by simple but intensive topical care consisting of frequent wet dressings and topical applications of midrange-potency corticosteroids. Often this regimen is sufficient to clear the eruption. Pain, swelling, and blister formation

Figure 41-3 • **A** and **B,** Palmar-plantar dysesthesia and erythrodysesthesia. Early manifestation with prominent erythema and edema.

Figure 41-4 • Late manifestation of palmar-plantar dysesthesia showing palmar desquamation after clofarabine use.

clear within 1 week without residual effects. Many patients heal completely without therapeutic intervention.

In some patients a moderate reduction in chemotherapy dosage and intensive topical care allows continuation of infusion therapy. A return to the original chemotherapy dosage is usually associated with recurrence of skin disease.

In other patients cutaneous manifestations have been ignored, and treatment with the offending agent has been continued at presyndrome dose levels. Only symptomatic treatment measures were required. Successful treatment of a group of patients using daily oral dosages of pyridoxine during infusions has been noted. Its use has permitted continued treatment with high-dose infusions, without recurrence or worsening of the palmar-plantar dysesthesia syndrome, or adverse effects on disease response to chemotherapy.[46] The use of pyridoxine for prevention of dysesthesia is empiric. Topical 99% dimethyl sulfoxide has shown promising results for treatment of liposomal doxorubicin-induced palmar-plantar erthrodysesthesia.[47]

Outcome

Severe acral pain and blister formation can cause considerable morbidity and poor patient compliance. No matter how severe the process may appear, it has no effect on the patient's disease status. Most chemotherapists agree that acral dysesthesia is not life-threatening, yet it can cause sufficient discomfort to require withdrawal of drug or alteration in drug dosage.

Hyperpigmentation

A variety of patterns of hyperpigmentation have been described in association with cytotoxic agents. Cutaneous hyperpigmentation can be generalized or can occur in specific localized patterns. Mucous membranes, hair, teeth, and nails can be affected by changes in pigmentation produced by cancer chemotherapy.[48–50]

Etiology

Generalized hyperpigmentation has been described in association with busulfan, cyclophosphamide, bleomycin, 5-FU, mechlorethamine, hydroxyurea, daunorubicin, dactinomycin, doxorubicin, and procarbazine. Localized patterns of skin hyperpigmentation occur after administration of cyclophosphamide, thiotepa, bleomycin, doxorubicin, daunorubicin, 5-FU, vinca alkaloids, plicamycin, and paclitaxel. Mucosal pigmentation is seen after doxorubicin, 5-FU, cisplatin, and busulfan therapy. Nail pigmentation is produced by cyclophosphamide, bleomycin, doxorubicin, daunorubicin, 5-FU, and hydroxyurea. Alteration in hair pigmentation has been caused by methotrexate. Cyclophosphamide may also produce pigmentation of the teeth.

Increased pigmentation from cancer chemotherapy is due to increased deposition of melanin in the affected tissue; a similar mechanism is shown to occur when hyperpigmentation is produced by antimalarials, tetracyclines, or heavy metal therapy, and is not caused by an accumulation of drug or its byproducts. Melanin, a pigment product or polymer, is manufactured within the basal layer of the epidermis of skin, nails, and hair follicles by melanocytes. Melanocytes package the pigment into containers called melanosomes and distribute them to neighboring epithelial cells through tubular cytoplasmic extensions called dendritic processes. Alterations in baseline pigmentation can occur when there is an increase in melanin production, an increase in the size of melanosomes, or a change in the distribution of melanosomes within the epithelial cells of skin, nails, and hair. How chemotherapeutic agents act to produce increased pigmentation is unknown. They may act to increase pigmentation by a direct stimulatory or toxic effect on melanocytes and/or by slowing the turnover and transit rates of epithelial cells, thus allowing more time for the transfer of melanin to occur. Adrenocorticotropic hormone (ACTH) and melanocyte-stimulating hormone (MSH) are central nervous system–produced polypeptides that stimulate overall pigmentation in humans. ACTH and MSH are known to produce generalized hyperpigmentation in Addison's disease after bilateral adrenalectomy and after parenteral administration. The role of these hormones in the normal regulation of human pigmentation is poorly understood. ACTH and MSH levels have been studied in patients with pigmentary abnormalities while receiving cytotoxic agents; no elevation of these hormones has been detected.[51,52]

Clinical Manifestations: Alkylating Agents

BUSULFAN. Busulfan can produce generalized brown hyperpigmentation that is accentuated on the face, trunk, and forearms. Hyperpigmentation may be accompanied by symptoms of fatigue, nausea, anorexia, and weight loss, resulting in a condition much like Addison's disease. In such patients, however, hyperpigmentation of mucous membranes and palmar creases is rarely observed, and there is no evidence of increased ACTH or MSH activity. Busulfan hyperpigmentation occurs in 5% to 15% of treated individuals. It resolves when the drug is discontinued.

CARMUSTINE. Carmustine has produced erythema followed by postinflammatory hyperpigmentation when it is spilled on the skin inadvertently, but parenteral use is not associated with pigmentary changes.

CYCLOPHOSPHAMIDE. Cyclophosphamide can cause generalized skin pigmentation (which could be photoaccentuated) in addition to localized pigmentation of the palms, soles, and nails. Nail pigmentation can be diffuse or can present as horizontal or longitudinal dark bands. On cessation of therapy, this pigmentation usually resolves as the nail grows. In one large series of patients treated with cyclophosphamide, the incidence of skin and nail pigmentation was less than 50%. There is a single report of a child in whom a persistent brown line developed on the teeth as a result of cyclophosphamide therapy.

MECHLORETHAMINE. Used topically in the treatment of mycosis fungoides, mechlorethamine produces diffuse hyperpigmentation. This problem can occur with or without clinical evidence of allergic or irritant contact dermatitis.

THIOTEPA. Given intravenously in high doses, thiotepa may cause discrete areas of hyperpigmentation corresponding to sites occluded by adhesive patches or tape. This effect might result from an enhanced local toxic effect of the drug, which is excreted in sweat.

Clinical Manifestations: Antibiotics

ACTINOMYCIN. Persistent serpentine surpravenous hyperpigmentation has been associated with actinomycin and vincristine chemotherapy.

BLEOMYCIN. Bleomycin causes several patterns of hyperpigmentation. These include a generalized darkening of the skin that includes the palmar creases and cuticles, and patchy pigmentation at pressure points that might be delayed in appearance over the elbows, shoulders, and buttocks. The most distinctive pattern seen in 30% or more of patients consists of linear or "flagellate" streaks on the trunk that appear to correspond to areas of pruritus and trauma (Fig. 41-5). Attempts to reproduce these lesions experimentally have met with variable success. Flagellate hyperpigmentation has its onset after 3 weeks of therapy and persists up to 5 months. Horizontal brown nail banding has also been observed.

DACTINOMYCIN. Intertriginous, trauma-induced, and diffuse hyperpigmentation have been associated with dactinomycin therapy.

DAUNORUBICIN. Chemically related to doxorubicin, daunorubicin has also been reported to cause skin and nail pigmentation, but with less frequency. Transverse pigmented nail bands and polycyclic pigmentation of the scalp have been reported.

DOXORUBICIN. Doxorubicin is associated with localized pigmentation of the nails, palms and soles, dorsa of the hands, face, and interphalangeal and palmar creases. Diffuse pigmentation also can occur. Intraoral pigmentation occurs on the buccal mucosa and tongue. Nail pigmentation can present as horizontal or longitudinal bands or in a diffuse manner. These changes are more common among black patients. MSH levels are not elevated in patients with doxorubicin-induced pigmentation.

Figure 41-5 • Bleomycin pigmentation. This is the most distinctive pattern of pigmentation following the administration of bleomycin. Erythematous, linear lesions often precede the appearance of increased pigmentation.

Clinical Manifestations: Mitotic Inhibitors

ETOPOSIDE. Hyperpigmentation occurs in occluded areas.

IFOSFAMIDE. Hyperpigmentation on the hands, feet, and occluded areas has been reported.

MITHRAMYCIN. Mithramycin has been associated with postinflammatory hyperpigmentation following intense flushing and facial edema.

PACLITAXEL. Causes localized hyperpigmentation.

PROCARBAZINE. Localized hyperpigmentation has been reported.

Clinical Manifestations: Antimetabolites

5-FLUOROURACIL. 5-FU causes uniform pigmentation in sun-exposed areas in 2% to 5% of patients. Localized hyperpigmentation can occur at previously irradiated sites. Many localized patterns of pigmentation in nonirradiated areas have also been described. Serpentine supravenous hyperpigmentation occurs over veins used for repeated 5-FU infusions even in the absence of phlebitis or thrombosis. Serpentine pigmented streaks and reticulate pigmentation on the back and buttocks have also been reported. Hyperpigmentation can present in stria distensae. Banded pigmentation over small joints of the hands, diffuse pigmentation of the palms, and macular pigmentation of the palms and soles have been described. Nail pigmentation can occur as transverse banding, and pigmentation of the oral mucosa can result after long-term therapy.

METHOTREXATE. Methotrexate has been reported to cause horizontal dark banding of the hair after intermittent therapy, similar to the "flag sign" of kwashiorkor.

Clinical Manifestations: Miscellaneous Drugs

CISPLATIN. Cisplatin has been reported to produce a gingival band of pigmentation similar to a "lead line." Hyperpigmentation at sites of pressure is common and is seen in as many as 70% of patients.

HYDROXYUREA. Hydroxyurea has caused generalized hyperpigmentation and scaling in patients receiving long-term maintenance therapy. Pigmentation is accompanied by partial alopecia, cutaneous and subcutaneous atrophy, and erythema of the face and hands. Multiple longitudinal pigmented nail bands have also been observed.

Pathology

Skin biopsy specimens have demonstrated a variety of alterations in both the amount of melanin present and its distribution within the epidermis. Melanin can also be seen in dermal macrophages. On occasion, melanocytes might be increased in number, are larger than normal, and might appear to have more dendritic processes.[53]

Differential Diagnosis

Diffuse generalized hyperpigmentation can be seen in Addison's disease or primary adrenal insufficiency, which could be caused by metastatic carcinomas or Hodgkin's lymphoma. Addison's disease is also characterized by constitutional symptoms of fatigue, anorexia, and malaise, which are noted commonly among patients receiving cancer chemotherapy. Pigmentation in Addison's disease usually involves the oral mucosa and is accentuated in skin folds and creases, on the areolae and genitalia, and in sun-exposed areas. ACTH levels are elevated, and there is an abnormal response to ACTH stimulation. These laboratory findings are not present in patients with hyperpigmentation due to cytotoxic drugs.

Patients with hemochromatosis, an iron storage disease, show diffuse bronze pigmentation. The acquired form can present in patients who have received multiple blood transfusions. Hepatomegaly is usually present. Hyperpigmentation is due primarily to melanin, but hemosiderin deposition can be present in the skin also. Serum iron levels are elevated, and saturation of transferrin is noted in patients with hemochromatosis. Generalized hyperpigmentation and melanuria can occur in patients with advanced metastatic melanoma.

Melasma is an acquired macular brown pigmentation of the face that becomes pronounced with sun exposure. It can be seen during pregnancy and in patients on oral contraceptive or phenytoin therapy. Multiple pigmented longitudinal nail bands can occur as a normal finding among dark-skinned individuals and can be seen in metastatic melanoma. These are caused by benign melanocytic hyperplasia, lentigos, or junctional nevi within the nail matrix. Diffuse brown nail pigmentation can be caused by drugs other than cytotoxic agents, such as antimalarials, phenothiazines, tetracyclines, psoralens, and gold salts.

Treatment and Outcome

Hyperpigmentation secondary to cytotoxic agents is primarily a cosmetic problem and does not affect the continuation of treatment. Some patients might suffer psychologic distress but should be reassured that cutaneous hyperpigmentation, though persisting for several months, usually resolves after cessation of treatment. Nail pigmentation also resolves as the nails grow after treatment is discontinued.

Prevention

Use of sunscreens and avoidance of excessive sun exposure might prevent accentuation of pigmentary changes.

Nail Disorders

In addition to pigmentary nail abnormalities, cytotoxic drugs may disturb normal nail growth to produce a variety of nail changes, including Beau's lines, transverse white bands, onycholysis, and brittle nails.

Etiology and Pathogenesis

Cytotoxic agents can cause a direct toxic effect on the mitotically active cells of the nail matrix, which, as noted in the discussion on alopecias, can lead to cessation of growth with incomplete formation of the nail plate and the formation of Beau's lines. Disruption of nail keratinocyte differentiation can produce an abnormal nail plate. Measurements of the distance between Beau's lines and transverse white bands have shown a temporal relationship between nail abnormalities and the sequence of drug administration.[54]

Signs and Symptoms

Beau's lines are transverse depressions of the nail plate produced by the temporary cessation of nail growth. Typically, all nails are affected, but Beau's lines are most readily visible on the thumbs. They are commonly observed after short, intense chemotherapy regimens.[54]

Multiple transverse white bands of all 10 fingernails can result from combination chemotherapy featuring a variety of agents that include cyclophosphamide, doxorubicin, vincristine, prednisone, bleomycin, methotrexate, procarbazine, carmustine, semustine, and cisplatin.[55]

Onycholysis, or separation of the nail plate from the nail bed, has been reported among patients receiving 5-FU and bleomycin.[56] Doxorubicin may cause onycholysis, subungual blistering, blistering of the soles, and subsequent callus formation.[57] Brittle nails have been reported secondary to the administration of 5-FU and hydroxyurea.

Differential Diagnosis

Beau's lines can be seen after many severe febrile illnesses, after myocardial infarction, and with Raynaud's syndrome, zinc deficiency, or

chronic dermatitis of the nail folds. Transverse white bands can sometimes be seen after an acute illness or after ingestion of arsenic, thallium, or fluoride. Onycholysis is common in psoriasis and fungal infections of the nail and secondary to trauma.

RADIATION-ASSOCIATED REACTIONS

Two types of reactions have been associated with the use of chemotherapeutic drugs and ionizing radiation: radiation enhancement and radiation recall. The resulting reactions correlate with the specific drug given and with the sequence of administration.

Radiation Recall

Radiation recall is an acute inflammatory cutaneous or organ reaction that develops within a previously irradiated site and after administration of a chemotherapeutic agent.[58] Involved organs may include skin and mucous membranes, lung, esophagus, gastrointestinal tract, central nervous system, bladder, and heart.

Etiology

Multiple drugs have been reported to cause radiation recall. The most common drugs known to cause this reaction are the cytotoxic antibiotics (dactinomycin, doxorubicin, daunorubicin, and bleomycin), the taxanes (paclitaxel, docetaxel), and methotrexate.[59]

Clinical Manifestations

Radiation recall may develop without clinically apparent antecedent radiation damage to the skin. Clinical manifestations usually develop within days after chemotherapy is given; however, the time interval between radiotherapy and the resultant radiation recall reaction can vary from several days to years. Mild reactions appear as erythema and edema followed by dry desquamation, similar to first-degree burns (Fig. 41-6). More severe reactions are associated with moist desquamation, painful blistering, weeping, and in the most severe cases, full skin necrosis and painful ulcerations. The severity of the cutaneous reaction seems to correlate with the time interval between radiation and chemotherapy, with the shortest time intervals resulting in more severe reactions.

Pathology

The pathogenesis of radiation recall is controversial. The severity of the radiation recall reaction is also related to the tissue at risk, type and dosage of drug, the radiation dose utilized, and the sequential relationship between the administration of radiation and the administration of the chemotherapeutic agent.[60,61]

Figure 41-6 • Radiation recall. This patient had small-cell cancer of the lung treated with radiation. Cyclophosphamide treatment some months later elicited erythema and desquamation within the portal of radiation. This lesion is now in the healing phase.

Differential Diagnosis

Radiation recall reaction could be difficult to differentiate from cytostatic drug recall of acute inflammation caused by ultraviolet light or other cutaneous irritants and infections. Areas that have experienced an acute or remote sunburn reaction or have been sites of previous irritation or infection can also become further inflamed during the administration of a chemotherapeutic agent. The resulting skin reaction does not differ from that noted as radiation recall.[62]

Treatment and Outcome

Mild cases of radiation recall, which are characterized by erythema, edema, and dry desquamation, are self-limiting. Cool compresses and lubricating creams or ointments provide symptomatic relief. In the more severe cases in which exudates and/or blisters predominate, wet to dry compresses should be used to promote drying. Upon cessation of exudates formation, moist wound healing strategies should be implemented. Infected sites should be cultured and treated.

Radiation-induced necrotic ulcers are slow to heal. They are poor candidates for grafting because neovascularization and fibroblastic repair is limited. Strategies that attempt to both limit the amount of exudates and provide for moist wound healing should be implemented. Topical corticosteroids have little effect in treatment of radiation recall injuries.[61]

Radiation Enhancement

Certain chemotherapeutic drugs, termed *radiation sensitizers,* potentiate or enhance the effect of ionizing radiation. The occurrence of radiation enhancement depends on drug delivery being concurrent with or following within 3 weeks of radiation therapy. Although radiation enhancement might be planned to increase tumor destruction, this technique often causes significant injury and morbidity in adjacent noncancerous tissues.

Etiology

Radiation sensitizers include gemcitabine, IFN-α2a, 13-*cis*-retinoic acid, doxorubicin, docetaxel, carboplatin, cisplatin, dactinomycin, methotrexate, 5-FU, bleomycin, and hydroxyurea.

These drugs interfere with the repair processes that allow sublethally damaged cells to recover from radiation injury. The degree of reaction depends on the type of drug and dosage, the radiation dosage, and the time interval between the delivery of radiation and drug.

Clinical Manifestations

The clinical manifestations of radiation enhancement fall into one of three patterns:

1. A mild reaction consisting of erythema, edema, and dry desquamation
2. A moderate reaction with moist desquamation, vesiculation, blister formation, and erosion
3. Severe necrotic ulcerative reactions that could result in residual skin hypopigmentation.

The affected sites are not limited to the radiation port but also involve contiguous skin.

Differential Diagnosis

Acute radiation-induced dermatitis may show clinical findings similar to those of radiation enhancement. However, they differ in time of occurrence following irradiation. Radiation dermatitis tends to occur within 1 to 3 weeks after radiation. Recall reactions occur weeks to months after irradiation.

Treatment and Outcome

Prognosis and treatment are dependent on the severity of the reaction and are similar to those described in the section on radiation recall reactions.

Reactivation Dermatitis

Cytostatic drugs frequently reactivate acute inflammation and exacerbate pre-existing eczema and other cutaneous diseases[63,64] (Figs. 41-7 and 41-8). IFN-α often exacerbates psoriasis and psoriatic arthritis.[65]

It is paradoxical that immunosuppressive agents can enhance cutaneous hypersensitivity reactions. Methotrexate blocks the induction of allergic contact dermatitis during the period of its administration, yet it can reactivate a positive patch test to 10% benzalkonium chloride solution.[63] Cyclophosphamide-treated guinea pigs can experience an enhanced allergic contact dermatitis when challenged with dinitrochlorobenzene.[66]

Although both topical and systemic administration of 5-FU can result in a seborrheic dermatitis-like eruption, this reaction does not appear to be reactivation but instead a de novo cutaneous adverse effect.[67]

Neutrophilic Eccrine Hidradenitis

Neutrophilic eccrine hidradenitis is an acute dermatosis associated with the administration of multiple chemotherapeutic agents including bleomycin, chlorambucil, cytarabine, daunorubicin, doxorubicin, mitoxantrone, vincristine, and topotecan.[68] Once considered rare and confined to adults receiving cytarabine for acute myeloid leukemia, it has been suggested more recently that the entity is more common than previously admitted. Not only has it been observed in children undergoing systemic chemotherapy, but neutrophilic eccrine hidradenitis has been reported in association with bacterial infections, acquired immunodeficiency syndrome, and a variety of medications.[69,70] It has been observed to occur in children and adults with several different malignancies and receiving a wide spectrum of systemic chemotherapeutic drugs. The clinical appearance is quite variable, yet the histopathologic picture remains characteristic.

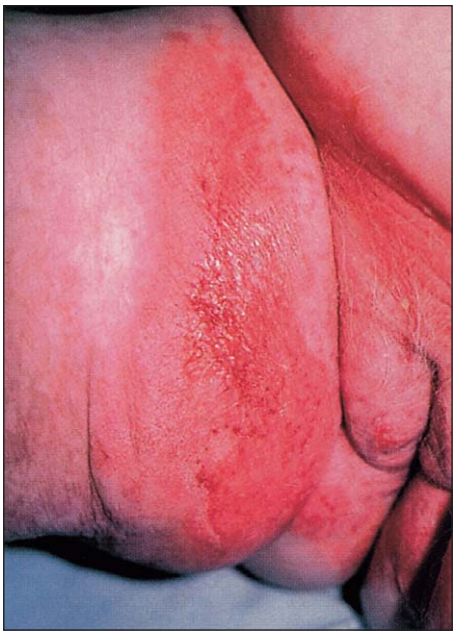

Figure 41-7 • Reactivation dermatitis. This elderly diabetic female had a previous history of a *Candida* infection of the groin several years before. Methotrexate administration on each of several occasions caused the development of a weeping erosive dermatitis.

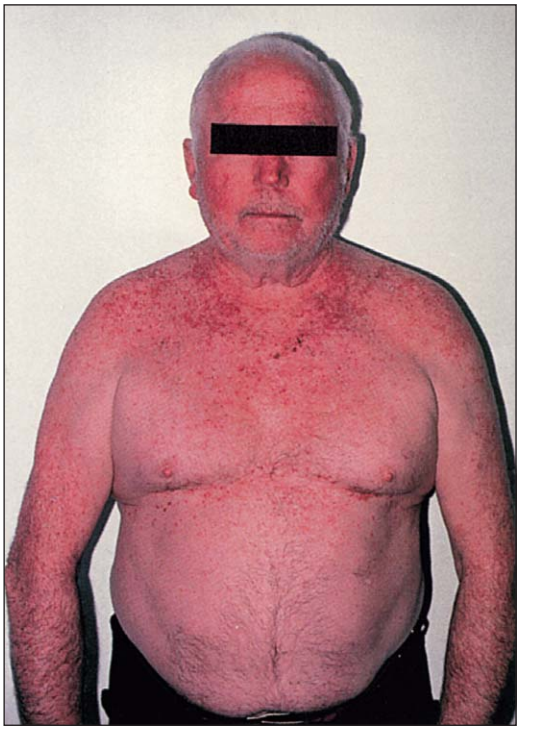

Figure 41-8 • Inflamed actinic keratoses secondary to the administration of systemic 5-FU.This patient had extensively photodamaged skin showing "activation" of previously unrecognized actinic keratoses. Red scaling papules and cutaneous ulcerations predominate.

Etiology

The primary histopathologic lesion in this disease is localized necrosis of the eccrine glands in the skin. Associated necrosis of apocrine glands has been reported. The mechanism whereby necrosis is induced is unclear.[71] The histologic picture, which is quite characteristic, tends to rule out hypersensitivity vasculitis as a cause. Necrosis caused by the accumulation of high concentrations of cytotoxic agents within the sweat glands cannot be excluded.

Clinical Manifestations

Affected patients present with a wide variety of cutaneous lesions. Tender erythematous to purpuric macules, papules, nodules, and plaques, some with dark central areas, will suddenly appear on any body area during active administration of a cytotoxic agent. Lesions might appear within 2 to 3 days of starting chemotherapy or may go unnoticed until weeks after chemotherapy has started. Some unusual presentations include periorbital edema with erythema and injection site reactions.[72] Usual manifestations include hyperpigmented plaques and painful edema of the ears. Spiking fevers often accompany the onset of cutaneous lesions.

In many patients, skin lesions begin to resolve within 7 to 21 days after onset despite continuous chemotherapy administration. Likewise, new lesions can appear days and weeks after resolution of an original outcropping or might recur with the reinstitution of a course of chemotherapy. New papules, plaques, and nodules also might develop within sites previously involved by initial lesions.

Pathology

Histopathologic changes within affected skin sites are quite characteristic for this disease. There is pronounced neutrophilic infiltration

of the dermis about and focally within the eccrine glands, resulting in focal epithelial necrosis and basilar vacuolization of eccrine epithelial cells. The neutrophilic infiltrate is heaviest in those glands demonstrating vacuolar changes and less intense around those glands showing intense necrosis. Neutrophilic infiltration of the coiled duct and straight duct may or may not be observed. Some secretory coil epithelial cells show marked nuclear pyknosis and cytoplasmic eosinophilia. Mucinous degeneration of the eccrine gland adipose tissue cuff, along with an infiltrate of lymphocytes, eosinophils, and neutrophils, may be present, as well as focal areas of hemorrhage within the dermis, mild to moderate spongiosis, and occasional vacuolization of the epidermis. In patients with active leukemia, abnormal or immature leukemia cells do not make up part of the tissue infiltrate.

Differential Diagnosis

Because neutrophilic eccrine hidradenitis is a fairly benign, self-limiting disease, it is imperative that it be differentiated clinically from other, more serious diseases that it might mimic. The variety of cutaneous lesions described in patients with neutrophilic eccrine hidradenitis could easily cause confusion with a fairly large number of clinical entities. Among these are leukemia cutis, cutaneous tumor metastases, erythema multiforme, vasculitis, drug hypersensitivity, sepsis (bacterial and fungal), Sweet's syndrome, and pyoderma gangrenosum. The localized nature of lesions associated with neutrophilic eccrine hidradenitis, and the temporal relationship of cutaneous lesions to the administration of chemotherapy, should aid clinically in differentiating neutrophilic eccrine hidradenitis from most diseases. Because the abnormal histopathologic picture presented by this disease is quite unique, histologic sampling of tissue is of importance.

The histologic differential diagnosis would include several entities involving necrosis of the eccrine gland, including bacterial sepsis with eccrine hidradenitis or other neutrophilic dermatoses; however, the well-trained pathologist, aided by the astute clinician, should combine to make a definitive diagnosis possible.

Treatment and Outcome

Neutrophilic eccrine hidradenitis is a benign, self-limiting disease that generally requires no treatment. The course or the disease does not appear to be influenced by chemotherapy protocols that often include high dosages of systemic corticosteroids. Within 7 to 10 days of origin, most lesions tend to resolve. Recurrent lesions appear to be less severe than preceding lesions and have been suppressed with concurrent dapsone administration.[73] In all patients described to date, healing occurs without residual scarring.

Prognosis

The prognosis for total recovery without sequelae is excellent.

Syringosquamous Metaplasia

Although it can present as a histopathologic finding in association with various other cutaneous conditions, syringosquamous metaplasia has become increasingly associated with the administration of a variety of chemotherapeutic agents and cancers.[74] It has been described in association with bleomycin, cytarabine, daunorubicin, doxorubicin, mitoxantrone, suramin, and docetaxel.[75]

Etiology

The exact etiology of syringosquamous metaplasia is unknown. It is presumed to be a reactive or inflammatory response of the eccrine duct epithelium to the offending agent.

Clinical Manifestations

During or soon after the administration of chemotherapy, there is the onset of nondescript erythematous papules, plaques, or vesicles. These may be generalized or localized and have been reported to occur only in the intertriginous areas.[76,77]

Pathology

The characteristic histopathology shows eosinophilic squamous metaplasia of the eccrine ducts within the dermis. Focal necrosis of the ductal epithelium has also been noted. The prominent neutrophilic infiltrate of neutrophilic eccrine hidradenitis is not present.

These pathologic changes are not specific and have been described in other disorders unrelated to chemotherapy.[77]

Differential Diagnosis

The differential diagnosis is extensive and includes neutrophilic eccrine hidradenitis; bacterial, viral, or fungal infections; erythema multiforme, metastatic disease; and drug hypersensitivity. Histopathology is necessary to differentiate among these various entities.

Treatment and Outcome

The eruption is benign and resolves spontaneously after cytotoxic treatment is discontinued.

REACTIONS TO BIOLOGIC RESPONSE MODIFIERS

The recent introduction of a group of agents referred to as biologic response modifiers in the treatment of cancer has led to the occurrence of a host of cutaneous reactions.

These powerful physiologic agents used in the setting of underlying malignancy, immunosuppression, other medications, and individual genetically determined host factors have precipitated a variety of specific and nonspecific cutaneous responses. These reactions are summarized in Table 41-2.

Cutaneous Reactions to Interleukin-2

Recombinant human IL-2, or T-cell growth factor, is a glycoprotein that exerts a wide variety of biologic effects on the immune system. It has found use in the treatment of advanced malignancies, including malignant melanoma, cutaneous T-cell lymphoma, renal cell carcinoma, advanced colorectal carcinoma, and advanced lymphoma.[78–83] IL-2 has been used after autologous bone marrow transplantation to prevent or reduce the high relapse rate of advanced hematologic malignancies.[84] In the clinical setting, IL-2 is often used in combination with other biologic response modifiers, including lymphokine-activated killer (LAK) cells and IFN-α.[84] IL-2 has also been used in complex with diphtheria toxin as a fusion protein (denileukin diftitox) for the treatment of malignancies characterized by a predominance of activated T and B cells and/or macrophages that express the IL-2 receptor.

IL-2 alone and in combination with LAK and IFN-α has produced a wide variety of toxicities, including one characteristic cutaneous eruption. It is estimated that 50% to 100% of patients treated with IL-2 alone or in combination with other biologic response modifiers will experience some form of cutaneous eruption.[85]

Etiology

Within 48 to 72 hours after the start of an infusion of IL-2 alone or in combination with another cytokine, patients develop a skin eruption of varying severity. The precise etiology is unclear, except it seems that cutaneous reactions occur more often when high doses of IL-2 (100,000 μg/kg) rather than low doses (30,000 μg/kg) are used.[85] There is no difference in rate of occurrence, whether bolus or continuous infusions are administered.

Thus far, no racial or sexual predominance has been observed. More than one-quarter of all patients treated with IL-2 develop a capillary leak syndrome, which, except for extensive edema, does not as yet seem to be entirely related to the development of cutaneous

lesions. Nearly all patients receiving IL-2 therapy develop fever and chills. These symptoms tend to occur almost immediately with the initiation of treatment. Gaspari and colleagues[85] have studied IL-2 cutaneous reactions extensively and have concluded that there is immunohistochemical and histologic evidence to support the presence of a cell-mediated immune response during IL-2 therapy. Other studies have implicated a possible role for nitric oxide, Fas ligand and perforin, and complement and other inflammatory mediators in affecting vascular permeability, resulting in a capillary leak syndrome.[86–88] It is likely that vascular leak syndrome occurs as a result of multiple mechanisms: cell-mediated damage, cytokine-mediated damage, inflammatory mediators, and modification of endothelial cell integrity and the extracellular matrix.[89]

Clinical Manifestations

Chills and fever along with transient cutaneous flushing occur during the first 24 to 48 hours of IL-2 administration. After 48 to 72 hours, persistent erythema associated with itching and a burning sensation develop, first on the malar aspects of the face and then on the neck and chest. In other patients, total body erythema (erythroderma) develops along with erythema and edema of the palms and soles (Fig. 41-9). If the use of IL-2 is combined with LAK cell infusions, it appears that the onset of the eruption might begin within 24 hours. Resolution of disease can occur within 2 to 3 days, when drug administration is stopped. Resolution is associated with continuing pruritus and desquamation of involved skin. There are other reports of erythema progressing to life-threatening bullous eruptions and toxic epidermal necrolysis-like lesions. Some investigators report that the histopathologic findings in these cases separate these patients from those suffering the most frequently observed IL-2 reactions. Erosions of the buccal mucosa, icterus, glossitis, and cutaneous erosions have also been described. A persistent but not progressive vitiligo-like depigmentation has been described after IL-2 and IFN-λ, plus carmustine, cisplatin, and dacarbazine treatment of malignant melanoma.[90]

Figure 41-9 • IL-2 cutaneous reaction. This patient's disease is characterized by intense facial redness, red swollen hands and feet, and a generalized macular eruption.

Pathology

Histopathologic findings thus far are nonspecific. Within the epidermis, foci of spongiosis, focal vacuolar basal cell degeneration, rare necrotic keratinocytes, and exocytosis of mononuclear cells are seen. In the dermis, mild papillary edema, mild to moderate perivascular mononuclear cell infiltrates, and occasional engorgement of blood vessels occur. These are nonspecific findings. Immunohistochemistry shows activated T cells within the epidermis and dermis with approximately equal numbers of major histocompatibility complex class I and II reactive cells.

Differential Diagnosis

Viral and bacterial exanthems, drug or phototoxic reactions, toxic shock syndrome, staphylococcal scalded skin syndrome, toxic epidermal necrolysis, and acute graft-versus-host reactions must be considered and ruled out with appropriate tests.

Treatment and Outcome

Cessation of treatment is followed 48 to 72 hours later with complete clearing of the skin and little or no residual effect except transitory hyperpigmentation.

Antihistamines given during drug administration and the application of emollients have shown some benefit in the relief of pruritus. The use of systemic glucocorticoids that could offer some immediate relief of symptoms is not indicated; glucocorticoids decrease IL-2 toxicity but might also reduce IL-2 efficacy.[91,92]

Cutaneous Reactions to Proteasome Inhibitors

Proteasomes exist as large multiprotein particles within the cytosol and cell nucleus and are responsible for regulation of protein expression and degradation of damaged or obsolete proteins within the cell. Proteasome inhibitors have been recently introduced as anticancer agents.[93–95] The ubiquitin-proteasome pathway is the major proteolytic system in eukaryotic cells. Some of the proteins regulated by this pathway are mediators of cell-cycle progression and apoptosis. These pathways are needed for the survival of all cells including cancer cells. Proteasomes allow the cell to progress through the cell cycle by such mechanisms as degrading cell-cycle regulatory proteins or regulating transcriptional factors such as nuclear factor-κB (NF-κB).[93]

It has been suggested that malignant cells are more susceptible to proteasome blockade than noncancerous cells.[94] Proteasome inhibitors fall into five classes: peptide aldehydes, peptide vinyl sulfones, peptide boronates, peptide epoxiketones, and beta-lactones. All except peptide boronates have been found unsuitable for clinical development.[93] Cutaneous toxicity has been variously described in from 20% to 30% of patients treated. Severity grade varies from 1 to 3.

Etiology

The proteasome inhibitor bortezomib, a peptide boronate, was approved for treatment of refractory multiple myeloma. Investigations are currently underway for treatment of non-Hodgkins lymphoma and a variety of solid tumors. It has been suggested that bortezomib's cutaneous toxicity occurs as an inflammatory response associated with delayed hypersensitivity, cell-mediated immune responses, vascular damage, or direct toxic reactions.[96] Enhancement of the release of pro-inflammatory cytokines may also be involved.[97]

Clinical Manifestations

In most patients described thus far cutaneous adverse reactions vary in severity and occurrence. An undefined "exanthem" consistent with a hypersensitivity reaction seems to be most common. It resolves spontaneously without treatment but recurs with additional treatment cycles.

At least 20% of patients develop lower extremity edema. An unspecified rash, pruritus, urticaria, sweating, dry skin, and eczema

appear commonly, whereas alopecia seems to be rare.[98] Red nodules or plaques on the trunk, and a generalized exanthem associated with ulceration and fevers may appear during the second to fourth treatment cycles; however, they can be seen in the first cycle.[98] Drug-induced Sweet's syndrome[98,99] and erythematous maculopapular eruptions that on biopsy display "leukocytoclastic vasculitis" have been seen in many patients.[97,100,101] It has been suggested that the development of vasculitis may be a possible surrogate marker of disease response.[101] A folliculitis-like eruption has also been described,[102] as has reactivation of latent varicella zoster virus.[103] Finally, a solitary paranasal plaque and eschar have been described.[104]

Pathology

Histology differs depending on the type of skin eruption. In patients with nodules, plaques, and exanthem, histology ranged from perivascular dermatitis to interstitial and interface dermatitis.[96] In those with leukocytoclastic vasculitis, perivascular neutrophilic infiltrates with fibrinoid necrosis is seen. In Sweet's syndrome there are diffuse neutrophilic infiltrates in the reticular dermis with papillary dermal edema. Leukocytoclastic nuclear debris is often seen interstitially, but true vasculitic changes are absent. In the folliculitis-like lesions, perivascular lymphoid infiltrates were seen.[102] In a solitary alar lesion, a superficial perivascular and interface dermatitis compatible with drug eruption was seen.[104]

Differential Diagnosis

Infectious exanthems and other eruptions due to medicines other than bortezomib must be considered. Sweet's syndrome must be distinguished from other reactions such as neutrophilic eccrine hidradenitis, pyoderma gangrenosum (bullous), erythema multiforme, vasculitis, and other infectious or neoplastic causes. Vasculitis must be distinguished from capillaritis, vasculopathy, and other inflammatory dermatoses such as Sweet's syndrome, urticaria, and erythema multiforme. Additionally, Sweet's syndrome and leukocytoclastic vasculitis can be due to several etiologies, and there do not seem to be any unique features suggesting bortezomib as the etiology.

Treatment and Outcome

In some cases lesions resolve without specific treatment, or with the use of oral corticosteroids and/or antihistamines.[96–98,100,102] Oral corticosteroids have been used prophylactically to prevent recurrence of lesions[96–98,102] or reduce the number and extent of lesions.[96] Antihistamines alone were not sufficient to prevent occurrence.

Histone Deacetylase Inhibitors

Histone deacetylase inhibitors (HDACs) have recently emerged as potential agents for use in cancer therapy.[105] Acetylation of histone proteins can affect gene activation. Histone deacetylases remove acetyl groups from histones leading to repression of gene transcription. Dysregulation of acetylation has been implicated in cancer development when genes involved in cell-cycle control or apoptosis are affected. HDACs are thought to work by allowing gene reactivation of tumor suppressor or apoptotic pathway genes leading to cell-cycle arrest or cell death.

Five classes of HDACs have been described. A few medications have been tested in phase I and II trials including depsipeptide, suberoylanilide hydroxamic acid, and MS 275.[105] Thus far, skin toxicity appears to be minimal. In two phase I trials for depsipeptide[106,107] it was noted that skin toxicities seem to be distinct from conventional agents. No alopecia or mucositis was noted. No sign of skin toxicity or bleeding was noted. Similarly, in a recent phase I study by Kelly and associates no cutaneous reactions were described for suberoylanilide hydroxamic acid.[108] Finally, another HDAC, MS-275, was evaluated in a phase I trial by Ryan and coworkers.[109] Cutaneous reactions were rare, with edema noted in four patients, and sweating and nail changes noted in one patient each. An allergic reaction was noted in one patient, but this was not further described. Further use of these medicines will better elucidate the adverse cutaneous effect profile.

Toll-like Receptor Agonists

Toll-like receptor agonists have emerged as other potential cancer medications.[110] There are 10 Toll-like receptors (TLRs) in humans that are expressed on cells of the innate immune system. Most signaling through these pathways results in the production of proinflammatory cytokines. Agonists have been found to drive adaptive immunity toward a Th1 response, which then targets tumor cells. In chronic lymphocytic leukemia, these agonists may enhance the activity of T cells and natural killer cells, and inhibit angiogenesis. TLR-7 and TLR-9 agonists in particular may lead to production of cytokines that render tumor cells more susceptible to killing. In this way they may be useful as adjuvant medications.

TLR-7 agonists, imidazoquinolines, are currently being studied (including S28690). There is minimal information available on cutaneous adverse effects of these medications. Imiquimod (Aldara) is also an imidazoquinoline that has been used topically for treatment of verruca and skin cancers. Topical use of this medication has been associated with systemic and cutaneous side effects. In recent trials itching, pain, and tenderness at the site of the application were the most common cutaneous complaints.[111] Other local reactions included scabbing, erosion, ulceration, erythema, and vesiculation.

Cutaneous Reactions to Epidermal Growth Factor Receptor Inhibitors

The EGFR (or ErbBl) is a 170-kd transmembrane protein that includes an extracellular ligand-binding domain and an intracellular protein tyrosine kinase.[112] Stimulation of this often overexpressed receptor in aberrant cell lines propagates pathways of cellular proliferation (including tumor growth, progression, and metastasis of human cancer); thus, EGFR therapeutic blockade has proven beneficial in treating a variety of solid tumors.[113] Two classes of EGFR inhibitors are currently in use: monoclonal antibodies that target the extracellular domain to inhibit ligand binding and induce receptor downregulation, and receptor tyrosine kinase inhibitors that competitively block receptor phosphorylation.[112] Dermatologic reactions are the most commonly reported toxicities with both classes. The most characteristic is an acneiform eruption reaction, which is seen in 50% to 90% of treated patients.[114]

Etiology

Within the first 2 weeks of treatment, a characteristic rash appears as an acne-like folliculitis, typically starting on the face, upper chest, back, and scalp but potentially extending to the extremities (Fig. 41-10). The descriptive term "acneiform" is commonly encountered in the literature, but it is important to emphasize that the pathophysiology of the primary lesion, a pustule, seems to be distinct from that of acne vulgaris.[115] The precise etiology is unclear. It has been postulated that inhibition of the EGFR pathway results in disruptions of normal development and maintenance of the hair follicle. Follicular rupture and an inflammatory reaction result.

Clinical Manifestations

There seems to be a drug-dosage relationship to the severity of the skin reaction. Severity is often rated 2 to 3. Most commonly the face is affected, including forehead, nose, nasolabial folds, cheeks, and chin.[115] There may be caudal progression of disease, but mucosa and acral surfaces are spared. Pustular lesions are primary, although erythema and cystic nodules have also been described.[115] The rash typically appears 1 to 3 weeks after onset of treatment, appearing maximal between weeks 3 and 5. It commonly resolves once treatment is

Figure 41-10 • EGFR typical eruption. **A,** Right breast with numerous pink acneiform papules and macules. **B,** Forehead with characteristic acneiform eruption of several pink papules and pustules some with crust. **C,** Bilateral forearms and dorsal hands with small pink papules and macules.

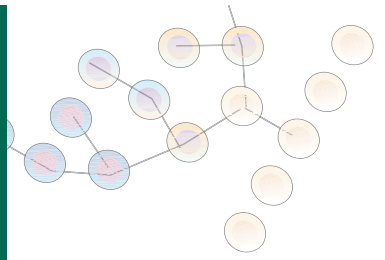
stopped but may persist for more than 12 weeks after cessation. Resumption of treatment may cause reappearance or worsening of the rash. Other than hyperpigmentation there are few residual effects.[116] Limited data suggest that patients with a skin rash of any grade may have a superior survival as compared with patients with no skin rash, and furthermore, there may be a trend toward improved survival with increasing grade of rash.[117] There is some evidence to suggest that the rash parallels saturation of receptor clearance and may be used as a measure of optimum biologic dose in those patients so affected.

Histopathology

Two primary reaction patterns have been identified: suppurative folliculitis with epithelial rupture and superficial perifollicular dermal inflammation with hyperkeratotic and ectatic infundibula.[114,115] The stratum corneum demonstrates compact orthokeratosis with focal parakeratosis and prominent follicular plugs. Also occasionally reported are basilar vacuolar degeneration, lichenoid patterns, and intradermal acantholysis.[115]

Treatment and Outcome

Depending on severity, which ranges from grade 1 to 4,[117] cutaneous toxicity, management may include drying agents, topical antibiotics and antiseptics, systemic antibiotics, topical retinoids, topical or systemic corticosteroids, or topical immunomodulatory agents. Secondary complications including *Staphylococcus aureus* infections and severe pruritus may occur and will require appropriate interventions.[116] Several published studies have even suggested that the severity of the skin eruption may parallel patient survival.[117]



Other Dermatologic Side Effects of Anti-EGFR Therapy

Additional and less common cutaneous effects reported include nail bed infections and paronychial inflammation with associated swelling of the lateral nail folds of the toes and fingers, onycholysis of nails, with the great toes and thumbs as the most commonly affected digits[114,115]; generalized exfoliation and desquamation; xerosis; pruritus; urticaria and angioedema (primarily with trastusumab); alopecia; skin fissures; and mild to moderate stomatitis and mucositis.[115] Treatment is primarily symptomatic.

42 Lymphedema

Lance Wyatt and Julian Pribaz

SUMMARY OF KEY POINTS

Definition
- Lymphedema is the accumulation of protein-rich interstitial fluid within the skin and subcutaneous tissue.

Etiology and Classification
- Primary lymphedema is thought to be a genetically determined disease with expression at or shortly after birth (Milroy disease), puberty (lymphedema praecox), or after 35 years of age (lymphedema tarda).
- Secondary lymphedema occurs as a result of a precipitating cause.

Incidence
- The incidence of lymphedema is not known.
- The most common cause of secondary lymphedema worldwide is lymphatic filariasis.
- In Western countries the most common cause is damage to or removal of lymph nodes by surgery, radiotherapy, tumor invasion, or as the result of infection or inflammation.

Diagnosis
- Diagnosis is made in the majority of cases by history and physical examination; lymphoscintigraphy, computed tomography and magnetic resonance imaging may be needed.
- Soft, pitting edema generally begins distally and progresses proximally over months to years.

Goals of Treatment
- There is no cure for lymphedema.
- Goals of therapy are to (1) reduce fluid production and accumulation, (2) reduce associated complications, and (3) improve limb function and appearance.

Medical Treatment
- Skin care, extremity elevation, compressive garments, pneumatic compression pumps, noninvasive complex lymphedema therapy, and treatment of infection are the mainstays of medical therapy.

Surgical Treatment
- Surgery is a continuum of medical management and is performed for failure of medical management, gross extremity size and weight with impaired extremity function, severe skin changes, and/or recurrent lymphangitis (more than three episodes per year).
- Physiologic procedures attempt to restore lymphatic drainage.
- Excisional procedures remove lymph-producing as well as fibrosclerotic tissue and fat.

INTRODUCTION

Lymphedema is the accumulation of protein-rich interstitial fluid within the skin and subcutaneous tissue. Cases in which the etiology is unknown or that develop as a result of congenital lymphatic dysfunction are referred to as primary lymphedema. All forms of lymphedema that occur as a result of a precipitating cause are termed secondary lymphedema. No cure exists for lymphedema. The aims of therapy are to reduce fluid production and accumulation, to reduce associated complications, and to improve limb function and appearance.

ETIOLOGY AND CLASSIFICATION

The most commonly used classification categorizes the etiology of lymphedema as primary or secondary to some inciting event. Primary lymphedema, which is thought to be due to aplasia or hypoplasia of the lymphatics, has long been thought to be a genetically determined disease with expression at or shortly after birth (Milroy disease), puberty (lymphedema praecox), or after 35 years of age (lymphedema tarda). The time of onset may be related to the relative number of functioning lymphatics. It is generally thought that the fewer lymphatics the earlier the onset. The molecular basis for congenital primary lymphedema (Milroy disease) has been established as autosomal dominant with incomplete penetrance due to a mutation in the gene locus encoding VEGFR3.[1,2] This condition may be diagnosed prenatally.[3]

Lymphedema praecox, the most common form of primary lymphedema, is responsible for as many as 94% of cases in large reported series. The uncertainties of this condition derive from its unusual, unexplained features: female predominance (ratio of females to males is estimated to be 10 : 1), development around the time of menarche, more common involvement of the left leg, and rare upper extremity involvement. Estrogenic hormones have been implicated.[4] The edema typically is limited to the foot and calf. Lymphedema tarda, which develops later in life, accounts for fewer than 10% of cases of primary lymphedema. The precipitating cause often follows minor trauma or an inflammatory process (e.g., cellulitis) that can damage and possibly obstruct an already reduced number of lymphatics, tipping the balance in favor of lymphedema.

The most common cause of secondary lymphedema worldwide is lymphatic filariasis. In its most obvious manifestations, lymphatic filariasis, also known as elephantiasis, causes edema of the entire arm or leg; the genital regions (vulva, scrotum, breasts) also may be involved. Lymphatic filariasis is a significant cause of poverty in more than 80 countries in which it is endemic, primarily in Asia, Africa,

the Western Pacific, and the Americas. Approximately 90% of these infections are caused by *Wuchereria bancrofti*, with most of the remainder by *Brugia malayi* and *B. timori*. The major vectors for *W. bancrofti* are *Culex*, *Aedes* species, and *Anopheles* mosquitoes. The World Health Organization estimates that at least 120 million people are infected, with approximately 40 million disabled as a result of this condition.

In Western countries, damage or removal of lymph nodes by surgery, radiation therapy, tumor invasion, or as the result of infection or inflammation are the most common causes of secondary lymphedema. The onset of upper extremity edema following axillary lymph node dissection is probably the most common cause of lymphedema in the United States.[5] The incidence of lymphedema following breast cancer therapy ranges broadly depending on the definition of lymphedema, on type of therapy, and on time elapsed since therapy; however, an overall incidence rate of 25% has been reported. The incidence rate climbs to 38% among patients with axillary node dissection and radiation.[6] Changes in clinical practice, such as the use of sentinel lymph node biopsy rather than full axillary dissection in breast cancer treatment, may lead to a reduction of this rate. Studies have shown that, at least in the short term, the incidence of lymphedema is reduced in patients undergoing sentinel lymph node biopsy as compared with standard axillary dissection.[7,8] In the ALMANAC trial,[8] self-assessment among 954 patients randomized to each of these treatment groups, the relative risk self-reported of moderate to severe lymphedema within 12 months of surgery in the sentinal node biopsy group was 0.37 in comparison to the axillary dissection group. Furthermore, objective measurements of arm circumference were shown to be greater in the axillary dissection group at all sampling time points. The difference was statistically significant at 1, 3, and 6 months, but failed to meet that threshold at the 12-month measurement. No long-term results have yet been reported on the effect of sentinal node biopsy on the incidence of lymphedema, but studies are under way. Lymphedema of the lower extremity may occur after inguinal and pelvic lymph node dissection or irradiation, with a published frequency of 1% to 47%.[9,10]

Why do the vast majority of individuals not develop lymphedema after surgery, regional node dissection, malignancy, radiotherapy, trauma, inflammation, and infection? The capacity for compensation by collateral flow and regeneration of damaged lymphatics may explain whether lymphedema develops. Disrupted lymphatics are not reconnected during replantation or microsurgical free-tissue transfer. Temporary swelling of a re-implanted or transplanted part resolves without intervention. Radiocolloid lymphoscintigraphy with technetium-99m–antimony trisulfide colloid (Sb_2S_3) studies in individuals without lymphedema have demonstrated spontaneous regeneration or reconnection of lymphatics after free-tissue transfer.[11] These findings suggest that persons with lymphedema lack compensatory mechanisms necessary to prevent the development of lymphedema.

Lymphedema may be either genetic or syndromic. Turner's syndrome, Noonan's syndrome, and Hennekam syndrome are examples of syndromic lymphedema. Lymphedema-distichiasis syndrome, cholestasis-lymphedema syndrome, all forms of primary, and most forms of secondary lymphedema may be classified as genetic lymphedema. Individuals who manifest the disease at or shortly after birth may have a more severe form of lymphedema without sufficient compensatory mechanisms. The mildest forms of the condition may exist as a subclinical process, with expression only after an inciting event.

PATHOPHYSIOLOGY

Lymphedema is confined to the subcutaneous compartment; the deep muscle regions appear to be clinically uninvolved. Extravasation of protein-rich fluid occurs when lymphatic transport capacity is reduced because of reduced numbers of functioning lymphatics or increased lymphatic load. This high-protein edema causes a shift in Starling's equilibrium, resulting in the accumulation of more fluid. In time, low oxygen tension, decreased macrophage function, and the presence of increasing amounts of protein-rich fluid give rise to a chronic inflammatory state and gradual tissue fibrosis. In chronic lymphedema, a hypertrophy of adipose tissue also occurs, but the mechanism for this has not been elucidated. The high-protein edema serves as a medium for bacteria, and episodes of infection so characteristic of the condition lead to additional lymphatic sclerosis and further lymphatic transport dysfunction (Table 42-1).

Table 42-1 Pathophysiology of Lymphedema

REDUCED NUMBER OF LYMPHATICS BELOW CRITICAL LEVEL
Congenital lymphedema
Surgical ablation
Scar, radiation, infection
INCREASED LYMPHATIC LOAD
High-protein edema
Increased osmotic pressure
Inflammation
Perilymphatic scarring
Increased fatty deposition
PROGRESSIVE DETERIORATION
Increased volume
Induration
Fibrosis

DIAGNOSIS

In the vast majority of patients, diagnosis can be made by history and physical examination. The National Cancer Institute's Common Terminology Criteria for Adverse Events (NCI CTCAE, version 3) outlines the diagnostic and staging criteria for lymphedema related to malignancy (Table 42-2).[12] Edema generally begins distally and progresses proximally over months to years. Early in the course of lymphedema the accumulation of protein-rich interstitial fluid results in a soft, pitting edema. With time the chronic inflammatory state and accumulation of fat and gradual tissue fibrosis give rise to a nonpitting edema. Skin changes may occur, but ulceration is infrequent. Individuals with lymphedema may complain of fatigue or pressure in the extremity, but the complaint of pain should prompt the physician to search for an alternative cause. Lymphoscintigraphy with radiocolloids has been successful in delineating the anatomy of lymph vessels and in evaluating the dynamics of lymph flow. This technique has replaced lymphangiography, which may damage lymphatics and worsen lymphedema.[13] Lymphangiography is not recommended. Computed tomography and magnetic resonance imaging may be useful to rule out malignancy.

Edema from cardiac, renal, or hepatic insufficiency is distinguished from lymphedema by history and examination. Chronic venous insufficiency and postphlebitic syndrome are associated with aching discomfort and chronic pruritus.[14] Physical examination reveals hemosiderin deposits in the skin, dusky discoloration and venous engorgement with dependence, varicosities, and ulceration in advanced cases.

Myxedema of thyroid disease may be confused with lymphedema and develops when abnormal mucinous substances accumulate in the skin. Individuals with myxedema develop roughening of the skin of the palms, soles, elbows, and knees. These individuals also may have diminished sweat production, yellow-orange discoloration of the

Table 42-2 National Cancer Institute's Common Terminology Criteria for Adverse Events Staging and Diagnosis for Lymphedema

	GRADE				
Adverse Event	**1**	**2**	**3**	**4**	**5**
Edema: head and neck	Localized to dependent areas, no disability or functional impairment	Localized facial or neck edema with functional impairment	Generalized facial or neck edema with functional impairment (e.g., difficulty in turning neck or opening mouth compared with baseline)	Severe with ulceration or cerebral edema; tracheotomy or feeding tube indicated	Death
Edema: limb	5% to 10% interlimb discrepancy in volume or circumference at point of greatest visible difference; swelling or obscuration of anatomic architecture on close inspection; pitting edema	>10% to 30% interlimb discrepancy in volume or circumference at point of greatest visible difference; readily apparent obscuration of anatomic architecture; obliteration of skin folds; readily apparent deviation from normal anatomic contour	>30% interlimb discrepancy in volume; lymphorrhea; gross deviation from normal anatomic contour; interfering with ADL	Progression to malignancy (i.e., lymphangiosarcoma); amputation indicated; disabling	Death
Edema: trunk/genital	Swelling or obscuration of anatomic architecture on close inspection; pitting edema	Readily apparent obscuration of anatomic architecture; obliteration of skin folds; readily apparent deviation from normal anatomic contour	Lymphorrhea; interfering with ADL; gross deviation from normal anatomic contour	Progression to malignancy (i.e., lymphangiosarcoma); disabling	Death

ADL, activities of daily living.

skin, thinning hair, and uneven nails. The process may be localized to the pretibial region in thyrotoxicosis[15] but is more generalized in hypothyroidism.

Lipedema is caused by the abnormal accumulation of fatty substances in the subcutaneous regions, typically between the pelvis and the ankle. The feet are spared, and the swelling is symmetric, bilateral, and often painful. The condition affects women or men with a feminizing disorder and arises within 1 to 2 years after the onset of puberty. Patients often have a propensity to bruising, possibly as a result of increased fragility of capillaries within the adipose tissue. Skin changes characteristic of lymphedema are not present, and consistent fat pads anterior to the lateral malleoli are found in individuals with lipedema.[16]

In the United States a frequent cause of lymphedema of both the upper and lower extremities is neoplastic disease. Individuals previously treated for neoplastic disease who develop new or worsening lymphedema must be evaluated for the recurrence of cancer. Malignant lymphedema often develops rapidly and results in intrinsic or extrinsic obstruction of lymph flow. Pain, generally absent in lymphedema, may be present (Fig. 42-1).[17]

Lymphangiosarcoma is an extremely rare tumor that initially appears as multiple blue-red subcutaneous nodules. In the upper extremity, it most frequently occurs in cases of chronic lymphedema after mastectomy (described by Stewart and Treves in 1948 and known as Stewart-Treves syndrome[18]). Lymphangiosarcoma seldom occurs in the lower extremity but may develop in the presence of lymphatic filariasis. The usual interval between mastectomy and the appearance of lymphedema is approximately 1 year; lymphangiosarcoma develops approximately 5 to 9 years after mastectomy. The reported incidence varies from between 0.07% and 0.45%.[19] Immunologic and electron microscopic studies suggest that these tumors arise from vascular endotheliocytes, despite the clinical appearance of arising from lymphatic vessels.

Why lymphangiosarcoma has a predilection for lymphedematous tissue is unknown. It has been shown that these tumors grow more

Figure 42-1 • A 59-year-old man with gross end-stage obstructive lymphedema after recurrent squamous cell cancer excision and irradiation. The limb was nonfunctional and was treated with amputation.

consistently in lymphedematous as opposed to non-lymph-rich tissue. Some have speculated that the presence of a local immune deficiency creates a climate for malignant degeneration. Lymphangiosarcomas develop multicentrically and spread rapidly. These are extremely aggressive, highly malignant tumors; limb-sparing procedures are not recommended. Amputation may be the only hope for survival. Prognosis for patients with lymphangiosarcoma is extremely poor, with 5-year survival reported in between 8.5% and 13.6% despite aggressive treatment.[19]

MEDICAL MANAGEMENT

The aim of all forms of management is to restore the balance between lymphatic load and transport capacity. No treatment option is completely and permanently curative. The patient must understand the chronicity of the condition as well as the patient's important role in controlling the edema and preventing complications.

Limb girth should be assessed at the initial visit and at regular intervals thereafter to provide an accurate determination of the effect of therapy. Various methods allow assessment of limb volume, and all are prone to error in reproducibility. Measuring tapes may be used, and circumferential measurements should be obtained from standard, regional landmarks (antecubital fossa, etc.; Table 42-3). The physician should recognize that measurements taken at various times of the day may yield different results; the girth of an extremity may increase throughout the day, because it is in a dependent position and subjected to the effects of gravity. Measurements of water volume displacement are more precise, but do not identify changes in a specific area of the limb (Fig. 42-2). Another useful modality to measure is the degree of limb tissue turgor; the degree of hardness or softness can be measured by a specially designed tonometer (Fig. 42-3).[20] Patients should be serially followed up by physical examination, with any combination of the following: circumferential measurements, volume displacement, tonometry, serial photography, lymphoscintigraphy, and patient survey.

Weight reduction and extremity elevation are important measures that decrease edema. The individual must elevate the affected extremity at night. A sling may be used for the upper extremity, and elevating the foot of the bed on 4- to 6-inch blocks is recommended for edema of the lower extremity.

Custom-fitted elastic compressive garments (sleeves or stockings) are often worn during the day to maintain limb volume. The length of the garment should match the extent of disease. A comfortable fit is essential to ensure compliance.

Intermittent pneumatic compression with multichamber pumps removes excess fluid from the involved limb and may be helpful if used early in the course of disease, before the development of fibrosclerotic tissue changes. These devices apply a sequential pattern of compression to the extremity, permitting a physiologic distal-to-proximal milking action of the lymphedematous limb.[21] Therapy is most effective if continued at regular intervals, and compressive garments should be worn between treatments. Cardiac failure, active infection, and deep venous thrombosis are contraindications to pump therapy.

Elbow (knee)
15 cm above elbow (knee)
Volume
Water tank: volume displacement
Tonometry

Figure 42-2 • Volume measurement of the upper limb.

Noninvasive complex lymphedema therapy, which consists of manual lymph drainage, compressive bandaging, and physical therapy exercises, may be used with promising results.[22] Complex lymphedema therapy facilitates lymph drainage by recruiting collateral vessels so that the lymphedematous area can be drained into normally functioning lymphatic systems. Recent series have demonstrated therapeutic responses in compliant patients.[23,24]

Basic skin care is essential in the prevention of infection and may assist in preventing associated skin changes, including dermatitis,

hyperkeratosis, warty verrucosis, as well as breakdown of the epidermis and leakage of lymph fluid (lymphorrhea). Meticulous foot care for individuals with lower extremity lymphedema with daily use of a low-pH, water-based lotion will help to prevent fungal infections of the web spaces. Topical antifungal therapy is recommended for localized fungal infections, but invasive infection may require systemic antifungal therapy.

Aggressive and prompt treatment of lymphangitis and cellulitis is recommended to prevent the development of sepsis. It is thought that each bout of sepsis causes further sclerosis of existing lymphatics. Systemic antibiotic therapy targeted toward staphylococcal and streptococcal species for 5 to 7 days, combined with bedrest and extremity elevation, is suggested. Approximately 15% to 25% of patients will have recurrent lymphangitis and cellulitis, and these individuals may require long-term prophylactic antibiotic therapy.

Benzopyrones have been advocated in the treatment of lymphedema.[25] Benzo-α-pyrone (coumarin) is thought to have a stimulatory effect on macrophages and other elements of the immune system, enhancing proteolysis in breaking down large complex tissue proteins into peptides, which can be absorbed by the venous system. Although coumarin is used in mild cases of lymphedema outside of North America, its hepatotoxicity and studies showing a lack of efficacy in lymphedema have led North American experts to conclude that the risk-to-benefit ratio does not justify its use.[26] Parasitic infections involving *W. bancrofti*, *B. malayi*, and *B. timori* are initially treated with albendazole and ivermectin or albendazole with diethylcarbamazine. Antihistamine and/or anti-inflammatory agents are used to control the allergic reactions to the dying parasite.

Laser therapy,[27] hyperthermia,[28] and intra-arterial injection of lymphocytes[29] are investigational treatments purported to play a role in the management of lymphedema. Further evidence is needed to better clarify the role of these modalities in the management of lymphedema (Box 42-1).

SURGICAL MANAGEMENT

Numerous surgical procedures have been described for the treatment of lymphedema. None is curative, and quantitative, long-term data on outcome are sparse. Individuals must view surgery as a continuum of management; the physician must emphasize that surgery does not obviate the need for continued medical therapy.

It is estimated that approximately 10% of patients with lymphedema will need surgery.[30] Operative intervention has traditionally been recommended if medical therapy is ineffective in controlling lymphedema or preventing complications. Surgery also is recommended for impaired extremity function secondary to gross extremity size and weight, severe skin changes, and recurrent lymphangitis (more than three episodes per year; Box 42-2).

Box 42-2. LYMPHEDEMA: SURGICAL INDICATIONS

Failure of medical management
Excessive extremity size and weight, with functional impairment
Severe skin changes
Recurrent infection (more than three episodes of cellulitis or lymphangitis per year)

All procedures aim to reduce lymph fluid accumulation, halt the progression of disease, improve limb function, reduce bulk, improve appearance, and facilitate conservative therapy. Physiologic procedures attempt to re-establish lymphatic drainage, whereas excisional procedures debulk the limb, removing both fibrosclerotic and normal, lymph-producing tissue and fat. This distinction is blurred, in that many physiologically designed operations have excisional components; moreover, excisional procedures have an apparent physiologic effect.[31] Combinations of excisional and physiologic procedures also are commonly used to maximize the improvement in lymphedema (Box 42-3).

Physiologic Procedures

Physiologic procedures include lymphangioplasty,[30–37] pedicle flap procedures (omental transposition, enteromesenteric bridge),[38–41] and microsurgical anastomosis (lymph nodal-venous, lymphaticovenous, lympholymphatic shunts).[42–49]

Lymphatic Bridging

One of the earliest procedures for lymphedema was the subcutaneous implantation of silk threads (lymphangioplasty) advocated by Handley in 1908.[32] Many materials (rubber,[33] polythene,[34] polyvinylchloride[35]) have subsequently been used in the attempt to create drainage channels. This technique was abandoned because of the consistently high incidence of infection and extrusion of material.

Pedicle flap procedures juxtapose lymphatic-rich flaps and lymphedematous tissue to induce lymphatic communication and provide drainage. Initially, tube pedicles with a random blood supply were fashioned in multiple stages by Gillies and Fraser[50] and Mowlem.[51] These resulted in considerable scarring and poor function. Clodius and colleagues[52] found that skin flaps with an axial blood supply also contained axial lymphatics and allowed spontaneous lymphatic

connections. He reported using these flaps to improve brachial neuritis and upper extremity lymphedema simultaneously (Fig. 42-4). Omentum and small bowel have also been used as pedicle flaps. These operations require celiotomy; hernia, adhesion formation, and bowel obstruction have been reported with these procedures (see Fig. 42-4).

The omental transposition operation depends on lymphatic connections developing between the omentum and lymphadematous tissue (Fig. 42-5). This was first used by Dick[53] in 1935 in two cases of scrotal lymphedema. The omentum is rich in lymphatics and can easily reach the chest and axilla, but when it has to be lengthened to reach farther into the upper or lower limb, many of the lymphatics may be divided. Goldsmith[39] reported long-term results but provided no objective data on the extent of extremity size reduction. The complication rate was high, and there was no clarification as to how many patients were followed up beyond 3 years (see Fig. 42-5).

Hurst and associates[41] followed up for 2.5 to 7 years eight patients who underwent the enteromesenteric bridge procedure. This operation, physically limited to individuals with proximal lymphatic obstruction at the level of the iliac or lower aortic nodes, also requires a celiotomy. Of patients in this series, 25% failed to improve and underwent a subsequent excisional procedure. Five patients were noted to improve clinically, but the authors provide no objective data.

Drainage into Deep Lymphatics

Thompson[54] proposed that a dermal wick of a lymphedematous tissue could be transposed deep to the muscle fascia, to allow bypass of lymph from superficial to deep lymphatics. The reported results may have been due to the excisional aspect of this procedure that accompanies the dermal wick. Sawhney[55] studied this procedure with radioactive serum albumin but was unable to demonstrate an increased uptake after dermal-wick procedures.

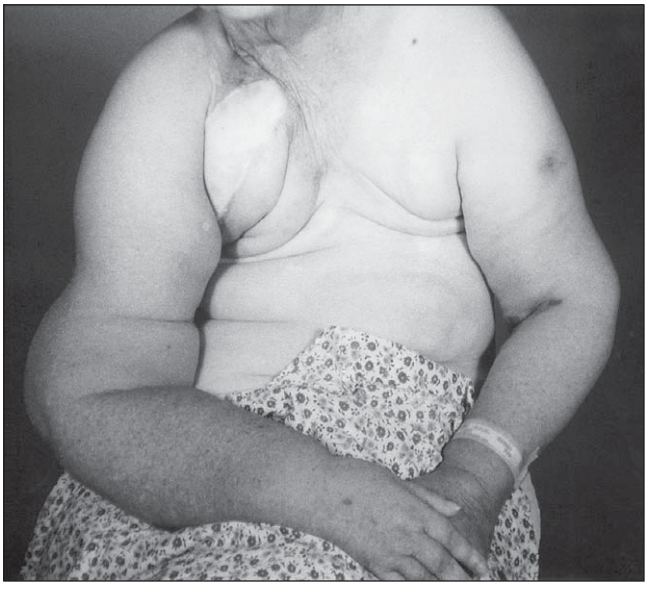

Figure 42-4 • Patient with lymphedema and brachial plexus neuropathy after right radical mastectomy and irradiation for breast cancer. She was treated with excision of dense axillary contracture, brachial plexus neurolysis, and latissimus dorsi myocutaneous flap to provide better coverage with well-vascularized tissue to the brachial plexus and also to help bridge obstructed upper limb lymphatics. Upper extremity volume decreased, and the arm felt subjectively softer and less heavy for this woman.

Microsurgical Procedures

Microsurgical procedures designed to reestablish lymphatic drainage to an affected extremity may be divided into three categories: (1) lymph nodal–venous shunts, (2) lymphaticovenous anastomoses (LVAs), and (3) lympholymphatic anastomoses.

Lymph Nodal–Venous Shunts

Lymph nodal–venous shunts involve anastomosis of a transected lymph node to a neighboring vein. This was first described by Neilubowicz and Olszewski.[56] These procedures have been used for lymphedema involving the male and female genitalia, and these authors have reported good results in 50% of the patients. However, Calnan and coworkers[57] found that these lymph node–venous anastomoses remained patent for only a limited time in individuals with lower extremity lymphedema, and by 3 months they were all obstructed. Unfortunately, obstructive lymphedema usually results after lymphadenectomy, and thus lymph nodes are typically not available for use in this type of anastomosis.

Lymphaticovenous Anastomoses

Because lymph eventually drains into the venous system via the thoracic duct, in cases in which obstruction to flow occurs, it makes intuitive sense that it should be possible to bypass a lymphatic obstruction by allowing the lymph to enter the venous system more peripherally. In obstructive lymphedema lymphatic pressure is higher than venous pressure,[58] which should theoretically keep the LVA patent.

One of the pioneers of microlymphatic research for treatment of obstructive lymphedema was O'Brien, working at St. Vincent's Hospital in Melbourne, with whom the senior author trained and subsequently worked. In the first results, reported in 1976, an 83% patency of LVA was achieved in nonlymphedematous dogs. Considerable work was involved in creating a canine chronic lymphedema model, and once this was achieved, extensive research in LVA, free microvascular nodal transfers, and free microvascular omental transfers followed.[59–61]

Concurrent with this basic research, clinical studies on individuals with obstructive lymphedema ensued. A 15-year study of 134 persons (116 females and 18 males) with established obstructive lymphedema from various causes and treated with LVA was reported in 1990.[45] Most patients (102) had lymphedema of the upper extremity, and 32, of the lower extremity. These individuals were all treated with LVA with or without additional reduction procedures. Of these patients, 90 were available for long-term follow-up (Tables 42-4 and 42-5): 52 patients had LVA only (mean, five anastomoses), and 38 patients had LVA plus segmental reduction (mean, 4.1 anastomoses). The results were graded both subjectively ("limb smaller and softer," "less weight," "more comfortable," "clothes fit better," etc.) and objectively with linear, volume, and tonometry measurements (see Tables 42-4 and 42-5)

Subjectively, 73% and 78% of these individuals reported improvement after LVA alone and LVA plus segmental reduction, respectively. Objectively, 42% had improvement after LVA alone, and 60% had improvement after LVA and reduction. Of the entire group, 58% reported fewer episodes of cellulitis. The results were generally better in the upper extremity compared with the lower extremity, a finding that other authors also reported.[49] Furthermore, of the persons who obtained postoperative improvement, none subsequently became worse. Of the remaining individuals whose condition did not improve, 12% reported no change in lymphedema, and in 46%, the lymphedema became gradually worse, as is the natural history of untreated lymphedema.[45]

The technique used in this series of patients involved performing multiple LVAs at multiple levels (wrist, medial forearm [upper calf], medial arm [leg]). In individuals who would benefit from a segmental reduction, this was done laterally (upper lateral arm,

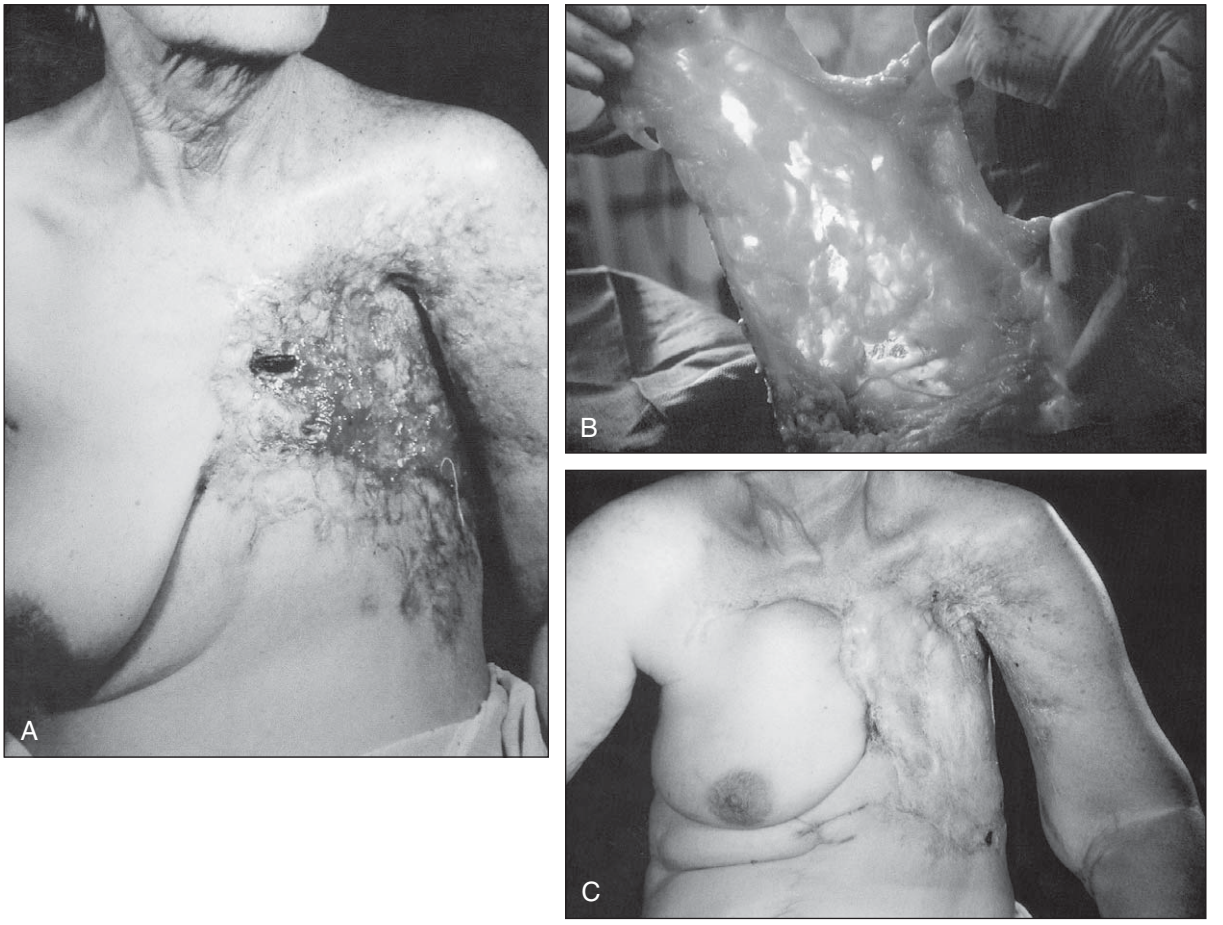

Figure 42-5 • **A,** A 79-year-old woman with radiation necrosis of the left chest wall and axilla after radical mastectomy and irradiation with upper limb lymphedema. **B,** Omental flap was raised and pedicled on right gastroepiploic vessels. The chest wall and axilla were debrided; the omentum was transferred to cover both the chest wall and axilla and to serve as a bridge for lymphatic drainage. **C,** Nine months after radical debridement, omental flap, and skin graft to chest wall and axilla, with some improvement in upper limb lymphedema.

lateral thigh). Patent blue dye was injected subdermally into the web spaces. A tourniquet was used, but the limb was not exsanguinated. With 4× loupe magnification, the subcutaneous tissues were carefully dissected to isolate the lymphatics, which appeared as beaded, blue, thin, fragile vessels measuring 0.3 to 0.5 mm in diameter. Adjacent veins also were located or transposed from adjacent areas to lie near the dissected lymphatics. The lymphatics and veins were tagged with loose silk loops. The anastomosis of the lymphatic to the vein was performed in end-to-end fashion with the operating microscope and 11-0 nylon suture on a 75-mm needle.

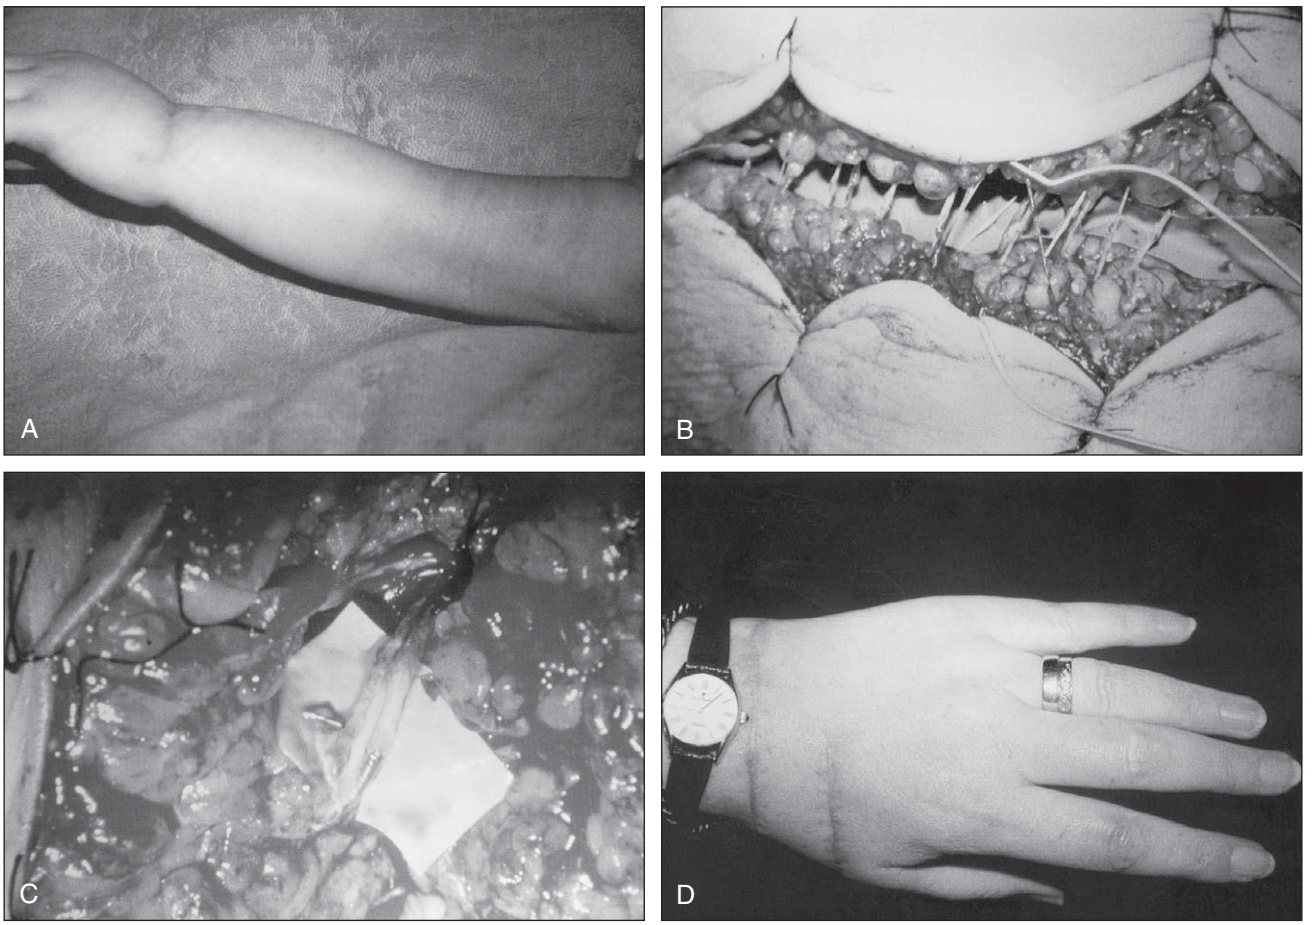

Figure 42-6 • **A,** Patient with lymphedema of upper extremity affecting hand and forearm. **B,** Patent blue dye has been injected into web spaces and lymphatics, and veins dissected out at wrist, proximal forearm, and arm levels. **C,** Magnified view. Typical lymphaticovenous anastomoses completed. This patient had a total of six anastomoses at three levels. **D,** Three months after surgery, with complete resolution of the lymphedema; this woman was able to wear her rings.

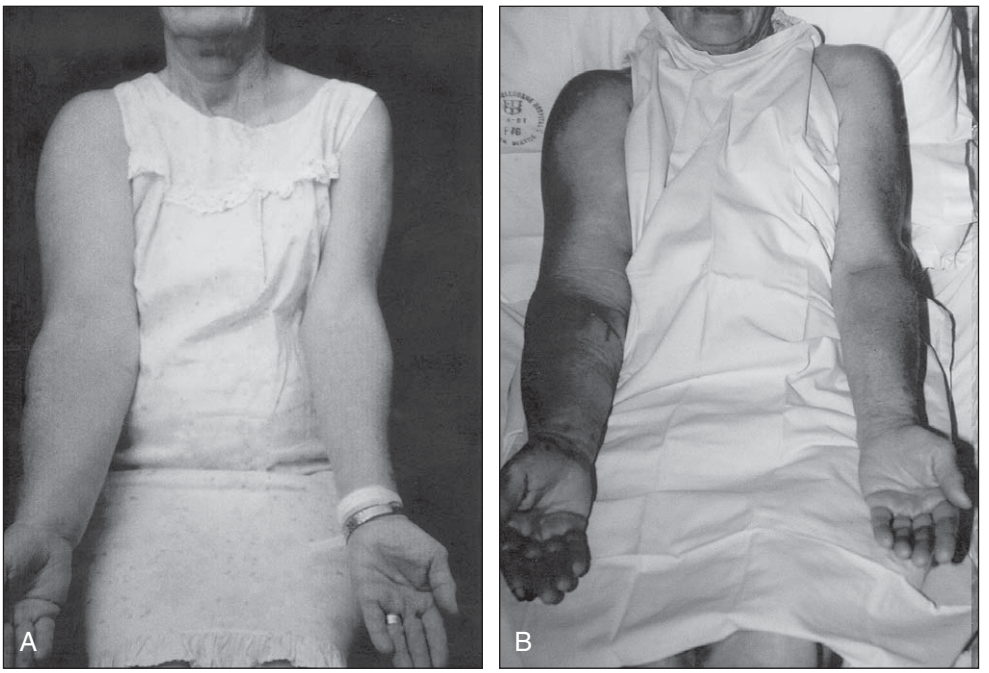

Figure 42-7 • **A,** Woman with lymphedema of right upper limb after mastectomy and irradiation. **B,** Six months after multiple-level lymphaticovenous anastomosis with smaller, softer limb.

Approximately four to six sutures were used per anastomosis. As many anastomoses as possible were performed at multiple levels (Figs. 42-6 and 42-7).

This type of surgery is very demanding, but a significant number of patients obtain subjective improvement, and approximately half obtain measurable objective improvement. Critics of this type of surgery argue that no easy way exists of knowing how many LVAs stay patent in the long term.[47,49]

Similar results have been reported by Huang and colleagues,[58] who reported excellent and good results in 79% of patients, most of whom had obstructive lymphedema of the lower limb resulting from filariasis.[58] Both Huang and O'Brien have found that the results are better when the duration of the edema is shorter, and Huang, but not O'Brien, found that the number of anastomoses performed was significant, whereas O'Brien's group did not find the same correlation.

Lymphaticolymphatic Anastomosis

Lymphaticolymphatic shunts bypass regional areas of lymphatic obstruction. Baumeister and associates[62] first reported this technique in 1981 and later reported his results in 55 patients in 1990. He believes that lymphaticolymphatic anastomoses are better than LVAs, because no increased back pressure is found, as can sometimes occur in higher venous pressure. He described the harvest of two to three lymphatic tracts from the anteromedial aspect of the thigh (adjacent to the saphenous vein).[62] In the lower extremity, these are pedicled from the normal limb to the lymphedematous limb, across the pubic area, and the lymphatics anastomosed to the dilated obstructed lymphatics on the involved side. For the upper extremity the lymphatic grafts are harvested and transferred as free grafts to bridge the obstruction across the axilla with the proximal anastomoses into a lymphatic trunk in the neck. In his series of patients Baumeister was able to show an 80% reduction in limb volume over a 3-year follow-up and also was able to demonstrate graft patency and improved transport index with lymphoscintigraphy. Better results were obtained in the upper limb (Fig. 42-8).[63]

Excisional Procedures

Excisional procedures include total skin and subcutaneous skin excision (erroneously referred to as the Charles procedure),[64–66] staged subcutaneous tissue excision (erroneously referred to as the Kondoleon operation),[67–72] and suction-assisted lipoplasty.[73–75] The buried dermal flap described by Thompson is an excisional procedure proposed to have a physiologic component.[76–79] Excisional procedures are suitable for both primary and secondary lymphedema.

Charles[64–66] described a surgical technique for the treatment of scrotal edema. The Charles procedure, however, has become an eponym for an operation in which the skin and subcutaneous compartment is completely excised and resurfaced with skin grafts.[64–66] Chronic ulceration, skin graft breakdown, and hypertrophic, unstable scarring have been consistently seen when split-thickness grafts are used.[65] Coverage with full-thickness grafts provides a more durable graft site, but graft breakdown and substantial scar formation also may occur.

Staged subcutaneous tissue excision was initially described by Sistrunk,[68] and modifications of the procedure have been reported by others, notably Homans.[69,70] This excisional approach removes significant amounts of skin and subcutaneous tissue, recognizing that the pathology of lymphedema is essentially limited to the superficial tissue compartment. The operation reduces the amount of subcutaneous tissue that produces lymph, and excisions of redundant skin also result in circumferential compression, which probably works in concert with muscular activity to facilitate the subdermal lymph drainage preserved within the flap. A recent study demonstrated long-lasting results for improvement in lower extremity lymphedema, regardless of cause, in a majority of patients treated.[71] This procedure has not been as effective for upper extremity lymphedema (Figs. 42-9 and 42-10). [64]

Although presented as a physiologically designed procedure, the buried dermal flap procedure described by Thompson[76] incorporates the excision of considerable amounts of tissue. In this procedure the subcutaneous compartment is buried in the deep subfascial area in an attempt to drain lymph. Radioactive iodinated human albumin clearance studies have been reported to support a physiologic improvement.[78] However, identical improvement in postoperative clearance was demonstrated in patients after skin and subcutaneous excision.[79] These findings could indicate that the reduction of the subcutaneous tissue improves overall function.

Suction-Assisted Lipectomy

Many authors have advocated the use of liposuction in both primary and secondary lymphedema to reduce the size of lymphatic extremities, as an alternative to segmental wedge excision, removing excess fluid and fat.[73–75] Most authors agree that individuals who will benefit most from this procedure are those who have lymphedema of short duration and have yet to develop the fibrosclerotic changes associated with long-standing disease. However, Brorson and colleagues[73,80,81] in Sweden have advocated a new concept in the management of upper extremity lymphedema in women after mastectomy. Brorson has made a distinction between the presence of edema fluid and the increased fatty deposition that is seen in individuals with chronic lymphedema. His hypothesis is that liposuction should address only the increased fatty deposit, and conservative methods should be used to treat the increased lymphatic fluid. He has rightly observed that individuals with chronic lymphedema have an increase in subcutaneous fatty deposition, a finding that has been greatly underappreciated by advocates of physiologic-type approaches to the management of lymphedema. Brorson's strategy has been to reduce the edema first, using compression therapy until all the pitting edema has subsided, and then proceed to extensive circumferential liposuction with a specially designed cannula. His experience thus far has been in lymphedematous upper extremities in women after mastectomy, and he has been able to achieve excellent long-term results with minimal complications. However, a mainstay of therapy after the surgery is ongoing controlled compression therapy, day and night, indefinitely. His studies have shown that the excess fat is permanently removed, and that there is no worsening of an already impaired lymph transport system.[73,80,81]

Heat Treatment

The Chinese have been able to demonstrate that the use of local limb hyperthermia also is a useful adjunct for the treatment of lymphedema. In 1984 Zhang[82] reported a regimen of heating the involved limb to 6°C to 7°C above normal for 1 hour per day for 20 days. He used three to four courses that were 7 to 10 days apart. Between treatments, bandaging was used to compress the limb. He reported a reduction in limb volume in two thirds of patients and a sixfold decrease in incidence of cellulitis.

The continuing debate on the most efficacious medical and surgical approach underscores the need for intensified research. Management of individuals with lymphedema suffers because of a lack of randomized, controlled prospective studies. Furthermore, no well-defined standards exist with respect to the definition of edema, documentation of results, and outcomes of therapy.

OUTCOMES

Little information exists on the economic outcome after surgery for lymphedema. This condition may manifest as recurrent infections, discomfort, functional impairment from increased extremity size and weight, musculoskeletal problems, psychosocial distress caused by cosmetic issues, and difficulty in carrying out activities of daily living.[83] However, patients should be informed that regional and Internet-based support groups exist, and individuals with lymphedema who are compliant with management regimens can decrease

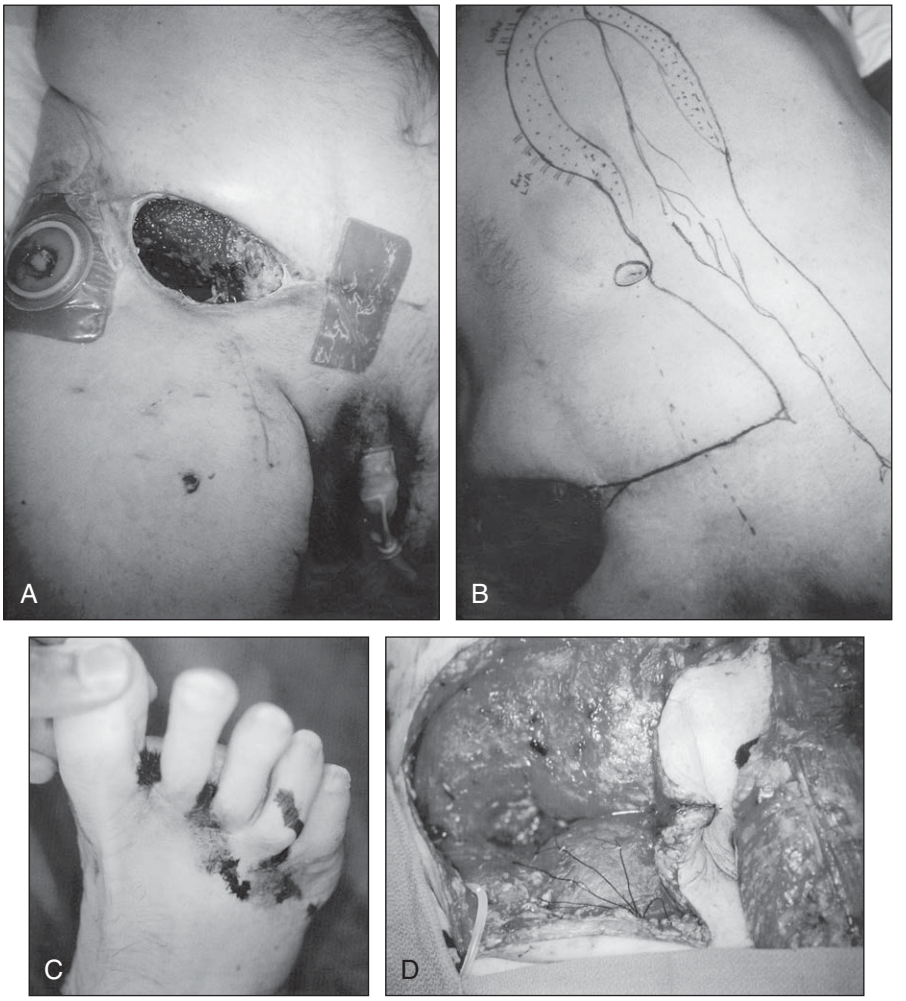
in-hospital stays; many will enjoy a normal or near-normal quality of life.

THE FUTURE

Those in whom lymphedema develops seem to be incapable of lymphatic generation or regeneration. Evidence suggests the presence of growth factors specific for the lymphatic system[84,85] and a capacity for lymphatic regeneration in individuals who do not have lymphedema.[11] Do those in whom lymphedema develops after some inciting event lack the mechanisms needed for lymphatic vessel repair? Or is there a deficit in the response to a growth factor(s), or is there a lack of growth factor(s)? We submit that a genetic etiology explains why, in a fraction of individuals who undergo similar procedures, this condition develops.

SUMMARY

The large number of medical therapies and surgical procedures that have been described in the treatment of lymphedema emphasize the discouraging fact that this condition remains incurable by any means. The severity of symptoms may vary from mild extremity swelling to serious disabling or life-threatening complications such as recurrent infections and rarely, lymphangiosarcoma. Most patients are diagnosed by history and physical examination alone and may be managed conservatively. If this is unsuccessful, and the individual has primary lymphedema, then a reduction procedure is all that is available. Traditionally, this has involved staged resection of skin and subcutaneous tissue. However, liposuction is gaining popularity, especially in relatively early cases in which the quality of skin is good and little fibrosis is found. In individuals with secondary or obstructive lymphedema that is not well controlled with conservative management, a physiologic procedure, often using multiple modalities (e.g., pedicle flaps plus LVAs or LVAs with or without segmental reduction or liposuction) has been the authors' preferred method of treatment (Fig. 42-11). Regardless of treatment modality, patient cooperation is critical for successful outcome. Future efforts should focus on clarifying the genetic etiology of lymphedema, with hope that a better understanding of the basis of disease will lead to more effective treatment strategies.



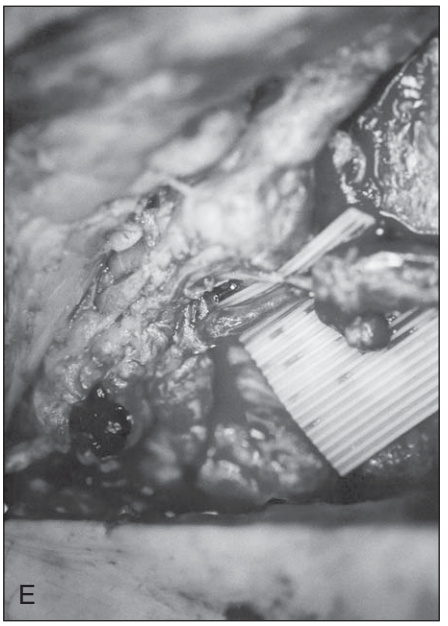


Figure 42-11 • **A,** A 74-year-old patient with chronic wound draining lymphatic fluid in right hip area, after radical excision of chondrosarcoma and irradiation. The right leg is lymphedematous. **B,** Design of contralateral vertical rectus abdominis musculocutaneous (VRAM) flap (based on superficial and deep inferior epigastric vascular pedicle). The lymphatic drainage into left groin is intact. Plan to dissect out multiple small venous channels at upper aspect of flap for lymphaticovenous anastomoses (LVAs). **C,** Methyl blue dye injected intradermally into web spaces for foot. **D,** Multiple dilated lymphatics dissected out in upper right thigh, marked with silk loops.

43 Fatigue

Victoria Mock

SUMMARY OF KEY POINTS

Incidence
- Fatigue may be a presenting symptom of malignancy or a signal of disease recurrence.
- Fatigue is the most prevalent symptom in patients with cancer.
- Fatigue affects more than 70% of patients who receive chemotherapy, radiation therapy, or biologic response modifier therapy.
- A significant level of fatigue occurs in more than 75% of patients with advanced cancer.
- Fatigue significantly reduces functional status.
- Fatigue significantly reduces quality of life.
- Fatigue in patients with cancer is often managed poorly.

Etiology of Complications
- The etiology of fatigue is usually multifactorial.
- Direct factors include the malignancy and cancer treatments.
- Contributing factors include pain, emotional distress, sleep disturbance, anemia, nutritional deficits, deconditioning, and comorbidities.
- Specific pathophysiologic mechanisms are unclear.

Evaluation of the Patient
- Screening should be done at the initial visit, at regular intervals, and as clinically indicated.
- Patients should be evaluated by means of focused history and physical examination, fatigue assessment, selected laboratory tests, and assessment of contributing factors.

Grading of the Complication
- Fatigue intensity should be measured with valid and reliable scales.
- Serial measurements should be recorded in the medical record for comparison.

Treatment
- Any identified contributing factors should be treated.
- Pharmacologic and nonpharmacologic should be added treatments according to the patient's clinical status (e.g., active cancer treatment, disease-free follow-up, or palliative care at end of life).

INTRODUCTION

Definition

Fatigue in patients with cancer, often referred to as cancer-related fatigue (CRF), has been defined by the National Comprehensive Cancer Network as a "distressing persistent, subjective sense of tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning."[1]

Fatigue is a universal human experience that, in healthy individuals, is regarded as a basic protective mechanism against the depletion of body reserves of adenosine triphosphate and resulting exhaustion and possible tissue damage. Compared with the fatigue of healthy individuals, which resolves with adequate rest and sleep, the fatigue of patients with cancer often remains after a period of rest or sleep, is of greater magnitude and persistence, is more disruptive to activities of daily living, and has a more negative affective impact.[2] When patients with cancer were asked to describe their fatigue, responses revealed three major characteristics: physical sensations (59% of responses) such as weakness and decreased physical performance, affective sensations (29% of responses) such as sadness and diminished motivation, and cognitive effects such as difficulty concentrating and decreased problem-solving ability (12% of responses).[2]

CRF has been accepted as a diagnosis in the International Statistical Classification of Diseases, 10th Revision—Clinical Modification with the required criterion of "significant fatigue, diminished energy, or increased need to rest, disproportionate to any recent change in activity level" plus five or more criteria related to the impact of fatigue and present every day or nearly every day during 2 weeks of the previous month.[3] Although these criteria are promising in the diagnosis of CRF, they have been tested in only one study of cancer survivors, in which the prevalence of CRF was determined to be 17%.[3]

Incidence

CRF is the most prevalent unmanaged symptom reported by patients being treated for cancer, and it affects 70% to 100% of patients receiving cytotoxic chemotherapy, radiation therapy, stem cell or marrow transplantation, or treatment with biologic response modifiers.[4–8] Fatigue is a persistent, distressing symptom in 17% to 40% of patients who have completed treatment[3,9–11] and is a significant symptom in more than 75% of patients with metastatic disease.[12–14] The increasing prominence of CRF is related to both the increase in intensive multimodal cancer treatments, characterized by increased dose density and dose intensity, and better management of formerly predominant symptoms of pain, nausea, and vomiting. Patients report fatigue to be the most distressing symptom associated with cancer and its treatment, more distressing even than pain.[7,8]

Management of CRF is important for several reasons beyond its prevalence and the discomfort and distress that it causes. First, high levels of fatigue affect functional status and the ability to tolerate cancer treatment. Research reports indicate that fatigue can have a profound effect on functional status,[15,16] and it is uncertain whether

patients regain full functioning when treatment is over.[9] If fatigued patients cannot tolerate their cancer treatment or must choose between treatment and quality of life, control of their malignancy may be compromised.[6] In addition, high levels of fatigue affect patients' quality of life and interfere with their ability to engage in valued roles and activities.

DESCRIPTION OF FATIGUE

Etiology

Fatigue in patients with cancer is a complex and multifactorial phenomenon that may have a variety of causes and contributing factors. The exact mechanisms that are involved in its pathophysiology are unknown.[17,18]

Fatigue may be caused by the malignancy itself or by cancer treatment and treatment-related anemia.[19,20] Physiologic factors that are known to contribute to CRF are cachexia, deconditioning, and high levels of certain cytokines, such as interleukin-1, interleukin-6, and tumor necrosis factor-α.[21] Psychosocial factors that contribute to fatigue include anxiety, depression, and insomnia. Fatigue is also associated with high levels of other symptoms.[16] In fact, fatigue commonly occurs in the context of multiple symptoms and, in this context, is highly correlated with decreased functional status.[15]

Patterns of Fatigue

Patients with cancer frequently state that fatigue begins with cancer treatment or during the stressful diagnostic process. They report that fatigue continues during the course of active cancer treatment and declines when treatment is over.[18] The fatigue may persist after treatment at a higher-than-baseline level, and a significant percentage of disease-free survivors report disruptive levels of fatigue for years after treatment. For example, in a survey of 1957 survivors of breast cancer, one-third reported severe and persistent fatigue 3 years after diagnosis.[9]

Patterns of fatigue during the course of cancer treatments vary according to the type of treatment. Fatigue typically rises sharply after intravenous cytotoxic chemotherapy to a peak 48 to 72 hours later and drops to near-normal levels 3 weeks later, with a smaller peak occurring on days 10 to 14 with some regimens.[22,23] Studies have not shown substantial increases in fatigue during successive infusions.[24]

During radiation therapy for breast cancer, fatigue levels typically increase linearly over time to a maximum intensity during the fourth week of treatment and then plateau.[25] Levels of fatigue after radiation therapy return to normal in most patients within 3 weeks to 3 months[25] but are more likely to persist at high levels after chemotherapy. In a study of 322 patients with breast cancer in remission, post-treatment fatigue levels were highest in women who received chemotherapy in addition to radiation therapy and lowest in those who received radiation therapy only.[26]

EVALUATION

The National Comprehensive Cancer Network has developed guidelines for the evaluation and treatment of CRF on the basis of available research findings and clinical experience (see www.nccn.org for the most recent guidelines).[1] This multidisciplinary panel of experts in CRF developed an algorithm in which patients are screened regularly for fatigue by means of a brief screening instrument and are treated according to their level of fatigue and clinical status. The algorithm includes phases of screening, primary evaluation, intervention according to three levels of clinical status, and reevaluation (Fig. 43-1).

Progress in the management of CRF has been limited by several factors relating to screening. Patients are reluctant to report fatigue to health care professionals because they fear that their cancer therapy may be modified, doses may be reduced, or treatment may be stopped. Another reason patients give for not reporting CRF is that they believe that it is a symptom to be endured (like sleep problems or emotional distress), which they should be able to manage themselves. Many health care professionals are reluctant to screen for CRF because they are unaware of evidence-based treatments or because they are unaware of the distress and interference with function that accompany fatigue. The result is that fatigue in patients with cancer is underreported, underdiagnosed, and undertreated.[27]

The guidelines recommend that screening for the presence and severity of fatigue occur at the patient's initial contact with an oncology care provider, at appropriate intervals (including the follow-up period after treatment ends), and as clinically indicated. If the patient reports the presence of fatigue during screening, the fatigue should be quantified for future comparison. Although a variety of valid and reliable research instruments are available to measure the multiple dimensions of fatigue,[28] many are lengthy and burdensome for patients with CRF. The guidelines recommend measuring the intensity of fatigue by using a brief clinical instrument such as the 0 to 10 rating scale commonly used to measure pain. On the 0 to 10 scale, 1 to 3 is generally considered to be a mild level of fatigue; 4 to 6 is moderate; and 7 to 10 is severe. Although moderate levels of fatigue may cause distress and a reduction in activity level, severe fatigue levels are accompanied by a marked decrease in the ability to work and perform other activities of daily living.[29,30]

If the patient reports no fatigue or a mild level of fatigue, education should be provided regarding fatigue as a possible or common side effect of treatment, especially if the patient is embarking on a treatment regimen that is known to cause fatigue. A plan to reevaluate the fatigue level as cancer treatment proceeds is appropriate because fatigue levels commonly rise in later stages of treatment. Patients and family members who do not receive this information often interpret decreased energy as a lack of treatment effectiveness or even a progression of disease, and the fatigue becomes a major source of worry.

If the screening process reveals a moderate or severe level of fatigue (4 to 10 on the 0 to 10 scale), the clinician should perform a focused history and physical examination as part of the primary evaluation phase. This evaluation includes an assessment of the patient's current disease status to rule out recurrence or progression and a review of current medications. Many of the medications that are used during cancer treatment, such as antiemetics and narcotics, may interact to produce lethargy and fatigue. Other medications the patient may be taking for comorbidities, such as β-blockers for cardiac conditions, may contribute to worsening of fatigue.[31] The focused history should also include an in-depth fatigue assessment that evaluates the intensity and pattern of fatigue, the duration and changes over time, the exacerbating or alleviating factors, and interference with daily activities.[31]

An essential component of the focused history is an assessment of treatable factors that are known to commonly contribute to fatigue. The factors that have been identified by the National Comprehensive Cancer Network practice guidelines panel are pain, emotional distress, sleep disturbance, anemia, nutritional status, activity level, and comorbidities.[1] The guidelines recommend that these factors be assessed and treated as a first step in managing fatigue. Although these seven factors might not be the primary cause of the patient's fatigue, because they are known to increase the intensity as well as the distress of fatigue, treating these factors—if they are present—as an initial approach often reduces the fatigue to a tolerable level.

Numerous studies have shown that fatigue commonly clusters with pain, emotional distress, or sleep disturbance.[16,32,33] Depression, in particular, has been associated with fatigue.[34,35] Preliminary evidence suggests that the relationship between fatigue and depressive symptoms is mediated by functional status.[36] Anemia commonly occurs in patients with cancer as a result of the neoplastic process or myelosuppressive therapies. Hemoglobin levels below 9 g/dL are

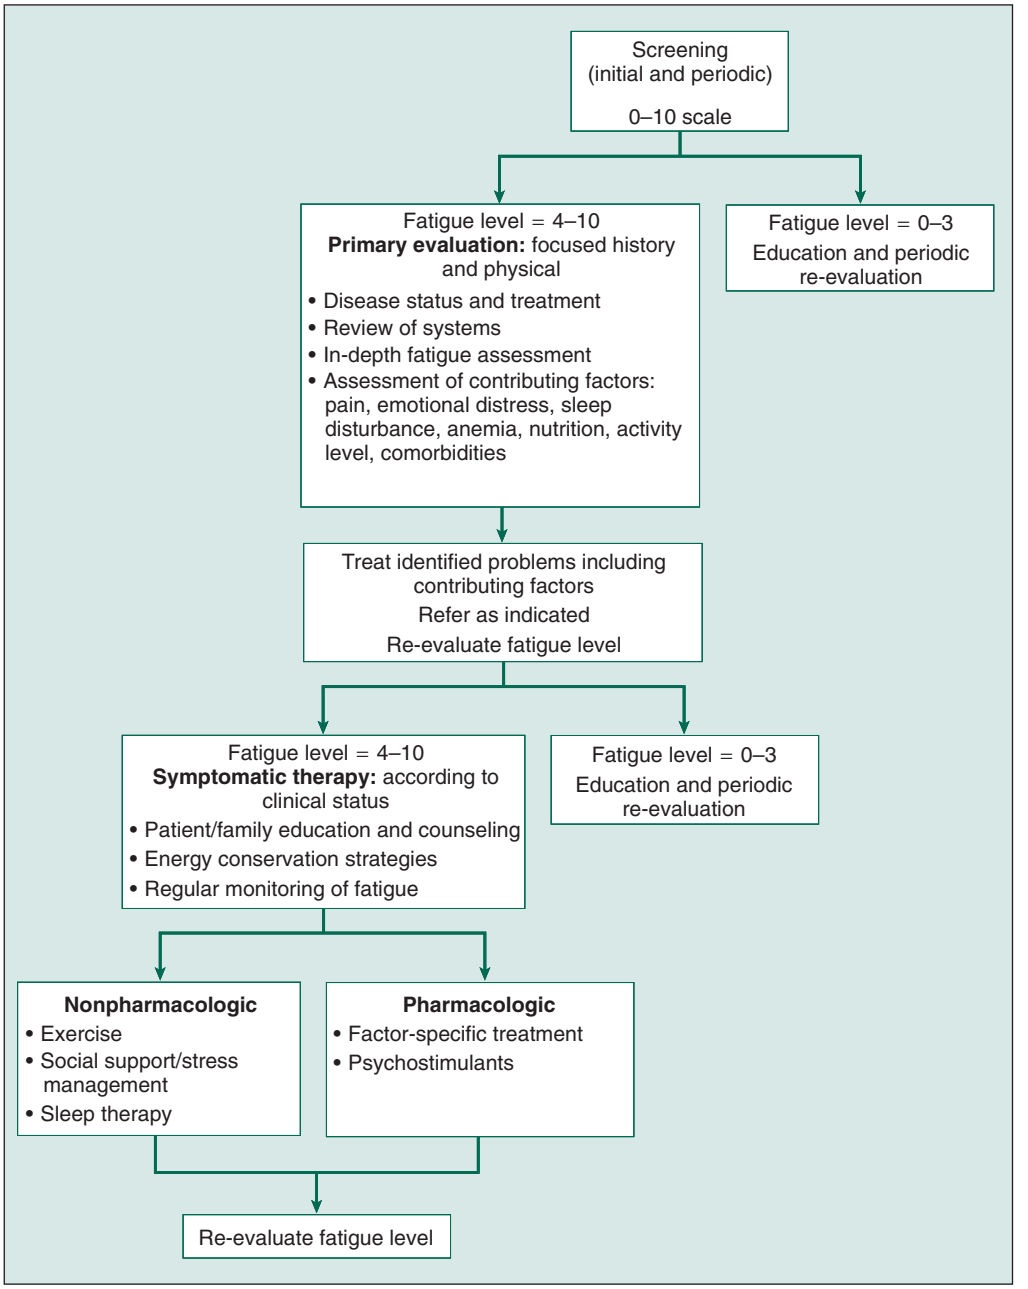

Figure 43-1 • Evaluation and management of cancer-related fatigue. (Adapted with permission from the National Comprehensive Cancer Network, Inc. Mock V, Atkinson A, Barsevick A, et al. NCCN [v.1.2003]. Cancer-related fatigue clinical practice guidelines in oncology. J Natl Comp Cancer Network 2003;1:308–331.)

often accompanied by severe fatigue, and improvements in energy are measurable with anemia correction to hemoglobin levels of 12 to 13 g/dL.[37]

Nutritional deficits related to anorexia, nausea, vomiting, diarrhea, or mucositis can lead to impaired protein synthesis, weight loss, muscle wasting, cachexia, weakness, and fatigue in patients with cancer.[38,39] Appropriate treatment with supplementation and correction of fluid and electrolyte imbalances provides nutrients that are necessary for energy. Consultation with a nutrition expert may be appropriate.

Patients with moderate to severe fatigue should be assessed for changes in their ability to tolerate exercise and other daily activities. A decrease in regular activity frequently accompanies cancer diagnosis and treatment. The resulting deconditioning can be ameliorated by a progressive increase in activity, which could decrease fatigue.

Noncancer comorbidities are important potential contributors to CRF. The status and current management of identified comorbidities should be evaluated, and more effective treatment should be instituted if the comorbidity is not optimally managed. Comorbidities that require evaluation include infections; cardiac, pulmonary, renal, hepatic, neurologic, and endocrine dysfunction; and hypothyroidism.[1]

If any of the seven contributing factors that are known to be associated with CRF are identified, they should be treated, and the fatigue should be reevaluated. If the patient continues to have moderate to severe levels of fatigue, treatment with nonpharmacologic and pharmacologic clinical interventions should be instituted in accordance with the patient's clinical status (e.g., receiving active cancer treatment, receiving disease-free long-term follow-up, or receiving palliative care at end of life). In many instances, a combination of approaches must be used to successfully reduce the fatigue and restore optimum functioning.

CLINICAL INTERVENTIONS

Interventions for the clinical management of CRF include both specific and general approaches. When an etiologic or contributing factor for CRF, such as anemia or insomnia, can be identified, it should be treated by using clinical practice guidelines as an initial approach to fatigue management. Guidelines provide "best care" information based on current evidence to support treatment. However, in many patients with cancer, no cause for fatigue can be readily identified beyond the disease and cancer therapies. In this situation, the approach to management is a general one.

Pharmacologic Therapy

Pharmacologic interventions include administration of erythropoietin alfa for chemotherapy-induced anemia, administration of medications for cause-specific treatments, such as antidepressants for depression, and thyroid hormone replacement for hypothyroidism. Corticosteroids have been shown to increase feelings of well-being and energy levels in some patients with advanced cancer,[40] and psychostimulants have been used on a limited basis to increase energy and decrease fatigue.

Anemia is a common cause of CRF; it occurs in a majority of patients receiving myelosuppressive chemotherapy.[41] Three community-based, nonrandomized, open-label studies[42–44] and two double-blind randomized trials comparing erythropoietin alfa[45,46] with placebo have shown a beneficial effect on CRF, transfusion requirements, and quality of life. Erythropoietin alfa is effective in subcutaneous doses of 10,000 U three times a week or 40,000 U weekly.[44] Crawford and colleagues[37] demonstrated that the incremental increase in the patient's quality of life was highest when the hemoglobin level rose from 11 to 12 g/dL. Research reports confirm the relationship between increases in hemoglobin during erythropoietin alfa treatment and quality-of-life improvements in patients with chemotherapy-related anemia.[37,47,48] These studies provide good clinical evidence for reduction of CRF by returning the hemoglobin level in the patient with cancer and anemia to a more normal value. Published guidelines support treatment with erythropoietin alfa.[19,49] It is important to note that although most patients with anemia report significant fatigue and there is good evidence of fatigue reduction with anemia correction,[50] the causes of CRF are multifactorial, and many cancer patients with cancer and fatigue are not anemic.

Aside from the treatment with erythropoietin alfa, there have been few controlled studies that have investigated pharmacologic therapy for CRF, although a few clinical reports have been published. Psychostimulants have been found to relieve fatigue in other chronic conditions such as human immunodeficiency virus infection,[51] but the data are limited regarding efficacy in CRF.

Methylphenidate has been found to be effective in reducing opiate-induced somnolence, acute depression, and cognitive dysfunction in the palliative care setting,[52] but a randomized trial in cancer patients found no difference between methylphenidate and placebo in reducing fatigue levels.[53]

Pemoline, a central nervous system stimulant similar to methylphenidate, has shown some effectiveness in relief of fatigue in patients with multiple sclerosis (46% response) but has not been tested in patients with cancer.[54] In addition, serious liver problems have been reported in some patients receiving this drug. Modafinil has been used to treat narcolepsy, and some reports suggest that it might be helpful in managing CRF,[55] but no clinical trials have been reported.

In summary, the evidence is strong for pharmacologic treatment for CRF in the case of erythropoietin alfa for correction of anemia, but evidence is insufficient to support the use of psychostimulants. More research is needed before recommendations can be made regarding the use of psychostimulants to manage CRF.

Nonpharmacologic Therapy

Nonpharmacologic interventions for CRF are notable in that they are effective, safe, and usually inexpensive; however, they have not been widely recognized for their efficacy, nor are they commonly included as standard of care for fatigue management. Nonpharmacologic treatments include alterations in activity and rest—including exercise, sleep therapy, and energy conservation—and psychosocial support programs and coping strategies to reduce stress.

Strong evidence from clinical trials supports the efficacy of exercise to manage fatigue in patients with cancer.[1] The theory that supports exercise as a treatment for CRF suggests that the combined effects of cytotoxic treatments and reductions in physical activity during lengthy, often debilitating treatments lead to a decreased capacity for physical performance. Thus, even ordinary activities are perceived as fatiguing. Regular exercise, even at a moderate level, can maintain and increase functional capacity and result in greater exercise tolerance as evidenced by increased cardiac output, reduced heart rate, and less fatigue as less energy is required to perform equivalent work (Box 43-1). If the patient has severe deconditioning, advanced disease, or significant comorbidities, referral to a rehabilitation program supervised by a physical therapist or specialist in physical medicine or rehabilitation is indicated.

The cumulative evidence from studies of exercise in patients with cancer who are receiving active cancer treatment, as well as in long-term survivors, demonstrates that this health-promoting activity has

Box 43-1. EXERCISE PRESCRIPTION FOR CANCER-RELATED FATIGUE

At the Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, we have evaluated a moderate symptom-limited walking exercise program to manage cancer-related fatigue in patients with solid tumors who are beginning outpatient treatment with adjuvant chemotherapy or radiation therapy. After initial testing with more than 100 patients with breast cancer, we have extended the program to include patients with prostate and colorectal cancer.

On screening during the cancer therapy planning visits, we identify patients who do not have metastatic disease or comorbidities that would contraindicate a regular walking program. In consultation with the patient's oncologist and an exercise physiologist, our oncology nurses teach the walking exercise program to consenting patients. Patients are given an individually tailored exercise prescription to follow throughout their cancer treatment. The initial prescription is to walk briskly for 15 to 20 minutes per day on 5 to 6 days of the week at a moderate intensity (with a target heart rate range of 60% to 80% of maximum heart rate), but the regimen is modified according to the patient's age, physical condition, and planned cancer therapy. Each walking session begins and ends with 3 to 5 minutes at a slow pace as "warm-up" and "cool-down" periods to protect the heart. Patients progress, as tolerated, to a maximum of 30 minutes of walking on 5 to 6 days per week. Very debilitated or sedentary patients might need to begin by walking for 5- to 10-minute sessions twice daily until they can tolerate longer periods. We contact patients every 2 weeks to discuss their progress with the program and the side effects of cancer treatment. The exercise program is adjusted as indicated. Patients are taught how to exercise safely—including how to monitor pulse rate—and when to contact the oncology care team to report signs and symptoms (e.g., dizziness, chest pain). Patients are encouraged to walk with a family member or friend at a convenient location, such as in their neighborhood, at a shopping mall, or at a community exercise facility. The program is well accepted by patients, the cost is low, and walking is beneficial and safe. Our patients have experienced no adverse events that could be attributed to the exercise program.

many positive benefits and few risks for patients with cancer. Furthermore, a few cohort studies report significant improvements in survival related to increased levels of physical activity after cancer diagnosis.[56–58]

Four meta-analyses[59–62] and a number of systematic reviews[63–68] have addressed exercise as an intervention for cancer patients and survivors. The number of studies in the meta-analyses ranged from 14 to 35 depending on whether all types of trials or only randomized controlled trials were included. The reviewed studies examined the effects of various forms of aerobic exercise, resistance exercise, and combinations. They included supervised laboratory programs and home-based programs, both during cancer treatment and initiated after treatment. The majority of interventions consisted of aerobic exercise of moderate intensity (60% to 85%) of estimated maximal oxygen uptake (VO_2 max) 3 to 5 days per week for 20 to 30 minutes each day for less than 3 months' duration. All of the studies showed positive results for physical functioning, psychological well-being, and symptoms—including fatigue, difficulty sleeping, and nausea—as well as for health-related quality of life. Fatigue levels were found to be 40% to 50% lower in exercising subjects. Although no adverse events were reported in any of the studies, high-risk patients with serious comorbidities were excluded from participation. Adherence to exercise programs is a challenge for both healthy and chronically ill populations. In the studies of patients with cancer, adherence ranged from 60% to 80% in the home-based programs to 100% in laboratory studies, a marked contrast to the 50% dropout rate for healthy individuals who begin an exercise program.[69] Apparently, patients with cancer are sensitized to the potential beneficial effects of health-promoting activities.

The published exercise studies of patients with cancer have notable limitations.[70] The majority of the studies were samples of female patients with breast cancer, and ethnic diversity and age ranges were limited. Thus, the study results have limited generalizability to other cancer diagnoses, older individuals or children, and varied ethnic groups. Another limitation of the studies is that the exercise interventions were begun at a specific point in patients' cancer therapy—either the beginning or the end—regardless of their level of fatigue. There is limited information about the effectiveness and feasibility of initiating an exercise program for patients who already have high levels of fatigue and have difficulty performing activities of daily living. Current evidence indicates preventing CRF by initiating regular exercise early in the course of cancer treatment may be more effective than managing high levels of fatigue after it develops.[1]

Rest and Sleep

Oncology care providers commonly recommend additional rest and sleep to patients with cancer who report distressing levels of CRF.[71] Patients who use additional rest and sleep to manage fatigue report that it helps but does not relieve the symptom.[72] Several studies, in which actigraphy was used to measure activity and sleep, indicate that patients with cancer spend increased time resting and sleeping but that their pattern of sleep may be severely disrupted, with awakenings nearly every hour.[22,73] Frequent night awakenings were accompanied by lower levels of daytime activity, more daytime napping, and high levels of fatigue.[74] The potential for deconditioning resulting from reductions in activity during lengthy cancer treatments may be an important contributing factor to CRF. Although sleep disturbances have been identified as a neglected problem in oncology,[75] the relationship between sleep problems and CRF has been inadequately explored. Few studies in which a sleep intervention was tested in cancer patients have been published.[76]

Energy Conservation

Energy conservation is an intervention that utilizes planned management of personal energy resources to prevent their depletion. Strategies include priority setting, use of labor-saving devices, balancing periods of rest and activity, and delegating activities of lesser importance.[77] Energy conservation may be a particularly useful intervention for patients with advanced disease or those with significant weakness or debilitating fatigue. Although research is limited, results of a pilot study testing an energy conservation intervention has been published and indicates beneficial effects.[77]

Stress Reduction

Studies of psychosocial interventions aimed at stress reduction and improved coping have also demonstrated reductions in fatigue. Since both depression and anxiety may be characterized by fatigue, it has been proposed that CRF is a response to the stress of cancer diagnosis and treatment through activation of the hypothalamic-pituitary-adrenal axis.[17] Since it is also evident that high levels of fatigue may lead to emotional distress when valued roles and activities are affected, the precise relationship between emotional distress and fatigue is not clearly understood.

Psychosocial interventions tested include cognitive behavior therapy,[78] psychoeducational counseling,[79,80] a comprehensive coping strategy,[81] and stress management training.[82] The investigations were randomized controlled clinical trials with adequate sample sizes and included a variety of cancer populations. All studies demonstrated significant effects of the intervention on fatigue levels. A limitation of several of the studies was that fatigue was a secondary endpoint that was measured by either a single item or a subscale of an instrument used to measure emotional distress.

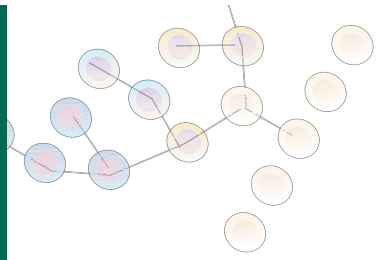
CONCLUSION

Fatigue is the most prevalent symptom reported by patients with cancer and the source of much distress for them. Fatigue may have profound effects on functional status and quality of life. However, clinical evaluation and management of this disturbing side effect of cancer and cancer treatment have been limited as a function of both patient and care provider barriers. Patients have been hesitant to report fatigue, and clinicians have been unaware of effective treatments.

Effective management of CRF begins with informed and supportive oncology care providers who perform initial and regular screening for fatigue and provide treatment as indicated by the patient's fatigue level. When the patient's fatigue levels are mild, education about fatigue is indicated. When fatigue levels are moderate or severe, the initial screening is expanded to include a focused evaluation of current disease and treatment status, review of body systems, and an in-depth fatigue assessment. The patient should be assessed for the presence of treatable contributing factors such as pain, emotional distress, sleep disturbance, anemia, nutritional deficits, decreased activity level, and unmanaged comorbidities. If any of these conditions are present, they should be treated as an initial step, and the fatigue should be reevaluated. If none of these factors are present or if fatigue levels remain moderate or severe, fatigue management strategies should be considered as appropriate for the patient's clinical status.

Evidence-based interventions for managing CRF include correction of anemia, moderate exercise regimens, and psychosocial support programs. A combination approach might be needed, and referral to other members of the multidisciplinary team should be considered. Although CRF is common and expected, it can be managed and does not need to be distressful and disruptive to quality of life.

Several important gaps exist in our knowledge of fatigue and fatigue management. These are reflected in the recommendations for future research presented in Box 43-2. However, evidence-based practice guidelines are available to guide clinical care of patients with CRF, and health care professionals are increasingly aware of the importance of addressing this distressing symptom.



Box 43-2. RECOMMENDATIONS FOR FUTURE CANCER-RELATED FATIGUE RESEARCH

1. Additional intervention testing research, especially with pharmacotherapeutics, psychosocial interventions, sleep quality therapies, and conservation of energy approaches
2. Use of more rigorous research designs with larger sample sizes, control groups including healthy control subjects and attentional control subjects as appropriate, and greater standardization of interventions to facilitate replication and increase internal validity
3. Targeting of more diverse populations of patients with cancer and selection of diverse samples, especially with regard to ethnicity, socioeconomic status, age, and type of cancer diagnosis
4. Exploration of fatigue interventions in recurrent disease and palliative care
5. Use of more objective instruments and outcomes to increase validity and reliability (e.g., actigraphy to measure activity and sleep, biochemical markers for fatigue)
6. Theory-based research with a focus on elucidating the mediating mechanisms for every intervention to facilitate our understanding of cancer-related fatigue
7. Investigation of secondary outcomes of fatigue interventions such as quality of life, return to work, use of health care resources, sleep quality, mood state, and survival

44 Caring for Patients at the End of Life

Janet L. Abrahm

SUMMARY OF KEY POINTS

- Physicians must be clear about prognosis, not overly optimistic.
- Patient decisions about resuscitation and entry into phase I trials should be predicated on receiving accurate prognostic estimates.
- A sense of purpose can be maintained by patients who work on completing legacies, reconciliation, saying goodbye, and making plans for support or care of bereaved survivors.

Distress

- Physical comfort is a prerequisite for exploring other sources of distress; consultation with anesthesia pain or palliative care specialists can be useful.
- Depression can be ameliorated even in the last weeks of life; delirium can be mistaken for pain and may be exacerbated if treated with increases in opioid medication alone.
- Problematic relationships can create open wounds as painful as any physical injury.
- Families with young children are in special need of counseling and support.
- Ongoing losses (in physical attractiveness or physical or mental function or of roles in family, community, or workplace) contribute to spiritual and existential distress. Life reviews and reconnection with sources of spiritual support, including religious rituals, can help.

Hospice Care

- Hospice is the gold standard of care at the end of life. Hospice teams are multidisciplinary (M.D., R.N., social worker, chaplain, volunteers), but the referring physician remains in charge of the plan of care. Hospice programs provide care in the home, including all medications and durable medical equipment related to the terminal diagnosis. Patients need not have signed a "Do Not Resuscitate" order to enroll.
- Barriers to hospice referral include physician and patient reluctance to accept a terminal prognosis (i.e., less than 6 months); current inadequate reimbursement for palliative therapies; and physician, family, and patient misconceptions about entry criteria and services provided.

Grief and Bereavement

- The intensity of a survivor's grief depends on the characteristics of the mourner, the nature of the death, and societal and cultural factors.
- Skillfully communicating the diagnosis and terminal prognosis; providing emotional, psychological, and spiritual support and physical comfort; helping families to resolve outstanding issues; and making the death as peaceful as possible are all measures that diminish the suffering of the survivors.
- Survivors appreciate ongoing communication with the patient's physician. The formal bereavement program that hospice programs offer takes place during the first year after the patient's death. The program includes descriptions of typical manifestations of grieving and offers of counseling, support groups, and services of remembrance.

INTRODUCTION

When cure or even prolongation of life is no longer possible, oncologists have one last task remaining: to provide expert care to patients at the end of life and support for their families.[1] Despite physical comfort, patients can experience profound suffering from any of the following causes:

- Difficulty in maintaining personal dignity
- Losses of significant aspects of who they were at home, in the community, or in the workplace
- Lack of closure in important relationships
- Feelings of spiritual alienation
- Inability to discern the meaning in their lives[2]

When those problems are addressed, patients have the chance to attain transcendence, a sense that who and what they have been will persist long after they have died.[3,4] Through collaborations with psychiatry, nursing, social work, and chaplaincy, oncology clinicians can promote physical comfort, social functioning, and psychological and spiritual well-being.[5,6] We need never say, "There is nothing more I can do."

Patients rely on us to help them achieve a comfortable death that follows a time when goodbyes have been said, legacies have been established, and relationships have been brought to an acceptable closure. Their families need us to minimize the patient's suffering, obtain expert palliative care consultation when needed, and communicate clearly and often with them. Currently, however, such care is the exception rather than the rule.[7,8] This chapter provides an outline for oncology clinicians who wish to provide excellent care at the end of life and includes discussions of communication with patients and their families, approaches to ameliorating distress at the end of life, hospice care issues, manifestations of grief and bereavement, and suggestions for supporting bereaved survivors.

COMMUNICATION NEEDS OF PATIENTS AND FAMILIES

Timely, truthful, compassionate communication among patients who are dying, their families, and their physicians is needed to dispel fears (e.g., of unrelieved pain or of abandonment), to promote feelings of autonomy and control, to set goals of care, and to enable patients and families to be prepared for what is to come. The vast majority of patients (80% to 98%) want to be able to do the following:

- Name a proxy to make health care decisions
- Know what to expect as their physical condition deteriorates
- Put their financial affairs in order
- Know that the doctor is comfortable talking about death and dying
- Feel that the family and they themselves are prepared for their death
- Have funeral arrangements in place
- Have treatment preferences, especially about resuscitation, in writing[9]

Families want to be able to say goodbye and be present when the death occurs, talk about their fears, and talk about the death with the clinicians.[10] Bereaved survivors are more likely to have a major depressive disorder if they feel that they have not been prepared for the death.[11] For patients and survivors to be prepared, physicians must be clear about prognosis.

The cultural norms of medicine, however, favor optimism over accuracy in delivering prognosis.[12] Physicians might assume that patients will ask when they are ready for the information. There are no data, however, on how often patients with advanced refractory disease ask about their prognosis. Moreover, patients are known to be reticent about raising other important topics—such as uncontrolled pain or their wishes regarding resuscitation—with their physicians.[13,14] Physicians might also worry that giving a truthful prognosis will eliminate hope.

Through a truthful prognosis, however, patients with far-advanced disease can be helped to reframe what it is they are hoping for in the time that remains. Most patients hope for time to say goodbye and to bring closure to their lives. Even patients with far-advanced disease want to work on their legacies. Some dictate letters to be opened at significant events (e.g., graduations, weddings); others might want to narrate a scrapbook. Most want time at least for a personal, private review of who they were, what they did, and the difference they made.

Further, patients need to decide whether it still makes sense for them to be resuscitated. The likelihood of bad functional or cognitive outcomes affects their decisions, as does their understanding of their prognosis.[15] It is important, therefore, to tell a patient who has widely metastatic cancer that resuscitation has very limited efficacy.[16–19] We also need to tell their caregivers, because they, too, are usually unaware that the patient is incurable or that the patient would benefit from hospice care until they hear it directly from their physician.[20] It is equally important to correct mistaken impressions of patients who really have only weeks or months to live. Patients who think that they have a greater than 10% chance of surviving 6 months, for example, usually want to be resuscitated. Only patients who think that they have a less than 10% chance of surviving for 6 months overwhelmingly choose comfort care and do not want to be resuscitated.[21]

Conversations about life-support preferences and those in which news of relapse or progression must be delivered take a significant emotional toll on the clinicians who conduct them, especially those in busy practices in which many such talks are needed each week. Using straightforward communication strategies such as the S-P-I-K-E-S protocol can enhance the effectiveness of the communication both for the clinician and the patient and family who are receiving the bad news.[22]

Table 44-1 Dignity Psychotherapy Question Protocol

Can you tell me a little about your life history, particularly those parts that you either remember most or think are the most important?
When did you feel most alive?
Are there specific things that you would want your family to know about you, and are there particular things you would want them to remember?
What are the most important roles (e.g., family, vocational, community service) you have played in life?
Why are they so important to you, and what do you think you accomplished in those roles?
What are your most important accomplishments, and what do you feel most proud of?
Are there particular things that you feel still need to be said to your loved ones, or things that you would want to take the time to say once again?
What are your hopes and dreams for your loved ones?
What have you learned about life that you would want to pass along to others?
What advice or words of guidance would you wish to pass along to your _____ (son, daughter, husband, wife, parents, other[s])?
Are there words, or perhaps even instructions, you would like to offer your family to provide them with comfort or solace?
In creating this permanent record, are there other things that you would like included?

Chochinov HM: Dignity-conserving care—A new model for palliative care: Helping the patient feel valued. JAMA 2002;287:2253.

Communication with dying patients must also be culturally effective and extend to include psychosocial and spiritual needs, addressing loss, dignity, and the need for meaning.[4,5,23,24] Clinicians who are not experienced in such conversations might find it helpful to use the questions crafted by experts in this field (Table 44-1).[5,23–25]

DISTRESS

Dying patients might experience problems of a physical, psychological, social, or spiritual nature. These patients define quality of life at the end of life as including physical comfort, a sense of control and dignity, relieving burden on their loved ones, strengthening and completing relationships with significant others, and avoiding prolongation of the dying process.[26] To provide high-quality care, therefore, oncologists need to collaborate with an interdisciplinary team such as that provided by palliative care and hospice programs. In 2006, the specialty of Hospice and Palliative Medicine was recognized by the American Board of Medical Specialties, and ACGME-approved training started in 2007. Physicians and nurses trained as palliative care practitioners address all dimensions of distress, including communication, decision making, management of complications of treatment and the disease, symptom control, psychosocial care of patients and their families, and care of the dying.[27]

Physical Causes

In the last days to weeks before death, a significant percentage of people exhibit or experience one or more of the following:

- Fatigue or pain (70%)
- Restlessness/agitation/delirium or noisy or moist breathing (60%)
- Urinary incontinence or retention (50%)

Table 44-2 Treatment of Common Physical Problems in the Last Days of Life

Problem	Agent(s)	Routes, Doses
Pain (continuous)	Morphine, hydromorphone	IV/SC infusion
	Fentanyl	Transdermal
	Morphine, oxycodone	SL oral concentrates
Pain (intermittent)	Morphine, oxycodone	SL oral concentrates
	Fentanyl	Buccal lozenge
"Death rattle"	Scopolamine	Transderm Scop patch 1–3 every 3 days
	Hyoscyamine	0.125–0.25 mg SL 3–4 times daily
	Glycopyrrolate	0.1–0.2 mg IV 3–4 times daily
Anxiety	Lorazepam	0.5–2 mg SL; every 2 hours
	Clonazepam	0.5–2 mg twice daily PO
Depression	Methylphenidate	2.5–5 mg PO every morning or every morning and noon
Delirium (mild)	Haloperidol	1–5 mg PO, PR or 0.5–3 mg SC, IV, every 2–12 hours
	Chlorpromazine	12.5–50 mg PO, IV, PR every 4–8 hours
	Olanzapine	2.5–5 mg PO or SL every hour or bid
Agitated delirium/or palliative sedation for refractory symptoms	Midazolam	0.4 mg–1 mg load; 0.4–1 mg/hr IV initial dose
		Rebolus and titrate as needed to target symptom/sign relief
	Pentobarbital	1–3 mg/kg IV load; 1–3 mg/kg/hr IV drip
		120–200 mg PR every 4 hours
	Lorazepam	0.5–1 mg/hr IV
	Propofol	2.5–5 μg/kg/min IV
Dyspnea (anxiety)	Lorazepam	1 mg SL, PO every 2 hours
Dyspnea (other)	Morphine	5–10 mg PO/PR every 2 hours; 1–3 mg IV every hour
	Chlorpromazine	25–50 mg PO, IV, PR every 4–12 hours
Nausea	Lorazepam/metoclopramide or haloperidol	Compounded suppositories with desired agents (depending on presumed cause of nausea) every 6 hours PR

IV, intravenous; PO, oral; PR, per rectum; SC, subcutaneous; SL, sublingual.

Data from Abrahm JL: A Physician's Guide to Pain and Symptom Management in Cancer Patients, 2nd ed. Baltimore, Johns Hopkins University Press, 2005 p. 408; and Cowan JD, Palmer TW: Practical guide to palliative sedation. Curr Oncol Rep 2002;4:242–249.

- Dyspnea (20%)
- Nausea and vomiting (10%)[28]

Most of the physical problems that dying patients experience can be controlled by using a limited number of medications given by the rectal, transdermal, or, if necessary, parenteral route (Table 44-2).

Pain Control

If oncologists use World Health Organization guidelines for cancer pain relief, 50% of their patients near death will experience no pain, 25% will experience mild to moderate pain, and only 3% will experience severe pain.[29] Patients require close monitoring, and both opioids and nonopioid adjuvants are usually required. For patients who are unable to take pills, buccal, sublingual, transmucosal, or rectal opioids are usually effective.[30–32] There are no data on the absorption of transdermal opioids newly placed in patients near the end of life. Concentrated morphine or oxycodone oral solutions (20 to 40 mg/mL) can be given hourly or every 2 hours and are often satisfactory. Rectal administration of sustained-release opioid preparations are not FDA approved, but studies indicate that morphine absorption from a sustained-release preparation placed in the rectal vault is equivalent to that from oral administration,[33] while absorption from a sustained-release oxycodone preparation is increased by ~30%.[34] If pain is a new problem and the patient is opioid-naive, institute therapy with 15 to 30 mg sustained-release morphine every 12 hours.

Adjuvants can also be given rectally or subcutaneously.[31] Patients who have previously benefited from oral nonsteroidal anti-inflammatory drugs (NSAIDs) can receive rectal indomethacin; patients on a stable glucocorticoid dose for bone or nerve pain can receive subcutaneous dexamethasone or specially prepared dexamethasone suppositories. Rectal doxepin can replace oral tricyclic antidepressants.

Pain control must be maintained as death approaches. If the calculated opioid dose is too large to be delivered by sublingual, transdermal, or rectal routes, if pain relief does not seem to be satisfactory using any of these routes, or if the routes are unacceptable to the patient or the caregiver, use a subcutaneous or intravenous opioid infusion.

Although pain relief is the goal in dying patients, the family is sometimes concerned that the opioid is "killing" the patient. If the patient's respiratory rate declines, the family might mistakenly think that the patient is oversedated. Unlike patients who are in less advanced stages of their illness, the normal respiratory rate in terminal patients is about six to twelve breaths a minute. If the rate falls to fewer than six breaths per minute, reducing the dose of the opioid by 25% is usually effective; naloxone is almost never indicated in such situations.

Death Rattle

Pooling of secretions in the hypopharynx of dying patients causes the loud rasping sounds referred to as the "death rattle." Patients are usually unaware of these loud respirations, but they can be very distressing for families. Reposition the patient to a lateral recumbent position and, if needed, add hycosamine (0.125 mg three or four times daily sublingual [Levsin SL]), glycopyrrolate (subcutaneously 0.2 mg every 4 to 8 hours or 0.6 to 1.2 mg per day by subcutaneous or intravenous infusion), or scopolamine in a transdermal patch.[35]

Dyspnea

The prevalence of cancer-related dyspnea in dying patients is approximately 70%.[36] These patients benefit from the same symptomatic therapies that are recommended for patients with less advanced disease. Any opioid that is being used for pain control can also be used to ameliorate the patient's dyspnea. Aggressive treatment of panic due to perceived breathlessness includes an oral or parenteral opioid (e.g., morphine 5 to 10 mg orally), rectal or parenteral chlorpromazine, or parenteral midazolam for refractory panic.

Xerostomia

Although patients are unlikely to be thirsty or hungry, they might have dry mouths caused by opioids.[37] Rehydration is not indicated to relieve this symptom because there is no difference in the reports of thirst or dry mouth between dehydrated and normally hydrated dying patients, and no controlled studies have shown that rehydration is effective.[38] Providing parenteral hydration increases distress, causing nausea and vomiting from increased gastric secretions; dyspnea from ascites, upper airway secretions, and pulmonary edema; and pain from ascites and peripheral edema.[37] Moistening the mouth with swabs or offering sips of water, ice chips, or fruit-flavored ice usually ameliorates the xerostomia.

Exsanguination

Massive hemoptysis, hematemesis, hematochezia, or exsanguination from a tumor eroding into a major vessel is rare but can be horrifying for professional caregivers, family members, or friends to observe. If the patient is likely to develop such a complication, ensure that there are dark-colored sheets, towels, and blankets available to mask the blood. Consider insertion of a peripherally inserted central catheter line in patients who have no indwelling venous access device to ensure emergency intravenous access for patient sedation. Appropriate medications should be on hand, either on the hospital unit or in the home. If the patient is enrolled in a hospice program, the nurse can provide instruction for administering prefilled syringes of morphine, to be given intravenously when possible, or a benzodiazepine. Midazolam (Versed) can be given intramuscularly or intravenously; diazepam or lorazepam (e.g., Ativan) can be given rectally. When the event occurs, the patient is placed bleeding side down, in the Trendelenburg position if possible, and given midazolam for anxiety and opioids if there is dyspnea or pain.

Psychological Causes

According to Dr. Susan Block, "grief, sadness, despair, fear, anxiety, loss and loneliness are present, at times, for nearly all patients facing the end of their lives."[39] They need "good communication and trust among patient, family, and clinical team, the ability to share fears and concerns, as well as meticulous attention to physical comfort and psychological and spiritual concerns."[39] The elements of a thorough discussion of the patient assessment (which includes "developmental issues; meaning and impact of illness; coping style; impact on sense of self; relationships; stressors; spiritual resources; economic circumstances; physician-patient relationship" can be found in Dr. Block's review.[39]

Anxiety

Anxiety in dying patients can arise from physical or psychological disorders.[40] Sepsis, hypoxia, metabolic abnormalities, withdrawal from opioids, selective serotonin reuptake inhibitors (SSRIs), or benzodiazepines, drug reactions (e.g., akathisia from metoclopramide or paradoxical agitation from benzodiazepines), and uncontrolled pain all can present as anxiety. Patients with panic disorders, agitated depression, phobias, or adjustment disorders also can present with anxiety.

Nonspecific pharmacologic treatments usually include benzodiazepines (e.g., the short-acting lorazepam, 0.5 to 2 mg every 2 hours as needed, or long-acting clonazepam, 0.5 to 2 mg orally twice daily), SSRIs, and, when there is evidence of delirium, neuroleptics (e.g., haloperidol, 1 to 5 mg orally or 0.5 to 3 mg intravenously every 2 to 12 hours, or olanzapine, 2.5 to 5.0 mg at bedtime or twice daily). Opioids with or without benzodiazepines are useful for patients whose anxiety is due to dyspnea.[41] Nonpharmacologic treatments, such as relaxation training, hypnosis, supportive psychotherapy, and counseling, are also very effective.[40]

Depression

Terminally ill patients who answer, "Yes," to the screening question "Are you depressed?" are likely to be diagnosed as depressed in a more comprehensive evaluation.[42] To explore the subject further, clinicians can try to determine whether the patient exhibits hopelessness, a sensation of helplessness, or guilt or reports being a burden to caregivers. Clinicians can ask, "How do you see your future? What do you imagine is ahead for yourself with this illness? What aspects of your life do you feel most proud of? Most troubled by?"[43] The clinician can serve as a therapeutic agent by listening actively and by providing support for both the patient and the family. For depressed patients who have only a few weeks to live but can still take oral medications, methylphenidate (2.5 to 5 mg orally at 8:00 A.M. and noon, initial dosing) can provide rapid symptomatic improvement.[44] For those with 4 weeks or more to live, an SSRI should also be included.

Delirium

Delirium (hypoactive, hyperactive, or mixed) has been reported in up to 88% of dying patients.[45] Hypoactive delirium can be confused with depression, and agitated delirium can be confused with uncontrolled pain, especially in dying patients.[46,47] Patients with hypoactive delirium might appear withdrawn, paranoid (e.g., fearing that the caregiver is trying to poison them with medications), or sad, and careful mental status testing with tools such as the Folstein Minimental or "draw a clock with the hands indicating a time of 10 minutes to 2" might demonstrate significant cognitive impairment. Patients with agitated delirium may cry out, be restless, and pick at clothes or bedsheets. Patients with any type of delirium can experience insomnia and daytime somnolence, nightmares, agitation, irritability, distractibility, hypersensitivity to light and sound, anxiety, difficulty in concentrating or marshaling thoughts, fleeting illusions, hallucinations and delusions, emotional lability, attention deficits, and memory disturbances.[48] It is therefore important to treat the delirium even among patients without overt agitation.

The etiology of delirium among patients with advanced cancer is often multifactorial.[45] Medical causes include metabolic abnormalities (hypercalcemia, hyperglycemia, and uremia), malnutrition, dehydration, hypoxia, fever, infection, bladder outlet obstruction, obstipation, uncontrolled pain, hepatic failure, primary brain tumor, and brain metastases. Medications—especially opioids, benzodiazepines, NSAIDs, and high-dose corticosteroids—often contribute to delirium. Substitution of another opioid might help to reverse the delirium.[49] A comprehensive psychiatric evaluation (which can be done at home by appropriately trained clinicians) can differentiate delirium from anxiety, minor depression, anger, dementia, and

psychosis.[48] Among patients who are very near the end of life, the burden of the evaluation might exceed the benefit of finding a specific, reversible cause. Empiric therapy that controls the delirium might suffice. Discussion with the patient's health care proxy can help to clarify the best course of action. Treatment protocols for delirium are included in Table 44-2.

AGITATION IN THE DYING PATIENT

Almost half of the patients who are actively dying of cancer show signs of restlessness and agitation. They might toss and turn, moan, have muscle twitching or spasm, and be awake only intermittently. Some are suffering from unresolved spiritual or social problems. The approach to assessment and treatment of agitated dying patients involves, sequentially, nonpharmacologic symptomatic therapy, an evaluation for reversible causes and treating those that are found, and empiric symptom management (Fig. 44-1). Whenever a treatment resolves the agitation, it should be continued, and the patient should be reassessed. In rare cases, patients with agitation require sedation. The aggressiveness of the evaluation and the nature of the treatments that are given should be guided by the patient's goals and the burdens and benefits of each intervention. The site of care (hospital, nursing home, home) need not be the deciding factor in the decision about which palliative assessment and therapies to offer.

Many patients' agitation responds to nonspecific, nonpharmacologic measures, such as adjusting the lighting, decreasing extraneous noise in the room, playing favorite music, gently touching the patient, or having family and friends read to, pray with, or quietly talk with the patient. A visit from one of the hospital chaplains can be comforting. A visit from an estranged family member or friend, reassurance that loved ones are well cared for and are prepared for the patient's departure, and family permission to "let go" can have significant impact.

If these measures are not effective, the family and caregivers should weigh the burdens and benefits of searching for reversible causes. Those such as a full bladder, a fecal impaction, poorly cleared secretions, pain, or side effects from opioids or other medications are usually easy to detect and correct. Metabolic disturbances leading to delirium and pulmonary processes causing hypoxia or anxiety could require invasive maneuvers that do not seem appropriate. When a specific cause is found, decisions can be made regarding the burden and benefits of specific versus symptomatic treatment. The patient's condition and goals, for example, dictate whether a patient who has dyspnea from a large pleural effusion should undergo a thoracentesis or simply receive opioids. If correction of one specific cause does not resolve the agitation, resume the search, as appropriate, for another one.

If no specific cause is detected or if the search for specific causes is felt to be inappropriate, empiric therapies based on the likeliest process(es) causing the distress should be tried. Empiric treatment for delirium, pain, hypoxia, and anxiety often relieves the agitation. If the agitation persists, sedation will be required (see Table 44-2).

Social Causes

Family concerns can weigh heavily on dying patients. Practical concerns are often the easiest to resolve, although a major concern of dying patients is the burden they feel they are imposing on their loved

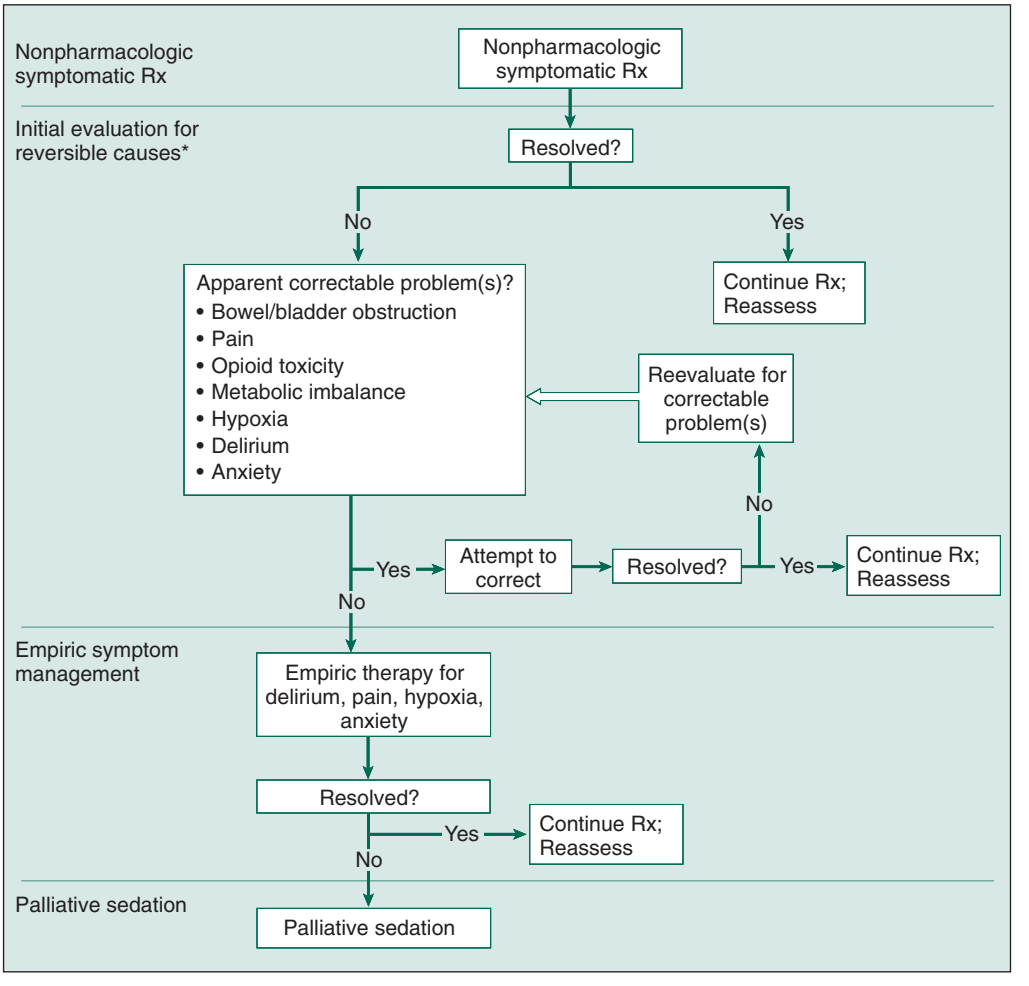

Figure 44-1 • Treatment of agitation in the last days. *Guided by patient/family wishes, burden/benefit.

ones.[26] They also want to strengthen and complete their relationships. For this reason, problematic relationships can create open wounds that are as painful as those from any physical injury. Dr. Ira Byock offers five simple phrases ("The Five Things") that encompass the subjects people can benefit from discussing with those they love: "Forgive me; I forgive you; thank you; I love you; and goodbye."[3] Many patients and families find it difficult to say these phrases or discuss these subjects. Social workers, chaplains, psychologists, and psychiatrists can be of great help in facilitating these conversations and bringing peace to a dying patient and to the soon-to-be-bereaved family members.

Families of dying patients face an extraordinary number of challenges. They must cope with their own losses, organize and pay for home care, and care for the family members who are not ill. They are best helped by the following measures:

- Patient comfort
- Communication with health care providers
- Help with caregiving and meeting financial and social costs
- Maintaining stability
- Adapting to change
- Support for their grief and upcoming bereavement[50–52]

Oncology clinicians can help by simplifying medication regimens and planning for emergencies that can be foreseen.[53] See also Box 44-1 for suggestions about how oncologists can address some of the family's needs. Social workers collaborate with the patient's primary oncology team to provide most of the support, explain the benefits of hospice and other needed services, and arrange family access to them.

Families with young children are in special need of counseling and support. Guidelines for clinicians who work with these parents and their children include six steps (which are described in detail in the reference provided):

1. Learn about the children.
2. Maximize the child's support system.
3. Facilitate honest communication about the illness.
4. Address common questions.
5. Prepare for hospital visits.
6. Say goodbye.[54]

Cultural Considerations

To avoid communication difficulties, physicians and nurses should explore with patients and families what they feel are appropriate context and structure of end-of-life discussions (Box 44-2).[55] Non-Hispanic whites and African Americans, for example, differ in many areas: who they want present (immediate family only versus extended family, friends, and pastor); having durable power of attorney or

Box 44-1. ADDRESSING THE NEEDS OF THE CAREGIVER

During the last weeks to months of the patient's life, office visits become impractical. Regular contact by telephone, supplemented, when possible, by one or more home visits, retains the connection that patients and families need with their primary treatment team. Clinicians also can promote continuity and minimize feelings of abandonment by collaborating with the home care or hospice nurses and, as requested, with the social workers who are part of the home care team. Praising the family caregivers for the work they are doing, helping them to anticipate upcoming problems and make contingency plans, and checking in with them at regular intervals promote timely identification and, when possible, resolution of new problems.

Many family members and medical trainees have never seen anyone die an expected death outside an intensive care unit. The clinician who is familiar with the dying process can be a crucial source of information and comfort. For inpatients, the clinician works with the nursing team that is caring for the patient and also serves as an attentive observer striving to provide maximum comfort. I make at least two visits a day to stable patients to monitor their comfort through reports from nursing and family, to answer questions, and to educate professional and family caregivers as to what they should expect in the last days.

Patients who were formerly alert and communicative usually become less so. They are apparently still comforted by the touch and voices of those they love and might even emerge from what seemed to be an insensible state to greet a welcome newcomer. I tell families that to me, it is as though the patient lives in a house with many rooms, a mansion. As they come closer to dying, the patient moves farther and farther back in the house, and it is more and more effort for them to greet callers at the front of the house. But the callers are still welcome, as are their voices and conversation. I ask families to let patients know they have arrived and then to add that patients should not feel obliged to speak to them. Patients can also be asked to provide a hand squeeze or other sign of recognition. With close family, I discuss the "Five Things" (see the section of the chapter entitled "Social Causes") and suggest that they find the time to share with the patient any of those sentiments they feel would be appropriate.

I reassure families that we know that dying patients are rarely hungry or thirsty and that moistening the mouth is all that is needed. If necessary, I review the burdens of hydration (see the section entitled, "Xerostomia"). I also explain about Cheyne-Stokes breathing and that it does not indicate that the patient is gasping for breath. I also ask them to feel free to let us know if the patient seems uncomfortable or develops noisy breathing, as we want to address any source of discomfort as rapidly as possible. I offer the services of chaplaincy, and I am alert to whether a social worker would be helpful, if chaplains and social workers are not already involved. Many family members do not know that this kind of help is available to them in the hospital.

If the family has not done so already, I urge them to choose a funeral home and make all the necessary arrangements before the patient has actually died, to free themselves of that task when the death occurs. Families often ask how they will know that the patient is dying. I ask them to look for a marked decrease in urine output (in a foley bag or diapers), cooling of the arms and legs, and new pallor or mottling of the skin. Some patients develop fecal incontinence as they die, so if hospice is not involved and the patient is at home, I alert the family to this possibility.

Supporting the Ward Personnel and the House Staff

To decrease potential feelings of guilt and anxiety, I review with all team members the history of the illness, the limits of the treatments that remain, the burdens of those treatments, and, when appropriate, the limits the patient has placed on further supportive measures. I also remind them that despite our best efforts, patients still die and that it is no one's fault. I also suggest things they can do that will enhance the patient's last days and that will further the healing process of the survivors.

During the hospitalizations that lead to death and after the death itself, I try to dispel any misconceptions they have about their "fault" for the death and to praise the work they did to make the dying as comfortable as possible. This kind of support goes a long way toward enabling young physicians and ward staff to recover from the pain they experience when a patient dies and to allow themselves to feel a sense of satisfaction for a job well done.

Box 44-2. KEYS TO A SUCCESSFUL FAMILY MEETING

One of an oncology clinician's hardest tasks is conducting a successful family meeting when the burden of disease-directed therapies exceeds the benefits. While chemotherapy or radiation might no longer offer benefit, it is never true that "there is nothing more we can do for you." The following steps increase the chance that the meeting will enhance communication among clinicians, patients, and family members; relieve concerns of abandonment; enhance trust; and provide a conversational template for the tough times to come.

1. Schedule a pre-meeting (actual or virtual) and consider:
   - A. Who needs to be there (which family members, which members of the clinical team)?
   - B. What is the realistic prognosis or functional goal for the patient?
   - C. Who will run the meeting? How can others help (e.g., the palliative care clinicians, the social worker)?
   - D. Who will stay with the patient and family to debrief?
2. During the meeting
   - A. Everyone must be seated.
   - B. Introduce everyone present.
   - C. **ASK**–tell–ask
     - i. How do you think you (or "the patient") is/are doing?
     - ii. What changes have you seen in the last (days, weeks, months)?
     - iii. What are you hoping for? And what else? And what else?
     - iv. What are you most concerned about? What are your worst fears?
     - v. How can we help?
   - D. ask–**TELL**–ask
     - i. Answer their questions.
     - ii. Provide key medical information, but **AVOID** giving medical details that obscure the big picture.
       - a. Example: The (disease) is clearly progressing despite our best efforts. In my best judgment, s/he has only (days, weeks, months) of good time left. S/he may well live longer, but this is the time when s/he will have the most energy, think the most clearly, and be most him/herself.
     - iii. **STOP TALKING**
       - a. Counting silently to 20 helps.
     - iv. Respond to their grief.
   - E. ask–tell–**ASK**
     - i. What do you still want to accomplish during your life?
     - ii. What might be left undone if you were to die today?
     - iii. What legacy do you want to leave to your family?
     - iv. What do you want your children and grandchildren to remember about you?
     - v. How can we help **NOW?**
3. After the meeting
   - A. Review with your team how everyone is doing.
   - B. Make a plan for who will follow up next with the family.
   - C. Success is measured by how much they trust you and how little they feel abandoned. Feeling bad is normal and expected, both on your part and theirs; that does not mean that you were not successful.

living will in place and interest in knowing about hospice programs[56] (more common in non-Hispanic whites[55–57]); and what the focus and tempo of the discussion should be (concerns about prognosis, irreversibility of the illness, quality of life, financial concerns and medical choices versus spiritual concerns, lack of trust, concerns about "do not resuscitate" orders and hospice, allowing adequate time for decisions and not feeling pressure to make them).[57,58] More patients who are not of non-Hispanic white or African-American descent prefer to have surrogates informed of their prognosis and make treatment decisions for them. Some patients from Asian, Bosnian, or Italian-American cultures might perceive frank communication about a serious illness or prognosis as "at a minimum, disrespectful, and more significantly, inhumane."[55] It is therefore important to determine from the patient whether the patient or his or her designees are to be involved in these discussions and to respect that choice as the exercise of that patient's autonomy. Every effort should be made to provide a qualified translator in conversations about prognosis and goals of care where the clinician is not a fluent speaker of the patient's language.[55]

Spiritual and Existential Causes

Dying patients also can suffer from spiritual and existential concerns. As cancer advances, patients face ongoing losses in terms of normal appearance and physical and mental function; roles in the family, community, or workplace; control, autonomy, and privacy.[2] Suffering arises when the illness robs patients of something fundamental to who they are, and consequently, each person's sources of suffering are unique. For example, although loss of mobility might be irrelevant to someone whose major avocation is reading, it can be devastating to an avid golfer. Young patients in particular search for the meaning in their existence, their illness, and their premature deaths. Counseling, including life reviews ("What have you been most proud of in your life? What surprised you most? What has made you happiest? What do you wish you could have done better or differently?") may help dying patients to find a context and a meaning for their lives.

Some patients seem to blame themselves for their illness, even though scientific evidence does not support their belief. The concern could arise from a much larger sense of guilt about the patients' sense of failure to live the lives they should have lived. Other patients—those with uncontrolled pain, for example—might feel that God is testing or punishing them. They search their consciences for a transgression so dreadful that it deserved such punishment.[59] A mental health professional or chaplain might be able to provide reassurance or to help patients develop strategies to right the wrongs they feel that they caused. Even dying patients can be provided hope that in the absence of a cure, they will still be able to heal these wounds.

Religious rituals can be an important source of comfort and healing to dying patients and their families.[59] Even in a hospital setting, therefore, every effort should be made to identify and accommodate these spiritual practices. Appropriate hospital or community religious leaders should be welcomed as part of the patients' care team and should be assisted in performing the necessary rites after the patient dies.

Palliative Sedation for Refractory Symptoms

Sedation is considered when, despite expert evaluation and management, a patient who is near death continues to experience intolerable physical, psychological, or spiritual-existential distress.[60] Fewer than 5% of patients need palliative sedation; those who do most commonly suffer from refractory pain, cough, dyspnea, seizures, or delirium. The doses of opioid, benzodiazepine, or neuroleptic that are needed to control the symptom(s) sedate the patient. In other cases, the request for sedation for refractory symptoms arises when psychological or spiritual-existential concerns coexist with physical problems. Expert palliative care and pastoral consultation, evaluation by a psychiatrist, and discussions among the health care team, the patient, and the family members should be undertaken before

palliative sedation is administered. Most often, all the people concerned reach a consensus on the need for and acceptability of sedation as a means of achieving symptom control. Obtaining formal informed consent, either from the patient or from the health care proxy, is recommended.

Medications that are used to produce the sedation that relieves the distressing symptom(s) include opioids, neuroleptics, intravenous benzodiazepines, and subcutaneous or intravenous barbiturates (see Table 44-2).[61] Intravenous hydration or enteral or parenteral nutrition can be provided if they meet the goals set by the patient and family. They are rarely used in imminently dying patients whether or not the patients are sedated, as these patients are rarely suffering from hunger or thirst.[37]

HOSPICE CARE

Hospice care can be an enormous source of comfort to families of dying patients and professional caregivers, particularly those who have never witnessed a "natural" death. The team members have "been there," can explain what is likely to happen, and can provide expert symptom management during the last hours to days. Hospice care might also decrease the risk of death of surviving elderly widows.[62]

American patients, however, are generally very resistant to accepting a terminal prognosis.[63,64] To enroll in hospice, patients must acknowledge their 6 months prognosis, relinquish further curative therapy, and give informed consent. These requirements and common misconceptions about hospice care (Table 44-3) can be serious obstacles to enrollment in hospice programs.[65]

Table 44-3 Common Misconceptions about Hospice

- *Patients enrolling in hospice must choose not to be resuscitated.* Patients do not have to relinquish resuscitation to enroll in hospice. After they and their families fully understand the implications of the resuscitation, most patients elect not to be resuscitated.
- *Patients enrolled in hospice lose their primary physicians.* The referring attending physician continues to direct and approve all the patient's care.
- *Hospice patients cannot be hospitalized and remain enrolled in hospice.* Any hospice patient can be admitted to an acute, inpatient level of care to control a distressing symptom. Hospices can admit patients to contract beds in acute care hospitals or to their own inpatient facilities.
- *Hospice patients cannot participate in research projects while enrolled in hospice.* Hospice patients have the right to participate in research studies. Hospice ethics and research committees usually evaluate the burden vs. the benefit of the research on the patient, family, and hospice staff.
- *Hospice nursing personnel do not provide sophisticated care.* Hospice personnel provide expert palliative care that requires astute assessment and expert intervention tailored to the patient and family goals.
- *Patients can "use up" their hospice eligibility, so it is important not to enroll them too soon.* Patients are initially certified for three months of service, after which their physician and the hospice medical director are asked to recertify them indefinitely, at two-month intervals. Patients who choose to revoke the hospice benefit to seek life-prolonging therapies may choose to re-enroll if their goals change.
- *Patients must have a live-in caregiver to enroll in hospice.* With appropriate safeguards (e.g., "lock-boxes" to provide access in emergencies, and daily phone contact) hospice care can be safely provided to patients who "live alone."

Financial Considerations

The hospice benefit (under Medicare) is a managed care, capped reimbursement program that reimburses a hospice program a per diem rate based on the patient's level of care (approximately $130 per day for routine or respite care, approximately $500 per day for inpatient acute care). In skilled nursing facilities, patients are receiving Medicare benefits for skilled care and cannot retain these and simultaneously enroll in the hospice Medicare benefit. If they choose a hospice program, either a Medicaid program or their families must pay the room and board costs in the nursing home. Medicaid, private insurance, and health maintenance providers reimburse the hospice at various rates; with the last, services must be approved through the plan's case manager. Aggressive palliation using chemotherapy or radiation is often prohibitively expensive for small to moderate-size hospices, given this reimbursement schedule. Individual hospices must decide both which treatments are consistent with their philosophy and which they can afford. Most hospices must secure additional funding from grants and donations to provide the mandated services.

Further, the majority (80%) of the services a hospice program delivers must, by law, be to patients at home. Fewer than 1% of patients who are enrolled in hospice programs die in hospitals. Although the hospice program provides some help, the majority of the patient's care at home must be provided by family or friends or by privately paid professional caregivers. Therefore, some patients will not be able to stay at home even with the maximum help that hospice personnel and volunteers can offer.

Clinical Care Provided

Patients in hospice programs are cared for by medically directed, interdisciplinary teams that include the referring physician, the hospice medical director, a nursing director of patient services, an office administrator, a nurse, a social worker, a bereavement counselor, a home health aide, a chaplain, and volunteers. The core team also can request additional consultations from physicians, registered dietitians, or occupational, speech, or physical therapists (Table 44-4).

Levels of Care

Hospice programs provide a continuum of care, from home to the inpatient setting. Whereas most patients are cared for in their homes,

Table 44-4 Medicare-mandated Hospice Services

PRACTITIONERS AVAILABLE

Medical director, nurses, social workers, home health aides, chaplains, volunteers, administrative personnel, medical consultations, occupational therapy, physical therapy, speech therapy, bereavement counseling

PALLIATIVE TREATMENT OF TERMINAL ILLNESS

Prescription medications

Durable medical equipment and supplies

Oxygen

Radiation and chemotherapy

Laboratory and diagnostic procedures

OTHER BENEFITS

Transportation when medically necessary for changes in level of care

When needed, continuous care at home or in a skilled nursing facility or inpatient setting

Respite care (care in a nursing facility that provides a "respite" for the caregivers)

Medicare Hospice Regulations: 42 Codes of Federal Regulations, Part 418, 1993.

all Medicare-certified hospices, as stated in the 1983 federal regulations, are required to provide four levels of care: routine, continuous, inpatient, and respite. They also provide bereavement care both to support family members who are experiencing "anticipatory grief" before the patient's death and to communicate with and support the bereaved for the year after the death.

Routine care services are offered seven days a week, 24 hours a day. In addition to the patient's nurse, there is always an on-call registered nurse to provide phone support and make home visits when necessary. The registered nurse monitors the patient's comfort and works with the referring physician to adjust the treatment regimen as needed. Occupational, speech, or physical therapy and home health aides are provided as required. As death approaches, the patient's registered nurse reviews the dying process and provides the family or the inpatient or long-term care facility personnel with written materials that explain how they can determine that death is imminent. The nurse also describes the signs and symptoms of dying, instructs the family in emergency procedures, and is available for support while the patient dies.

Social workers offer support and family counseling and identify those who are at risk for a particularly painful bereavement period. They engage the patient and family in advance care and funeral planning and in completion of living wills and durable powers of attorney, provide applications for financial aid or waivers, and help to identify financing for additional home health care. They assist patients in making plans for their survivors (e.g., guardianship for children) and in completing life reviews; they often work alongside the chaplain to facilitate family reconciliation.

The team chaplain also offers home visits or coordinated care with the patient's own clergy. Chaplains are of help even to nonreligious patients who have spiritual or existential sources of distress (e.g., loss of hope, loss of connection or of love, a need for forgiveness or to forgive, or a need to identify the meaning of their lives).

Volunteers, who are usually available 2 to 4 hours a week, help families in nonclinical areas. A hospice medical director works with the team and the patient's primary physician to optimize symptom management.

Continuous home care is provided for patients who require continuous symptom management and for whom the home care setting remains appropriate. Patients with, for example, unrelieved cough, dyspnea, pain, or delirium can receive 24-hour nursing services until the problem is brought under control. Home visits from a hospice medical director can also be provided.

If the patient's symptoms cannot be controlled at home, inpatient care is offered. Orders are written by inpatient unit personnel and inpatient staff provide the care. The hospice team, however, continues to be responsible for the plan of care. Team members visit the patient as they would visit an outpatient, and the hospice medical director provides consultation as needed. The referring physician remains the primary physician and can bill for services under Medicare Part B.

Respite care is available generally for 5 days every month in a community skilled or intermediate nursing facility with which the hospice has a contract. The goal of the respite is either to provide a rest for the caregiver or to remove the patient to an adequate facility when the home is temporarily inadequate to meet the patient's care needs.

Medications and Treatments Provided

Hospice programs provide 95% of the cost of prescription drugs related to the terminal diagnosis and necessary for its palliative treatment (and many waive the other 5% if there is no insurance coverage). They also provide all durable medical equipment, supplies, and oxygen for needs related to the terminal diagnosis; laboratory and diagnostic procedures related to the terminal diagnosis; and transportation when this is medically necessary for changes in the patient's level of care (see Table 44-4).

GRIEF AND BEREAVEMENT

Survivor's grief is a "process of experiencing the psychological, behavioral, social, and physical reactions to the perception of loss," and it is distinguishable from the anxiety and depression that survivors might also be experiencing.[66,67] The intensity of a survivor's grief is based on the characteristics of the mourner himself or herself, the nature of the death, and societal and cultural factors. Rando writes that being very attached to or very dependent on the deceased, having a great deal of ambivalence in one's feelings toward the deceased, having a personal history of clinical depression, or having difficulty with previous losses all can exacerbate the grief.[66] Recent studies of psychiatric outpatients confirmed the association between attachment and dependence and severity of grief but also found that having more ambivalence predicted for less grief.[68] Sudden or accidental death, suicide, or homicide magnify the grief.[66] The perception of a violent death is associated with major depression in the survivors, but religious rituals, a good support system, and involvement with hospice programs for more than 3 days decrease depression.[69,70]

Each bereaved person's loss is unique, as are the experiences and manifestations of grief and mourning. Many people manifest typical symptoms of grief, some of which become less persistent as the people rebuild their lives.[66,67,71,72] Recurrent intense symptoms typically occur at the anniversary of the death of the patient but can occur at unpredictable times, sparked by any type of reminder of the deceased. Although there are no rigid stages through which bereaved survivors pass, there are some typical manifestations of grief.

At the time of death, survivors appear numb, confused, or dazed and usually express some form of denial as the reality of the death intensifies.[73] Behavior can range from uncontrolled shrieking to an unnerving calm.

In the weeks and months that follow, pain intensifies as the absence of the person who has died asserts itself repeatedly. Mourners yearn for the one who is dead and experience repeated pangs of intense grief; denial is replaced by disorganization, depression, disinterest, and despair.[72] Survivors commonly experience the feelings, behaviors, physical symptoms, spiritual concerns, and thoughts listed in Box 44-3.

As the roles the deceased played in the marriage, the family, and the community become apparent to the survivors, they grieve each loss as they learn to cope with the increasing responsibilities. It is very difficult for people to move beyond loss if they never allow themselves to feel it in some way that is appropriate for them. Family obligations and unspoken strictures against demonstrations of grief can further impair a survivor's ability to experience the pain of the loss adequately. Putting those feelings away to deal with later or denying their existence only prolongs or inhibits the grieving process.

Often by a year or two after the loss, survivors accommodate to it.[66] They tacitly acknowledge the changes that must be made if they are ever to resume old relationships and responsibilities or to establish new ones and risk recurrent loss. Accommodation involves realizing that loving someone new need not mean betraying the memory of the person who has died.[66]

About 10% to 20% of survivors, however, suffer either from depression and/or from "complicated grief." Patients with depression have "symptoms of sadness, impassivity, and psychomotor retardation,"[74] but they do not yearn for the deceased and they can accept the death. Depressed survivors benefit from counseling and consideration of pharmacologic treatment.[74,75] Patients with complicated grief disorder, in contrast, have grief that causes serious functional impairments. They do have profound yearning for the deceased, as well as "numbness, feeling that part of oneself has died, assuming symptoms of the deceased, disbelief, or bitterness."[74,76] These patients are at increased risk of medical and psychiatric illness[77] and should

Box 44-3. WHAT YOU CAN EXPECT WHEN SOMEONE CLOSE TO YOU DIES

Grief is associated with feelings, thoughts, and physical symptoms that include the following:

Common Feelings/Behaviors
- Fear or anxiety
- Anger or guilt
- Depression or despair
- Separation or longing
- Sudden wave of mental pain
- Confusion or inability to concentrate or make decisions
- Tearfulness or crying
- Sighing
- Restlessness
- Yearning
- Helplessness
- Relief
- Disbelief
- Hope

Spiritual
- Sense of the deceased's presence
- Faith may be strengthened, altered, or abandoned

Common Physical Symptoms
- Decreased or increased appetite
- Decreased energy; weakness of muscles
- Nausea and diarrhea
- Decrease or increase in sex drive
- Inability to sleep or sleeping too much
- Feeling something stuck in the throat
- Tightness in chest, breathlessness
- Increased sensitivity to noise
- Vivid dreams
- Dry mouth

Common Thoughts
- Preoccupation with "if only," "what if," and with memories
- "Who am I now?"

Most people find that their grief lasts anywhere from 6 months to 2 years. However, remember that each person is a unique individual, and for some people, much more time is needed before the pain lessens.

What You Can Do
1. Allow yourself to feel the loss and to grieve over it.
2. Realize that your grief is unique.
3. Expect yourself to have some negative feelings.
4. Accept the help of others and let people know how they can help.
5. Give yourself time alone.
6. Exercise.
7. Read books about feelings of grief and the process of recovery.
8. Talk to others about your loss.
9. Attend community support groups.
10. Most important: Understand that it is very likely that your pain will lessen.

What It Is Better Not to Do
1. Try not to make major changes.
2. Resist withdrawing from social activities.
3. Avoid excessive smoking or drinking.

When You Should Call Us
- If you have any questions or would like further information.
- If you feel that you would like professional counseling.
- If you need our help.

Abrahm JL, Cooley ME, Ricacho L: Efficacy of an educational bereavement program for families of veterans with cancer. J Cancer Ed 1995;10:207–212.

Box 44-4. SAMPLE OFFICE-BASED BEREAVEMENT PROGRAM

At the Time of Death
Family members are often in a state of shock; their moods can swing widely from feeling numb to feeling distraught. This volatility can be frightening, so our staff explains that this reaction is normal and that they should not worry about controlling themselves.

If I am sad, I cry with the family; if family members need to talk things over, I ask leading questions that help them share their feelings. Most families want to review the circumstances of the death, to assure themselves that the patient did not suffer and that everything that could have been done was done. I always try to find something for which I can praise them (e.g., their care of or their advocacy role for the patient) and add how lucky the patient was to have had them there when he or she needed them. If I cannot do this in person, I try to offer as much support as I can by telephone.

Initial Follow-up Call
We next call the family within 24 to 48 hours of the death to offer our condolences and our help. During this call, we offer comfort and provide a listener for a reiteration of the story of the death and the meaning of it for the bereaved. If necessary, we again reinforce the normality of the wide emotional swings or other symptoms of acute grief that they might have been experiencing. We listen empathetically and indicate our continued support. We end the conversation by asking whether we can keep in touch, and we let them know we will call again in about a month. We also send a condolence letter. If the family was involved with hospice, we remind them that the hospice team is still available to them.

Four to Six Weeks
About a month after we send the letter, we call again and offer to send a variety of materials we think would be helpful. These include a list of feelings and physical signs commonly experienced by those who are grieving and what to do or not to do about them (see Box 44-3).

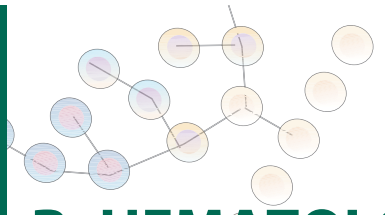
We also include a list of support groups in the family's area, including those hosted by the hospice, because talking about their loss with skilled bereavement counselors or others who have suffered the same losses can help their recovery. Groups such as Widow-to-Widow, or, for parents who have lost a child, Compassionate Friends or Candlelighters (www.candle.org) provide much needed help with rebuilding a life.

Other Contacts
Because this has been shown to be a time of most need for bereaved families, we call again at six months and repeat our offer of various materials. We also participate in the once- or twice-yearly memorial services held by our cancer center and by the hospices who cared for our patients and their families. And, because we anticipate recurrence of grief, we send a letter at the first anniversary of the person's death, and we send a "Holiday letter" a few weeks before Thanksgiving letting them know that they are still in our thoughts and would welcome a call.

Our staff finds the process very rewarding. I have noticed that as I speak to the survivors at longer and longer intervals and begin to remember the patients as they were before the terminal stages, it helps me achieve closure and makes it easier for me to move on.

Abrahm JL, Cooley ME, Ricacho L: Efficacy of an educational bereavement program for families of veterans with cancer. J Cancer Ed 1995;10:207–212.

be referred for psychiatric or spiritual counseling. Survivors with a history of attachment disorders (e.g., childhood abuse, childhood separation anxiety) or an aversion to lifestyle changes, who are unprepared for the death and unsupported after it, are at higher risk of developing "complicated grief." Additional risks include a "dependent, close, confiding" relationship with the deceased.[74] There is no randomized control trial of a pharmacotherapy that is effective for the extreme grief symptoms,[73,74] but a new effective psychotherapy has been developed specifically for this disorder that is superior to standard interpersonal psychotherapy.[78]



Skillfully communicating the diagnosis and terminal prognosis; providing emotional, psychological, and spiritual support and physical comfort; helping families to resolve outstanding issues; and making the death as peaceful as possible are all measures that diminish the suffering of the survivors. Survivors who feel unprepared for the patient's death have a higher risk of developing complicated grief.[69]

After the patient dies, survivors appreciate ongoing communication with the patient's physician.[75] When a formal bereavement program is offered, it usually takes place during the first year after the patient's death. After the formal program ends, the bereaved are welcome to continue to participate in any bereavement activities that have been meaningful to them (Box 44-4). Survivors who experience severe grief symptoms or depression should be referred for formal assessment and consideration of pharmacologic treatment.[75,79] Unfortunately, although the depression often responds to standard therapy, there is no widely accepted effective therapy for the symptoms of extreme grief.[75]

B. HEMATOLOGIC PROBLEMS

45 Disorders of Blood Cell Production in Clinical Oncology

John Glaspy

SUMMARY OF KEY POINTS

- Anemia is very common in oncology patients and is multifactorial.
- Many patients with cancer have in part the anemia of chronic disease.
- The anemia of chronic disease is associated with decreased absorption of oral iron and decreased ability to access storage iron pools.
- Iron-restricted erythropoiesis may limit the efficacy of erythropoietic agents for the treatment of anemia in these patients and can be overcome with parenteral iron.
- Treatment of anemia in cancer patients reduces transfusions and improves quality of life.
- The safety of increasing hemoglobin levels to greater than 13 g/dL is not established, and the target hemoglobin level during treatment should be 12 g/dL.
- Neutropenia in oncology is usually due to treatment.
- Myeloid growth factors can be used to reduce infection risk in patients in whom the risk is unacceptably high, and this is preferable to delaying or reducing the dose of chemotherapy when cure is the intent.
- There are new agents for the stimulation of platelet production in clinical development.

INTRODUCTION

Disorders of blood cell production, usually manifest as anemia, leucopenia, or thrombocytopenia, are both very common and enormously important in the clinical practice of oncology. Under ordinary conditions in the healthy adult, blood cell production is extraordinarily prolific, with daily outputs in the range of 2×10^{11} erythrocytes,[1] 5×10^{10} neutrophils,[2] and 2.5×10^{11} platelets,[3] as well as substantial numbers of lymphocytes, macrophages, antigen-processing cells, eosinophils, and basophils. With more than 5 million blood cells produced every second under ordinary conditions, the mitotic yield of normal bone marrow is greater than that of almost any malignancy, where the production of a similar number of new cells would result in a daily increase of tumor cell burden of more than 0.25 kg per day. It is not surprising therefore that among the most common unintended consequences of cancer treatments with antimitotic mechanisms of action are clinically important degrees of anemia, neutropenia, or thrombocytopenia.

The rate of blood cell production is both tightly regulated and highly variable. Under conditions of either increased destruction of cells, such as bleeding, hemolysis, or immune destruction of platelets, or demand for increased numbers of cells, such as infection, production rates of appropriate cells increase several fold. The regulation of this dynamic system is complex[4] but for practical purposes can be conceived of as involving an interaction between a pool of pluripotent hematopoietic stem cells, capable of both infinite self-renewal and differentiation into mature blood cells and regulatory factors, including both a well-characterized set of glycoprotein hematopoietic growth factors and a less well-understood group of inhibitory factors. Cancer and its treatment are very often associated with profound perturbations in this system controlling blood cell production. Understanding this biology is key to rational intervention and optimal care of the oncology patient.

DISORDERS OF RED CELLS

Anemia

Pathophysiology

Anemia is common in cancer patients[5,6] and is often multifactorial, with frequent contributors including: bleeding, general malnutrition, iron, folate or vitamin B_{12} deficiency, hemolysis, myelosuppressive chemotherapy, radiation to marrow-bearing bones, and the anemia of chronic illness. In addition to these factors, for B-cell malignancies and solid tumors extensively involving the marrow, disruption of the normal interactions of hematopoietic progenitor cells and endothelial and connective tissue stromal cells in the marrow microenvironment may play an important role. For patients with secretory multiple myeloma, renal insufficiency is a frequent and often unrecognized factor in the anemia. Finally, for patients with myelodysplasia and myeloid malignancies, the hematopoietic stem cells themselves are reduced in number and/or dysfunctional.

It has been recognized for some time that, in patients with chronic inflammatory illnesses including cancer, a diminished endogenous erythropoietin (EPO) response to anemia is frequently observed.[7] More recently, it has been shown that inflammation is frequently associated with increased production of the iron-regulatory peptide, hepcidin, by the liver.[8–11] Hepcidin binds to and inactivates the iron transporter, ferroportin, impairing both absorption of dietary iron and access to storage iron pools.[12,13] These discoveries strongly suggest that iron-restricted erythropoiesis may occur despite the presence of what are believed to be adequate iron stores and be more common in patients with cancer than has been previously suspected. Our current understanding of the biology of anemia in cancer patients is shown in Figure 45-1.

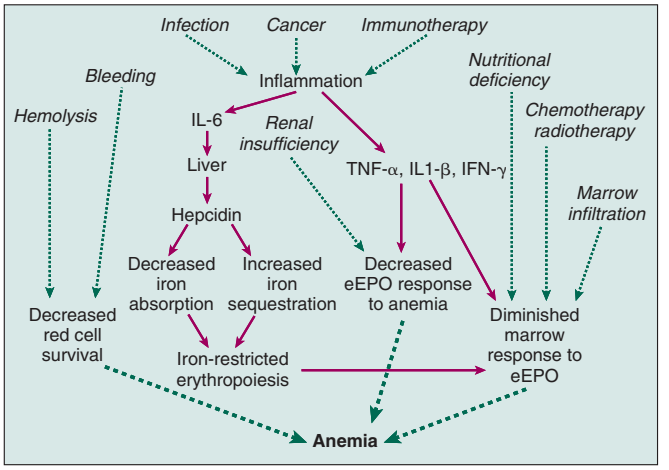

Figure 45-1 • The pathophysiology of the anemia frequently observed in cancer patients. Type I acute-phase cytokines decrease the endogenous EPO response to anemia and suppress the effects of EPO on the marrow. Type II acute-phase cytokines induce hepcidin production in the liver, which decreases iron availability to erythropoiesis through decreased gastrointestinal absorption and accessibility of storage iron in reticuloendothelial cells. Other common factors include marrow suppression through disruption of the normal microenvironment, the myelosuppressive effects of chemotherapy, and nutritional deficiencies other than iron. Renal insufficiency is particularly common in patients with multiple myeloma and patients treated with cisplatin chemotherapy. eEPO, endogenous erythropoietin; IFN-γ, interferon γ; IL1-β, interleukin-1β; IL-6, interleukin-6; TNF-α, tumor necrosis factor α.

Management

It is surprising how frequently the anemia observed in cancer patients is due, at least in part, to reversible factors, such as iron loss through bleeding or previously unsuspected vitamin B_{12} deficiency. In one recent study, 5% of cancer chemotherapy patients being considered for inclusion in an erythropoiesis-stimulating protein (ESP) clinical trial were found on screening evaluation to have serum vitamin B_{12} concentrations below normal.[14] Historically, the only available treatments for the remaining patients with cancer and anemia were red cell transfusions and successful treatment of the underlying malignancy. Because of the well-known risks associated with transfusions and the need to conserve a limited blood supply, specific anemia treatment was limited to those patients with profound degrees of anemia (hemoglobin [Hb] levels 8 g/dL or lower) or severe cardiovascular symptoms, such as chest pain or dypsnea at rest.

The key regulator of red cell production is the glycoprotein hormone EPO. The cloning, development and introduction into clinical use of recombinant human EPO represented a watershed in anemia management. Two preparations of recombinant ESPs are currently available in the United States, epoetin alfa and the hyperglycosylated recombinant EPO, darbepoetin alfa,[15] which has a longer half-life. In randomized, placebo-controlled trials, both epoetin alfa[16–20] and darbepoetin alfa[21,22] have been shown to reduce red cell transfusion rates in patients with cancer receiving chemotherapy, and both agents are approved by the U.S. Food and Drug Administration (FDA) for this indication.

It had long been known that even mild and moderate degrees of anemia can impair function and limit productivity in otherwise healthy adults.[23] When ESPs became available and were applied to the treatment of patients with renal failure, it was shown that quality of life and productivity improved when Hb levels increased and that this relationship continued to hold even at Hb levels well above the traditional transfusion threshold.[24–27] Comparisons of data gathered during ESP treatment of anemic dialysis patients to those from anemic cancer patients suggested that the impacts of anemia and the benefits of treatment in terms of improved quality of life and energy level were quite similar in the two settings.[28] Analyses of the relationship between Hb level and energy, activity, and overall quality of life observed in large, uncontrolled series of cancer patients during treatment for anemia with epoetin alfa suggested that larger incremental increases in these patient-reported outcomes were observed with Hb increases from 11 to 12 g/dL than with any other 1-g increase.[29] Two large surveys had demonstrated that fatigue is common and often the dominant symptom in cancer patients in the United States, limiting function and quality of life.[30,31] When analysis of data from randomized trials confirmed that ESP therapy for anemia is associated with improvements in fatigue in cancer patients,[16,20,32–46] a second goal of ESP therapy beyond transfusion prevention emerged: maintenance of functionality and relief of fatigue. Although no ESP is currently approved by the FDA for relief of fatigue in anemic cancer patients, in clinical practice these agents are used with both goals in mind.

Both ESPs are currently used for the treatment of anemia in patients with cancer receiving chemotherapy, and randomized trials to date have failed to demonstrate that either agent is superior in terms of transfusion prevention or fatigue reduction when used at starting doses of epoetin alfa of 40,000 U/week and darbepoetin alfa of 200 μg every 2 weeks.[47,48] Recently, it has been shown that darbepoetin alfa is effective for the treatment of chemotherapy-associated anemia when given every 3 weeks at doses of either 300 μg[49] or 500 μg[50]; every-3-week dosing on the same day as chemotherapy seems to be as effective as asynchronous dosing.[51] Studies using initial weekly dosing followed by every-3-weekly epoetin alfa at a dose of 120,000 U have demonstrated that it is also feasible to administer this agent every 3 weeks for at least a portion of the treatment period; trials exploring less frequent dosing of this agent throughout the treatment period are in progress.[52] There is little evidence that higher doses of either ESP results in improved outcomes for cancer patients, and although it is common practice to increase doses in hyporesponsive patients, this practice has never been studied and its benefit, if any, is unknown.

It is important to bear in mind that weeks are usually required before ESP therapy increases Hb levels, and there is still a role for red cell transfusion for acute intervention in severe anemia and ominous symptoms such as chest pain and dypsnea at rest. The relatively slow onset of ESP effects has important implications for the optimal utilization of ESPs in the management of chemotherapy-induced anemia. Theoretically, when intervention with an ESP is withheld until the Hb level is less than 10 g/dL, some responsive patients will require transfusions for acute management of severe anemia before they respond to treatment. Several trials have now prospectively addressed the issue of early versus late intervention, and taken in aggregate the results strongly suggest that later intervention is associated with a substantial increase in transfusion risk.[53] Moreover, later intervention will probably result in more fatigue for cancer patients. Both of the recently developed guidelines by the National Comprehensive Cancer Network[54] and the European Organization for Research and Treatment of Cancer (EORTC)[55] support the initiation of treatment when Hb levels fall to 11 g/dL, especially when symptoms such as fatigue are manifest and continued chemotherapy is contemplated.

Once ESP treatment is initiated, it should be continued, with doses adjusted to maintain a Hb level of approximately 12 g/dL. The safety of targeting higher Hb levels has not been demonstrated (see later discussion). This titrated treatment should be continued until the chemotherapy is completed and Hb levels remain in the target range without ESP support.

Problems of Iron

When therapy with recombinant EPO is given to patients with the anemia of renal failure, an increase in platelet count is observed in some patients. Although this was initially believed to reflect an effect of EPO on megakaryocyte growth and development, it has been

shown to be due to inadequacy of iron supply to the marrow.[56] When patients are treated with ESPs, evidence of iron-restricted erythropoiesis can develop, even in the presence of apparently adequate body iron stores.[57] This phenomenon, thought to be due to an inability to mobilize storage iron rapidly enough to support the accelerated erythropoiesis associated with ESP treatment, has been termed functional iron deficiency to distinguish it from the more familiar absolute iron deficiency reflective of diminished total body iron stores. The limited quantity of oral iron that can be absorbed on a daily basis, coupled with the poor gastrointestinal tolerance of and consequently patient compliance with oral iron makes parenteral iron an attractive option for reversing functional or absolute iron deficiency during ESP therapy. For patients receiving ESPs for the anemia of chronic renal failure, treatment with parenteral iron has become a frequent adjunct that appears to enhance response and/or decrease the ESP dose required.[58] Although earlier preparations of iron dextran were associated with infrequent but potentially life-threatening anaphylactic reactions, the newer low-molecular-weight dextran preparations and the iron salts ferric gluconate and ferric sucrate are relatively safe.[59–61] A summary of the available parenteral iron preparations and practical aspects of their administration is contained in Table 45-1.

As noted previously, chronic illness such as cancer is associated with diminished absorption of oral iron and decreased accessibility of body iron stores (see Fig. 45-1) When patients with this anemia of chronic illness receive ESP therapy, it would be expected that the increased iron demand of the erythron would frequently result in functional iron deficiency. It is therefore surprising how few studies are available addressing the potential of parenteral iron to improve the response to ESPs in anemic cancer patients. In one randomized trial, iron dextran, given either as a weekly fixed dose containing 100 mg of elemental iron or as a single total dose infusion, was associated with a significantly better response to epoetin alfa than that observed with either oral iron or no iron support.[62] Similar results have been reported in trials using ferric gluconate[14] and darbepoetin alfa. These data strongly suggest that parenteral iron will play a substantially greater role in the future in the management of anemia in cancer patients.[63,64]

The most formidable challenge to rational iron support during ESP treatment of the cancer patient is the reliable detection of iron-restricted erythropoiesis in this patient population. The anemia of chronic illness is associated with reductions in serum iron and iron-binding capacity and with increases in serum ferritin levels, rendering transferrin saturation and ferritin determinations less reliable indicators of adequate iron delivery to the marrow or of body iron stores.[65] Serum levels of soluble transferrin receptors are normal in patients with the anemia of chronic disease and increased in patients with iron deficiency anemia and therefore might be useful in distinguishing the two conditions[66]; however, this laboratory parameter is not yet widely available. Moreover, soluble transferrin receptor levels are increased by ESP treatment and fluctuate during the chemotherapy cycle, making their future usefulness for monitoring iron supply to the marrow in anemic cancer chemotherapy patients during ESP therapy less promising. Similar limitations may apply to the use of the transferrin receptor-to-ferritin ratio.[67–69] Two parameters that can be reliably determined using flow cytometric techniques available in some hemogram autoanalyzers include the percentage of hypochromic red cells[70–72] and the reticulocyte hemoglobin content.[71,73–77] The relationship of these parameters to iron delivery to the marrow is not affected by the inflammatory milieu of chronic illness, ESP therapy, or chemotherapy, and both have been shown to be useful in guiding iron therapy in patients with renal failure receiving ESP therapy. When the proportion of red cells with a Hb concentration of less than 28 g/dL exceeds 5%, it can be concluded that there has been significant iron restriction of erythropoiesis over the preceding 2 weeks. Although the usefulness of the test is limited in the presence of macrocytosis, when the reticulocyte Hb content is less than 29 pg, iron-restricted erythropoiesis has occurred during the preceding 2 days. Until these two tests are more widely available and validated for monitoring iron supply during ESP therapy for chemotherapy-associated anemia, it is prudent to consider parenteral iron therapy whenever the transferrin saturation is less than 25% to 30% or when the response to ESP therapy is inadequate. If the percentage of hypochromic red cells or reticulocyte Hb content is available, these values can be integrated into the evaluation. An algorithm for the

Table 45-1 Summary of Available Parenteral Iron Preparations

Preparation	Brand Name	Administration
Low-molecular-weight dextran	Infed	Anaphylactic reactions have been reported, and an intravenous test dose of 0.5 mL infused over ≥30 sec is recommended before the first dose. Intravenous doses containing ≤100 mg elemental iron (2 mL) can be given at a rate of ≤50 mg (1 mL) per minute as frequently as daily. Infusion of the total dose (TDI) calculated as $$\text{dose (mL)} = 0.0442\ (\text{desired Hb} - \text{observed Hb}) \times \text{LBW} + (0.26 \times \text{LBW})$$ is feasible in one session.* Premedication with corticosteroids will decrease the frequency of myalgia and arthralgias following TDI.†
High-molecular-weight dextran	Dexferrum	Similar to low-molecular-weight dextran, although reported rates of adverse drug reaction are greater[60,61] and the use of this preparation with ESP therapy in cancer patients cannot be supported.
Ferric gluconate complex	Ferrlecit	A test dose is not required. TDI is not feasible because of a high frequency of adverse events when doses of >10 mL (125 mg iron) are given in a single session. Doses of up to 125 mg can be diluted in 100 mL of normal saline and infused intravenously over 1 hour, or the solution can be pushed undiluted at a rate of 1 mL (12.5 mg) per minute.
Iron sucrose	Venofer	A test dose is not required. TDI is not feasible, although doses of up to 400 mg can be administered by slow infusion over 3 hours. Doses of 100–200 mg can be given by slow intravenous push over 5 min. Alternatively, 100 mg can be diluted in 100 mL of normal saline and infused intravenously over 15 min or more.

management of anemia during cancer chemotherapy is shown in Figure 45-2.

Safety of Erythropoiesis-Stimulating Proteins in Oncology

Erythropoietic agents are generally well tolerated, although there are three issues regarding their safety that merit consideration on the part of the oncologist. First, shortly after the introduction of a new formulation of epoetin alfa in Europe and Canada, an increase in pure red cell aplasia was noted in chronic renal failure patients receiving ESP therapy.[78] This complication was found to be caused by autoantibodies to EPO apparently developed in response to a subtle alteration in tertiary structure of the recombinant molecule and cross-reactive with endogenous EPO. With changes in the storage and handling of recombinant EPO, the incidence of red cell aplasia has diminished,[79] and it did not occur in patients with cancer receiving ESP therapy, possibly as a result of either the short duration of treatment in this setting or the immunosuppressive effects of chemotherapy. However, this episode has implications for the development of generic EPO preparations and serves to emphasize the importance of correct and careful storage and handling of these agents.

Recent meta-analysis of randomized, placebo-controlled trials of ESPs administered to patients with cancer during chemotherapy has demonstrated an increase in the incidence of thrombotic events in patients receiving these agents.[80,81] The overall relative risk of thrombosis associated with ESPs is 1.5 to 1.9, but it appears that, rather than the incremental risk being spread evenly over all patient groups, it is greater in patients with gynecologic malignancies and those receiving combined radiotherapy and chemotherapy treatment regimens.[82,83] The mechanism by which ESP therapy affects thrombosis risk is unknown; significant correlations of thrombotic events with Hb level, rate of Hb rise, or ESP dose have not been observed with sufficient consistency to permit a conclusion that the increased risk is due, in whole or in part, to altered blood rheology. The increase in diastolic blood pressure that can occur with the initiation of ESP treatment suggests the possibility of a direct effect on vasculature, and there is some biochemical evidence of endothelial cell and platelet activation during ESP treatment in humans.[84] There is in vitro evidence that ESPs may synergize with endogenous thrombopoietin in inducing platelet activation[85] and that platelets may be activated through interaction with young red blood cells.[86] Further studies are needed, both to elucidate the mechanism(s) of ESP-induced thrombosis and to establish rational approaches to prediction and prevention.

Recently, in two randomized trials of recombinant EPO used to prevent, rather than to treat, anemia in patients with breast cancer receiving chemotherapy[87] or with head and neck cancer undergoing radiation therapy,[88] an increase in the rate of tumor progression has been observed in the EPO-treated patients. Although there were methodologic issues in both trials, the results must be taken seriously until additional, better powered tumor progression and survival studies currently underway are completed and the final results are available. Meta-analyses of randomized, controlled trials of ESP treatment during cancer chemotherapy have not shown an increase in tumor progression or a decrease in overall survival in anemic patients treated with ESPs.[89–92] For the present, there is no evidence of decreased survival or enhanced tumor progression when anemic cancer patients receive ESPs. Until there is a much better understanding of the safety of erythropoietic agents used to prevent anemia or to normalize Hb levels in these patients, these practices cannot be condoned and a target Hb level of 12 g/dL is prudent in clinical practice.[93]

It is important to bear in mind that anemia is associated with cellular hypoxia, especially in tumor cells,[94–100] and that tumor cell hypoxia has been associated with both enhanced mutation rates and selection of more apoptosis-resistant or invasive phenotypes[97,101–117] and with resistance to both radiation[103,118–123] and chemotherapy.[124–126] Anemia is an independent negative prognostic factor across a wide range of malignancies[127]; although this is an association rather than a demonstrated cause-and-effect relationship, the observation does serve to underscore the potential importance of rational anemia management to optimal cancer care and outcomes. One critical issue that remains to be addressed is the "optimal" Hb level for cancer patients. The vasculature of solid tumors is more tortuous and disorganized than that in normal tissues; just as tumor cell oxygenation drops off more rapidly as Hb levels fall below 12 g/dL,[97,128,129] there is some evidence that oxygenation may decline again as Hb levels rise above 13 g/dL, because of the altered rheology of blood in tumor vessels.[98–100,130] If tumor cell hypoxia is an important driver of tumor progression and resistance to treatment, it may be deleterious to

patients to allow Hb levels to fall below 11 to 12 g/dL or to increase them to levels much greater than 13 g/dL. This hypothesis will be very difficult to test in clinical trials, but the answer is obviously essential to rational oncology care aimed at optimizing outcomes.

Several recent publications have reported on the detection of EPO receptor (EPO-R) protein in human cancer cells.[131–134] These studies have used immunohistochemistry with polyclonal rabbit antisera. Recent work has demonstrated that these antisera reagents also bind tumor-associated proteins other than EPO-R and are therefore not specific.[135] The issue of the potential of ESPs to directly induce proliferation or apoptosis resistance in human cancers is obviously a very important one and merits more attention in future work rigorously addressing both the specificity of techniques used in EPO-R detection and the functionality of any true EPO-R found. Thus far, in vitro work with human cancer cell lines and in vivo studies using human tumor xenografts have not consistently demonstrated any effect of ESPs on cancer cell proliferation or tumor progression.[136,137]

Polycythemia

Paraneoplastic polycythemia is an uncommon syndrome observed in a variety of human cancers[138] including renal cell carcinoma,[139,140] hepatocellular cancers,[141–143] Wilms' tumor[144,145] and, rarely, other malignancies.[146–149] The mechanism is usually ectopic production of EPO,[147,148,150–152] although increased EPO levels are not always observed[139] and other mechanisms, such as ectopic renin secretion, have been suggested.[149] In renal cell carcinomas, in which inactivating mutations of the von Hippel-Lindau gene are common, accumulation of hypoxia-inducible factor, the transcription factor driving EPO gene expression, occurs, causing polycythemia.[140] In most cases of paraneoplastic polycythemia, Hb levels are only modestly elevated, presumably as a result of compensatory decreases in EPO production by the normal kidney. Rarely, polycythemia can be severe, with hematocrit levels exceeding 50% and/or the development of symptoms such as fatigue, headache, visual blurring, and dyspnea. In these cases, it is prudent to rule out other causes of polycythemia, including hypoxemia and coexisting myeloproliferative disorders, before treating the patient with phlebotomy or surgical removal of tumor.[139]

DISORDERS OF WHITE CELLS

Neutropenia

Pathophysiology

By far the most common cause of neutropenia in oncology practice is the relatively straightforward myelosuppressive effects of cytotoxic chemotherapy and radiation treatment. Because of their relatively short life spans, neutrophil counts are particularly sensitive to the effects of recently administered chemotherapy, and nadirs of these counts are frequently observed 7 to 10 days following the administration of chemotherapy. Less commonly, antibodies to neutrophils, bone marrow infiltration with disruption of normal marrow stromal function, and splenic sequestration can play a role. Neutropenia is a critically important problem in oncology practice for two reasons. First, neutropenia is the major factor driving the risk of life-threatening infections, one of the most serious and costly toxicities of cancer treatment.[153] Second, neutropenia frequently results in substantial reductions in the delivered dose intensity of chemotherapy, causing even patients with curable malignancies to receive less than the planned, optimal antitumor treatment. For both reasons, good neutropenia management is essential in oncology care.

Although there are several glycoproteins with effects on neutrophil precursor cells including interleukin-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor, granulocyte colony-stimulating factor (G-CSF) seems to be the primary regulator of basal and emergency neutrophil production[154–158] as well as mature neutrophil function.[2,159–161] GM-CSF plays a critical role in pulmonary homeostasis,[162–165] and a defect in this function seems to be involved in the pathogenesis of pulmonary alveolar proteinosis.[165–167] There are also negative regulatory factors of neutrophil production that are less well understood, including neutrophil elastase[168] and the *src* family kinases.[169] Neutropenia can also result from decreased neutrophil survival associated with immune destruction, sequestration, consumption at sites of infection, and the effects of inflammatory cytokines such as tumor necrosis factor.[170]

Management

PREVENTION OF INFECTION. There are two effective strategies for the prevention of infection during myelosuppressive chemotherapy: the administration of myeloid growth factors and prophylactic antibiotics. Prophylactic antibiotics have the advantage of being less costly and the disadvantage of selection of resistant bacteria. There are three myeloid growth factor preparations currently in use in clinical practice in the United States: recombinant G-CSF (filgrastim), pegylated recombinant G-CSF (pegfilgrastim), and recombinant GM-CSF (sargramostim). In randomized, controlled clinical trials in patients receiving myelosuppressive chemotherapy for nonmyeloid malignancy, filgrastim, administered as a daily subcutaneous injection at doses of 5 μg/kg, commencing the day following chemotherapy and continued until resolution of the white blood cell nadir (usually 10–12 days of treatment), has been consistently associated with a reduction in the duration of neutropenia and in the incidence of febrile neutropenia across all cycles of chemotherapy.[171–174] The results with sargramostim, usually administered at a daily subcutaneous dose of 250 μg/kg, have been less consistent, with some trials suggesting reduction in febrile neutropenia across all planned cycles,[175,176] others not demonstrating an impact on febrile neutropenia,[177–179] and some demonstrating an effect on febrile neutropenia only during the first chemotherapy cycle.[180,181] There are some studies suggesting that the myeloid growth factor can be started later during the chemotherapy cycle or given on less than a daily basis to conserve resources.[182,183] However, in the best-powered randomized trial that has been carried out addressing the issue of late initiation of myeloid growth factor treatment, initiating filgrastim treatment once neutropenia was established was not effective in reducing infection risk.[184] There are data suggesting that a daily G-CSF dose of 2 μg/kg may be as effective as 5 μg/kg in shortening the duration of neutropenia following standard dose chemotherapy.[185]

Pegfilgrastim has a longer half life than filgrastim, particularly following the administration of chemotherapy.[186] Because pegfilgrastim is cleared by neutrophils and their precursors, its half-life is prolonged by chemotherapy, and in this setting the drug is "self-regulating" with levels persisting through the postchemotherapy nadir and until the neutrophil count begins to recover. In randomized, placebo-controlled trials in patients with nonmyeloid malignancies receiving myelosuppressive chemotherapy, pegfilgrastim given as a once-per-cycle subcutaneous dose on the day following the completion of chemotherapy was at least as effective as daily filgrastim in shortening the duration of neutropenia and reducing the incidence of febrile neutropenia.[187–189] In these comparative trials, pegfilgrastim was not associated with more toxicity, and specifically bone pain was not reported more frequently with pegfilgrastim. In a randomized, placebo-controlled trial involving patients with metastatic breast cancer, pegfilgrastim was associated with a reduction in the risk of febrile neutropenia.[190] In prior studies of myeloid growth factors, the incidence of febrile neutropenia in the control group had been relatively high, at approximately 40% or greater, and myeloid growth factor treatment was associated with a 50% reduction in this risk. In the placebo-controlled trial of pegfilgrastim, the incidence of febrile neutropenia in the control group was approximately 20%, and pegfilgrastim treatment was associated with a 95% reduction in risk. This

demonstration of efficacy of myeloid growth factor therapy at lower risks of febrile neutropenia has resulted in a change in practice guidelines, acknowledging the potential of myeloid growth factors to reduce lower risks of infection.[191,192] The issue of the cost effectiveness of myeloid growth factors used to prevent febrile neutropenia remains controversial.[193–197] Largely because of its increased convenience for patients, pegfilgrastim has become the most frequently used myeloid growth factor for the reduction of infection risk during chemotherapy. The increasing popularity of every-2-week chemotherapy regimens for the treatment of early breast cancer and lymphoma made it necessary to document the safety and efficacy of pegfilgrastim with every-2-week chemotherapy. Pegfilgrastim seems to be both safe and effective when used in this setting.[198] When chemotherapy and myeloid growth factors are administered on the same day, it is possible that myeloid progenitors will be recruited into the cell cycle while cytotoxic chemotherapy is still in their environment, with myeloid growth factors having the paradoxic effect of increasing myelosuppression.[199] Because it would be more convenient for patients, there has been an interest in exploring the administration of pegfilgrastim and chemotherapy on the same day. At the time of this writing, the preliminary results of studies of synchronous pegfilgrastim and chemotherapy are conflicting, and the safety and efficacy of this approach has not been documented. In practice, it remains prudent to administer pegfilgrastim the day following the completion of chemotherapy.

In approaching the decision to administer myeloid growth factors during chemotherapy, it is appropriate for the clinician to assess the patient's risk factors for infection, including the chemotherapy regimen being used, the patient's functional status and comorbidities, age, and the presence of open wounds.[200,201] If the risk of serious infection with the planned chemotherapy is unacceptably high, it is appropriate to use a myeloid growth factor. If the chemotherapy is being given every 2 weeks or less frequently, pegfilgrastim at a fixed dose of 6 mg administered on the day following the completion of chemotherapy is appropriate management.

Myeloid growth factor therapy is associated with both an increase in neutrophil numbers and enhanced function of mature neutrophils.[202] In animal models of sepsis, the addition of G-CSF to antibiotic treatment results in improved outcomes as compared with antibiotics alone.[203] It is therefore logical to investigate the combination of antibiotics and myeloid growth factors for the prevention of infection in chemotherapy patients at particularly high risk for infection. In one large randomized trial, the addition of filgrastim to prophylactic antibiotics (ciprofloxacin and roxithromycin) for patients receiving cancer chemotherapy was associated with a reduction in infection risk as compared with antibiotics alone,[204] although the authors raise questions regarding the cost-effectiveness of filgrastim in this setting.[205] The clinician has two options in the managing a cancer chemotherapy patient at risk of infection: prophylactic antibiotics[206] and myeloid growth factors. For patients in whom the risk of infection remains unacceptably high despite prophylactic antibiotics, the addition of myeloid growth factor therapy will further reduce risk.

TREATMENT OF ESTABLISHED NEUTROPENIA OR NEUTROPENIC INFECTION. As noted previously, the initiation of myeloid growth factors treatment late in the chemotherapy cycle, after neutropenia has already occurred, may shorten the duration of neutropenia but is not associated with a meaningful reduction in infection risk.[184] There have been several randomized trials of myeloid growth factors for the treatment of chemotherapy patients with established febrile neutropenia who have not been receiving prophylactic myeloid growth factor.[207–212] Taken in aggregate, these studies document that treatment with either filgrastim or sargramostim probably shortens the duration of severe neutropenia, but for the typical patient with uncomplicated febrile neutropenia this hematologic effect does not translate into significant clinical benefit in terms of reduction in the duration of hospitalization or parenteral antibiotic use. For the exceptional patient who is quite ill and in whom a modest reduction in the duration of neutropenia may be expected to be of benefit, the initiation of myeloid growth factor treatment is prudent. For these patients, either filgrastim at a dose of 5 to 10 μg/kg per day or sargramostim, 250 to 500 $\mu g/m^2$ per day is a reasonable treatment approach.

USE OF MYELOID GROWTH FACTORS TO MAINTAIN CHEMOTHERAPY DOSE INTENSITY. When chemotherapy is being given with the intention to cure or significantly prolong life, substantial dose reductions may compromise those therapeutic goals. Studies of charts from community oncology practices suggest that the administered dose intensity of both adjuvant breast cancer chemotherapy[213] and lymphoma treatment[214] are frequently substantially lower than the published and planned regimen, suggesting that chemotherapy dose reductions and delays are common, even when cure is the therapeutic goal. In these and other studies, myeloid growth factor treatment use was highly variable between practitioners,[215] and these agents were usually not used to maintain dose intensity. Myeloid growth factors can be used to enhance the delivered dose intensity and support the administration of full chemotherapy doses on time in these settings.[216–219] In clinical practice, when there is good evidence that a given chemotherapy regimen administered in full, planned doses given on time produces an improvement in cure rate or survival, it is prudent to use myeloid growth factors rather than dose delays or reductions to manage bone marrow tolerance and infection risk.

Leukocytosis

Leukocytosis occurs in oncology practice as a result of myeloid growth factor treatment, as a result of marrow involvement with tumor with a leukoerythroblastic pattern in the peripheral blood smear, or, rarely, as a paraneoplastic syndrome. In patients with squamous cell carcinomas, a paraneoplastic leukocytosis with hypercalcemia with or without cachexia and thrombocytosis can occur[220–225] The pathophysiology of this syndrome seems to be production of parathyroid hormone-like peptides coupled with G-CSF.[226–229] Isolated production of G-CSF can occur in any tumor and produce a neutrophilic leukocytosis[230–232]; in fact, this factor was initially discovered and isolated from the conditioned medium of a human bladder cancer cell line. In general, paraneoplastic leukocytosis does not require specific therapy; knowledge of its existence is primarily important in aiding the clinician in differential diagnosis.

DISORDERS OF PLATELETS

Thrombocytopenia

Pathophysiology

The primary regulator of the platelet count in humans is thrombopoietin,[233,234] a glycoprotein that is produced primarily in the liver and cleared primarily by platelets and their precursors. Thrombopoietin induces growth and development of megakaryocytes[235]; levels fluctuate with changes in platelet count due to variations in clearance. Interleukin-11 induces a modest increase in platelet counts but is not required for thrombopoiesis[236–240]; its primary constitutive role seems to be the maintenance of female fertility.[234,241] Thrombocytopenia that is encountered in oncology practice may be due to the effects of chemotherapy, particularly with agents such as bortezomib, gemcitabine, or ifosfamide, or after multiple cycles of treatment, liver disease with decreased thrombopoietin levels, immune destruction, particularly in patients with lymphoid malignancies or infection with the human immunodeficiency virus, and sequestration. Occasionally, patients with underlying collagen vascular diseases present with thrombocytopenia due to autoantibodies directed against the thrombopoietin receptor.[242,243]

Management

The mainstay of management has been the use of platelet transfusion to treat severe thrombocytopenia and/or bleeding patients, and treatment of the underlying cause. Recombinant interleukin-11, oprelvekin, has been shown to accelerate platelet recovery following chemotherapy and to reduce platelet transfusion burden in transfusion-dependent chemotherapy patients.[244–247] Oprelvekin is approved by the FDA for this indication. However, toxicities of this agent are substantial and include: fluid shifts, cardiac arrhythmias, optic neuropathy, and the potential for anaphylaxis; these toxicities have limited the usefulness of this drug in oncology practice. Oprelvekin is administered at a dose of 50 μg/kg per day, as a daily subcutaneous injection, commencing the day following chemotherapy and continuing until the nadir has past and the platelet count has returned to 50,000 cells/μL; the drug should be stopped 2 days before the next chemotherapy dose is given. For patients with significant renal impairment, the daily dose is reduced to 25 μg/kg/day.

The cloning of human thrombopoietin was met with hope that this would represent a safer platelet growth factor for clinical practice. Both a full-length clone (rTPO) and a truncated, pegylated preparation, megakaryocyte growth and differentiation factor (MGDF)[234,238,248] were introduced into clinical trials. Therapy with either rTPO[249–252] or MGDF[253–256] was associated with an increase in platelet counts and a reduction in the duration of postchemotherapy thrombocytopenia, without fluid shifts or arrhythmias. Unfortunately, some patients treated with MGDF developed antibodies to thrombopoietin,[257] resulting in sustained thrombocytopenia, and the development of this molecule was discontinued in the United States. For reasons that are less clear, the development of rTPO has not been completed and therefore neither agent is available for prescription in this country. However, the potential of a thrombopoietin receptor agonist to provide oncologists with a rational, safe, and effective platelet growth factor was demonstrated.

Recently, two promising thrombopoietin receptor agonists have been introduced into clinical trials. AMG 531 is a peptibody that has no sequence homology with human thrombopoietin.[258–261] Eltrombopag is an orally bioavailable member of a new class of small molecule thrombopoietin receptor agonists.[262] Neither agent would be expected to induce antibodies to thrombopoietin, and the initial results with both drugs suggest that they will be both safe and effective in increasing platelet counts.

It has been shown that immune thrombocytopenic purpura is associated with a relative thrombopoietin deficiency,[263–270] presumably because of increased clearance of this factor by the expanded platelet precursor pool.[271,272] It would therefore be expected that therapy with a thrombopoietin receptor agonist would increase platelet counts in immune thrombocytopenic purpura, and treatment with MGDF has been shown to do so.[273] Both AMG 531 and eltrombopag have shown promising results in the treatment of immune thrombocytopenic purpura.[261,274] They are also being developed for the treatment of thrombocytopenia associated with liver disease, chemotherapy, and myelodysplasia. An approach to the thrombocytopenic patient in oncology practice is shown in Figure 45-3.

Thrombocytosis

When thrombocytosis is encountered in oncology practice, it is most often due to functional or absolute iron deficiency, infection or inflammation, or hyposplenism. As noted previously, thrombocytosis can occur in conjunction with leukocytosis and hypercalcemia, as a paraneoplastic syndrome, usually occurring in patients with a squamous cell malignancy. Rarely, it can occur as an isolated paraneoplastic syndrome,[275] or as a coexisting myeloproliferative disorder such as essential thrombocytosis or polycythemia vera. In most instances the thrombocytosis does not require specific intervention. Platelet counts exceeding 800 to 1,000 cells/μL warrant a workup for a myeloproliferative syndrome, and if one is present, consideration should be given to antiplatelet therapy.

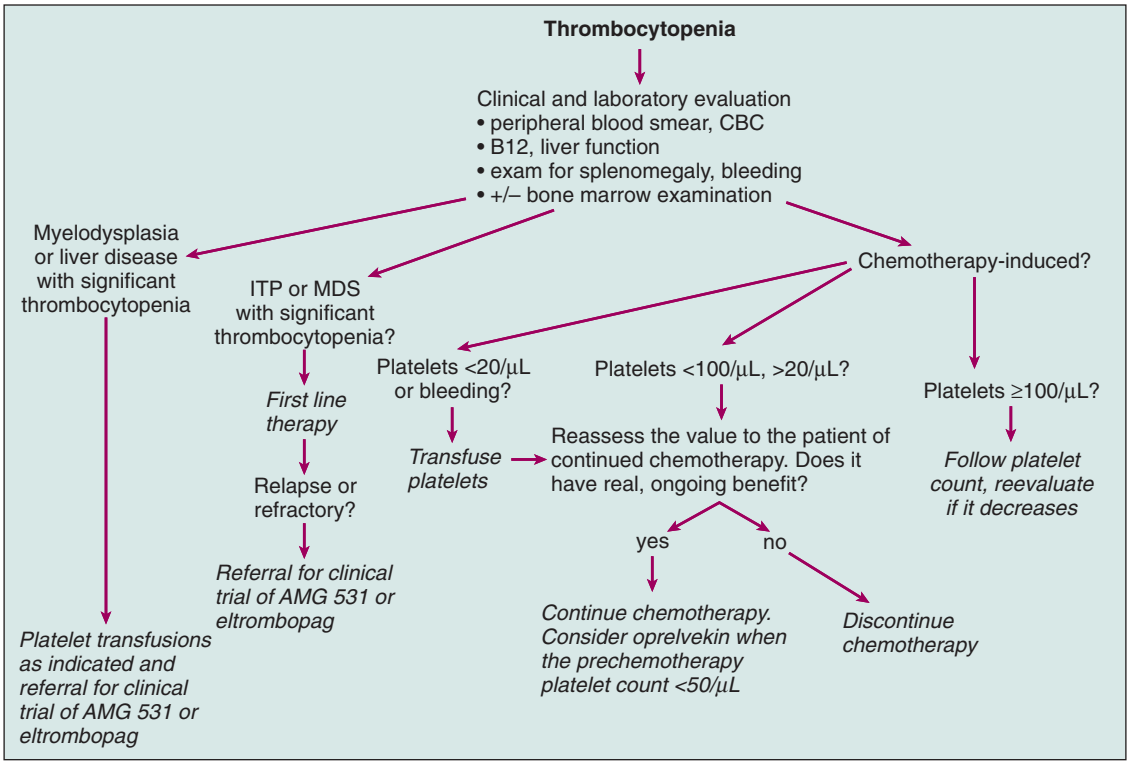

Figure 45-3 • An approach to the evaluation and treatment of thrombocytopenia in the cancer patient. B12, vitamin B_{12}; CBC, complete blood count; ITP, idiopathic thrombocytopenic purpura; MDS, myelodysplastic syndrome.

ACQUIRED MARROW FAILURE STATES

Myelodysplastic Syndrome

This syndrome is quite common in oncology practice, and usually presents as a clinically significant cytopenia. The reader is referred to Chapter 105 for a complete discussion of this topic. It is important to consider in the differential diagnosis of anemia, thrombocytopenia, or leukopenia, especially in patients who are elderly or have been treated in the past with cytotoxic chemotherapy. For the anemia that occurs in these patients, both recombinant EPO[276–285]and darbepoetin alfa[286–289] have been shown to increase Hb levels or reduce transfusion requirements in 30% to 60% of patients with low or intermediate-1 stage disease. There is some evidence that coadministration of a myeloid growth factor may enhance the erythropoietic response,[290–297] although the cost-effectiveness of this approach has been questioned.[298] It is reasonable to treat a patient with either transfusion-dependent or symptomatic anemia, who has an IPSS low or intermediate-1 stage MDS with and ESP alone or an ESP with a myeloid growth factor, and to continue this therapy if it is effective in improving clinical status and not associated with increasing thrombocytopenia or the percentage of circulating blasts.

In early clinical trials, myeloid growth factors were shown to increase the neutrophil counts[299–304] and improve neutrophil function[305,306] in neutropenic patients with MDS. Myeloid growth factors have also been used to support myelosuppressive therapy for MDS.[307,308] There is not sufficient data available to support the long-term administration of myeloid growth factors to patients with MDS, except to support the treatment of anemia. Short-term administration of myeloid growth factors to support myelosuppressive therapy or to transiently increase neutrophil counts during an infection is reasonable.

A persistent vexing problem in these patients is transfusion-dependent thrombocytopenia, and it is hoped that one of the new thrombopoietin receptor agonists will be useful and become established in this setting.

Acute Nonlymphocytic Leukemia

Patients with acute nonlymphocytic leukemia (AML) develop prolonged and profound cytopenias during induction and consolidation chemotherapy. The reader is referred to Chapter 105 for a complete discussion of this topic. The mainstay of blood cell support in this setting has been and remains transfusion of red cells and platelets. There was initial concern regarding the safety of administering hematopoietic growth factors in this setting, because of the logical concern that they may stimulate or protect the malignant clone of cells.

The initial studies of a myeloid growth factor in this setting suggested that the treatment was safe and may have promise in shortening the duration of neutropenia, the main driver of morbidity during AML treatment.[309] Subsequent studies shown that treatment with a myeloid growth factor during induction and consolidation treatment does not compromise remission rates and shortens the duration of neutropenia, with some benefit to patients, particularly those from vulnerable populations such as the elderly.[310–312] Attempts to utilize myeloid growth factors to recruit AML cells into cycle and enhance their sensitivity to chemotherapy have met with mixed results.[307,313,314]

CONGENITAL MARROW FAILURE STATES

Congenital and Cyclic Neutropenia

The congenital neutropenias are the only congenital marrow disorders for which specific treatment of the cytopenia other than transfusion has established benefit. These are rare disorders, usually diagnosed in childhood, but occasionally mild cases of cyclic neutropenia are identified in young adults. The administration of filgrastim to these patients has been shown to lead to sustained improvements in neutrophil counts and infection risk in some patients with congenital neutropenia and most patients with cyclic neutropenias.[315–317] Patients with severe congenital neutropenia frequently require relatively high doses of filgrastim,[318] and long-term treatment could be a financial burden. Fortunately, filgrastim for these patients can currently be obtained through the Chronic Neutropenia Registry (http://depts.washington.edu/registry/). For the subset of these patients with severe congenital neutropenia, with the prolonged survival that filgrastim has supported has come the development of acute leukemia in some patients. Current data suggest that these leukemias are occurring in a clone that is unresponsive to G-CSF, suggesting that they are not caused by the filgrastim treatment but instead are occurring with a higher frequency because of the prolonged survival of patients at risk for evolution to leukemia.[319–323]

CELLULAR TREATMENT OF CYTOPENIAS

Until the development of hematopoietic growth factors, the mainstay of treatment for anemia and thrombocytopenia was transfusion, and this was reserved for severe cases. Transfusions are still the preferred treatment for patients in need of a rapid increase in these blood counts. The risks of transfusion include infections (hepatitis viruses, human immunodeficiency virus, malaria, and prion-mediated illness), nonhemolytic allergic reactions, and transfusion-associated graft versus host disease. For red cell transfusions, added risks include acute and delayed hemolytic transfusion reactions and iron overload. For platelets, repeated transfusions can be associated with allo-immunization, limiting the life span and clinical benefit of future platelet transfusions. Limiting the side effects of these transfusions is an important part of oncology practice; key strategies include: (1) Transfuse only when medically necessary (Hb < 8 g/dL or severe anemia symptoms, platelets <20,000 cells/μL, or bleeding). (2) Discontinue all chemotherapy that is not associated with a benefit that more than offsets the risk of transfusions. (3) Limit the numbers of blood donors to whom the patient is exposed (use of single-donor platelets for instance). (4) Use white cell filters whenever possible. (5) Use irradiated blood products, especially when transfusing patients who have received bone marrow transplants or transfusing blood from related donors.

When granulocyte transfusions were initially attempted before the development of myeloid growth factors, they were unsuccessful, as a result of the relatively low dose of granulocytes that could be harvested and to the transmission of cytomegalovirus infection to compromised recipients. More recent trials of granulocyte transfusions harvested from filgrastim-treated donors have yielded promising results,[324,325] although in the postmarrow transplant setting human lymphocyte antigen incompatibility may limit the benefit.[326] It is reasonable to consider granulocyte transfusions, if the institution has the capability, in the acute management of neutropenic patients who have infection that is not responding to antibiotics and who are not expected to recover granulopoiesis in the near future.

Therapy with myeloid growth factors is associated with the mobilization of progenitor cells into the peripheral blood progenitor cells which can be harvested by leukapheresis. As compared with traditional bone marrow, autologous peripheral blood progenitor cells used to support high-dose chemotherapy are associated with more rapid engraftment.[327–332] Use of peripheral blood progenitor cells has made it possible to modify the dose of progenitor cells given and aided attempts to manipulate the graft.[333–336] Engraftment following these transplants is sufficiently rapid that the benefit of additional myeloid growth factor given during this recovery phase is relatively small, though safe and probably cost-effective.[337–339] The use of peripheral blood progenitor cells as an alternative to marrow is feasible in the allogeneic transplant setting as well.[340–351] Finally, myeloid growth factors can be used to mobilize and harvest dendritic cell precursors for cancer vaccine applications.[352]

46 Diagnosis, Treatment, and Prevention of Cancer-Related Venous Thrombosis

Steven R. Deitcher

SUMMARY OF KEY POINTS

- Venous thrombosis has an incidence of approximately 15% in cancer patients.
- Venous thrombosis has been identified in up to 50% of cancer patients at autopsy.
- Cancer patients with venous thrombosis at diagnosis have a worse prognosis.
- Cancer patients are more likely to have large, proximal, persistent, and recurrent venous thromboses.
- Venous thrombosis can complicate the management of any and all types of cancer.
- Malignant tumors can cause venous stasis, vascular injury, procoagulant accumulation, natural anticoagulant deficiency, and impaired endogenous fibrinolysis.
- Plasma markers of coagulation activation do not predict development of thrombosis but can assist in prognosis determination.
- Cancer-associated venous thrombosis is likely underdiagnosed because of inadequate physician suspicion, underutilization of proper objective tests, and the asymptomatic nature of many thrombotic events.
- Clinical diagnosis alone lacks sensitivity and specificity for acute venous thrombosis.
- Diagnostic imaging studies such as duplex ultrasound and lung scintigraphy may provide more false-positive and false-negative results in cancer patients.
- Cancer patients might not respond to or benefit from standard approaches to venous thrombosis management, as do patients without cancer.
- Tendencies toward thrombocytopenia, osteopenia, malnutrition, brain metastasis, hepatic metastasis, and bleeding all complicate thrombosis care in cancer patients.
- Cancer patients are more likely to manifest heparin resistance and warfarin failure and to have limited venous access to support therapeutic anticoagulant monitoring.
- Low-molecular-weight heparins are safe and effective for the short- and long-term management of venous thrombosis in cancer patients.
- Low-molecular-weight heparins are associated with lower recurrent thrombosis rates than is oral warfarin during up to 6 months of anticoagulation therapy.
- Low-molecular-weight heparins may affect survival in subgroups of cancer patients with and without venous thrombosis.
- Diagnosis should be sought by using duplex ultrasound with magnetic resonance venography, computed tomography, and venography reserved for confirmation.
- D-dimer testing is likely less sensitive and less specific in cancer patients.
- Low-molecular-weight heparins are likely to be the best drugs to minimize recurrence rates without significantly increasing bleeding complication rates.
- It is prudent to continue anticoagulation for a minimum of 6 months and until all cytotoxic therapy has been completed and no evidence of active cancer is found.
- Duplex ultrasound and venography are the mainstay of upper extremity thrombosis diagnosis.
- Upper-extremity thrombosis should be treated like lower-extremity thrombosis, with the exception of catheter-related thrombosis, which may require catheter removal.
- Helical computed tomography (CT) and lung scintigraphy are both means of objectively diagnosing pulmonary embolism. Helical CT is preferred when the chest radiograph is not normal.
- Pulmonary embolism should be treated in a similar fashion and on the basis of the same principles as lower extremity deep venous thrombosis.
- The risks of thrombolysis should be reserved for patients with hemodynamically unstable pulmonary embolism.
- Incidental findings of intra-abdominal vein thrombosis on standard CT scans should be confirmed by a more appropriate diagnostic method.
- Treatment should be the same as that for lower-extremity deep venous thrombosis.
- Superficial venous thrombosis may herald the diagnosis of cancer and should be treated with local measures such as warm compresses and analgesics.
- Patients with superficial thrombophlebitis may harbor asymptomatic deep venous thrombosis, so screening duplex ultrasound is recommended.
- Inferior vena cava filters should be reserved for patients with acute lower extremity or pelvic thrombosis who have a contraindication to anticoagulation or documented anticoagulation failure.
- Inferior vena cava filters may reduce the incidence of all pulmonary embolism in the short run after diagnosis of a deep vein thrombosis but may also increase the risk of recurrent deep vein thrombosis in the long run.
- Greater attention to prevention would reduce our need to provide thrombosis treatment to this challenging population of at-risk patients.
- Pharmacologic prophylaxis is safe and effective in a wide range of surgical and medical oncology patients and settings.

INTRODUCTION

Venous thromboembolic disease (VTE), including deep venous thrombosis (DVT) and pulmonary embolism (PE), is a common but often underdiagnosed and underappreciated clinical problem in oncology that results in significant patient morbidity and mortality. Timely and accurate diagnosis of VTE is imperative because of the unacceptable outcomes associated with a misdiagnosis. VTE diagnosis based on clinical grounds alone is unreliable, so physicians should select an appropriate objective diagnostic test to confirm or refute their clinical suspicions. Compression duplex ultrasound remains the first-line imaging test for both suspected upper and lower extremity DVT. Magnetic resonance venography (MRV) is a valid alternative when ultrasound is inconclusive. Helical (spiral) computed tomography (CT) and ventilation-perfusion (V/Q) lung scintigraphy remain the first-line imaging modalities for suspected acute PE. Spiral CT is preferred in cases of obvious pulmonary or pleural-based disease. Indeterminate initial studies should prompt performance of additional tests, possibly including the "gold standard": contrast venography and pulmonary angiography. Evidence to date suggests that D-dimer assays might be unreliable in excluding VTE in cancer patients.

Standard VTE treatment practices, including the use of intravenous unfractionated heparin (UFH) for initial anticoagulation, oral warfarin for chronic anticoagulation, and the prescription of only 3 to 6 months of total therapy, might not be optimal in the setting of active cancer and ongoing anticancer therapy. Challenges of VTE management in cancer patients include heparin resistance due to excess circulating acute-phase proteins, increased recurrence rates during and after standard-intensity warfarin therapy, limited venous access to support therapeutic monitoring, and anticoagulation intensity-independent increased bleeding rates during anticoagulation. Bleeding during anticoagulation is of particular concern in patients with disease- or chemotherapy-related thrombocytopenia, central nervous system (CNS) involvement with cancer, and recent invasive procedures. Low-molecular-weight heparins (LMWHs) have been shown to be at least as effective and safe for initial anticoagulation compared with UFH in patients with acute VTE and have gained popularity in the setting of VTE in cancer. The recently approved synthetic antifactor Xa pentasaccharide, fondaparinux, may also be an acceptable option in the cancer patient. LMWHs and fondaparinux have the advantage of less nonspecific protein binding, subcutaneous weight-based dosing without the need for monitoring in most cases, and less heparin-induced thrombocytopenia. Recent trials demonstrated efficacy superiority of select LMWHs in place of oral warfarin for long-term anticoagulation in the cancer patient.

The challenges of proper VTE diagnosis and treatment in the cancer patient are best averted by expanded use of VTE-prevention modalities. Trials have shown that medically ill patients have a high risk of VTE similar to that of high-risk surgical patients. LMWHs and fondaparinux have emerged as the premier pharmacologic agents for VTE prevention. Extended prophylaxis beyond acute-care hospitalization has a role in minimizing the total risk of VTE development. Newer oral agents may improve on the efficacy, safety, and convenience of LMWH-based prophylaxis.

This chapter addresses the diagnosis, treatment, and prevention of VTE specifically in the cancer patient population.[1–3] The potential for anticoagulant therapy to enhance cancer patient survival and the role of anticoagulants that are in development to affect cancer patient care also are addressed.

EPIDEMIOLOGY OF CANCER-ASSOCIATED VENOUS THROMBOEMBOLISM

The incidence of clinically apparent (i.e., symptomatic) VTE in cancer patients has been reported to be approximately 15%, with reported incidence rates ranging from 3.8% to 30.7%.[4,5] This is in comparison to an age-adjusted VTE incidence of 2.5% in the general population.[6] The wide range of reported incidence rates likely reflects differences in patient tumor histology, investigator level of VTE clinical suspicion, and VTE confirmation methods. Nonetheless, studies have uniformly demonstrated a higher incidence of VTE in patients with cancer of a specific organ compared with those with benign diseases of the same organ. In a Scandinavian retrospective study of more than 63,000 patients hospitalized for acute VTE, 18% had been diagnosed with cancer before the VTE.[7] A large Medicare registry study revealed that cancer patients were diagnosed with VTE at the time of initial hospitalization at a higher rate than were patients admitted for nonmalignant disorders.[8]

The risk of postoperative DVT in cancer patients after general surgery is as high as 36% and exceeds that of noncancer surgical patients by 1.5- to 3.6-fold.[9] VTE detection rates as high as 50% in autopsy series have been reported but might still not represent the true magnitude of VTE-related illness in cancer.[10] Limiting factors in the proper antemortem detection of VTE in cancer patients include an inadequate index of suspicion by many clinicians and idiosyncrasies of VTE diagnostic modalities, as will be described later.[2] The former is exacerbated by the fact that VTE is often asymptomatic, and even when symptoms are present, they are often nonspecific or mistakenly attributed to the underlying malignancy itself.

NATURAL HISTORY OF CANCER-RELATED VENOUS THROMBOEMBOLISM

Thrombosis may be a presenting feature of occult malignancy, a life-threatening component of early or advanced cancer, a harbinger of cancer recurrence, and a complication of anticancer therapy itself. Patients with cancer diagnosed at the time of acute VTE detection have a greater likelihood of distant metastases at the time of diagnosis compared with individuals without concomitant VTE [44% versus 35.1%; prevalence ratio: 1.26; 95% confidence interval (CI): 1.13 to 1.40] and significantly lower 1-year survival rates (12% versus 36%; $P < 0.001$).[7] VTE presentations in the cancer patient include symptomatic DVT, PE, superficial thrombophlebitis, central venous access device–associated thrombosis, arterial thrombosis, and nonbacterial thrombotic endocarditis. Asymptomatic VTE, although often viewed as clinically insignificant, can evolve into symptomatic VTE, and both may be particularly deleterious in the cancer patient by promoting vascular endothelial growth factor expression.[11] VTE is likely to be a common proximate cause of death in patients with solid tumors.

The natural history of VTE in the cancer patient differs significantly from that in the noncancer patient. Cancer patients are more likely than noncancer patients to present with proximal DVT.[12] Cancer patients have been shown to present with a greater initial thrombus burden, to experience greater clinical deterioration despite anticoagulant therapy, and to have less venographic improvement in response to standard treatment when compared with noncancer patients.[12]

The perception of many physicians has been that cancer patients have a greater propensity toward recurrent VTE, both during and after completion of a course of antithrombotic therapy.[13] Recent studies have substantiated the high risk of recurrence. A population-based retrospective study of 404 individuals showed that people with cancer have a twofold to threefold increased risk of recurrent VTE.[14] Antineoplastic therapy further accentuated the risk of recurrence in the cancer patient population. The 5-year cumulative incidence of recurrent VTE was 21.5% in a prospective cohort study of 738 consecutive patients with a first or second DVT.[15] The relative risk of recurrence was 1.97 in patients with cancer. Another prospective study reported an overall VTE recurrence rate of 10.3% in 58 patients with cancer compared with 4.7% in 297 patients without cancer.[16,17] The fact that cancer patients had a higher recurrence rate while

reportedly "therapeutically" anticoagulated suggests that the usual target international normalized ratio (INR) range of 2.0 to 3.0 might not be therapeutic at all. Prandoni and colleagues[18] recently reported a 20.7% (95% CI: 15.6–25.8) 12-month incidence of recurrent VTE in cancer patients with VTE compared with a 6.8% (95% CI: 3.9–9.7) 12-month incidence of recurrence in noncancer patients with VTE. The greatest risk of recurrent VTE was observed in patients with genitourinary tract, gastrointestinal tract, and lung cancers and predominantly during the first month of anticoagulation.[18]

A recent analysis of malignancy status-specific and INR range-specific VTE recurrence rates revealed that patients with VTE and malignancy ($n = 261$) have an overall thromboembolism recurrence rate of 27.1 events per 100 patient years compared with 9 recurrent events per 100 patient years in individuals with VTE and no malignancy.[19] In both patient populations, the rate of VTE recurrence was greatest during periods when the INR was 2.0 or less (the lower boundary of the target INR range). Patients without cancer had 15.9 recurrent events per 100 patient years during such periods of suboptimal warfarin anticoagulation, whereas patients with underlying malignancy had a VTE recurrence rate of 54 events per 100 patient years during similar periods of inadequate anticoagulation. Thus, it can be surmised that cancer patients are exquisitely sensitive to periods during which the INR is less than a target level of 2.0 to 3.0.

Venous thrombosis has been traditionally associated with aerodigestive tract adenocarcinomas involving the pancreas, stomach, and lungs. A closer look at DVT and PE incidence rates for different tumor histologic types, though, reveals that ovarian carcinoma, primary brain tumors, and lymphomas are among the four tumor types with the highest VTE rates.[8] This is of particular interest, considering that hematologic malignancies such as lymphoma have traditionally been viewed as coagulation-inert histologic types and management of malignancy-associated VTE has traditionally been viewed as the sole domain of the solid tumor medical oncologist. Thrombosis can affect the clinical course of all histologic types, of all stages, of all grades, and during any and all treatments.

Table 46-1 Venous Thromboembolic Event Risk Factors in Cancer Patients

TUMOR-ASSOCIATED PROCOAGULANT MECHANISMS IN THE CANCER PATIENT
Extrinsic vascular compression and invasion
Tissue factor production
Cancer procoagulant production
Sialic acid residue support of nonenzymatic factor X activation
Promotion of tissue factor production by monocytes and endothelial cells
Accentuated platelet activation and accumulation
Expression of phosphatidyl serine, which supports prothrombinase and tenase activity
Inflammation-mediated increases in factor VIII, fibrinogen, and von Willebrand factor
Impaired endogenous fibrinolysis due to excess levels of plasminogen activator-inhibitor 1
Acquired deficiencies of natural anticoagulants
NONTUMOR-ASSOCIATED PROCOAGULANT MECHANISMS IN THE CANCER PATIENT
Central venous access devices
Antineoplastic agent–induced platelet activation and endothelial cell damage
Antiangiogenesis therapy
Anthracycline-induced congestive heart failure
Immobility

CANCER-ASSOCIATED HYPERCOAGULABILITY

Different tumors of different extent, in different patients, with different comorbidities, and different inherited hypercoagulable states likely promote the development of VTE by different combinations of tumor-associated and non-tumor-associated procoagulant mechanisms (Table 46-1). Solid tumor–mediated extrinsic vascular compression and invasion can obstruct venous return, resulting in blood flow stasis, endothelial cell injury, and coagulation activation.[1] Tumor cells can directly promote thrombin generation by producing tissue factor, expressing the coagulation factor X activator known as cancer procoagulant, and by displaying surface sialic acid residues that can support nonenzymatic factor X activation. Tumor cells also can indirectly promote thrombin generation by eliciting tissue factor expression by monocytes and endothelial cells. Selected tumors may mediate an accentuation of platelet activation and accumulation, whereas other tumor cells may express surface phospholipid species such as phosphatidyl serine, which can support prothrombin and factor X activation.

Malignancy-associated inflammation can result in increased concentrations of acute-phase proteins such as factor VIII, fibrinogen, and von Willebrand factor. Whether in the setting of active malignancy or in otherwise normal patients, elevations of these acute-phase proteins are associated with an increased risk of thrombosis.[20] Tumor-associated increases in plasminogen activator inhibitor-1 can result in impaired endogenous fibrinolysis.[21] Malignancy-associated acquired deficiencies of natural anticoagulant proteins such as protein S have been described.[22] Baseline profiling of cancer patients with acute VTE found elevated levels of factor VIII, von Willebrand factor, plasminogen activator inhibitor-1, and the dilute Russell viper venom time (a specific lupus anticoagulant assay) in 17%, 71%, 34%, and 36% of patients, respectively. Deficiency of protein C, protein S, and antithrombin were found in 36%, 56%, and 6% of patients, respectively.[3] This study underscored the multifactorial pathogenesis of cancer-associated thrombosis. The variation between different cancer patients with regard to their hypercoagulable tendencies makes specific prognostic testing for cancer-associated thrombosis challenging and of limited clinical usefulness.

Although coagulation-marker testing may fall short of being able to predict which cancer patients are most apt to develop VTE, such testing might assist in prognosis determination. Beer and colleagues[23] performed a prospective evaluation of the predictive value of coagulation-activation markers for survival in cancer patients. They quantified thrombin-antithrombin complex, prothrombin fragment 1+2 (F1+2), D-dimer, fibrin monomer, and fibrinopeptide A. In general, patients with active malignancy, those with active adenocarcinoma, those with extensive disease, and those who died during follow-up (mean: 17 months) had significantly higher marker levels. A comparison of first and fourth quartiles in active cancer patients revealed significant odds ratios of death for fibrin monomer, thrombin-antithrombin complex, D-dimer, F1+2, and fibrinopeptide A of 4.1, 2.8, 2.7, 2.4, and 2.4, respectively.[23]

Non-tumor-derived VTE risk factors in the cancer patient include central venous catheters and antineoplastic agents themselves. Central venous catheters are the major risk factor for upper-extremity DVTs in the cancer patient population and can precipitate superior vena cava (SVC) thrombosis and SVC syndrome.[24,25] These DVTs may result in PE, cause catheter dysfunction, and serve as a nidus for catheter-related infection.[26] Antineoplastic agents themselves, including cytotoxic chemotherapy, selective estrogen-receptor modulators, antiangiogenic agents, and especially combinations of these drugs, are associated with an increased risk of VTE.[1,27] Thalidomide, an

immunomodulating and antiangiogenic agent, has been linked to VTE in patients with multiple myeloma, especially when combined with anthracycline antineoplastic drugs. Theorized mechanisms of antineoplastic agent-induced hypercoagulability are varied and have not been completely elucidated. Medical complications of cancer and its therapy (including congestive heart failure, major infection, pathologic fractures, extended immobility, and pre-existent VTE) can exacerbate the tendency to venous thrombosis. Common inherited risk factors for VTE such as factor V Leiden and prothrombin G20210A have not been found to be more prevalent in cancer patients with thrombosis than in the general population.[3]

CHALLENGES OF VENOUS THROMBOEMBOLISM DIAGNOSIS IN CANCER PATIENTS

Selection of the most appropriate and effective treatment for a patient's cancer depends on a timely and accurate assessment of tumor histology, disease stage, and patient performance status. In similar fashion, prescription of the most appropriate and effective treatment for a cancer patient's disease- or treatment-associated VTE is dependent on a timely and accurate diagnosis. Failure to surpass a minimum threshold of anticoagulant intensity [activated partial thromboplastin time (aPTT) >1.5 times control for intravenous UFH] within 24 hours of acute DVT diagnosis is associated with a markedly increased risk of late thrombosis recurrence.[28] It thus makes sense that patients with acute DVT in whom a proper diagnosis is significantly delayed should have similar suboptimal outcomes. Classification of venous thromboses as superficial versus deep and distal versus proximal, differentiation between acute and remote thrombotic events, and distinction between a venous filling defect and extrinsic vessel compression are required to ensure that patients are appropriately treated.

It has long been recognized that the diagnosis of DVT and PE made on clinical grounds alone is notoriously unreliable. The severity of limb edema and pain is often unrelated to the location and extent of DVT, whereas the symptoms of PE vary depending on the degree and extent of vessel occlusion, as well as on a patient's cardiopulmonary reserve. The classically described Homans' sign (calf discomfort triggered by passive dorsiflexion of the foot) has been found in only 8% to 60% of symptomatic patients with confirmed DVT and in up to 40% of symptomatic individuals without DVT.[2] Half of the patients with clinically suspected DVT do not have the diagnosis confirmed by objective testing.[2] Data from the Prospective Investigation of PE Diagnosis (PIOPED) Study revealed that dyspnea, pleuritic chest pain, cough, and lower-extremity edema, among other symptoms, were present in similar frequencies (30%–70%) among patients with or without angiographically confirmed PE. In cancer patients, the clinical diagnosis of DVT or PE is unlikely to be more accurate and may be even less accurate.

VTE is often asymptomatic or minimally symptomatic, and even when symptoms are present, they are nonspecific and can be easily attributable to the underlying malignancy. Surveys have shown that constitutional symptoms such as weakness and fatigue occur in 50% to 70% of patients in hospice or palliative care,[2] whereas dyspnea and cough occur in 25% to 50% of such patients and in more than 40% of patients with advanced cancer, respectively. The incidence of upper-extremity (UE) edema due to lymphedema in women after axillary lymph node dissection and/or radiotherapy for breast cancer has been reported to range from 6% to 30%.[2] In a series of more than 2000 palliative care patients with different types of pain syndromes, 22% and 11% had lower-extremity (LE) and UE pain, respectively.[2] None of these symptoms is unique to a particular disorder, and the etiology may be related to the underlying malignancy itself, a venous thrombotic complication, or both. Likewise, worsening dyspnea in a patient with primary or metastatic lung cancer; limb edema in a patient with bulky pelvic, axillary, or mediastinal tumor or adenopathy; and abdominal pain after colectomy or abdominal hysterectomy in patients with colon cancer or uterine cancer are a few examples in which VTE may mimic, be confused with, or be coexistent with the underlying disease. Therefore, awareness that VTE is a common complication of cancer and possession of a high index of suspicion are necessary to avoid missing a diagnosis of DVT or PE.

Compared with noncancer patients, those with cancer have a greater risk of bleeding while receiving oral anticoagulant therapy and a threefold to sixfold higher rate of recurrent VTE.[18,19] Therefore, the diagnosis of DVT and PE should not be made on clinical grounds alone, and objective diagnostic confirmation is mandatory. Failure to make a timely diagnosis of VTE can result in significant morbidity and mortality because of recurrent VTE, whereas empirical anticoagulation therapy without a confirmed diagnosis may expose the cancer patient to unnecessary and potentially avoidable risk in the absence of any tangible benefit. With the exception of cases of superficial thrombophlebitis, any signs and symptoms that are suggestive of VTE should be used not as diagnostic endpoints, but simply as a compelling reason to pursue further testing.

Although the methods that are used to confirm the diagnosis of DVT or PE in noncancer and cancer patients are the same, particular features of the underlying malignant disease may, in some circumstances, reduce the accuracy of those diagnostic methods. The presence of direct tumor invasion of blood vessels or extrinsic venous compression by a bulky tumor or adenopathy, as well as rare primary vascular tumors, may all lead to false-positive diagnoses of DVT. Likewise, primary pulmonary artery tumors and compression of a pulmonary artery or vein by tumor or adenopathy may result in impaired regional pulmonary perfusion. This might be interpreted as "high probability" or "indeterminate" for PE on V/Q lung scanning (V/Q scan) or can lead to interpretative pitfalls on helical (spiral) CT. Prior radiation therapy to the chest wall also might lead to false-positive perfusion defects on V/Q scan, whereas fluctuating platelet counts might impair the ability of nuclear scintigraphy methods to detect LE-DVT. Moreover, increased baseline D-dimer levels in some cancer patients and impaired endogenous fibrinolysis in others might at least in part explain the limitation of D-dimer assays in excluding VTE in this population. Thus, an understanding of the limitations inherent in the various diagnostic modalities and of the circumstances in which these modalities may result in false-positive and false-negative diagnosis are of the utmost importance. Because the cancer population may be subject to a higher rate of nondiagnostic, false-positive, and false-negative noninvasive tests than are patients without cancer, it is possible that many cancer patients will require more than one diagnostic test to prove or rule out conclusively a diagnosis of DVT or PE.

Historically, the diagnostic approach to DVT and PE has shifted from purely clinical (insensitive and nonspecific) and angiography-based (invasive) to being dependent primarily on noninvasive or minimally invasive imaging techniques. These newer methods are less accurate to detect calf, pelvic, and intra-abdominal DVT, as well as PE in the subsegmental branches of the pulmonary artery. As a consequence, a number of clinical management models have been reported and validated.[2,29] These models combine clinical assessment (pretest probability of DVT or PE) with noninvasive imaging tests and D-dimer assays, with the goal of reducing the need for repeated or invasive confirmatory tests but without compromising patient safety. The majority of patients who were included in these studies had a low-to-moderate pretest VTE risk, and the combination of a low pretest risk with a negative imaging test and a normal D-dimer has been shown to exclude DVT or PE safely. However, in these studies, patients with high pretest clinical probability of VTE and a negative or indeterminate initial test result almost invariably went on to undergo additional testing, including invasive studies.

Given the high incidence of VTE and the impact of such a diagnosis on cancer patients, it is our opinion that all patients with active cancer should be considered as having a "high pretest probability" or "high clinical suspicion" in models that rely on pretest clinical assessment. In addition, management models that include currently available D-dimer assays as part of the risk assessment should not be used to aid in the diagnosis of VTE in the cancer population for reasons that will be discussed later in this chapter.

CHALLENGES OF VENOUS THROMBOEMBOLISM TREATMENT IN CANCER PATIENTS

DVT and PE warrant prompt institution of antithrombotic therapy to effectively prevent thrombus propagation, embolization, and recurrence; to ameliorate patient symptoms; and to allow thrombus organization, plasmin-mediated lysis, and restoration of venous patency.[30] Specific therapy and duration of therapy in the cancer patient depend on thrombus location (e.g., iliofemoral DVT versus calf DVT), thrombus extent (e.g., massive PE versus subsegmental PE), underlying thrombosis "trigger" (e.g., major abdominal surgery versus thalidomide-based therapy for multiple myeloma), and patient comorbidities (e.g., self-limited thrombocytopenia and hemorrhagic brain metastases). Despite the special attention afforded the cancer patient with regard to other disease-related complications, such as hypercalcemia, nausea, fatigue, and pain, the recommended and most commonly used treatment of VTE in patients with active cancer is not significantly different from the regimens that are prescribed to VTE patients without malignancy. Ideally, unique features of individual cancer patients, the natural history of VTE in cancer patients, and cancer patient response to various anticoagulant agents should be noted and should affect our approach to VTE treatment in this group.

Heparin Resistance

Cancer patients, like others with acute illness and inflammatory processes, have a propensity toward heparin resistance. "True" heparin resistance causes inadequate anticoagulant and antithrombotic responses from what would otherwise be perceived as an adequate dose of heparin. Some have deemed a requirement of more than 35,000 units of heparin per 24-hour period, regardless of patient weight, to reflect this form of heparin resistance.[31] With true heparin resistance, both a measurement of anticoagulant activity such as the aPTT and a measurement of antithrombotic activity such as the antifactor Xa activity assay demonstrate inadequate degrees of heparin activity. True heparin resistance most likely results from the nonspecific binding of heparin to mononuclear white cells, vascular endothelial cells, and acute-phase protein such as histidine-rich glycoprotein, vitronectin, and platelet factor-4, resulting in an inadequate quantity of free or antithrombin-bound heparin.[1] Another potential cause of heparin resistance in the cancer patient is disseminated intravascular coagulation–associated antithrombin deficiency.

Cancer patients can also manifest an "apparent" heparin resistance characterized by dissociation between the aPTT and heparin assays.[31] In these patients, the aPTT may be normal or near normal, while the antifactor Xa activity assay reveals a heparin activity level within the therapeutic range of 0.3 and 0.7I U/mL. Simply escalating the dose of heparin to achieve the desired aPTT without checking a heparin assay can result in a pronounced bleeding risk. Dissociation between the aPTT and heparin concentration likely reflects elevated levels of factor VIII that can shorten the in vitro aPTT without affecting the antithrombotic actions of the drug.

Warfarin Failure

Warfarin failure is the term that is often used to describe the development of an objectively documented recurrent VTE, despite an apparently stable INR between 2.0 and 3.0. Such an event suggests that this degree of anticoagulation was insufficient to neutralize the sum of hypercoagulable stimuli in a given individual. Warfarin failure must be distinguished from early thrombus extension during the initial period of acute parenteral anticoagulation. Underlying cancer, because of its potent prothrombotic nature, is often suspected in the setting of warfarin failure. Patients with VTE and known cancer are at an increased risk for recurrent thrombosis compared with noncancer patients.[12,14,15,18,19,32] This may reflect cancer-associated hypercoagulability in excess of warfarin-induced anticoagulation or reflect less ability to keep cancer patients within the target INR range. Cancer patients have been shown to spend less time (43.3%) within the target INR of 2.0 to 3.0 than do control noncancer patients (56.9%) during standard warfarin anticoagulation.[1] It is likely that cancer patients spend approximately 30% of their time with an INR of 2.0 or less and 30% of their time with an INR of 3.0 or more. The remaining time is probably spent in transit between these out-of-target extremes. As Hutten and associates have shown,[19] cancer patients are at a particularly high risk for recurrent VTE when the INR is 2.0 or less. An increased frequency of therapeutic monitoring does not necessarily improve outcome in cancer patients with VTE.[1,17]

Malnutrition

Cancer patients can experience periods of excess catabolism, anorexia, corticosteroid-induced appetite stimulation, antimicrobial therapy, parenteral nutrition, and compromised hepatic function.[33] Each can affect either vitamin K supply or metabolism and thus vitamin K antagonist (i.e., warfarin) therapy. These often unpredictable aspects of the cancer patient may contribute to the greater degree of INR instability during oral warfarin therapy. An increasing number of cancer patients are relying on over-the-counter dietary supplements and herbal preparations to compensate for malnutrition, alleviate symptoms, and complement traditional anticancer therapy. Unfortunately, these preparations may contain vitamin K, vitamin K analogs, or compounds that are known to affect warfarin anticoagulation (e.g., Ginkgo biloba). Reliance on acetaminophen-containing narcotic and nonnarcotic analgesics also can affect the toxicity of oral warfarin.[34]

Thrombocytopenia

Thrombocytopenia in the cancer patient can develop for a multitude of underlying reasons. Some patients have decreased platelet production secondary to myelosuppressive chemotherapy or marrow infiltration by tumor. Others have peripheral consumption of platelets due to hypersplenism associated with Hodgkin's disease and lymphoproliferative disorders or congestive splenomegaly due to thrombosis and/or portal hypertension associated with extensive hepatic metastases. Other patients experience peripheral platelet destruction due to autoimmune clearance associated with low-grade non-Hodgkin's lymphomas and chronic lymphocytic leukemia, whereas others have consumption due to disseminated intravascular coagulation. Thrombocytopenia that develops during heparin administration for VTE prevention or treatment should be considered heparin-induced thrombocytopenia (HIT) until proven otherwise.[35] Detection of HIT in patients with pre-existent cancer-associated thrombocytopenia can be difficult. Because cancer patients may possess antiheparin:platelet factor-4 antibodies even in the absence of clinical HIT, testing should be reserved for the patient with new thrombocytopenia that develops during or shortly after a heparin exposure and without another possible explanation.[3]

The safety of administering systemic anticoagulation for any duration of time in patients with thrombocytopenia is likely dependent on the etiology and degree of thrombocytopenia, the presence or absence of concomitant platelet hypofunction, the location of primary and metastatic tumors, platelet transfusion responsiveness, and the

anticipated duration of thrombocytopenia. No exact cutoff value has been established below which it is uniformly unsafe to administer heparin, LMWH, or oral anticoagulation. The fact that diverse cutoff values of 20,000/μL, 50,000/μL, and 100,000/μL are often used reflects a lack of physician consensus about the bleeding risk associated with thrombocytopenia and a wide range of comfort levels with anticoagulation in this setting. Recent cancer-associated VTE treatment trials comparing long-term dalteparin and enoxaparin with standard warfarin anticoagulation used minimum platelet counts of 75,000/μL and 50,000/μL, respectively, as study inclusion criteria.[3,36] On the basis of thromboelastographic assessment of hematologic malignancy patients, some patients with chemotherapy-induced thrombocytopenia may even have evidence of overwhelming hypercoagulability.[37]

Bleeding Tendencies

Contemporary evidence on the risk of anticoagulation-related hemorrhage in cancer patients remains conflicting; primarily retrospective studies support a greater bleeding risk in cancer patients, and mainly prospective cohort studies suggest that the risk is no greater than that in noncancer patients. The true risk most likely depends on the temporal relationship between anticoagulation and major invasive and surgical procedures, concomitant thrombocytopenia or antiplatelet medication consumption, and the location and vascularity of cancerous lesions. Erosive, friable endobronchial, gastrointestinal, and genitourinary lesions are more likely to be prone to bleed during anticoagulation than at baseline. As in the noncancer population, older cancer patients and those with anemia, diabetes, recent myocardial infarction, renal insufficiency, history of stroke, and history of gastrointestinal bleeding are most likely at a greater risk for warfarin-associated bleeding.[38,39]

A large, retrospective, population-based study from the Mayo Clinic demonstrated that malignancy was associated with major bleeding with a relative hazard ratio of 4.26 (95% CI: 1.61–11.33) in univariate analysis and 4.07 (95% CI: 1.53–10.87) in multivariate analysis.[40] A recent retrospective analysis of 1303 patients enrolled in two large randomized, prospective trials comparing intravenous UFH with subcutaneous LMWH for initial VTE management also demonstrated a greater likelihood of major bleeding in patients with VTE and cancer.[19] The incidence of bleeding was 4.2, 2.1, and 13.3 events per 100 patient years in all patients, noncancer patients ($n = 1039$), and cancer patients ($n = 264$), respectively. The bleeding rate correlated with anticoagulation intensity in the noncancer patients but was independent of INR level in the cancer patient group. The major limitation of this study was the small total number of major bleeding events ($n = 12$). One small, prospective study revealed an odds ratio of 2.4 for bleeding in cancer patients with VTE compared with noncancer patients with VTE.[41] A recently published study revealed that the 12-month cumulative incidence of major bleeding in cancer patients treated for symptomatic DVT was 12.4% (95% CI: 6.5–18.2) compared with 4.9% (95% CI: 2.5–4.1) in treated noncancer patients ($P = 0.015$).[18] Two other prospective studies have shown that the overall and major bleeding rates noted in DVT patients with and without cancer were not significantly different. Prandoni and coworkers[16,17] reported major bleeding rates of 3.4% and 3.0%, respectively, in VTE patients with and without cancer during the first 3 months of oral anticoagulation. Overall bleeding rates in the same groups were 8.6% and 9.8%, respectively.

A recently published analysis, the largest study to date, suggests that the risk of major bleeding in cancer patients receiving oral warfarin after acute VTE is increased approximately sixfold and independent of the INR intensity.[19]

Osteopenia and Lytic Skeletal Lesions

Cancer patients, those affected by multiple myeloma and breast carcinoma in particular, are often plagued by osteopenia, lytic skeletal lesions, and pathologic fractures. Immobility as a result of chronic bone pain and fractures may promote DVT. Prolonged administration of UFH can result in osteopenia and osteoporosis in up to 30% of noncancer patients, is associated with a 1% to 2% incidence of vertebral fracture, and certainly has the potential to exacerbate cancer-associated bone loss.[42] Experimental models have demonstrated simultaneous increases in osteoclast activity and decreased osteoblast activity in response to UFH exposure. Less osteoclast activation is observed in response to LMWH exposure.[43]

Primary and Metastatic Central Nervous System Tumors

Patients with primary brain tumors and metastatic CNS lesions are at an increased risk for developing VTE and are viewed by many as having an absolute contraindication to systemic anticoagulation.[44] CNS hemorrhage is of particular concern in patients with highly vascular brain metastases, such as those from choriocarcinoma, melanoma, and renal cell carcinoma. VTE in these cancer patients may prompt the placement of an inferior vena cava (IVC) filter instead of systemic anticoagulation. Controlled CNS metastases (i.e., after radiation therapy) are often viewed as being less prone to bleed. Available limited data from several series suggest that the risk of spontaneous intracranial bleeding in patients with primary brain tumors (mainly glioblastoma multiforme) and CNS metastases might not be greater in those who receive anticoagulant therapy compared with those not receiving anticoagulant therapy.[45] A major limitation of these reports is that most studied patients received prophylactic, and not treatment, intensity of UFH or warfarin. Careful dosing and frequent therapeutic monitoring are imperative, especially in patients receiving concomitant phenytoin therapy. In the ONCENOX study, six patients with primary CNS cancer, CNS lymphoma, or CNS metastases were treated per protocol without developing minor or major bleeding or a recurrent VTE.[3,46]

Limited or Compromised Venous Access to Support Therapeutic Monitoring

Initial management of acute VTE with continuous infusion UFH requires short-term but consistent intravenous access and frequent phlebotomy for therapeutic monitoring. With regard to oral warfarin, a narrow therapeutic index and wide intraindividual and interindividual variations in degree of anticoagulation achieved with a particular dose warrant frequent therapeutic monitoring and dose adjustment. Both UFH and warfarin therapeutic monitoring are associated with cost, patient inconvenience, and patient discomfort. Because of fluctuations in nutritional status and unpredictable fluctuations in the INR in cancer patients, frequent INR monitoring (once to twice weekly) might be required. The need for frequent phlebotomy and intravenous-access insertion can result in a cancer patient having limited to no usable peripheral veins. Venous sampling via central venous catheter for therapeutic monitoring may result in false prolongations of the aPTT and prothrombin time due to sample contamination.

Persistent Hypercoagulability

Active residual cancer of any extent and active anticancer therapy of any form represent persistent hypercoagulable states. The magnitude of the prothrombotic stimulus may actually intensify with time as disease burden and metastases mount. As in other persistent hypercoagulable states, including congenital deficiencies of natural anticoagulants and chronic antiphospholipid antibodies, active malignancy and ongoing therapy should prompt an extended duration of anticoagulant therapy.

CANCER PATIENT RESPONSE TO LOW-MOLECULAR-WEIGHT HEPARINS

Several prospective, randomized, controlled trials have demonstrated the efficacy and safety equivalency of intravenous, aPTT-adjusted, UFH and subcutaneous, weight-based LMWH for the treatment of acute LE-DVT.[47–51] The major advantage of subcutaneous LMWH is that it can be self-administered at home, without the need for therapeutic monitoring. This translates into a significant reduction in mean hospital length of stay compared with UFH initial therapy (1.1 versus 6.5 days).[47] Patients may be begun on LMWH in the hospital and then discharged in an accelerated fashion to continue the bridging to oral warfarin or may be treated exclusively in the outpatient setting. A reduction in length or avoidance of hospitalization may be of particular importance in immunocompromised cancer patients who are prone to nosocomial infections. LMWH treatment does require once- or twice-daily subcutaneous injection but does not require phlebotomy for therapeutic monitoring in the majority of patients. Cancer patients might be even more adept and accepting of subcutaneous injections than are noncancer patients because of experience with self-administered hematopoietic growth factor therapy.

LMWHs are associated with less HIT than is UFH, especially in heparin-naive patients.[52] This statistic makes LMWHs particularly attractive for VTE prevention and treatment in cancer patients with disease- and chemotherapy-related thrombocytopenia in whom HIT detection may be hindered by pre-existent low platelet counts. LMWHs are associated with less osteopenia in animal models and could offer a theoretical treatment advantage in cancer patients with osteolytic lesions.[43] Osteoporosis, though, has been reported with long-term LMWH use, and an increase in spontaneous fracture has been described during long-term LMWH exposure in pregnant women.[42]

LMWHs display less nonspecific binding to acute-phase plasma proteins, platelets, mononuclear leukocytes, and endothelial cells.[51] Active cancer patients treated with LMWHs are thus theoretically less likely to experience true heparin resistance. LMWHs also have been shown to promote a small but significantly greater degree of thrombus regression and restoration of venous patency than does UFH.[12] Disadvantages of LMWHs include the inability to be completely reversed by protamine sulfate in the event of bleeding or unanticipated surgery. LMWH accumulation in patients with severe (creatinine clearance: <30 mL/min) renal insufficiency precludes its predictable use in cancer patients with renal failure.

Two early meta-analyses of randomized controlled clinical trials comparing LMWHs with UFH in patients with acute DVT demonstrated a reduction in short-term mortality in cancer patients treated with LMWH (relative risks: 0.44 and 0.33, respectively).[53,54] More recent meta-analyses demonstrated an overall survival advantage in VTE patients treated with LMWHs compared with UFH.[55,56] Much of this observed advantage was derived from a single trial comparing tinzaparin with UFH.[49,57] A total of 97 cancer patients were included in the analysis, 47 of whom received tinzaparin. Death rates at 3 months were 10.6% in those randomized to tinzaparin and 28% in those who received UFH ($P = 0.041$).[49] Proposed mechanisms for the survival advantage include tumor growth retardation, metastasis prevention, tumor neovascularization inhibition, and fatal VTE prevention.[58] If real, the survival advantage associated with LMWH is likely due to a combination of effects. Properly powered prospective randomized trials are needed to confirm the meta-analysis and preclinical experimental observations.

Kakkar and associates[59] reported on a randomized, placebo-controlled trial of dalteparin, 5000 anti-Xa units daily, in patients with advanced solid tumor malignancy without evidence of underlying thrombosis, with the primary objective of determining effect on survival at 1 year. The Kaplan-Meier survival estimates at 1, 2, and 3 years after randomization were 42%, 19%, and 13%, respectively, for placebo and 45%, 27%, and 21%, respectively, for the dalteparin group ($P = 0.29$). Although no significant early impact on survival was seen, a post hoc analysis of those surviving more than 17 months demonstrated survival estimates at 2 and 3 years after randomization of 56% and 37%, respectively, for placebo versus 77% and 59%, respectively, for dalteparin ($P = 0.04$).[59] A recent analysis of the impact of dalteparin on survival in patients with thromboembolism reported no difference in mortality at 12 months between those treated for 6 months with dalteparin and those treated with oral warfarin (56% versus 58%).[60] A post hoc subgroup analysis suggested that long-term treatment-intensity dalteparin might reduce mortality in cancer patients with nonmetastatic disease and acute VTE compared with oral anticoagulation with warfarin (20% versus 35%). In a double-blind study in 302 patients with metastatic or locally advanced solid tumors, 6 weeks of subcutaneous nadroparin resulted in a median survival of 8 months in comparison to 6.6 months in those treated with placebo.[61] The major benefit from the nadroparin was observed in the prespecified subgroup of patients with a life expectancy of greater than or equal to 6 months at enrollment.[61] In a study of 84 patients with limited or extensive stage small cell lung cancer randomized to chemotherapy alone versus chemotherapy plus once-daily dalteparin 5000 U for 18 weeks, both progression-free survival (10 months versus 6 months) and overall survival (13 months versus 8 months) were longer in the chemotherapy plus LMWH arm ($P = 0.01$ for both).[62] Larger-scale trials are needed to confirm these findings.

LMWH preparations differ in manufacturing methods, mean molecular weight, molecular weight distribution, effect on tissue factor pathway inhibitor expression, and possibly clinical effect. In part, for these reasons, LMWHs should not be viewed as interchangeable, and favorable data on one preparation do not necessarily apply to any other.

LOWER-EXTREMITY DEEP VENOUS THROMBOSIS MANAGEMENT

Diagnosis of Lower-Extremity Deep Venous Thrombosis in Cancer Patients

The LE deep venous segments that can be affected by thrombosis include, in ascending order from the ankle, the paired calf veins (posterior tibial, anterior tibial, peroneal, gastrocnemius, and soleal), the popliteal, superficial femoral, deep femoral (profunda femoral), common femoral, and external and common iliac veins. The superficial and deep femoral veins converge to form the common femoral vein in the proximal thigh. Despite its terminology, the superficial femoral vein is actually a deep vein, not a superficial vein; isolated superficial femoral vein thrombosis should therefore be treated as a DVT and not viewed as a superficial thrombophlebitis. Currently available diagnostic methods for the objective diagnosis and exclusion of lower-extremity DVT include several imaging techniques and biochemical assays (Table 46-2). Although contrast venography remains the gold standard method for lower-extremity DVT diagnosis, duplex ultrasound is the most appropriate initial diagnostic test owing to the combination of accuracy, noninvasiveness, short examination time, portability of newer equipment, and lower cost.

Contrast Venography

Contrast venography has the ability to outline the deep venous system after the injection of radiopaque contrast medium into a dorsal foot vein. A central deep venous access (e.g., popliteal or common femoral vein) is usually necessary for adequate opacification of the pelvic (iliac) veins.[2] Available contrast agents include ionic and nonionic iodinated aromatic-acid salts of varying osmolality and CO_2. CO_2 may provide an uneven intravascular distribution but is not nephrotoxic and is quite inexpensive to use. The presence of a constant intraluminal filling defect in at least two distinct projections is the

most reliable diagnostic criterion for acute DVT.[63] Nonfilling of one or more venous segments proximal to the site of injection, abrupt termination of the column of contrast at a constant site, and the presence of flow in collateral veins are indirect signs that can be caused by artifacts. Artifacts can result from improper contrast administration and flow artifacts, particularly at the common femoral vein level, when nonopacified blood from the deep femoral vein mixes with opacified blood from the superficial femoral vein.[2]

The greatest limitations of venography are primarily related to its invasiveness and need for intravenous injection of contrast medium. The procedure also requires meticulous technique as well as experienced radiologists to avoid misinterpretation of inadequate studies. Unsuccessful venograms have been reported in 2% to 20% of examinations, because of either inadequate technique with failure to outline a venous segment properly or inability to perform the test,[2] and interobserver disagreement ranges from 4% to 21%.[63] Although the deep femoral (profunda) vein is visualized only 50% of the time, isolated deep femoral vein DVT appears to be very rare.[2] Indeterminate findings also may result from the lack of visualization of the calf veins, which may occur because of nonfilling of the calf veins either because of improper test technique or occlusive DVT.[2] Other limitations include the fact that examinations cannot be performed at the bedside and are restricted to the limb where venous access has been gained.

Complications of contrast venography include postprocedure DVT in approximately 2% to 10% of examinations and superficial thrombophlebitis at the site of contrast injection.[2] Rare complications include tissue necrosis due to extravasation of contrast during injection and hypersensitivity reactions.

Nonfilling of the iliac veins during contrast venography in cancer patients with known or suspected pelvic masses neither rules in nor rules out DVT. Such finding may be due to DVT, extrinsic venous compression by tumor, or both. In one study, 51% of all high-grade non-Hodgkin's lymphoma patients who were diagnosed with VTE also had concomitant pelvic venous compression by bulky lymphadenopathy.[2] In this situation of nonvisualization of the pelvic veins, an alternative imaging method, such as CT or magnetic resonance imaging (MRI), should be considered to assess for the presence of extrinsic vascular compression.[2]

Duplex Ultrasound

A venous duplex ultrasound study combines real-time B-mode ultrasound with pulsed-color Doppler flow imaging. The former provides direct visualization of the vessels and surrounding tissues, whereas the latter detects blood flow when the emitted ultrasound energy is reflected by red blood cells and sensed at a different frequency (Doppler shift).[2] The lower-extremity deep venous segments that can routinely be examined by duplex ultrasound include the very distal external iliac, common femoral, superficial femoral, popliteal, and calf veins.

The diagnosis of DVT with duplex ultrasound relies on a combination of the following findings: vein noncompressibility, vein dilatation, visualization of echogenic intraluminal material, and lack of spontaneous and augmented blood flow.[2,64] The most widely used and reliable, validated criterion is lack of vein wall compressibility on B-mode ultrasound. The other criteria are relatively inaccurate when applied individually. Most important, however, the use of these criteria in combination does appear to increase the accuracy of the examination.[65]

Although the sensitivity and specificity of compression duplex ultrasound for acute femoropopliteal DVT have been reported to be quite high in symptomatic patients (92%–100% and 94%–100%, respectively), this method lacks adequate sensitivity when used for screening of asymptomatic individuals.[2] In addition, duplex ultrasound has been reported to lack adequate sensitivity (36%–95%) for the detection of calf DVT, despite comparable specificity (89%–100%).[2,65] A number of conditions can impair the ability of duplex ultrasound to detect calf vein thrombi, such as edema, large calf size, and the presence of open wounds, surgical bandages, or even large collateral veins, all of which lead to a high rate (10% to 40%) of inadequate examinations that impair interpretation.[2] This technical inadequacy is the likely explanation for the lower sensitivity of duplex ultrasound to detect calf DVT. Two studies comparing the sensitivities of all (adequate plus inadequate) calf examinations versus adequate-only examinations have shown sensitivities that increased from 73% and 85% to 95% and 99%, respectively.[2] In addition, the use of color Doppler has been shown to facilitate the localization and visualization of the calf veins, yielding fewer indeterminate examinations than venography in patients with isolated calf DVT.[2] Lack of color Doppler examination might explain the lower accuracy in early studies. Visualization of the calf veins by duplex ultrasound also has been enhanced by the use of an intravenous contrast agent, which in a small series led to reduction in the number of inadequate calf vein examinations from 55% to 20%.[66] Contrast ultrasound has the potential to improve the accuracy of this diagnostic modality even further.

The advantages of duplex ultrasound include the facts that it is noninvasive and that bilateral examinations can be performed in a timely fashion. Unlike venography, duplex ultrasound might also increase the overall diagnostic yield of calf examinations because of its ability to detect extravascular pathology, such as hematomas and Baker's cysts.[2]

Pitfalls of duplex ultrasound include the risk of false-positive incompressibility of the distal superficial femoral vein at the level of Hunter's (femoral) canal; the risk of setting the color gain inappropriately high, leading to "color-blossoming" that might obscure nonocclusive DVTs; and the potential to miss a DVT diagnosis in patients with duplicate venous systems or with the rare cases of isolated deep femoral DVTs.[2]

An important limitation of duplex ultrasound is the inability to perform compression maneuvers adequately in the veins above the inguinal ligament (common iliac and proximal external iliac veins). The lowest accuracy of duplex ultrasound was reported by a study that attempted to visualize and interpret iliac vein compression maneuvers routinely.[65] Although these venous segments may be visualized and interrogated for the presence of spontaneous blood flow and normal respiratory phasicity, these criteria are insensitive because normal flow may be present in cases of nonocclusive DVT. Only the distal 3 cm of the external iliac veins could be adequately visualized by one study, partial visualization of the external and common iliac veins being accomplished in 79% and 47% of the examinations, respectively.[2] Therefore, a negative LE duplex ultrasound does not rule out iliac vein thrombosis, whereas attempts to diagnose iliac vein DVT by compression ultrasound alone may lead to a number of false-positive DVT diagnoses. Conversely, the use of Doppler flow

imaging may assist in the diagnosis of pelvic vein DVT or extrinsic compression: In a study of 37 cancer patients with leg edema and negative compression ultrasound, a 100% correlation was found between a monophasic waveform in the common femoral vein by spectral Doppler and the presence of either more proximal, not directly visualized DVT or extrinsic pelvic venous compression by a mass.[67] However, this finding does not differentiate iliac DVT from extrinsic venous compression by tumor.

A controversial issue is the need for bilateral LE duplex ultrasound in patients with unilateral LE symptoms. Six studies have shown rates of isolated DVT in the asymptomatic, contralateral leg ranging from 0% to 5%, with another 2% to 22% of patients having bilateral DVT despite unilateral symptoms.[2,68,69] One study that was performed exclusively in cancer patients found that 1% of patients had DVT in the asymptomatic contralateral leg, and an additional 7% had bilateral DVT.[68] A further study that used bilateral duplex ultrasound examinations in patients with unilateral symptoms found that eight (53%) patients who had DVT in the asymptomatic limb had active cancer, and in seven of those eight patients, symptoms developed in the previously asymptomatic limb during the first month of anticoagulation therapy.[69] Of these seven, four were diagnosed with a new DVT in a previously unaffected venous segment, but three were found not to have a new DVT, illustrating the relevance of detecting symptomless DVT in the cancer population.[69] Lack of documentation of acute DVT in an asymptomatic limb could negatively affect patient management by leading to a false diagnosis of recurrent VTE and "warfarin failure" in future duplex ultrasound examinations. Thus a cancer patient should always undergo bilateral duplex ultrasound examinations for suspected LE-DVT, even if the symptoms are unilateral.[2]

Another limitation of duplex ultrasound is that the accuracy of compression maneuvers to detect recurrent DVT is uncertain. The ability to distinguish acute from remote (chronic) DVT is hampered by the fact that 50% of patients with prior LE-DVT will have some degree of residual vein obstruction.[2] Old, organized thrombi may appear hyperechoic and heterogeneous sonographically, but this might not help to differentiate acute from remote DVT.[64] Unless the new DVT is found in a previously normal venous segment, compression ultrasound could be unreliable. Although serial duplex ultrasound evaluation of vein diameters and comparison with prior ultrasound measurements has been proposed as an alternative means of diagnosing recurrent DVT (with an incremental increase in vein diameter being attributed to recent DVT),[70] this method has not been validated by a large-scale prospective comparison with contrast venography. It also is unclear whether the same protocol would be as useful in cancer as in noncancer patients.

Contrast-Enhanced Computed Tomography

CT has not been validated as a method for DVT diagnosis (i.e., no accuracy studies have been performed comparing it with the gold standard contrast venography, no interobserver variability has been formally assessed, and no validation (outcome) studies have been performed).[2,71] Therefore, it should not be routinely used for this purpose. However, because cancer patients frequently undergo body CT as a component of initial tumor staging, assessment of cancer recurrence and surveillance, or a workup for persistent fever, physicians are frequently faced with the dilemma of an incidental finding of filling defects involving the pelvic veins or common femoral veins. In this situation, it is imperative that the diagnosis be confirmed by a validated method, such as duplex ultrasound or contrast venography.[2]

The use of combined helical CT pulmonary angiography with CT venography (venous phase CT) of the pelvis and proximal legs has been studied as a means to detect DVT in patients with suspected PE.[2] The examination starts 2 to 4 minutes after contrast is injected for helical CT of the chest, and images are obtained either at 4- to 5-cm intervals or contiguously from the diaphragm to the ankles. Criteria for acute DVT include visualization of a filling defect in an opacified vein, a nonopacified segment between normally opacified proximal and distal segments, venous dilatation (when compared with the contralateral side), and venous wall ring enhancement. The sensitivity and specificity range from 71% to 100% and 87% to 100%, respectively, when compared with duplex ultrasound.

Advantages of helical CT venography include its ability to visualize the IVC, portal, ovarian, and renal veins, as well as the soft tissues, to detect the presence or absence of intra-abdominal DVT and concomitant extrinsic venous compression.[72] No formal studies have been performed to assess the usefulness of this modality in differentiating acute from chronic DVT, although possible signs of chronicity include venous wall calcification and "shrunken" vessels. A disadvantage of helical CT venography is that it requires the use of iodinated contrast and if contiguous image acquisition is used the effective radiation dose is exponentially increased. This possibility has led some to state that the use of this technique should be limited in individuals younger than 30 years.[2]

False-positive DVT diagnoses have occurred because of flow artifacts, particularly at the level of the calf and pelvic veins and also because of muscle hematomas and abscesses.[72] False-negative findings have occurred in cases of extensive bilateral DVTs, in which no normal vein enhancement in either limb is seen, so no contralateral normal vein is present for comparison, and a case of a thrombosed left-sided IVC that was misinterpreted as necrotic lymph nodes.

Although observational and accuracy studies of helical CT venography do exist, no comparisons with venography and no clinical outcome studies have been performed. The appropriateness of this technique in cancer clinical practice is unclear at this time.

Magnetic Resonance Venography

Magnetic resonance angiography (MRA) to evaluate the venous system (MRV) can be performed with time-of-flight and phase-contrast techniques. The most commonly used is an axial, two-dimensional time-of-flight technique based on standard two-dimensional gradient-echo imaging, with or without gadolinium enhancement.[2] The observed signs of acute DVT as seen by MRV include total obstruction of the vein and venous dilatation, as well as the presence of a rim of increased signal intensity surrounding the thrombus. Although one study suggested that the pattern of rim enhancement was useful in differentiating acute from chronic DVT, no correlation with contrast venography was performed.[73]

MRV has been shown to be as accurate as duplex ultrasound for diagnosing LE-DVT in three prospective studies that compared the two methods with contrast venography (100% sensitivity, 95%–100% specificity). False-positive diagnoses occurred in patients with extrinsic compression of the iliac veins. The method is less accurate when evaluating for calf DVT.

Advantages of MRV include the lack of need for intravenous iodinated contrast and the ability to assess for the presence of extrinsic venous compression when combined with soft tissue-weighted MRI and the fact that, unlike duplex ultrasound, MRV can routinely visualize the pelvic veins.[74] Disadvantages include cost and lack of wide availability.

Nuclear Scintigraphy

Activated platelets expressing glycoprotein IIb/IIIa (GP IIb/IIIa) that become incorporated into acute evolving venous thromboses serve as the physiologic target for [^{99m}technetium]-apcitide (AcuTect) in the diagnosis of LE-DVT. A phase III prospective clinical trial in 280 patients who underwent both [^{99m}Tc]-apcitide scintigraphy and contrast venography demonstrated an overall sensitivity and specificity of 76% and 73%, respectively, for imaging acute LE-DVT.[75] Higher sensitivity and specificity (91% and 84%, respectively) were seen in

patients with their first DVT event and signs and symptoms of less than 3 days' duration, and false-negative diagnoses occurred more frequently in patients with calf DVT.[75] Because [^{99m}Tc]-apcitide is a functional rather than anatomic diagnostic imaging method, it has the theoretical potential to discern acute from chronic (without activated platelets) thrombus. In cancer patients, thrombocytopenia of any etiology and tumor-associated platelet activation likely limit the usefulness of this technique for the diagnosis of acute LE-DVT.

[^{125}I]-Fibrinogen leg scanning was used mostly in the 1970s and early 1980s for the diagnosis of acute LE-DVT. It was highly sensitive (90%) for calf DVT but insensitive (60%–80%) for DVT involving the proximal veins because the isotope is a relatively low gamma emitter and because the bladder frequently contained radioactive urine. The use of this method has largely been abandoned because of its attendant risk of transmissible viral diseases and the wide availability of duplex ultrasound. In addition, [^{125}I]-fibrinogen leg scanning was never used alone for the diagnosis of acute DVT because it can take up to 72 hours to become positive. Other radiolabeled peptides under investigation for DVT diagnosis include [^{99m}Tc]-DMP 444 and [^{99m}Tc]-FDB (fibrin domain of fibronectin). A radiolabeled antibody targeted against the DD domain of fibrin also is under development.

D-Dimer

D-dimer is a cross-linked degradation product resulting from the plasmin-mediated lysis of cross-linked fibrin. Three readily available techniques are used to assay D-dimer: enzyme-linked immunosorbent assays (ELISA), plasma-based latex agglutination, and whole-blood hemagglutination (WBA) assays. Qualitative latex agglutination assays are relatively inexpensive to perform, widely available, and rapidly performed but are not sufficiently sensitive to exclude VTE. Both ELISA and WBA assays have been prospectively studied in clinical management trials and found to have high negative predictive values in outpatients with suspected VTE.[2] These studies suggest that lack of D-dimer elevation combined with a negative noninvasive imaging test reliably excludes LE-DVT, but D-dimer elevation alone neither rules in nor rules out thrombosis. In general, these D-dimer assays are excellent screening tests for VTE, but the negative predictive value of the WBA D-dimer assay has been shown to be lower in cancer patients (78.9%) than in those without cancer (96.5%).[76] Thus, it is not as useful for excluding VTE in cancer patients. Conversely, false-negative D-dimer results have been described in cancer patients with PE and baseline impaired endogenous fibrinolysis due to excessive levels of plasma plasminogen activator inhibitor-1.[21] More recently, however, both a subgroup analysis of a retrospective cohort study and a prospective cohort study showed that the negative predictive value of a new latex agglutination assay remained high and reliably excluded DVT in cancer patients.[77,78] However, confidence intervals in the latter study were somewhat wide; therefore, additional studies are needed to determine whether the D-dimer assay is truly reliable in excluding DVT in the cancer population.[78] Until conclusive evidence from larger studies is available, D-dimer assays should not be used to exclude VTE in cancer patients.

Lower-Extremity Deep Venous Thrombosis

Patients with clinically suspected LE-DVT or an incidental finding of DVT on CT should be initially evaluated with duplex ultrasound. A nondiagnostic ultrasound examination should prompt further evaluation with contrast venography. If the patient is known to have a pelvic mass and has either no opacification of the pelvic veins by venography or a monophasic Doppler signal during sonographic interrogation of the common femoral vein, MRV or CT should also be considered to rule out concomitant extrinsic venous compression. Given the high rate of VTE recurrence and "warfarin failure" in cancer patients, it is advisable to pursue contrast venography in cases of suspected DVT recurrence in which the duplex ultrasound does not detect a new DVT in a previously normal segment. Unfortunately, however, venography also has limitations in diagnosing recurrent DVT involving previously involved venous segments, and neither MRV nor CT has been validated or conclusively shown to differentiate acute from chronic DVT reliably.

Treatment of Lower-Extremity Deep Venous Thrombosis in Cancer Patients

General guidelines for VTE management have been published elsewhere.[30,79] Specific, evidence-based guidelines for VTE management in the cancer population are lacking. Analysis of recently completed and ongoing clinical trials could provide the basis for future detailed guidelines. In the meantime, cancer patients with VTE should be treated in a manner that takes the previously described unique features, subgroup analyses of prospective, randomized VTE treatment trials, and recently completed LMWH trials into account (Box 46-1).

Box 46-1. DEEP VENOUS THROMBOSIS ANTICOAGULANT TREATMENT IN THE CANCER PATIENT

Initial Phase Anticoagulant

- Acute treatment with a parenteral agent (unfractionated heparin or low-molecular-weight heparin) should be initiated in the inpatient or outpatient setting.
- Intravenous unfractionated heparin should initially be dosed on the basis of patient weight and adjusted to achieve an activated partial thromboplastin time that corresponds to an antifactor Xa activity level of 0.3 to 0.7 U/mL.
- Subcutaneous low-molecular-weight heparins should be dosed on the basis of patient weight, avoided in individuals with calculated or actual creatinine clearance rates less than 30 mL/min, and not monitored in the majority of cases.
- When using enoxaparin sodium for initial phase anticoagulation, I prefer to use 1 mg/kg twice daily instead of 1.5 mg/kg once daily.
- I prefer using a low-molecular-weight heparin rather than unfractionated heparin to facilitate outpatient management and because of evidence suggesting a possible survival advantage.

Subacute Phase Anticoagulant: Up to 6 Months

- Subacute management can consist of oral warfarin with a target international normalized ratio (INR) between 2.0 and 3.0 or once daily subcutaneous low-molecular-weight heparin without therapeutic monitoring.
- Warfarin therapy requires a minimum of 4 days overlap with the parenteral agent used for initial phase anticoagulant and can be difficult to maintain between an INR of 2.0 and 3.0 because of variable nutrition, concomitant medications, and hepatic dysfunction.
- I favor low-molecular-weight heparin because of excellent patient compliance, reduced on-treatment thrombosis recurrence rates, and a possible survival advantage.

Chronic Phase Anticoagulant: Beyond 6 Months

- Patients with persistent hypercoagulability from their malignancy, anticancer therapy, antiphospholipid antibody, or underlying inherited prothrombotic state such as deficiency of a natural anticoagulant have their subacute phase therapy extended until the persistent hypercoagulable state has resolved or completed.
- Attenuated intensity therapy with warfarin (INR 1.5 to 2.0) and low-molecular-weight heparin (primary prophylaxis intensity) are not recommended for patients with active malignancy and those receiving anticancer therapy.

Initial Anticoagulation Therapy

The mainstay of pharmacologic therapy for VTE in all patients remains anticoagulation. Initial (acute-phase) therapy typically consists of parenteral UFH or LMWH for a minimum of 4 days and until a stable, target intensity of warfarin treatment has been achieved.[79] Treatment with UFH or LMWH should be begun as soon as possible after VTE diagnosis unless an absolute contraindication exists. Whenever possible, therapy should actually begin as soon as VTE is suspected and even before diagnostic tests are obtained. A delay in achieving a therapeutic intensity of initial parenteral therapy may negatively affect a patient's long-term VTE recurrence rate.[28,80] Weight-based initial dosing of UFH (80-U/kg bolus followed by 18 U/kg/hr) with subsequent dose adjustments based on a standardized nomogram achieves a therapeutic aPTT within 24 hours of treatment commencement.[81] Because of problems with heparin resistance, greater than usual doses of UFH may be required in the cancer patient.

LMWH may be preferred for both initial inpatient and outpatient treatment of acute VTE in the stable cancer patient for the safety, efficacy, and survival reasons already discussed. The optimal LMWH preparation, dose, and dosing frequency remain to be determined. Acute DVT treatment safety and efficacy data exist for enoxaparin, 1.5 mg/kg once daily, and enoxaparin, 1.0 mg/kg twice daily, in cancer patients.[82] No statistically significant difference in VTE recurrence rate was observed between patients randomized to initial treatment with intravenous UFH, once-daily enoxaparin, and twice-daily enoxaparin. Of the 47 cancer patients randomized to the twice-daily dosing (total daily dose of 2.0 mg/kg), 3 (6.4%) developed recurrent VTE compared with 6 (12.2%) of the 49 cancer patients allocated to once-daily dosing (total daily dose of 1.5 mg/kg). This trend has led many physicians to advocate twice-daily dosing of enoxaparin for initial VTE treatment in cancer patients. The observed difference probably reflects the difference in total daily dose rather than an inherent inadequacy of once-daily dosing. This fact is important to note in considering the use of once-daily LMWHs such as tinzaparin and dalteparin. Tinzaparin, 175 IU/kg once daily, has an excellent safety and efficacy track record in cancer patients.[49] Dalteparin is given at a dose of 200 IU/kg up to a maximal dose of 18,000 IU once daily. Whether these or higher total daily doses of these two agents given as divided twice-daily injections in cancer patients would be superior to the standard dosing is not known. Concerns about underdosing cancer patients weighing more than 90 kg with standard-dose dalteparin might be justified.

Despite the excellent safety profiles of LMWHs in cancer and noncancer patients alike, initial inpatient UFH treatment may be preferred in patients who are at very high risk for bleeding and in those who are likely to require urgent invasive procedures. Such patients include those with recent surgery, gastrointestinal lesions, any past gastrointestinal or neuraxial bleeding, significant anemia, and marked thrombocytopenia. At present, cancer patients with severe renal dysfunction and most weighing more than 120 kg should be treated with adjusted-dose, monitored UFH. On the basis of a recent pharmacokinetic analysis in obese patients up to 165 kg, tinzaparin appears to be able to be dosed on the basis of actual weight without dose adjustment.[83] Patients with nonhemorrhagic CNS primary tumors or metastatic CNS lesions and VTE should be considered for anticoagulation, preferably begun in the hospital. The randomized study of enoxaparin sodium alone versus initial enoxaparin sodium followed by warfarin for a 180-day period as secondary prevention of venous thromboembolic events in patients with active malignancy (ONCENOX) trial enrolled six patients with confirmed CNS malignancy, all of whom were treated exclusively in the outpatient setting and in none of whom did recurrent VTE or bleeding complications develop.[3] Patients with hemorrhagic CNS lesions are probably best treated with IVC filter placement.

Subcutaneous fondaparinux, 7.5 mg once daily, has been shown to be as safe and effective as subcutaneous enoxaparin for the initial treatment of patients with acute DVT and adjusted-dose intravenous UFH for the initial treatment of patients with acute PE.[84,85] Specific data in patients with active cancer and VTE have not been published.

Chronic Anticoagulation Therapy

Chronic-phase anticoagulation for VTE has traditionally consisted of oral warfarin dosed to achieve an INR between 2.0 and 3.0. Cancer patients with lupus anticoagulants and baseline elevated prothrombin times may require alternative warfarin therapeutic monitoring in place of the INR.[86] Chromagenic factor X activity assays or assessment of individual vitamin K-dependent factor activity levels on dilute plasma samples are acceptable alternatives. Warfarin therapy can be started as soon as a therapeutic-intensity aPTT has been achieved with UFH or an initial weight-based dose of LMWH has been given. Bolus dosing of warfarin does not help to achieve a stable, target INR faster and might actually delay achievement of a stable INR and prolong hospitalization.[87] Initial dosing with 2.5 to 7.5 mg per day (based on patient weight and nutritional status) seems prudent. Frequent (weekly) INR monitoring might not actually facilitate a more stable INR in cancer patients but still seems prudent. Warfarin therapy alone is contraindicated in the setting of acute thrombosis because of the inherent delay in achieving therapeutic anticoagulation and the theoretical transient exacerbation of hypercoagulability caused by a rapid reduction in protein C functional activity.[87] This warfarin-induced paradoxical hypercoagulability may contribute to warfarin-induced limb gangrene in patients with HIT and to warfarin-induced skin necrosis and may be particularly troublesome in patients with hypercoagulability of malignancy.

Warfarin Failure

Patients in whom objectively confirmed recurrent VTE develops during periods of subtarget INR (≤2.0) should be restarted on treatment-intensity UFH, LMWH, or fondaparinux until a stable INR between 2.0 and 3.0 is achieved. Patients in whom objectively confirmed recurrent VTE develops despite an INR between 2.0 and 3.0 (warfarin failure) can either be treated with UFH or LMWH until a higher intensity of oral anticoagulation (INR: 3.0–4.0) is attained or be switched to primary long-term therapy with LMWH.[32,88] LMWH therapy is gaining popularity in patients with warfarin failure because of the challenges of warfarin therapy regulation at any target intensity, and data from early randomized trials suggest efficacy and safety comparability to warfarin.[1] The optimal long-term anticoagulation dose of any LMWH is not known and may be less than the dose used during initial VTE treatment. The ONCENOX trial evaluated the feasibility, safety, and efficacy of long-term enoxaparin at 1.5 mg/kg once daily and 1.0 mg/kg once daily based on this supposition.[3] In the event of warfarin failure followed by LMWH or fondaparinux failure, adjusted-dose, subcutaneous direct-thrombin inhibitor therapy with lepirudin should be considered.[89,90]

Long-Term Anticoagulation Therapy with Low-Molecular-Weight Heparin

Each of the three commercially available LMWHs in the United States has been recently studied as a substitute for oral warfarin in the management of cancer patients with acute VTE (Table 46-3).[3,36,91,92] In the randomized trial of long-term dalteparin LMWH versus oral anticoagulant therapy in cancer patients with VTE (CLOT), 8.0% of LMWH-treated patients experienced recurrent VTE during 6 months of treatment compared with 15.8% of those treated with warfarin (target INR: 2.5).[36] In the ONCENOX trial, in 3.3% of the patients treated for 180 days with one of the two once-daily doses of enoxaparin, recurrent VTE developed, compared with 6.7% of those treated with warfarin (target INR: 2.0–3.0).[3] In

Table 46-3 Long-Term Low-Molecular-Weight Heparin Therapy in Cancer-Associated Venous Thromboembolic Events

	VTE Recurrence Rate (%)	
	LMWH	**Warfarin**
CLOT (dalteparin)[36]	27/336 (8.0)	53/336 (15.8)
LITE (tinzaparin)[91]	6/101 (5.9)	11/105 (10.5)
CANTHANOX (enoxaparin)[92]	2/67 (3.0)	3/71 (4.2)
ONCENOX (enoxaparin)[3]	2/61 (3.3)	2/30 (6.7)
Total	37/565 (6.5)	69/542 (12.7)

the comparison of LMWH and warfarin for the secondary prevention of VTE in patients with cancer (CANTHANOX) trial, in 3.0% of the patients treated for 3 months with enoxaparin, 1.5 mg/kg once daily, recurrent VTE developed, compared with 4.2% of those treated with oral warfarin.[92] In the cancer subgroup of the randomized trial evaluating long-term LMWH therapy for 3 months versus intravenous heparin followed by warfarin sodium (LITE), in 5.9% of those treated with tinzaparin, recurrent VTE developed, compared with 10.5% of those treated with heparin followed by warfarin.[91] Major bleeding rates were not statistically different between the treatment groups in these clinical trials. These studies support the use of once-daily subcutaneous LMWH in place of oral warfarin in cancer patients with acute VTE to minimize recurrent VTE rates.

Duration of Anticoagulation

With regard to the optimal duration of anticoagulation in patients with VTE in the setting of cancer, it seems prudent to treat for a minimum of 6 months and at least until all cancer therapy has been completed and the patient has been deemed to have no residual malignancy. Residual malignancy constitutes a persistent hypercoagulable state, which typically warrants long-term anticoagulant treatment. Warfarin therapy itself has been shown to improve survival in patients with extensive-stage small cell lung carcinoma and a longer duration of oral anticoagulation (6 months versus 6 weeks) after acute VTE has been shown to reduce the risk of developing genitourinary tract cancers.[93,94]

The recently published study of long-term, low-intensity warfarin therapy for the prevention of recurrent VTE (PREVENT) demonstrated a 64% reduction in recurrent VTE without increased risk of major bleeding compared with placebo when warfarin with a target INR of 1.5 to 2.0 is prescribed to patients after completion of a standard course of anticoagulation for idiopathic VTE.[95] This study specifically excluded patients with known active malignancy and therefore should not be applied to this population.

UPPER-EXTREMITY DEEP VENOUS THROMBOSIS MANAGEMENT

Diagnosis of Upper-Extremity Deep Venous Thrombosis in Cancer Patients

The UE deep venous segments that can be affected by thrombosis include, in ascending order from the elbow, the brachial, axillary, subclavian, and brachiocephalic veins, as well as the SVC. Similar to LE-DVT, the prevalence of confirmed DVT is less than 50% among symptomatic patients who are suspected of having UE-DVT.[25] Therefore diagnostic confirmation by an imaging method is mandatory. In general, the same modalities that are used for the diagnostic approach of LE-DVT apply for patients with suspected UE-DVT. However, no formal studies of helical CT venography, nuclear scintigraphy, or impedance plethysmography have been performed to diagnose DVT in the upper extremities, and as was previously discussed, D-dimer assays should not be considered reliable for the exclusion of DVT in a patient with cancer.

Contrast Venography

A number of anatomic variants and the converging nature of the central venous anatomy in the UE can lead to flow turbulence artifacts that can complicate the interpretation of UE venography.[2] In addition, because the technique is usually performed by contrast injection in an antecubital vein, it does not visualize the internal jugular veins, which can be easily visualized by duplex ultrasound. Similar to its applicability in the lower extremities, the single most reliable criterion for acute DVT is the presence of a constant, intraluminal filling defect in at least two different projection views. The complications related to the use of contrast medium are infrequent and similar to those described for LE-DVT. However, no data are available on the incidence of DVT after venography in the UEs.

Duplex Ultrasound

The internal jugular, subclavian, axillary, and brachial veins can be routinely visualized in the neck and arms. However, the medial two thirds of the subclavian veins are not easily compressible because of their anatomic location behind the clavicles.[2] In addition, it is not technically feasible to perform compression maneuvers at the level of the brachiocephalic veins and the SVC; in fact, the right brachiocephalic vein and the SVC are usually not visualized by ultrasound examination. Even if these segments of the subclavian veins and left brachiocephalic veins are visualized, duplex ultrasound has not been validated for the detection or exclusion of DVT in these locations because the diagnosis cannot be established by the compression method. Rather, DVT in those locations is suggested by indirect Doppler-flow criteria, such as lack of diameter change with inspiration and incomplete color filling of the lumen, and by the presence of echogenic material on B-mode ultrasound imaging.[2]

The sensitivity and specificity of duplex ultrasound for the diagnosis of acute symptomatic axillosubclavian DVT range from 96% to 100% and from 94% to 100%, respectively.[2,25,96,97] Studies of the accuracy associated with other sonographic criteria than vein compressibility have been found to possess a lower sensitivity of 50% to 73%.[96] The presence of an indwelling catheter in an UE vein has been shown not to alter significantly the Doppler-flow dynamics compared with the contralateral vein that does not have a catheter in place. Nevertheless, duplex ultrasound appears to be unreliable as a screening method to diagnose asymptomatic, catheter-related UE-DVT.

Other Imaging Modalities

Neither contrast-enhanced CT nor MRV has been validated in evaluating the UEs, including the SVC. CT is not an ideal method because the convergence of the central veins in the upper chest is frequently associated with flow artifacts. Thus, the diagnosis of any suspected SVC or innominate DVT found by CT should ideally be confirmed by contrast venography. No studies have reported on the use of helical CT venography for central chest veins.

Two early studies (28 and 25 arms examined, respectively) correlating MRV with contrast venography for the diagnosis of acute axillary-subclavian DVT found a sensitivity and specificity of 80% and 100%, respectively.[98,99] However, in one study, the sensitivity for nonocclusive DVT was quite low (20%) in comparison with the one for occlusive DVT (80%).[98] Nevertheless, MRV appears to be very accurate in detecting conditions that may be associated with UE or central chest vein extrinsic compression or stenosis. Two studies in

selected patients with UE central venous abnormalities showed 100% correlation between 3D, gadolinium-enhanced MRV, and contrast venography for detecting SVC and brachiocephalic vein stenosis or compression.

Treatment of Upper-Extremity Deep Venous Thrombosis in Cancer Patients

Central venous catheter–associated DVT has been described in up to 56% of patients with indwelling catheters.[100] These "UE" DVTs may result in SVC thrombosis, SVC syndrome, and PE. The true risk of PE from central venous catheter–associated thromboses is often debated. Prandoni and coworkers and Bernardi[25] reported a 36% rate of PE complicating UE DVT; Monreal and colleagues[101] reported a 16% rate of PE in this setting. Ault and Artal,[102] in contrast, suggested that PE is uncommon in patients with central venous catheters based on a lack of any PE in 33 of their patients with DVT due to peripherally placed central catheters. In patients with symptomatic central venous catheter–related DVT and a functional catheter, line removal is often unnecessary. Anticoagulation management following the same guidelines as for LE-DVT in the cancer patient is recommended. Continuation of anticoagulation for the life of the catheter seems reasonable. This management approach allows uninterrupted cancer treatment and prevents the need for additional vascular-access surgery. Central venous catheter–related DVT in conjunction with a dysfunctional catheter usually warrants anticoagulation and line removal. Thrombolytic therapy followed by anticoagulation may alleviate thrombosis-related symptoms more quickly and completely than anticoagulation alone. Randomized trials comparing thrombolysis with anticoagulation for central venous catheter–associated DVTs are lacking.

PULMONARY EMBOLISM MANAGEMENT

Diagnosis of Pulmonary Embolism in Cancer Patients

Currently available tests for the diagnostic confirmation or exclusion of PE include various imaging methods and blood-based biochemical assays (Table 46-4). Although many believe that pulmonary angiography is no more accurate than helical CT, pulmonary angiography remains the gold standard diagnostic test for PE. However, helical CT and V/Q lung scanning are the most appropriate initial tests because they are noninvasive and widely available.

Pulmonary Angiography

Pulmonary angiography is typically performed via common femoral vein access (or internal jugular or brachial vein) and can include selective catheterization of either or both the right and left main pulmonary arteries. The pulmonary vascular tree is then visualized after an injection of iodinated contrast medium.

On the basis of clinical-outcome studies, the sensitivity and specificity of pulmonary angiography have been estimated to be 98% and 97%, respectively.[2,30,103] The specificity of pulmonary angiography approaches 100% when a filling defect or abrupt "cut-off" of a pulmonary artery branch is present.[103] Ancillary findings that may be present but are not specific for PE include abnormal distribution of flow to the different lobes, delayed venous return, and partially opacified, tortuous vessels.[103] The accuracy of the test is not influenced by the presence of chronic obstructive pulmonary disease.[103] In the PIOPED study, interobserver disagreement occurred more often for the exclusion of PE (17%) than for PE confirmation (8%) by pulmonary angiography.[104] Experts agreed 98%, 90%, and 66% of the time on the presence of lobar, segmental, and subsegmental PE, respectively.[105]

Complications reported with pulmonary angiography include minor and major complications as well as death. These three endpoints were observed in 5%, 1%, and 0.5%, respectively, of 1111 patients who underwent pulmonary angiography in the PIOPED study.[105] A review of more than 7000 patients undergoing pulmonary angiography revealed a 0.1% death rate with the procedure.[106]

Table 46-4 Tests for the Objective Diagnosis or Exclusion of Pulmonary Embolism

Pulmonary angiography
Ventilation-perfusion lung scintigraphy
Helical (spiral) computed tomography
Magnetic resonance angiography
D-dimer semiquantitative and quantitative assays

Ventilation and Perfusion Lung Scintigraphy

V/Q lung scanning combines ventilation and perfusion nuclear medicine imaging techniques. The ventilation (V) study involves the inhalation of a radioactive gas (e.g., xenon), which provides an image of all ventilated portions of the lung. The perfusion (Q) study consists of an intravenous injection of [^{99m}Tc]-labeled macroaggregated human serum albumin particles with the patient in supine position, and the particles become trapped in approximately 0.1% of the pulmonary capillary bed.[103] Any obstruction to arterial flow is viewed as an area of hypoperfusion and is called a "perfusion defect" on gamma-camera images. The presence of multiple segmental perfusion defects increases the test specificity for PE.[103] On the basis of the presence and extent of matched (absence of both perfusion and ventilation) and unmatched (absence of perfusion but preserved ventilation) defects, the V/Q scan can be interpreted by using PIOPED published criteria as either normal or low probability, intermediate probability, or high probability for PE.[104,107]

Because they provide indirect evidence of PE, V/Q scans are most clinically useful when considered in combination with an assessment of pretest clinical suspicion.[104] On the basis of PIOPED data, a normal V/Q scan essentially rules out clinically significant PE, and a high-probability V/Q scan alone has a high positive predictive value (88%) for PE, with 96% of patients with high pretest clinical suspicion and a high-probability V/Q scan having PE documented by pulmonary angiography.[104] Only 4% of patients with both low-probability V/Q scan and low clinical suspicion had PE on angiography.[104] Low- and intermediate-probability scans are now considered together as being "indeterminate" scans.

A plain chest radiograph is necessary before interpretation of a V/Q scan. Pleural effusions, bullous disease, pulmonary infiltrates or masses, and atelectasis have been associated with a higher frequency of indeterminate-probability scans and with a lower positive predictive value of high-probability findings.[103]

V/Q scan has the advantage of not using iodinated contrast. Its greatest limitation as a diagnostic tool for PE is that it provides a definitive result in a minority of patients. In the PIOPED series, only 13% had a normal study, and 14% had a high-probability scan.[104] Therefore, it can be expected that as many as 73% of all patients undergoing a V/Q scan will have a nondiagnostic, indeterminate scan that warrants further testing such as pulmonary angiography to confirm or exclude PE. In addition, it has been demonstrated that the rates of nondiagnostic V/Q scan findings increase significantly, from 21% to 63% in patients without chronic obstructive pulmonary disease to 46% to 91% in those with chronic obstructive pulmonary disease and from 9% in patients with normal chest radiographs to 48% in patients with abnormal chest radiographs.[108,109]

Pitfalls in the interpretation of V/Q scintigraphy may represent a significant problem in the cancer population, particularly when primary or secondary (metastatic) pulmonary involvement is present. Patients with a history of PE may have a high-probability V/Q scan that does not reflect a new, acute event but rather the remnants of old PE.[103,104] False high-probability scans may occur as a consequence of an abnormal perfusion scan due to pulmonary artery invasion or compression, regional hypoventilation secondary to bronchial compromise, pulmonary vein obstruction by hilar masses or adenopathy, and pulmonary leukostasis, which have been described in lymphoma, osteosarcoma, neuroblastoma, lymphangitic carcinomatosis, lung carcinoma, carcinoid, left atrial leiomyosarcoma, metastatic renal cell carcinoma, pulmonary artery sarcomas, and acute myelogenous leukemia.[2] Areas of V/Q mismatch also have been described as a result of prior radiation therapy to the chest in patients with breast and lung carcinoma.[2,110]

Helical (Spiral) Computed Tomography Angiography

Contrast-enhanced spiral CT is performed by scanning a distance of 10 to 12 cm from the aortic arch to 2 cm below the inferior pulmonary veins during a single 30-second breath hold while the pulmonary vasculature is opacified by the automated injection of iodinated contrast medium. Technical parameters such as collimation, rate and timing of contrast administration, and scanning delay, as well as breathing, motion artifacts, and even central venous catheters, can influence the timing and quality of opacification of the pulmonary arteries, thus having the potential to compromise the quality of the study.[2,103] The rate of studies that are inadequate for interpretation ranges from 2% to 13%.[2,108]

Spiral CT has an overall sensitivity of 53% to 100% and specificity of 78% to 100% for the diagnosis of PE.[2,30] These rates approach 95% to 100% for the central and segmental pulmonary arterial branches, but are lower (sensitivity: 53% to 63%) for PE involving the subsegmental branches. The accuracy of helical CT is highly influenced by, and dependent on, the equipment being used. Earlier CT scanners included 5-mm collimation that resulted in an effective section thickness of 6.57 mm and imaging reconstruction at 3-mm intervals.[2,111] Many currently available CT scanners include 2- to 3-mm collimation, resulting in effective section thickness of 2 to 4 mm and improved visualization of the subsegmental arterial bed. The newest-generation multislice CT scanners allow subsecond scanning with 1.25-mm collimation, 1.25-mm section thickness, and image reconstruction at 0.6-mm intervals. Although these modern scanners also have been shown to improve visualization of subsegmental arteries significantly, two recent studies disagreed on whether this improved visualization led to higher detection rates of subsegmental PE.[112,113] In addition, the use of workstations for image viewing and primary interpretation has been shown to increase the detection of PE by 25% in comparison to hard-copy image viewing.

Studies with the highest frequency of isolated subsegmental PE, and hence the lowest spiral CT sensitivity, have been reported in patients who also had nondiagnostic V/Q scans, and studies have shown that the prevalence of subsegmental PE ranges from 6% to 36%.[2,114] Whether subsegmental PE is clinically relevant and should definitively be detected remains a controversial matter. A total of six prospective management studies have been performed with spiral CT in patients with indeterminate V/Q scan findings.[115–120] In five of these studies, patients with a negative helical CT also underwent LE duplex ultrasound, anticoagulation being held after a negative result. Follow-up periods ranged from 3 to 6 months, and rates of recurrent VTE ranged from 2% to 4%. The only study that withheld anticoagulation on the basis of a negative helical CT alone reported a 1% rate of VTE recurrence in patients with low pretest probability for PE. Because these studies did not rely on a negative CT alone before withholding anticoagulation and because the sensitivity of helical CT is low in patients with nondiagnostic V/Q scans, the current evidence is insufficient to rely on a negative helical CT alone to justify withholding anticoagulation and even to support the hypothesis that subsegmental PE is not clinically significant.

The major advantages of spiral CT include the rapid nature of data acquisition and the lower percentage of nondiagnostic studies due to its ability to evaluate vascular as well as nonvascular intrathoracic structures simultaneously and provide an alternative diagnosis that either suggests or supports the final clinical diagnosis in 26% to 67% of examinations.[2] Although some studies have suggested that the presence of such alternative diagnoses adequately excludes PE, other studies have shown that the frequency of alternative diagnoses was the same in patients with and without confirmed PE.[121] Therefore, even the presence of an alternative explanation of the patient's symptoms does not necessarily imply that it is safe to withhold anticoagulation, and pursuit of pulmonary angiography might still be appropriate in such patients.

Magnetic Resonance Angiography

MRA is a promising technique in patients with suspected PE, particularly with the use of 3D, gadolinium-enhanced imaging.[2,103,122] The sensitivity and specificity of MRA for the detection of PE are 50% to 100% and 95%, respectively.[122,123] The sensitivity is less than 50% for subsegmental PE, and overall accuracy is highly dependent on the technique and experience of the interpreting physicians.[123] In cases of suspected pulmonary artery sarcoma, MRI appears to be more useful than CT because the presence of gadolinium enhancement suggests tumor instead of thrombus.

Echocardiography

The sensitivity and specificity of the transesophageal echocardiogram for the detection of central pulmonary artery PE range from 76% to 97% and from 77% to 100%, respectively, when compared with helical CT.[124] However, the sensitivity for peripheral PE is lower.[124] Echocardiography currently appears to be most useful in assessing patients who are hemodynamically unstable, are unable to undergo helical CT or V/Q scan, and need to have a workup initiated at the bedside.

Pulmonary Embolism Diagnosis in Cancer Patients

When a cancer patient is suspected of having PE, a chest radiograph should be performed to exclude other conditions that might require immediate intervention, such as a central line–related tension pneumothorax, pulmonary hemorrhage, and malignant pleural effusion. However, the chest radiograph should not be used as a means of supporting or refuting the need for specific diagnostic testing for PE. Helical CT is probably best indicated when the chest radiograph is abnormal and in individuals with known pulmonary disease. Alternatively, if the chest radiograph is normal, a V/Q-scan approach also is appropriate, but it is important that physicians clearly establish and document their pretest clinical suspicion of PE. Otherwise, PIOPED probability criteria may not be applicable. Regardless of the initial diagnostic approach, an indeterminate or negative initial test result should be followed by a duplex ultrasound of the legs and possibly of the arms as well, particularly in patients with symptoms of pain and swelling or who have an indwelling catheter. A positive duplex ultrasound does not confirm PE, but detection of acute DVT will prompt and justify systemic anticoagulation. In the cancer patient who is suspected of having PE, the combination of a nondiagnostic helical CT or V/Q scan with the absence of acute DVT by duplex ultrasound warrants the performance of pulmonary angiography. In this clinical setting, the risks of pulmonary angiography are sufficiently low and are outweighed by the benefits. Pulmonary angiography also is indicated in the setting of a normal spiral CT alone, particularly with a high pretest suspicion.

Treatment of Pulmonary Embolism in Cancer Patients

Most cancer patients with symptomatic PE should be treated with anticoagulation by following the same guidelines for treatment that are applied to DVT.[1,51,85,125] Initial inpatient intravenous UFH is recommended in symptomatic patients with extensive PE. Some patients, including cancer patients, with PE may derive benefit from thrombolytic therapy to degrade actively the thrombus obstructing the pulmonary vasculature. Clear indications for PE thrombolysis are debated.[126] Thrombolysis has been demonstrated to improve survival in patients with massive PE plus shock and is probably indicated in these patients regardless of cancer status. When compared with anticoagulation alone, thrombolytic therapy results in more rapid thrombus lysis, an early improvement in pulmonary blood flow, and improvement of right ventricular function.[127] However, these improvements in cardiopulmonary function alone have not resulted in decreased mortality in stable patients without significant hemodynamic compromise.[128,129] Thrombolysis is contraindicated in any cancer patient with significant transfusion-refractory thrombocytopenia, active bleeding, and CNS lesions.

INFERIOR VENA CAVA AND INTRA-ABDOMINAL DEEP VEIN THROMBOSIS MANAGEMENT

Diagnosis of Inferior Vena Cava and Intra-abdominal Deep Vein Thrombosis in Cancer Patients

Many cancer patients undergo serial imaging with CT as a means of assessing cancer-therapy efficacy, disease stage or progression, and nonspecific abdominal symptoms. Incidental findings of what appears to be a DVT should not affect patient treatment and prompt the placement of an IVC filter. Prompt and proper diagnostic imaging is especially needed in such a situation.

Contrast Venography

Popliteal or common femoral vein access is the most appropriate approach for performance of contrast cavography. Access through an internal jugular vein might be necessary in some circumstances. Contrast venography is the reference standard to show the presence or absence of IVC or renal vein thrombosis conclusively, and the same criteria that are used to diagnose LE- and UE-DVT by venography apply to the IVC. However, in cancer patients not all intraluminal filling defects represent thrombus, and the distinction between intravascular tumor and thrombus might require further investigation with CT or MRI and, in some selected cases, with transvenous catheter-guided biopsy. Likewise, if the column of contrast does not opacify the IVC, CT or MRI is indicated to assess for the presence of extrinsic compression or invasion by tumor. The diagnosis of portal, mesenteric, or ovarian vein thromboses by venography is more challenging because of limited ability to perform selective contrast injections.

Duplex Ultrasound

No studies have validated the use of duplex ultrasound for the detection of IVC thrombosis (i.e., duplex ultrasound has never been compared with the gold standard contrast venography, nor has it been subject to accuracy or management studies in this setting). Although visualization of the IVC and interrogation of its lumen for Doppler-flow measurements have been described in studies that imaged the IVC before IVC filter placement,[2,130] compression maneuvers are not technically feasible in the abdomen, and the indirect signs of impaired flow and loss of flow phasicity are not specific for IVC thrombosis. Moreover, duplex ultrasound cannot differentiate IVC thrombus from tumor, except in cases of suspected portal vein invasion by tumor. In this setting, color Doppler ultrasound can be a reliable diagnostic tool.[131]

Contrast-Enhanced Computed Tomography

CT remains a nonvalidated method to assess for the presence of thrombus in the IVC. Indirect signs that have been described in cases of IVC thrombosis include IVC enlargement, reduced IVC lumen density compared with that of the aorta, and rim enhancement. However, these signs may occur as a result of contrast flow phenomena mimicking an intraluminal filling defect and also have been described in patients with renal cell or adrenal cortical carcinoma extending into the renal veins and IVC, producing a "tumor thrombus."[132–136] Although spiral CT venography has been shown to visualize the intra-abdominal veins accurately, no formal studies have been published. Any incidental finding of an IVC or renal vein "filling defect" by CT should ideally be confirmed by venography and not prompt the initial placement of an IVC filter.

The previously mentioned features also are used in the diagnosis of portal and mesenteric vein thrombosis by CT.[137] These signs are of little value in a patient with a history of portal vein thrombosis who is suspected to have a recurrent event. Although the true sensitivity of contrast-enhanced CT in diagnosing portal vein thrombosis is unknown, its specificity has been suggested to be quite high. The presence of cavernous transformation—a "masslike" network of collateral veins—is suggestive of remote portal vein thrombosis.[137]

Only one retrospective case series pertaining to the diagnostic imaging of ovarian vein thrombosis in cancer patients has been published.[138] In this small study, none of the six patients with ovarian DVT had the related CT findings of uterine enlargement and other pelvic masses that are typically described in larger series of patients with puerperal ovarian DVT. Similar to portal DVT, these indirect CT signs are not useful in a patient with a history of ovarian vein thrombosis, because at least half of the patients will not have normalization of the original CT findings after 3 months to 2 years after the index event.[139]

Magnetic Resonance Venography

MRV is currently considered the diagnostic method of choice for diagnosing IVC, renal, and portal vein thrombosis, particularly when spin-echo and cine MRI techniques are used in combination. In a small series of 26 patients with puerperal ovarian DVT, MRV had 100% sensitivity and specificity.[139] Spin-echo MRI may help to differentiate acute from chronic thrombus on the basis of differences in patterns of signal intensity.[140]

Artifacts created by flow phenomena may cause signal voids at the junction of the renal vein and the IVC because this is an area of slow and convergent blood flow. This can lead to a false-positive diagnosis of IVC thrombosis.[141] MRI also is limited in distinguishing true portal DVT from tumor invasion of the portal vein unless an adjacent mass is seen.

The rare IVC leiomyosarcoma appears to be equally demonstrated by CT or MRI, although MRI is superior because it seems to be capable of differentiating tumor (homogeneous, intermediate signal intensity on T_1-weighted images, and high signal intensity on T_2-weighted images) from thrombus (hyperintense on T_1- and T_2-weighted images).[142–144]

Treatment of Inferior Vena Cava and Intra-abdominal Deep Venous Thrombosis in Cancer Patients

No specific guidelines exist for the treatment of IVC and other intra-abdominal DVT in the cancer patient or noncancer patient. Whether to use standard anticoagulant therapy as is used for proximal LE-

DVT or catheter-directed thrombolytic therapy depends on the extent of thrombosis, patient symptoms, and patient bleeding risk. Patients with acute, complete IVC occlusion may develop significant bilateral LE swelling and pain and are at risk for phlegmasia cerulean dolens (venous limb gangrene). Such patients could benefit most from pharmacologic or mechanical thrombolysis. Long-term anticoagulation is likely warranted.

SUPERFICIAL THROMBOPHLEBITIS MANAGEMENT

Diagnosis of Superficial Thrombophlebitis in Cancer Patients

Superficial venous thrombophlebitis (SVT) is the only manifestation of venous thromboembolic disease that does not require objective diagnostic imaging. The diagnosis can be made clinically by the detection of a palpable tender cord in the course of a superficial vein; the induration of the vein is usually associated with erythema of the overlying skin. The clinical differential diagnosis includes sarcoidal granulomas, Kaposi's sarcoma, and lymphangitis.

Duplex ultrasound should be considered to rule out concomitant DVT, particularly when the greater or lesser saphenous veins are involved. The most common location for progression from SVT to DVT to occur is at the junction between the greater saphenous vein (a superficial leg vein) and the common femoral vein (a proximal deep leg vein). Proximity of an SVT to the junction between the involved superficial vein and its connection to the deep venous system does not seem to affect the likelihood of PE. The rates of DVT in patients with clinical signs and symptoms of isolated SVT have been reported to range from 6% to 57%, and the rates of symptomatic PE have been reported to range from 4% to 10%.[145–150]

Trousseau's syndrome or migratory thrombophlebitis was initially described in patients with mucin-secreting carcinoma of the gastrointestinal tract. It is unclear whether the "thrombophlebitis" in many of the reported cases was manifested as SVT or DVT. The SVT related to Trousseau's syndrome typically was first seen as multiple tender nodules, which progressed to form palpable cords, usually involving the bilateral LEs and, on occasion, the UE veins and the abdominal wall veins as well.

Treatment of Superficial Thrombophlebitis in Cancer Patients

Typically, nonsteroidal anti-inflammatory drugs and warm compresses are adequate treatment for SVT symptom control. When the deep system is involved or symptomatic pulmonary embolism is diagnosed, standard anticoagulant therapy is indicated. Because of the reported high rate of progression from SVT to DVT, many physicians treat SVT with anticoagulants for a variable time. Anticoagulants such as UFH and LMWH may help to relieve symptoms related to vessel inflammation but are probably best reserved for individuals with recurrent SVT or documented DVT. Serial ultrasound to detect meaningful SVT progression seems prudent in selected cases such as those with SVT already at the saphenofemoral junction.

INFERIOR VENA CAVA FILTERS

IVC filters are often placed in cancer patients with acute VTE, especially in the settings of thrombocytopenia, active bleeding, and CNS malignancy.[151–154] Limitations to IVC filters include technical difficulties during insertion, insertion-site hemorrhage or thrombosis, caval thrombosis, and obstruction below the filter, filter change of position (migration or tilting), caval erosion and perforation, and filter failure.[154] IVC filters obviously play no role in the management of UE-DVT. SVC filter placement has been shown to be technically feasible, but outcome data are lacking.[155] A recent study published by Decousus and associates[155] addressed the impact of IVC filter placement on PE prevention and DVT recurrence rate. All patients had proximal DVT, and all received anticoagulation. Placement of an IVC filter conferred a significant benefit in preventing PE within the first 12 days after DVT, with PE developing in 4.8% of patients without filters compared with 1.1% of patients with filters ($P = 0.03$). At 2 years' follow-up, however, the benefit was no longer statistically significant with regard to symptomatic PE prevention. Moreover, at 2 years, those patients with prophylactic filter placement had a higher risk of DVT recurrence than did those who did not have a filter placed (20.8% versus 11.6%; $P = 0.02$).[155] These findings underscore the need for caution in placing filters, especially when patients are receiving cancer treatment with a curative intent, and long-term survival is contemplated. When a filter is placed because of a transient contraindication to anticoagulation, appropriate pharmacologic therapy should be commenced once the contraindication has passed.

VENOUS THROMBOSIS PREVENTION IN THE CANCER PATIENT

The relation between cancer and clinical thrombosis has been recognized for more than 150 years. The concept of and an appreciation of thromboprophylaxis have been widely accepted, primarily in the surgical setting, for more than 25 years. However, only in the last decade has the widespread application of thromboprophylaxis to patients with cancer begun to receive significant attention from the medical community. One of the observations driving this level of interest is the expanding body of data suggesting that the connection between thrombosis and cancer may well be bidirectional.

In the not-too-distant past, the prevailing opinion was that cancer caused thrombosis and that, although it was a regrettable complication, thrombosis did not significantly affect the overall clinical course of the patient with cancer. The interactions between cancer and thrombosis might not be as simple as that. Take the time-honored observation that in an inordinate number of patients with idiopathic VTE, cancer develops in the subsequent several months[156] and extend the follow-up for several years, and one finds that the rate of malignancy continues to increase inordinately in this population for at least 6 years, with no evidence of a plateau developing in the curve.[157] Although it is conceivable that some aspect of an occult malignancy (even one that does not become clinically apparent for 6 years) promotes thrombosis, it is equally conceivable that some pathophysiologic element related to the thrombosis itself promotes the development or progression of the cancer. If this were true, then it would logically follow that alterations in the biology of thrombosis might alter the likelihood of subsequent malignancy.

Data from randomized clinical trials support this hypothesis. Patients who received oral warfarin secondary prophylaxis for 6 months after an idiopathic VTE had a lower rate of subsequent malignancy over the ensuing 6 years than did patients who were randomized to receive only 6 weeks of anticoagulation.[157] Not only does it appear that thrombosis might, through mechanisms unknown, predispose to the development of cancer, but the presence of thrombosis[158] or even evidence of activation of coagulation without overt thrombosis[23] also is associated with more aggressive behavior of the associated malignancies. This body of data, taken to its logical conclusion, allows the development of a hypothesis that thromboprophylaxis could be used for both primary prevention of and treatment of some forms of cancer. Add to this the facts that standard anticoagulation treatment of acute VTE is less efficacious and more toxic in cancer patients than in noncancer patients (see the previous sections) and that the risk of death from PE might be higher in cancer patients than in noncancer patients,[1] and it becomes clear that prevention of thrombosis is clinically important in patients with cancer.

To date, the available data on thromboprophylaxis specifically in cancer patients is derived mainly from studies whose major endpoints included the incidence of any (primarily asymptomatic) DVT rather than more meaningful endpoints such as disease progression, fatal PE, and survival. However, with meta-analysis, heparin thromboprophylaxis that was successful in preventing asymptomatic DVT in patients without cancer has been shown to prevent both symptomatic DVT and fatal PE.[159] Therefore, it is reasonable to infer that any intervention that prevents asymptomatic DVT also prevents clinically significant thromboembolic disease in patients with cancer. Data discussed earlier also raise the possibility that thromboprophylaxis in the cancer patient could modify the course of the malignancy in a favorable direction. Consequently, comments in the remainder of this section are based on the assumption that thromboprophylaxis (operationally defined as any intervention that prevents asymptomatic DVT) is clinically useful and should be used in cancer patients in several common, clinically defined situations.

Thromboprophylaxis in Surgical Oncology

Most studies of surgical thromboprophylaxis, such as those focusing on elective joint replacement, have not differentiated between patients with and without underlying malignancy. Consequently, the quantitative risk added by the presence of cancer to each and every type of surgical procedure is unknown. Despite this, the American College of Chest Physicians Consensus Conference on Antithrombotic Therapy categorizes any patient older than 40 years undergoing any major surgery in the setting of active or prior cancer as being in the "highest risk" group of patients, with an estimated risk of proximal DVT of 10% to 20% and fatal PE of 0.2% to 5.0% without thromboprophylaxis.[160]

Two basic methods of thromboprophylaxis have been widely studied in surgical patients: mechanical and pharmacologic. For practical purposes in surgical oncology, mechanical forms of prophylaxis are limited to external pneumatic compression (EPC) boots, whereas pharmacologic methods are limited to heparin-related compounds.

EPC has been found to provide a modest degree of efficacy in surgical oncology, ultrasound-defined failure rates varying from 1% in gynecologic oncology patients[161] to 14% in cancer patients undergoing orthopedic procedures.[162] Assuming that they are applied correctly 100% of the time, EPC boots are a cost-effective form of prophylaxis during and after high-risk gynecologic oncology procedures.[163] Unfortunately, the assumption of proper application of EPC devices 100% of the time is generally incorrect in practice, rates of 33% being more common.[164] In evaluation of the efficacy of EPC in gynecologic surgery, the presence of cancer has been found to be an independent risk factor for failure, with a relative risk of DVT of 4.9 compared with noncancer patients.[165] EPC as the sole method of prophylaxis is not recommended for the "highest risk" patients[160] and should not be relied on for most surgical procedures performed on cancer patients.

Heparin and heparin-related compounds form the mainstay of pharmacologic methods of thromboprophylaxis, although other medications, such as oral direct thrombin inhibitors and factor Xa inhibitors, could begin to play a major role in the future. The efficacy of UFH and its derivatives has been studied primarily in noncancer patients undergoing surgery. The first major investigation of the efficacy of heparin in curative cancer surgery was a prospective, randomized, double-blind study comparing subcutaneous UFH, 5000 units three times daily, with subcutaneous enoxaparin, 40 mg once daily, begun 2 hours before surgery.[166] Contrast venography within 24 hours of the last drug injection (10 ± 2 days) was scheduled to be performed in all patients. Of 1116 randomized patients, 319 UFH-treated patients and 312 enoxaparin-treated patients were evaluable. Total VTE, symptomatic DVT, and any DVT were detected in 18.2%, 1.9%, and 17.6%, respectively, of the UFH-treated patients and in 14.7%, 1.3%, and 14.4%, respectively, of the enoxaparin-treated group. These rates of thrombosis are more than twice those generally seen in noncancer patients undergoing general surgery receiving the same medications and evaluated with the same endpoints.[160] As the data demonstrate, most detected thromboses were asymptomatic (any DVT minus symptomatic DVT). To deal with the high failure rate of pharmacologic thromboprophylaxis in this group of patients, two different, and not mutually exclusive, approaches could be taken: (1) find a way to improve in-hospital efficacy and/or (2) find a way to prevent these asymptomatic thrombi from propagating and posing a risk of death after hospital discharge. The first approach might be accomplished by combining mechanical and pharmacologic methods of prophylaxis. This approach has been shown to be valid in noncancer patients by using EPC and graduated-compression stockings combined with UFH or LMWH[167,168] and has shown promise in patients undergoing craniotomy for brain tumors.[169] The second approach might be accomplished by extending the duration of thromboprophylaxis sufficiently that the asymptomatic thromboses fail to propagate, fail to embolize, and successfully undergo spontaneous thrombolysis. This approach has been recently found to be valid as well.

A similar group of patients undergoing planned curative open surgery for abdominal or pelvic cancer were all given enoxaparin, 40 mg once daily for 6 to 10 days, and subsequently randomized to 21 additional days of enoxaparin at the same dose or 21 days of placebo.[170] Bilateral venography was performed between days 25 and 31 after surgery, and patients were clinically followed up for a total of 3 months after surgery. A total of 501 patients were randomized with 332 patients included in the efficacy analysis. The group that was randomized to enoxaparin had a 4.8% rate of any DVT at 4 weeks compared with 12.0% in the placebo group ($P = 0.02$). The majority of detected DVTs were asymptomatic and involved calf veins. Approximately 1.5% of patients in both groups had clinically apparent VTE in the 2 months of follow-up with no prophylaxis (an annualized rate of 9%, roughly 90 times that of the normal population).[170] A recent clinical outcome-based study of venous thrombosis following cancer surgery reported that 40% of confirmed thrombotic events occurred more than 21 days after the operation.[171] In patients undergoing high-risk abdominal surgery, including cancer surgery, postoperative subcutaneous fondaparinux was at least as effective as perioperative subcutaneous dalteparin in preventing venous thromboembolism.[171] In the 1408 evaluated subjects in the PEGASUS study who underwent cancer surgery, 4.7% of those who were randomized to fondaparinux were diagnosed with postoperative venous thrombosis compared to 7.7% of those who were randomized to dalteparin.[172] Taken in total, these data suggest that the following scheme should be strongly considered for all cancer patients undergoing major surgery:

- All should be given combined EPC and prophylactic-intensity LMWH or fondaparinux during hospitalization (unless contraindicated by renal insufficiency or a history of heparin-induced thrombocytopenia)
- All should be considered for prophylactic dose anticoagulation for 3 weeks after hospitalization (with the same caveats)
- Extended thromboprophylaxis with prophylactic anticoagulation should be considered for those with continuing risk factors for VTE, such as chemotherapy, infection, paralysis, and use of central venous catheters

Prevention of Central Venous Access Device–Associated Deep Venous Thrombosis

The quantitative scope of the problem of central venous catheter–related UE, internal jugular, and thoracic vein thrombosis (a clinical entity distinct from catheter dysfunction due to a fibrin sheath or small, nonocclusive tip thrombosis) depends on the method of detection. The incidence ranges from 2.4% to 35% if only symptomatic

events are considered and from 36% to 66% if surveillance venography is used to detect all thromboses.[160,173–176] Because of the reported incidences of catheter-associated thrombosis, cancer patients with central venous catheters should always be considered as being at high risk for DVT.[160] These thrombi are not benign, having at least a 25% incidence of asymptomatic PE.[177] Given that PE is a significant cause of death among cancer patients, central venous catheter–related DVT must be considered a potentially lethal problem.

In addition to their shared relation with PE, central venous catheter–related DVTs also pose clinical problems that are different from those seen with LE-DVT. As with leg vein DVT, not all central venous catheter–related thromboses undergo complete physiologic thrombolysis. An unknown fraction undergo organization and remain as a permanent obstruction to the involved veins. These organized thrombi prevent insertion of subsequent catheters at that vascular site, such as at the time of tumor relapse, from 14% to 30% of the time.[175] Central venous catheter–related thrombi also can be a nidus for infection. The risk of sepsis in patients with central venous catheter–related DVT is 2.62 times that of patients with catheters but without thrombosis.[178]

By consensus, the gold standard for determining the efficacy of any method of thromboprophylaxis is the randomized clinical trial using contrast venography-documented thrombosis as an endpoint.[160] Studies using purely clinical endpoints are generally not used in this context. Relatively small studies that examined fixed, low-dose warfarin and fixed-dose subcutaneous LMWH have demonstrated successful catheter-related DVT prevention.[173,177] Reported rates of thrombosis in the active therapy groups were in the 6% to 10% range. Neither study showed toxicity with these methods of prophylaxis, although while receiving antibiotic therapy, patients taking fixed, low-dose warfarin often had sufficiently long prothrombin times that a bleeding risk was probable.[174] During times of acute illness, especially when antibiotics are used, prothrombin time monitoring is recommended in patients receiving low-dose warfarin for thromboprophylaxis. Despite the results of small, provocative studies, larger-scale and more rigorously executed studies of low-dose oral warfarin and LMWHs have failed to demonstrate greater thromboprophylactic activity than placebo.[179–181] In fact, these recently reported studies demonstrated much lower thrombosis rates than were previously reported. This might reflect improvements in catheter material and placement. At this time, routine prescription of thromboprophylaxis in cancer patients with indwelling central venous catheters is not recommended.[160]

Prevention of Central Venous Access Device–Associated Thrombotic Occlusion

Very little work has been directed at finding methods of prevention of central venous catheter thrombotic occlusion. Thrombotic occlusion can manifest as the inability to infuse, inability to withdraw, or a combination of the two, known as *total occlusion.* The methods that are used to prevent central venous catheter–associated DVT have not been evaluated for efficacy in prevention of catheter obstruction. Although it is widely held that heparin flushing and meticulous catheter care prevent this problem, no experimental data support this contention. Heparin flushing of catheters does, however, increase the risk of HIT in this already hypercoagulable population. Fortunately, a readily available and highly effective therapy is available for patients who are experiencing thrombotic catheter obstruction. Thrombolytic therapy with low-dose recombinant tissue–type plasminogen activator instilled into the obstructed catheter has roughly a 90% likelihood of restoring catheter function at 4 hours.[182,183] Consequently, in the face of limited data on efficacy, infrequent but potentially severe toxicity, and highly effective salvage therapy, routine flushing of catheters with UFH to prevent occlusion cannot be recommended. Flushing of catheters with normal saline after each use is suggested as a preferable alternative to heparin flushing.

The only parameter that has been found to affect rates of thrombotic catheter occlusion is the anatomic location of the catheter tip. Catheters whose tips have been placed in the innominate vein have an inordinate incidence of thrombosis, especially compared with those whose tips are in the lower portion of the SVC or right atrium. Use of intraoperative guide-wire measurement or alternative techniques to ensure that the catheter tip is placed in the lowest third of the SVC is recommended.

Thromboprophylaxis during Chemotherapy

Chemotherapy is an independent risk factor for both VTE[1,184,185] and death within 1 week of VTE,[159] above and beyond that conferred by the presence of cancer alone. Unfortunately, the absolute risk of VTE that is conferred has been studied in only a relative few of the many chemotherapy regimens used to treat the wide spectrum of known malignant diseases. The absolute risk of VTE varies from 1.3% per year with tamoxifen only to 7.9% per year with tamoxifen combined with CMF (cyclophosphamide, methotrexate, and 5-fluorouracil) as adjuvant therapy for breast cancer[1,27] to as much as 43% during shorter-duration therapy of a variety of malignancies with thalidomide-containing regimens.[186] The 0.1% per year risk in the general population pales in comparison to these rates of VTE.

Despite the growing recognition of chemotherapy as a risk for VTE, little has been done to evaluate the role of primary thromboprophylaxis. The only trial to evaluate prophylaxis formally was done in the setting of systemic therapy for randomized breast cancer patients on active therapy with either warfarin, 1 mg daily for the first 6 months, followed by adjusted-dose warfarin to achieve an INR between 1.5 and 1.9 or placebo. The study compared the rates of clinically detected VTE over a mean of 6 months.[187] Active therapy reduced the incidence of VTE from 4.4% to 0.7%, with no differences in the rates of major bleeding complications. This intervention did not increase the costs of medical care for these patients.[188] Secondary prophylaxis (prevention of recurrence after the initial episode of VTE) by using warfarin in therapeutic doses has been effective in a limited number of patients taking thalidomide, suggesting that standard methods of thromboprophylaxis may be effective in a spectrum of chemotherapy regimens. In short, this phenomenon of chemotherapy-related VTE has not been given the attention it deserves, given the potential scope of the problem. Despite this, because of the low toxicities of current thromboprophylactic measures, it seems reasonable to consider either warfarin in doses to prolong the INR to 1.5 to 1.9 or prophylactic doses of LMWH for patients receiving chemotherapy regimens associated with a meaningful increased risk of VTE.

Thromboprophylaxis for the Hospitalized Cancer Patient

Being sufficiently ill to require hospitalization for any reason is associated with a 100-fold increase in the risk of VTE[189] and an 18-fold increase in the risk of death within 1 week of VTE[159] compared with community residents. Patients who have been hospitalized for medical illness account for almost 23% of all cases of VTE.[185] Hospitalization for medical illness complicating cancer further increases the risk of VTE.[185,190] Patients with cancer who have been hospitalized for nonsurgical illness account for almost 30% of all cases of VTE,[184] making this population a prime target for the use of thromboprophylaxis.

Thromboprophylaxis has not been studied specifically in medically ill cancer patients. Inferences must be made from studies of a wide spectrum of patients with medical illnesses, some of whom have cancer. In this population, meta-analysis has shown that thromboprophylaxis with UFH or LMWH is associated with a more than 50% reduction in symptomatic DVT and PE without an increase in bleeding complications.[191] The first prospective, randomized, controlled trial of thromboprophylaxis in this group of patients using the

gold standard of contrast venography endpoint randomized 866 patients (14% of whom had cancer) to receive either placebo or one of two doses of enoxaparin (20 mg daily or 40 mg daily) during their hospitalization.[192] At the time of discharge, DVT had developed in approximately 15% in the placebo group and in the group randomized to receive 20 mg of enoxaparin daily but only in 5.5% in the group randomized to 40 mg of enoxaparin daily, a risk reduction of more than 60% that was highly statistically significant. This population of medically ill patients was at high risk of bleeding complications. As a group, 1.3% experienced major hemorrhage during their hospitalization (a median of 7 days). The use of enoxaparin was not associated with an increase in this basal rate of major hemorrhage. This therapy was associated with a small increase in the cost of hospitalization but could actually be cost effective if one considers the savings from not having to treat as many new VTEs.[193] These data strongly suggest that all hospitalized cancer patients receive thromboprophylaxis with an LMWH unless contraindicated by either severe renal insufficiency or a history of HIT.

Chemotherapy-related thrombocytopenia, intracranial malignancy, and gastrointestinal lesions have been perceived by some physicians as contraindications to the use of prophylactic doses of LMWH. Whereas no data formally evaluate the safety of prophylactic LMWH in these high-risk situations, inferences can be made from several sources. Patients undergoing elective neurosurgery, including surgery for intracranial malignancy, have an incidence of bleeding similar to that of hospitalized medical patients (approximately 2%–3%).[169,194] This rate of bleeding was not increased with the use of 40 mg of enoxaparin daily.[194] Patients undergoing curative abdominal and pelvic surgery for cancer do not have an increased rate of bleeding complications with the use of this dose of enoxaparin.[166] From these data, it appears that the use of prophylactic doses of LMWH is unlikely to pose an additive risk of bleeding over that inherent with the underlying disease. Consequently, unless the extent of the intracranial or gastrointestinal disease or the degree and duration of thrombocytopenia are great, these comorbidities pose only a relative, and probably small, contraindication to the use of pharmacologic thromboprophylaxis. In situations in which this type of prophylaxis is perceived to be contraindicated, use of EPC and/or periodic ultrasound surveillance[195] is strongly recommended.

In the previously mentioned thromboprophylaxis trial,[192] all patients were monitored for the development of symptomatic VTE for 3 months after discharge. In approximately 1% of the patients, symptomatic DVT or PE developed during this time, which is roughly 40 times the incidence of VTE in the general population. This incidence is similar to that seen in the 3-month follow-up of patients undergoing curative surgery for cancer,[170] in which prolonged use of enoxaparin after discharge has been shown to be safe and effective in prevention of DVT. These data suggest that the risk of VTE does not end as the patient passes out through the doors of the hospital but continues for a protracted period. Extended thromboprophylaxis, as used in cancer surgery, should be strongly considered, especially in patients whose in-hospital cancer therapy has not been completely curative.

FUTURE PROSPECTS

As more and more oncologists become aware of the importance and challenges of clinical thrombosis in patients with malignancy, we will likely see more attention paid to earlier venous thrombosis diagnosis, optimization of acute and chronic venous thrombosis management, and greater compliance with thromboprophylaxis recommendations. We hope that venous thrombosis will be viewed less as simply a nuisance during the care of cancer patients and more as a major source of patient morbidity, treatment delay, and mortality.

Continued improvements in duplex ultrasound, CT, and MRI are expected. The ability to scan the pulmonary vasculature, abdominal vasculature, pelvic veins, and lower extremities with one contrast injection and one imaging session will likely be perfected. This will provide a more comprehensive approach to thrombosis confirmation and will limit intravenous contrast exposure. Nuclear medicine scans that are capable of whole-body thrombus imaging are on the horizon and might even assist with the detection of occult malignancy in patients with an initial idiopathic VTE. Integration of diagnostic algorithms into one's oncology practice could assist the busy clinician with decision making in the case of suspected DVT and PE.

Continued interest in developing improved strategies to treat VTE specifically in the cancer patient is anticipated. Further reduction in both thrombosis recurrence rates and bleeding rates is needed. Prospective clinical trials are needed to support the long-term anticoagulation of the cancer patient with thrombosis. In particular, optimal management of women with thrombosis and the need for years of adjuvant hormonal therapy for breast cancer must be clarified. Despite excellent compliance with daily subcutaneous LMWH for up to 6 months of VTE therapy, newer oral anticoagulants could make long-term anticoagulation more palatable to all patient populations. Newer oral compounds might prove to be effective for primary and secondary venous thromboprophylaxis specifically in the cancer patient. Careful assessment for hepatic toxicity will be required before use in cancer patients who are prone to liver metastases and those receiving hepatically metabolized chemotherapeutic agents. Further research into the anticancer and survival prolongation properties of selected anticoagulants might identify a particular agent or class of agents as being ideal in cancer patients in general or in those with specific responsive tumor histologies.

Prevention will continue to be of paramount importance. It is always easier and less potentially toxic to prevent thromboses with low doses of anticoagulation than to treat life-threatening thromboses with longer courses of higher doses of the same drugs. Ongoing research attempting to link thrombosis with accelerated tumor neovascularization, growth, and metastases may highlight the importance and value of aggressive primary thrombosis prevention in all cancer patients. Time and significant research efforts will tell.

C. INFECTIONS

47 Infection in the Patient with Cancer

Alison G. Freifeld and Daniel R. Kaul

SUMMARY OF KEY POINTS

- Risk assessment is an important tool for evaluation and treatment in the patient with cancer who has fever and neutropenia. Patients who are expected to have neutropenia lasting more than 7 days, including those undergoing allogeneic stem cell transplantation or therapy for acute leukemia, are considered to be at high risk for infectious complications. Most patients with solid tumors will have neutropenia lasting less than 7 days and are considered to be at low risk.
- Other risk factors for infection in patients with cancer, besides chemotherapy- and disease-related neutropenia, are presence of indwelling catheters, comorbid medical conditions such as diabetes or chronic obstructive pulmonary disease, recent surgery, malnutrition, and cellular and humoral immune defects from underlying tumor and its treatment.
- Fever during neutropenia necessitates immediate evaluation, assessment of risk as high or low, appropriate cultures, and prompt institution of empirical broad-spectrum antibacterial therapy with a defined regimen that covers *Pseudomonas aeruginosa* and enteric gram-negative organisms, as well as common institutional pathogens. Gram-positive–active agents are not a standard component of the empirical treatment regimen for fever and neutropenia.
- Antibiotic prophylaxis with levofloxacin has been shown to decrease fever and infection in high-risk patients with acute leukemia or those undergoing stem cell transplantation, with neutropenia (<1000 neutrophils/mm^3) lasting more than 7 days, although no morality benefit has been consistently shown.
- Posaconazole prophylaxis reduces the incidence of invasive fungal infections and mortality in patients undergoing induction for acute leukemia and reduces fungal infections in patients treated for higher-grade graft-versus-host disease (GVHD). Voriconazole has been shown equivalent to fluconazole for prevention of fungal infections in allogeneic stem cell transplant recipients.
- Newer agents used to treat a variety of lymphoproliferative disorders (e.g., alemtuzamab, purine analogs) result in prolonged suppression of cellular immunity and predispose to certain infections; patients receiving these agents may benefit from prophylaxis against opportunistic infections.
- An epidemic strain of *C. difficile* has emerged as a major cause of morbidity and mortality in many centers, and fluoroquinolone use is a risk factor. Metronidazole is recommended for mild disease, but oral vancomycin should be given for more severe symptoms of *C. difficile* infection.
- Numerous antifungals may be used for empirical antifungal therapy after 4 to 7 days of broad-spectrum antibiotics in patients who are still febrile; however, some debate continues regarding whether all patients definitely require empirical antifungal therapy. A high-resolution computed tomography (CT) scan of the chest may identify possible mold infections and guide antifungal management.
- Patients scheduled for allogeneic hematopoietic stem cell transplantation (HSCT) should be screened for evidence of latent herpesvirus and hepatitis virus infections, and prophylaxis instituted accordingly.

INTRODUCTION

Numerous disease-related and chemotherapy-induced factors render the patient with cancer at increased risk for infection.[1,2] These include the type of cancer (solid tumor versus a lymphoma or acute leukemia), depth and duration of neutropenia, and impairments in cellular function caused by cytotoxic or immunosuppressive drugs; breaches in the integument from surgical procedures, presence of indwelling plastic venous catheters, or mucositis of the gastrointestinal tract secondary to chemotherapy; and comorbid conditions such as malnutrition, deconditioning, or medical problems such as chronic obstructive lung disease or diabetes. In recent years, it has become clear that prevention, diagnosis, and management strategies for infectious complications in patients with cancer are greatly influenced by overall immunosuppression status, as reflected by the cumulative burden of these risk factors. Nonetheless, neutropenia remains a critical risk factor for infection in these patients, and the oncologist must be informed of the most appropriate methods for managing fever and other possible infections during neutropenia.

This chapter addresses current standards for the management of fever during neutropenia and also highlights contemporary guidelines for the prevention and treatment of common infectious complications in patients with cancer.

INFECTION RISK FACTORS

Neutropenia as a Risk Factor for Infection

The association between neutropenia and increased infection risk initially was demonstrated by Bodey and colleagues in 1966 in a study of leukemic patients undergoing cytotoxic therapy.[3] The data show that the frequency of infectious complications is inversely related to the degree and duration of neutropenia (Fig. 47-1). Infection risk starts to increase when the absolute neutrophil count

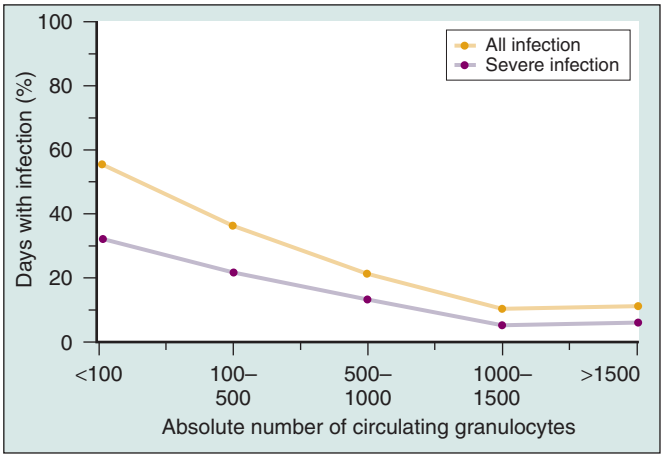

Figure 47-1 • Relationship between neutrophil count and infection in patients with acute leukemia.

(ANC) decreases to less than 1000 cells/mm^3 and increases dramatically when it is less than 500 cells/mm^3. Fewer than half of the neutropenic patients who become febrile will have an identified infection. In roughly 10% to 20% or more of patients with neutrophil counts less than 100 cells/mm^3, a bloodstream infection will develop. More than 50% of all episodes of fever and neutropenia represent *fever of undetermined origin* (FUO), with no identifiable infection source on physical and radiographic examination and cultures.[3,4] In addition to the depth of the ANC nadir, the duration of neutropenia also is an important determinant of both infection risk and infection type. Brief durations of neutropenia, particularly for less than 7 days, are associated with a rapid and favorable response to empirical antibiotic therapy. Fever often may be of unknown origin during this early phase of neutropenia, but if a causative pathogen is identified, bacteria and viruses predominate. A neutrophil count persistently less than 500 cells/mm^3 for more than 7 days is associated with greater risk for infection-related morbidity and mortality and is the setting in which *Aspergillus* and other invasive fungal infections most often occur. Other pathogens that may cause infection during the course of prolonged neutropenia (i.e., after 7 days) include antibiotic-resistant bacteria, *Candida* species, and other molds. Deaths during neutropenia usually are due to these subsequent infections. Overall mortality rates during fever and neutropenia are less than 1% for low-risk patients and approximately 5% for those with more prolonged duration of neutropenia.[5–9]

In addition to cytotoxic chemotherapy, other cases of neutrophil deficiency include bone marrow incompetence occurring as a result of myelodysplastic syndrome, or secondary to crowding out of normal granulocytic precursors by tumor cells. "Functional neutropenia" due to impaired neutrophil microbicidal activity may arise as a consequence of underlying disease such as leukemia or therapies such as steroids. In these instances, ineffective neutrophil killing leaves the patient highly vulnerable to infection despite seemingly normal peripheral white blood cell counts.

Other Risk Factors for Infection

Disruption of integumentary, mucosal, and mucociliary barriers by cytotoxic therapies provides opportunities for invasion by colonizing bacteria on the skin, gastrointestinal tract, or mucous membranes.[10] Shifts in normal colonizing microbial flora at these sites occur as a result of chemotherapy, antibiotic use, and nosocomial exposures, leading to increased colonization with gram-negative and antibiotic-resistant pathogens. Indwelling catheters create a significant breach in host defense, permitting direct access of skin flora and other pathogens to blood or subcutaneous tissue. Tumor growth can disrupt normal anatomic structures, and cancer surgery may result in anatomic alterations and wounds, providing local sites for pathogen entry.

Underlying diseases and cancer therapies also play important roles in infection risk. For example, hypogammaglobulinemia often complicates chronic lymphocytic leukemia (CLL) or multiple myeloma, so that patients are at increased risk for severe pneumococcal infections or *Haemophilus influenzae* or *Neisseria meningitidis* infection. In contrast to patients with solid tumors, those with acute leukemias are more likely to have overwhelming sepsis or invasive fungal infections because of prolonged periods of profound neutropenia related to the underlying leukemia. Patients with acute lymphocytic leukemia, Hodgkin's disease, or non-Hodgkin's lymphoma (NHL) typically have defects in cell-mediated immunity that predispose them to development of *Pneumocystis jirovecii* pneumonia (PCP), cryptococcal disease, or infections with intracellular organisms such as *Salmonella* or *Listeria*.

Steroid therapy induces a broad immunosuppressive effect, including impaired chemotaxis and killing by neutrophils, impaired T-cell function, and alterations in skin and mucosal barriers. Long-term or high-dose steroid therapy is a significant risk factor for invasive fungal infections in particular (i.e., *Aspergillus* and *Cryptococcus*), as well as *P. jiroveci* (usually seen with tapering of the steroid regimen). Such therapy also may predispose affected patients to development of bacterial infections and *Mycobacterium tuberculosis* reactivation. High-dose cytosine arabinoside therapy causes mucositis that may predispose to life-threatening streptococcal bacteremias.[11] Fludarabine and alemtuzumab cause prolonged suppression of CD4$^+$ lymphocytes and attendant susceptibility to infections with *Listeria*, *P. jiroveci*, and herpesviruses, as well as bacterial infections.[12,13] Temazolomide with radiation, given for glioblastoma, also is associated with increased susceptibility to *P. jiroveci*, as well as profound myelotoxicity.[14]

SOURCES OF INFECTION

Colonization by pathogenic bacteria, fungi, or viruses generally is a prerequisite for infection. Accordingly, endogenous bacterial and fungal flora and latent herpesvirus infections account for a majority of initial infections in the neutropenic patient with cancer.[11,15,16] These include skin colonizers such as *S. aureus* and coagulase-negative staphylococci, viridans streptococci, and herpes simplex from the oropharynx, and gram-positive bacteria as well as enteric gram-negative bacteria from the gut. *Candida albicans* infections often are derived from the skin or the gastrointestinal or female genital tract. Latent infections that may reactivate during immunosuppression include those due to herpes simplex or varicella-zoster virus, Epstein-Barr virus (EBV), and cytomegalovirus (CMV), as well as hepatitis B and C viruses, *M. tuberculosis*, and *Toxoplasma gondii*.

Exogenous sources of infection often are found in the hospital and home environments. Contaminated blood products, hospital equipment, water sources, and nosocomial spread of organisms from health care workers represent less common, albeit significant sources of infection. Common nosocomially spread infections include those due to *C. difficile*, respiratory viruses, vancomycin-resistant enterococci, and other multiresistant bacteria. Water sources such as faucets and shower heads have been implicated in the spread of *Legionella*. Outbreaks of infection related to intravenous solutions have been well documented with *Klebsiella* and *Enterobacter*.[17–19]

Foods can be a potential infection source, particularly unwashed fruits and vegetables. Neutropenic patients generally are advised to avoid raw foods of this type unless measures are taken to peel or thoroughly wash them. Potted plants, mulch, and excavation and building or renovation sites have been identified as sources of *Aspergillus* and other molds that may cause disease.[20]

APPROACH TO FEVER IN THE NEUTROPENIC PATIENT

Fever often is the only reliable sign of significant underlying infection in the neutropenic patient. No specific clinical features, such as hypotension or chills, or magnitude of the increase in body temperature can accurately distinguish between fever due to an infection and that due to a noninfectious cause. Nor are laboratory tests such as determination of C-reactive protein and procalcitonin considered specific or rapid enough to be relied on.[21] Therefore, all febrile neutropenic patients should receive empirical broad-spectrum antibiotics, ideally within 1 hour of presentation. Although a clinically or microbiologically documented source of fever is not found in most patients with fever and neutropenia, the rapid initiation of empirical antibiotic therapy remains an important standard of care for all patients in this setting. The choice of specific antibiotic regimens, however, depends on an assessment of the patient's infection risk during neutropenia, which is in turn dependent on duration of neutropenia, underlying cancer, and comorbid medical conditions. Conditions and findings that may alter the empirical antibiotic regimen are shown in Table 47-1.

DEFINITIONS

Guidelines for evaluating antimicrobial therapy for fever and neutropenia have been developed by the Infectious Diseases Society of America (IDSA) and the National Comprehensive Cancer Network (NCCN):[2,22] *Fever* is defined as a single temperature measurement of

Table 47-1 Approach to Management of Fever and Neutropenia

History and Physical Findings	Indicated Modifications in Antimicrobial Coverage or Diagnostic Test
Fever during neutropenia	*Empirical antibiotic regimen*: See text.
	If the patient is on antibiotic prophylaxis, then empirical therapy must be based on an agent of a different class from that for prophylaxis (e.g., if the patient is on fluoroquinolone-based prophylaxis, then switch to a beta-lactam–based regimen).
Hypotension, signs of sepsis	*Broad-spectrum antimicrobial coverage*: A triple-antibiotic regimen (e.g., carbapenem plus vancomycin plus an aminoglycoside) is recommended.
	If cultures are negative for gram-positive organisms, consider discontinuing vancomycin after 3 days.
Fever that is persistent or recrudescent on or after day 5 of antibiotic therapy	*Empirical antifungal therapy*: Add amphotericin B product, an echinocandin, or voriconazole if the patient is not already on prophylaxis with a mold-active agent. CT scan of the chest may help identify fungal infection.
	Consider CT scan of the chest and frequent galactomannan testing during neutropenia to guide preemptive treatment, as an alternative strategy to empirical antifungal treatment.
Severe oral or esophageal mucositis	Send swab for viral (HSV) culture.
	Add antiviral coverage (if not already being given).
	Consider antiviral resistance to prophylaxis if esophagitis occurs late in the course of neutropenia.
	Add antifungal agent for possible *Candida* esophagitis.
	Switch streptococcal coverage to vancomycin.
	Esophagoscopy may be indicated.
Catheter exit site or tunnel erythema, tenderness, or discharge or cellulitis at any site	Culture any discharge.
	Add vancomycin.
	For tunnel infection (erythema and tenderness 2 cm above exit site), catheter removal and surgical débridement generally are required.
Possible anaerobic infection	Add metronidazole to broad-spectrum antibiotics.
Abdominal pain, especially right lower quadrant, suggestive of neutropenic enterocolitis	Perform CT scan of affected area.
	Supportive care: Avoid surgical intervention if possible in a neutropenic patient.
Oropharyngeal or neck or soft-tissue swelling	
New pulmonary infiltrate	Bronchoscopy (with or without biopsy) is the preferred method for evaluating new infiltrates in the high-risk patient.
	Nodular: Add mold coverage with voriconazole, posaconazole, or amphotericin B preparation.
	Alveolar: Broaden gram-negative coverage and add *Legionella* coverage (quinolone or macrolide).
	Interstitial: Send specimen for diagnostic studies for both respiratory viruses and herpesviruses, particularly CMV.
	Review patient history for risk factors for tuberculosis or infection with endemic fungi.
Upper respiratory symptoms of coryza, congestion during fall/winter	Send nasal wash or swab for respiratory virus culture and rapid antigen tests for RSV and influenza virus.
Hemorrhagic cystitis	Indicated studies include urine viral culture and BK virus PCR assay.

CMV, cytomegalovirus; CT, computed tomography; HSV, herpes simplex virus; PCR, polymerase chain reaction; RSV, respiratory syncytial virus.

38.3° C (101° F) or greater, in the absence of other obvious causes; a temperature of 38° C or greater for an hour or longer is considered to represent a "febrile state" that also requires prompt evaluation and intervention in the setting of neutropenia.[2,22] *Neutropenia* is defined as an absolute neutrophil count (ANC) less than 1000 cells/mm^3 in some centers but more often is designated by a neutrophil count of less than 500 cells/mm^3, which is a level associated with a much higher risk for infection. For practical purposes, an ANC less than 500 cells/mm^3, or a count that is anticipated to fall below that level within 48 hours, constitutes a state of neutropenia.

Rarely, a neutropenic patient who is afebrile may exhibit signs or symptoms of infection (e.g., abdominal pain, severe mucositis, perirectal pain) and should be considered to have an active infection. The concomitant administration of corticosteroids also may initially blunt the fever response. With afebrile neutropenic patients who show signs or symptoms suggestive of an infection, empirical antibiotics should be started immediately because of their increased risk for serious invasive infections.

INITIAL EVALUATION

The initial evaluation should be directed toward determining the possible sites of infection and causative organisms and assessing the patient's level of risk for infection-related complications. A thorough site-specific review of systems is essential. Pertinent history includes recent antibiotic therapy, recent surgery or other invasive procedures such as biopsies or catheter placement, and possible exposure to infections from close contacts and household members, foods, animals, or travel.

The physical examination should focus on common potential sites of infection. Worthy of emphasis in this regard is that the manifestations of infection are muted in the absence of inflammatory cells. Careful examination of the oropharynx may reveal ulcers, or plaque-like lesions may be due to herpes or thrush, and specimens for appropriate tests should be sent for evaluation. Catheter sites require careful assessment for erythema, tenderness, or discharge. With bacterial cellulitis of the skin or perirectum, induration and erythema may be minimal; pimples or pustules are uncommon without neutrophils to create pus. Similarly, few respiratory signs or symptoms may be noted, and auscultation of the lungs may reveal few adventitial sounds, but an infiltrate may be seen on radiographs. A urinary tract infection may not be associated with dysuria. Gastrointestinal tract mucositis due to cytotoxic chemotherapy can lead to sore throat, oral ulcers, and diarrhea that are indistinguishable from the signs and symptoms of infection. Abdominal pain in neutropenic patients may signify a wide variety of problems, including intestinal tumor necrosis and neutropenic enterocolitis, both of which can result in intra-abdominal catastrophe or sepsis.

Initial laboratory evaluation should include a complete blood count and differential white cell count to determine the degree of neutropenia, liver and renal function tests, oxygen saturation determination, and urinalysis. Chest radiography should be performed routinely at presentation with fever and neutropenia, but initial findings may be minimal in neutropenic patients with pneumonia. Two blood culture samples, each consisting of 20 to 40 mL of blood, should be obtained from febrile, neutropenic patients.[4] An adequate volume of blood taken for culture will enhance the chances of recovering a pathogen.[23]

The usefulness of taking blood samples from both a vascular catheter and a peripheral vein has been confirmed, and this strategy is now standard practice in evaluation. Dual-site blood cultures may help determine whether the catheter is a source of infection if the differential time to positivity between catheter- and venipuncture-derived cultures is less than 2 hours.[24] One study, however, revealed that in patients with cancer, catheter-drawn blood culures without concomitant peripheral cultures have very good negative predicitve value and fairly good sensitivity (89%) and specificity (95%), albeit with low positive predictive value; accordingly, a positive result—especially for a common contaminant such as coagulase-negative staphylococci—requires careful clinical interpretation.[25] Quantitative blood cultures are rarely used because of their expense.

Cultures of any suggestive sites of infection should be performed: Diarrheal stools should be tested for the presence of *C. difficile* toxin, specimens from oral or perineal lesions suspected to harbor herpes simplex virus (HSV) should be sent for viral cultures, and nasal wash or swab specimens for culture for respiratory viruses should be obtained in patients with suggestive signs or symptoms during the winter season.

Risk Assessment

Risk assessment should be performed as part of the initial evaluation in an effort to predict the probability that a patient is at high or low risk for serious complications during a febrile episode.[2,22,26–33] The assessment of a patient's risk is driven largely by the duration of neutropenia expected to occur as a consequence of chemotherapy, and by certain historical and physical characteristics of the neutropenic patient who presents with fever (Table 47-2). Clinical features in low-risk patients include neutropenia anticipated to last less than 7 days, absence of serious medical comorbidity, and outpatient status at onset offever.[2,5,6] Typically, low-risk patients are those receiving chemotherapy for solid tumors or consolidation therapy for leukemia. These patients may be eligible to receive treatment outside of the traditional hospital setting or receive initial empirical therapy with oral antibiotics. Clinical features in high-risk patients generally include expected duration of neutropenia of 7 days or longer and presence of serious medical comorbidity. These patients may be recent recipients of allogeneic hematopoietic stem cell transplants or patients with acute leukemia not in remission, or with neutropenia secondary to induction therapy or other conditions such as aplastic anemia. Additionally, non-neutropenic patients with graft-versus-host disease (GVHD) treated with significant doses of corticosteroids also are considered to be at high risk for infections, particularly those due to encapsulated bacteria and invasive molds. Recipients of autologous hematopoietic stem cell transplants seem to be at intermediate risk for infections, even though prolonged (longer than 7 days) durations of neutropenia are likely in these patients. Similarly, patients with lymphoma or CLL and recipients of purine analog therapy (e.g., fludarabine) or those undergoing mini-allogeneic transplantation may be considered to be at intermediate risk for severe infection because they tend to have only brief periods of neutropenia, or none at all, but they may acquire significant impairments of cellular immunity that make them susceptible to certain types of infections. Although many clinicians rely on the criteria shown in Table 47-2, an important point is that these criteria are derived from clinical observations from numerous trials, rather than from a risk assessment algorithm.[2] The Multinational Association of Supportive Care in Cancer (MASCC) has put forth a set of validated clinical prediction rules that can distinguish high- from low-risk patients with substantial accuracy (see Table 47-2).[8,29] This prediction model has recently been validated, and the use of the MASCC prediction criteria is encouraged to distinguish between low- and high-risk patients.[33]

Once risk categorization has been assigned and after pertinent historical data have been acquired, physical examination and radiographic studies have been performed, and appropriate culture specimens have been obtained, then empirical antibiotics should be started promptly in the patient with fever and neutropenia. Preferably, these tasks should be completed within 1 or 2 hours, at most.

EMPIRICAL ANTIBIOTIC THERAPY: GENERAL PRINCIPLES

Numerous clinical trials over the last 3 decades have failed to demonstrate the clear superiority of one empirical antibiotic therapy

Table 47-2 Risk for Infectious Complications after Cytotoxic Chemotherapy: Clinical Features Defining Risk Status and Risk Prediction in Patients with Fever and Neutropenia

GENERAL CLINICAL FEATURES IN HIGH- VERSUS LOW-RISK PATIENTS

High risk

- Neutropenia anticipated to extend to or beyond 7 days
- Presence of any comorbid medical problems including but not limited to
  - Hemodynamic instability
  - Oral or gastrointestinal mucositis that interferes with swallowing or causes severe diarrhea
  - Abdominal pain or perirectal pain of new onset
  - Nausea and vomiting
  - Diarrhea (passage of six or more loose stools daily)
  - Neurologic or mental status changes of new onset
  - Intravascular catheter infection, especially catheter tunnel infection
  - New pulmonary infiltrate or hypoxemia, or underlying chronic lung disease
- Evidence of hepatic insufficiency (defined as aminotransferase values greater than 5 times normal values) or renal insufficiency (defined as a creatinine clearance less than 30 mL/min).

Low risk

- Neutropenia expected to resolve within 7 days
- Absence of any medical comorbidity as listed in high-risk criteria
- Adequate hepatic function and renal function

MASCC PREDICTION TOOL FOR DETERMINING HIGH AND LOW RISK FOR SERIOUS MEDICAL COMPLICATIONS

Characteristic	Weight (No. of Points)*
Age <60 years	2
Outpatient status	3
Clinical status at presentation	
No severe burden of febrile neutropenia	
No or only mild symptoms	5
Moderate symptoms	3
No hypotension: systolic blood pressure >80 mm Hg	5
No dehydration requiring parenteral fluids	3
Medical history, underlying disease, and/or comorbidity	
No chronic obstructive pulmonary disease	4
Solid tumor or hematologic malignancy without previous invasive fungal infection	4

MASCC, Multinational Association for Supportive Care in Cancer.

*If relevant, points are added to yield a sum score. If the score is >20, the patient is predicted to be at low risk (<10%) for the development of serious medical complications during the course of febrile neutropenia.

Adapted from IDSA Guidelines 2007.

regimen over all others. Effective and reliable regimens, however, are characteristically bactericidal for gram-negative pathogens, particularly *P. aeruginosa*, even in the absence of neutrophils. Several antibiotic approaches are acceptable, but an important point is that the final choice of a specific regimen will depend on the patient's risk factors for infection, the specific sites that may be sources of infection, and the prevailing institutional flora.

Monotherapy with a broad-spectrum antipseudomonal agent such as an extended-spectrum antipseudomonal cephalosporin (e.g., cefepime, ceftazidime), or piperacillin-tazobactam or a carbapenem (e.g., imipenem-cilastatin, meropenem), constitutes a standard approach to the management of fever and neutropenia in patients with cancer. [2,22,30–39] The choice of agent should be based on a review of local institutional bacterial susceptibility patterns. Some institutions routinely use combinationt therapy with either (1) an aminoglycoside plus either an extended-spectrum antipseudomonal cephalosporin or piperacillin-tazobactam or (2) ciprofloxacin plus an antipseudomonal penicillin. No clear benefit of combination therapy over montherapy has been demonstrated, and increased renal toxicity has been observed with aminoglycoside use.[39,40] In an era of increasing bacterial resistance, however, circumstances may arise in which initial empirical antibiotic combinations are advisable.[41] With the possibility of infection due to methicillin-resistant *S. aureus*, for example, addition of vancomycin is prudent. If a pneumonia is identified at the outset, then adding an antipseudomonal fluoroquinolone (i.e., ciprofloxacin or levofloxacin) ensures a broadened spectrum against potentially resistant gram-negative or atypical pathogens, as well as "atypical" organisms such as *Legionella*.[42]

INITIAL EMPIRICAL ANTIBIOTIC THERAPY

For patients who have been determined to be at low risk for developing infection-related complications during the course of neutropenia, oral ciprofloxacin plus amoxicillin-clavulanate (or clindamycin for patients who are allergic to penicillin) is an effective alternative to intravenous monotherapy, as indicated by several large randomized studies.[30–32] High-dose ciprofloxacin or ofloxacin oral monotherapy has been evaluated in small trials, but the evidence does not currently support the routine use of these fluoroquinolones for monotherapy in low-risk patients with fever and neutropenia.[43–46] Ciprofloxacin as a single agent does not provide adequate coverage for certain gram-positive organisms (e.g., *S. aureus*, alpha-streptococci), and therefore should never be used without an additional antibiotic directed toward those pathogens. Levofloxacin oral monotherapy has not been adequately studied.

Patients who are assessed as being in a high-risk category for complications during fever and neutropenia should receive intravenous antibiotics, as outlined earlier, in the inpatient setting. The choice of specific regimen is highly dependent on institutional profiles of pathogen susceptibility and on potential infection sites in a specific patient.

Use of Vancomycin or Other Gram-Positive Agents

Vancomycin or another agent with activity against drug-resistant gram-positive pathogens is not routinely recommended for inclusion in the initial empirical regimen, despite a predominance of gram-positive pathogens isolated in febrile neutropenic patients.[47] The dilemma is that a small proportion of infections caused by gram-positive pathogens can be fulminant, so some clinicians are anxious to use these agents. Regardless, a large, prospective, randomized trial from the European Organization for Research and Treatment of Cancer failed to show a clinical advantage for using a vancomycin-containing regimen over one that did not contain vancomycin, in adults with fever and neutropenia.[48] A major concern with widespread routine empirical use and prolonged courses of vancomycin has been the emergence of vancomycin-resistant organisms, especially

enterococci, associated with these practices. To limit the spread of vancomycin resistance, the Hospital Infection Control Practices Advisory Committee of the Centers for Disease Control and Prevention has issued guidelines to limit vancomycin use.[49] These guidelines include specific clinical situations that may justify initial use of vancomycin therapy in febrile, neutropenic patients with cancer (Table 47-3). Other agents active against gram-positive pathogens include daptomycin, quinupristin-dalfopristin, and linezolid. The use of these drugs should be similarly limited to distinct indications, rather than broadly applied. Caution is advised with use of these agents because each has significant adverse effects; of note, linezolid may cause myelosuppression when used for a prolonged course.

Documented serious, clinically apparent infections that are likely to be caused by gram-positive pathogens, such as cellulitis or obvious catheter-related infections, should be treated with vancomycin or another gram-positive–active agent. Many catheter-related bloodstream infections are caused by coagulase-negative staphylococcal isolates, which have high-level beta-lactam antibiotic resistance. Increasingly, *Staphylococcus aureus* also is being seen as a community-acquired pathogen.[50] If the patient is known to be colonized with methicillin-resistant *S. aureus*, then vancomycin should be added to the initial regimen until blood and other cultures are proved negative for this organism. Substantial mucosal damage increases risk for infection with viridans streptococci, of which 18% to 29% of are beta-lactam–resistant.[51–55] High-dose cytarabine or intensive therapy that damages oropharyngeal mucosal barriers has been associated with an increased risk of such overwhelming sepsis due to viridans streptococcal infections. Prophylaxis with ciprofloxacin or trimethoprim-sulfamethoxazole (TMP-SMX) also has been associated with an increased risk of gram-positive infections, particularly those due to viridans streptococci.[51–54] Viridans streptococcal breakthrough infections also have been observed with levofloxacin prophylaxis.[55,56]

Presence of hypotension or septic shock in a neutropenic patient necessitates very broad empirical antibiotic coverage, including the use of a gram-positive–active agent, until culture results are available. If a vancomycin (or other gram-positive–active agent) is added initially for empirical coverage, its use should be reassessed in 2 or 3 days. If a drug-resistant gram-positive pathogen cannot be identified, empirical vancomycin therapy should be discontinued.[49]

Table 47-3 Appropriate Use of Gram-Positive–Active Antibiotics in the Neutropenic Cancer Patient

VANCOMYCIN OR ANOTHER GRAM-POSITIVE–ACTIVE ANTIBIOTIC

Clinical situations for which addition of vancomycin or another gram-positive–active antibiotic is recommended include the following:

- Clinically apparent, serious catheter-related infection (e.g., tunnel or port pocket infection, any other skin or soft-tissue infection)
- Blood culture positive for gram-positive bacteria before final identification and susceptibility testing
- Known colonization with methicillin-resistant *Staphylococcus aureus* (MRSA)
- Hypotension or septic shock without identified pathogen (i.e., clinically unstable patient)
- Risk factors for viridans streptococcal bacteremia, including severe mucositis (typically associated with high-dose cytarabine and with TMP-SMX or fluoroquinolone prophylaxis)

OTHER AGENTS FOR USE WITH KNOWN VANCOMYCIN RESISTANCE

Linezolid, quinupristin-dalfopristin, or daptomycin may be used in very selected clinical situations in which vancomycin-resistant pathogens (e.g., VRE) are identified or in patients for whom use of vancomycin is not a clinical option.

GRAM-POSITIVE–ACTIVE ANTIBIOTICS FOR GRAM-POSITIVE INFECTIONS ONLY

Vancomycin or other gram-positive–active antibiotic should be discontinued in 2 to 3 days if no resistant gram-positive infection is identified.

TMP-SMX, trimethoprim-sulfamethoxazole; VRE, vancomycin-resistant enterococci.

Initial Empirical Therapy for Patients Who Are Clinically Unstable

Patients who have hypotension when with fever and neutropenia, or those who have a history of *P. aeruginosa* colonization or invasive disease, should receive multidrug therapy with an antipseudomonal beta-lactam (cephalosporin, carbapenem, or penicillin, depending on local susceptibilities) plus an aminoglycoside or ciprofloxacin, and vancomycin or other gram-positive active agent. Broad coverage is warranted in view of the high mortality rate in neutropenic patients with the systemic inflammatory response syndrome.[2,22]

Subsequent Modifications of Empirical Antibiotic Regimens

No empirical antibiotic regimen initially administered for fever and neutropenia can be expected to cover all possible infections that may occur during the course of neutropenia. Therefore, modifications of the initial regimen—additions or changes of antimicrobials—sometimes are required. An important consideration in the management of cancer-related infection is that the mean time to defervescence for febrile patients with neutropenia who receive appropriate initial antibiotic therapy ranges from 2 to 7 days.[5,6] Therefore, at least 3 to 4 days of the initial antibiotic regimen should be given to otherwise stable patients, regardless of continued fever, to determine effectiveness. For patients with a documented infection, it is important to note that tissue-based infections such as pneumonia may take longer to respond to antimicrobial therapy.[7]

Patients with a fever persisting beyond 4 days of initial antimicrobial therapy, and without an identifiable site or source of infection, should undergo reassessment of their initial antimicrobial therapy. Any change in antimicrobials should be based on the patient's clinical status, results of examination and cultures, and also the likelihood of early marrow recovery. Although fever resolution may be slow, persistent fever may suggest a nonbacterial infection, a bacterial infection that is resistant to empirical antibiotics, the emergence of a secondary infection, a closed-space infection, inadequate antimicrobial serum levels, or drug fever. A careful search for these etiologic conditions should be made. Frequent and arbitrary antibiotic changes for persistent fever, in an otherwise stable patient, are to be discouraged, however. The clinically stable patient with persistent fever may be safely watched without altering the initial antibacterial therapy. If vancomycin was started earlier, it should be discontinued if the patient does not meet the criteria for its use.[49] Addition of vancomycin, without specific indications, in a blind effort to suppress persistent fever after empirical antibiotics have been started, has not been shown to be effective.[57] If the fever persists beyond 4 to 7 days, a change in antibiotic regimen or initiation of empirical antifungal therapy should be considered.

For the patient who is persistently febrile and clinically unstable, a change in antibacterial antibiotics may be needed. The addition of increased gram-negative bacillary coverage often is recommended. The addition of vancomycin should be considered if the patient's clinical situation justifies its use, as indicated in Table 47-3. If fever

persists or is recrudescent beyond 4 to 7 days of empirical antibiotic therapy, empirical antifungal therapy probably should be initiated because the risk of invasive fungal disease increases with prolonged neutropenia.

Empirical Antifungal Therapy

Empirical antifungal therapy traditionally is started when neutropenic patients demonstrate continued or recrudescent fever after 4 days or more of an empirical antibacterial regimen. The empirical use of amphotericin B in early studies during the 1970s and 1980s actually failed to demonstrate an effect on defervescence or overall survival; however, a reduction in breakthrough fungal infections was noted.[58–60] Since then, in an attempt to reduce toxicity, numerous comparative studies have demonstrated that liposomal amphotericin B, amphotericin B lipid complex, itraconazole, and caspofungin are noninferior to, albeit less toxic than, amphotericin B desoxycholate for empirical therapy.[61–67] It is likely that the other echinocandins (anidulafungin, and micafungin) also are effective in this setting, but they have not been formally studied. In one large randomized trial, voriconazole failed to fulfill criteria for noninferiority in comparison with the comparator amphotericin preparation.[68] Breakthrough fungal infections, however, were less frequent in patients receiving voriconazole. Accordingly, many clinicians accept voriconazole as appropriate for empirical antifungal therapy. Itraconazole has been demonstrated to have efficacy in this setting as well, but concerns about liver and cardiac toxicities have discouraged use of this drug.[61,67]

Whether all patients with persistent fever require empirical antifungal therapy, and when it should be started, are subjects of longstanding debate. Invasive fungal infections are now relatively infrequent during neutropenia with the advent of more effective antifungal prophylaxis and the use of colony stimulating factors to abbreviate duration of neutropenia. Furthermore, it is clear that fever is a nonspecific surrogate marker for fungal infection. Patients who are not receiving antifungal prophylaxis but who have persistent or recurrent fever after 4 to 7 days of appropriate empirical antibiotics, and without prospect for imminent neutrophil recovery, may be candidates for empirical antifungal therapy. For patients not on antifungal prophylaxis, candidemia is the greatest concern, and persistent fever may be the only manifestation. An amphotericin B preparation, caspofungin, itraconazole, and voriconazole, or even fluconazole, are considered acceptable choices. If the patient is already receiving fluconazole prophylaxis, certain non-*albicans* species of *Candida*, including *C. glabrata* and *C. krusei*, and mold infections such as invasive aspergillosis must be considered, because fluconazole has reduced activity against these *Candida* species and lacks activity against molds. At present, no data are available to guide the use of empirical antifungal therapy in patients already receiving antimold prophylaxis, such as with voriconazole, posaconazole, or an echinocandin. In all cases, symptoms and signs of invasive fungal pneumonia or sinusitis should be sought; the workup may include CT scans of chest or sinuses (or both), with follow-up nasal endoscopy or bronchoalveolar lavage as indicated. Biopsy and culture of any suspected lesions should be pursued aggressively in order to make a definitive mycologic diagnosis that can guide therapy.

CT scan of the chest is increasingly used to evaluate the possibility of invasive aspergillosis in patients with prolonged fever and neutropenia; in one study, 90% of those with proven active disease showed radiographic abnormalities by CT.[69] Macronodules with or without a halo sign are characteristic of invasive aspergillosis, the halo sign being an especially important early clue.[70] Other manifestations include nodular, wedge-shaped, peripheral, multiple, and cavitary lesions. An air-crescent sign generally is a late finding. Initiation of antifungals on the basis of finding a halo sign has been associated with significantly better response to therapy and improved survival.[71,72] In a recent pilot study, Maertens and colleagues used intensive monitoring for clinical symptoms and signs, serial galactomannan testing (see later on), and early CT scanning to identify a group of patients with persistent fever while on fluconazole prophylaxis in whom antimold therapy did not appear to be required.[73] These data, as well as increasing clinical experience, have lead some experts to suggest withholding empirical antifungal therapy if the patient is clinically stable and has no clinical or chest CT scan signs of fungal infection, no *Candida* or *Aspergillus* organisms are recovered from any site, and neutrophil recovery is imminent. A high-resolution chest CT scan may be a useful screening tool in patients with persistent fever and neutropenia; any abnormalities should be investigated with nasal endoscopy or bronchoalveolar lavage; biopsy and culture of any suspected lesions should be pursued aggressively in order to make a definitive diagnosis, and an antimold agent should be started.

The serum galactomannan assay specifically detects *Aspergillus* organisms but not other common fungal pathogens.[74] Sensitivity varies widely in different patient populations. A recent meta-analysis reported sensitivities of 58% to 65% and specificities of 65% to 95% in patients with hematologic malignancies or HSCT.[75] Many conditions affect the performance of the galactomannan assay, especially the use of concomitant piperacillin-tazobactam (false-positive) or antimold antifungal agents (false-negative). Although prospective serial galactomannan monitoring may be useful for pateints at high risk for *Aspergillus* infections, routine use in low-risk patients is not advised.[74,75] Furthermore, a single negative test result is of little value in ruling out invasive aspergillosis, although a positive result in concert with abnormalities on the chest CT scan makes the diagnosis highly probable. Galactomannan testing of bronchoalveolar lavage fluid appears to be very sensitive and specific for identifying invasive aspergillosis, as confirmed in early studies.[76,77]

Duration of Antibiotic Therapy

It generally is recommended that empirical antibiotic therapy continue until recovery of the ANC to more than 500 neutrophilic cells/mm^3 on one occasion, so long as the patient is clinically stable. In a stable patient who remains febrile despite return of counts, it usually is safe to discontinue antimicrobials and look for a source of fever. In patients who are afebrile and clinically stable but have continued neutropenia, some clinicians recommend a 2-week course of antibiotics, at a minimum, and then stopping, with close observation.[2,22]

Documented infections should be treated for a minimum duration of 7 to 14 days with an antibiotic regimen that is narrowed and directed toward any organisms that have been documented microbiologically. Most experts prefer to continue antibiotics at least until the ANC returns to more than 500 cells/mm^3. A longer course is given if clinically necessary, regardless of neutrophil recovery.

For low-risk patients who typically have brief periods of neutropenia, some groups of investigators have examined stopping antibiotics before the ANC reaches 500 cells/mm^3. With a clear and steady increase in the ANC or, alternatively, in the absolute phagocyte count (APC = PMNs + bands + monocytes), it appears that discontinuing antibiotics before a count of 500 neutrophilic cells/mm^3 is achieved-generally is safe so long as no complicating comorbid conditions are present.[78–83]

ADJUNCTIVE THERAPIES

Hematopoietic Growth Factors

Prophylactic use of hemopoietic growth factors is common in the setting of intensive chemotherapy regimens such as stem cell transplantation. Treatment of fever or infection with growth factors, however, is not standard practice. No consistent benefit has been demonstrated in terms of morbidity (duration of fever and use of antimicrobial) or mortality among several randomized controlled trials of growth factors added to antibiotics at the time of fever during

neutropenia.[84–86] Both the IDSA[22] and the American Society of Clinical Oncology (ASCO)[86] guidelines do not recommend the routine use of growth factors in treatment for febrile neutropenic patients. Therapy with colony stimulating factors, however, could be considered for severely neutropenic patients who have serious uncontrolled infections such as bacterial sepsis, pneumonia, severe cellulitis or sinusitis, systemic fungal infections, hypotensive episodes, or multiorgan dysfunction secondary to sepsis.

Granulocyte Transfusions

Granulocyte transfusion may potentially increase the response to antimicrobial therapy in selected cases of uncontrolled fungal or gram-negative infection during prolonged neutropenia. Granulocyte colony stimulating factor use in donors has increased the granulocyte yield approximately fourfold. Multiple recent studies have shown that granulocyte transfusions can be helpful in controlling severe infections progressing despite the use of appropriate antibiotics, with a response rate of 40% to 80%.[87] Variability in results is a consequence of patient characteristics. This benefit is limited to a limited patient population, because the incidence of prolonged yet reversible neutropenia is relatively low. Rare adverse events associated with granulocyte transfusions include transmission of CMV, alloimmunization associated with fever, graft-versus-host reactions if granulocytes are not irradiated, and progressive platelet refractoriness.

INFECTIONS IN THE PATIENT WITH CANCER

Bacteremia

Bloodstream infections occur in about 10% to 20% of febrile patients during neutropenia, most often when neutrophil counts are less than 100/mm^3.[4–7] The risk of bacteremia is related to the depth of neutropenia, the presence of gastrointestinal mucositis or of an indwelling catheter, or the concomitant presence of a specific site of infection such as pneumonia or soft-tissue process. A majority of bacteremias are due to gram-positive organisms, with coagulase-negative staphylococci and streptococci predominating. Gram-negative pathogens, including *Escherichia coli*, *Enterobacter*, *Klebsiella*, and *Pseudomonas aeruginosa*, are important albeit less frequent pathogens (see Table 47-3).

A classification system for bacteremias in febrile neutropenic patients has been developed by Elting and colleagues, based on size and presence of associated tissue involvement.[7] Complex bacteremias were those associated with deep-tissue infections of the lung, the liver or spleen, the kidney, the colon, bone and joints, veins and heart, meninges, soft tissues with necrosis, or affected skin or soft tissue, wound, or cellulitis greater than 5 cm in diameter. Simple bacteremias were associated with less tissue involvement (bacteruria, otitis, pharyngitis, affected area of soft tissue less than 5 cm in diameter). The prognostic significance of complex infection associated with bacteremia on survival was dramatic. At 21 days, 20% of patients with complex infections were dead, compared with only 5% of patients with simple bacteremias ($P < 0.0001$). Profoundly neutropenic patients with simple bacteremias had a much higher response rate to antibiotics than that noted in patients with complex bacteremias (94% versus 70%; $P < 0.0001$). The median time to defervescence for patients with simple bacteremias was half that observed for patients with complex bacteremias (2.5 days versus 5.3 days; $P < 0.0001$).

With increasing incidence of MRSA in hospitals and the community, it is recommended that vancomycin be added to standard empirical antibiotic coverage if gram-positive cocci in clusters are isolated from a blood culture, pending identification.[15,41,50] Vancomycin-resistant enterococcus (VRE) also is common in high-risk cancer patients at some institutions. If gram-positive cocci in chains are identified in blood cultures in settings where VRE is prevalent, then empirical addition of an antimicrobial active against VRE (e.g., linezolid, daptomycin) is prudent, pending definite identification and susceptibility profile. Gram-negative bacteremias in the neutropenic patient are associated with high mortality unless treated promptly and with appropriate antibiotics.[88–90] A variety of resistance mechansims are evolving among gram-negative organisms. Therefore, if gram-negative rods are isolated in blood cultures during fever and neutropenia, an aminoglycoside or a fluoroquinolone should be added to empirical therapy regimens to ensure coverage of resistant strains until a full susceptibility report is available.

Pulmonary Infections

Pulmonary infections are associated with the greatest morbidity and mortality, even when a specific pathogen is not identified. Approximately 25% of all febrile episodes in the neutropenic patient, and 50% of documented infections, are pneumonias.[91–93] Numerous infectious and noninfectious causes of pulmonary infiltrates are found in cancer patient with cancer who has fever and neutropenia.[87] Noninfectious causes include the underlying disease itself, radiation therapy, drug toxicity, pulmonary hemorrhage, and leukostasis. Infectious involvement of the lungs may be caused by bacteria (pneumococci, members of Enterobacteriaceae, *Pseudomonas* spp., *Legionella* spp.), fungi (*Candida*, *Aspergillus*, *Fusarium* spp.), viruses (influenza virus, parainfluenza virus, respiratory syncytial virus [RSV], CMV, HSV), and protozoa (*Toxoplasma*, *Cryptococcus*, *Strongyloides*).

Auscultatory abnormalities in the chest may be minimal or absent, and the chest radiograph appears normal at the onset of clinical manifestations in 30% of neutropenic patients with subsequently identified pneumonia.[92] A CT scan of the chest is essential to better define a pulmonary process. Neutropenia will decrease the diagnostic advantage normally provided by the sputum examination, because purulent sputum production is rare in this setting. Bronchoalveolar lavage will increase the diagnostic yield, especially for *P. jiroveci*, viruses, and bacteria. The yield for molds such as *Aspergillus* with this procedure has been mostly in the range of 50% for suspected cases, so a negative result on bronchoalveolar lavage sampling does not rule out an invasive fungal process. Polymerase chain reaction (PCR) assay or galactomannan testing of lavage fluid may increase these yields, although these tests are not currently available commercially.[76,77] If the clinical picture, radiographic appearance, and findings on lavage fluid analysis are nondiagnostic, a thoracoscopic or CT-guided lung biopsy should be considered if the patient's platelet count is adequate.

The radiograph appearance of a pulmonary infiltrate may give clues to the etiology (Table 47-4).[93] Focal lesions are suggestive of bacterial etiology and should be treated accordingly with broad-spectrum antibiotics. Nodular lesions, particularly those with surrounding areas with a ground-glass appearance (i.e., halo lesions), are suggestive of mold infection—such as with *Aspergillus*. This is of particular concern in the two patient groups that are at particularly high risk for mold infection: patients with GVHD on high-dose steroids and patients with prolonged neutropenia, such as those undergoing induction treatment for acute myelogenous leukemia. In these types of patients, even minimal symptoms of low-grade fever, pleuritic chest pain, or nasal stuffiness should prompt an immediate CT scan of the chest and sinuses to look for signs of invasive aspergillosis.

A diffuse interstitial picture is suggestive of a noninfectious etiology such as pulmonary edema or diffuse alveolar damage; or it may represent an atypical pneumonia, such as that due to *Legionella*, community respiratory viruses (e.g., parainfluenza virus, RSV, influenza virus), or *Mycoplasma*, or opportunistic infections such as *P. jiroveci* and CMV infection in the susceptible host (see later). Addition of a fluoroquinolone or a macrolide will cover most atypical bacterial

Table 47-4 Pulmonary Infiltrates and Their Association with Specific Infectious and Noninfectious Disorders

Radiologic Sign	Potential Etiologic Disorder(s)
Interstitial infiltrates	Pulmonary edema
Diffuse alveolar damage	Idiopathic pneumonia syndrome
	Respiratory virus infection: RSV, parainfluenza virus, influenza virus, adenovirus, enterovirus
	Herpesvirus infection: CMV, HSV, VZV, HHV-6
	Pneumocystis pneumonia
Focal airspace disease	Bacterial pneumonia
	Fungal pneumonia
Nodules	Fungal pneumonia (aspergillosis)
	Nocardia infection
	Legionella infection
	Septic bacterial emboli
	Mycobacterial infection (with cavitation)
	EBV lymphoproliferative disorder
	Relapsed malignancy
	Pulmonary embolism (pleura-based)
Halo sign or air-crescent sign	Aspergillosis

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpesvirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

pathogens. For PCP, TMP-SMX at high doses (15 to 20 mg/kg per day) is standard treatment. CMV pneumonia requires initial treatment with intravenous ganciclovir plus administration of intravenous immunoglobulin as an adjuvant treatment.[94]

Pneumonia in a patient undergoing treatment for cancer is considered a health care-associated process. Accordingly, the empirical antimicrobial regimen is directed toward a range of pathogens. Current guidelines from the American Thoracic Society specify a combination of an antipseudomonal beta-lactam agent (cefepime, ceftazidime, a carbapenem, or piperacillin-tazobactam) plus vancomycin or linezolid plus an antipseudomonal fluoroquinolone or aminoglycoside.[95]

Fungal Infections

Fungal infections are due to yeast or mold pathogens. *Candida* organisms typically may colonize the gastointestinal tract and are the most common yeast pathogens in cancer patients. The spectrum of disease caused by *Candida* spp. ranges from mild mucocutaneous lesions (e.g., thrush) to disseminated deep tissue involvement (e.g., hepatosplenic candidiasis). An episode of candidemia probably precedes all tissue-invasive infections. Not all candidemias are clinically or microbiologically detected, however, and end-organ disease may be the first manifestation of invasive candidiasis. Blood cultures lack sensitivity for *Candida* and are positive in only approximately half of the patients with invasive disease.[96]

Neutropenia, the presence of an indwelling venous catheter, and chemotherapy-associated gastrointestinal mucosal injury are important risk factors for invasive candidiasis, rendering patients with cancer at especially high risk. *Candida*-related mortality rates of 33% to 75% are reported in these patients.[97] Because of the difficulty in diagnosing this infection and the associated high mortality, any blood culture found to grow even a single colony of *Candida* must be regarded as a sign of true infection, and the patient should receive therapy. Clinical signs of candidemia may range from fever alone to fulminant sepsis. Approximately 15% of neutropenic patients will have pustular skin lesions. *C. albicans* accounts for about half of the cases, but non-*albicans* species, especially *C. glabrata* and *C. krusei*, are increasing in incidence. Of note, these species are somewhat resistant and fully resistant, respectively, to fluconazole.

Catheter-related candidemia should be treated with antifungal therapy, and the catheter should be removed in most cases.[24] Determining if candidemia arises from a central venous catheter or the gut in a patient with neutropenia or gastrointestinal GVHD can be challenging. For a patient who has candidemia and a tunneled central venous catheter infection, the decision about its removal should be based on the likelihood of catheter-related candidemia. Factors indicating catheter-related candidemia include (1) isolation of *Candida parapsilosis* from blood samples; (2) quantitative blood cultures showing, in blood drawn through the catheter, five times the number of colonies isolated from blood drawn from a peripheral vein; (3) differential time to positivity (longer than 2 hours) for blood samples drawn from a percutaneous site, compared with that for samples drawn through the catheter; (4) candidemia in a patient who is receiving hyperalimentation through the catheter; and (5) persistent candidemia while receiving systemic antifungal therapy.[93] Catheter removal is strongly encouraged under any of these circumstances.[24,98–100]

The availablity of echinocandins (e.g., caspofungin, micafungin, anidulafungin) and newer-generation triazoles (posaconazole and voriconazole), combined with increasing prophylactic use of antifungals in certain populations (e.g., those with acute leukemia or GVHD) and the emergence of resistant *Candida* species in some institutions, has changed the treatment paradigm for candidemia. Some non-*albicans* species (e.g., *C. glabrata*) may have reduced susceptibility to fluconazole. In institutions with higher rates of these organisms, empirical treatment with an echinocandin (e.g., caspofungin, micafungin, anidulafungin) or a later-generation triazole (e.g., voriconazole or posaconazole) is appropriate pending identification when a yeast is identified in the blood. Candidemia that develops during prophylaxis with an azole should be treated with an echinocandin or a amphotericin B preparation. Complications of fungemia may include endocarditis, endophthalmitis, vertebral osteomyelitis, and hepatosplenic candidiasis.[101]

Aspergillus spp. are the most common mold pathogens in patients with cancer, but they are seen almost exclusively in two specific settings: during periods of prolonged neutropenia or in patients with GVHD after allogeneic transplantation. As discussed earlier (under Pulmonary Infections), the vast majority of *Aspergillus* and other mold infections occur in the lung, whereas fewer organisms disseminate to sinuses, skin, or abdominal organs.[102,103] Dissemination to brain occurs in approximately 5% of patients. Unfortunately, the sensitivity of diagnostic tests used to diagnose invasive aspergillosis remains very poor, and delay in diagnosis is all too common, contributing to poor outcome.[104] The CT scan has become an essential diagnostic tool for earlier diagnosis of invasive aspergillosis, with characteristic lesions such as nodules, the halo sign and the crescent sign having high predictive value for the diseasee.[69–72] Despite some improvements in antifungal therapy in recent years, invasive aspergillosis is still associated with an at least 50% mortality rate in patients with cancer.[102,103] Voriconazole has been shown to be superior to amphotericin B for for the treatment of proven or probable invasive aspergillosis, and it is now the agent of choice.[105] The use of combination therapy for invasive *Aspergillus* infections is an attractive approach that has scientific merit in that combinations of echinocandins with azoles or amphotericin B formulations have produced positive results both in vitro and in aspergillosis animal models.[106,107]

On the basis of a few small retrospective studies, combination antifungal treatment appears to be safe and has promising efficacy.[106,108] One recent open-label trial suggested that oral posacon-

azole was associated with a 42% response rate in patients who are refractory to or intolerant of conventional therapy for *Aspergillus* infection, although this is not better than results seen with voriconazole.[109] The enhanced efficacy of two- or three-drug antifungal combinations for invasive aspergillosis remains unproved, pending a prospective comparative clinical trial. Many clinicians, however, are anxious to employ combination therapy in an effort to improve the dismal outcomes for invasive aspergillosis.

Fusarium is notable for causing tender, red skin nodules and positive blood cultures for mold in approximately half of the cases.[110] Infection with any of the zygomycetes (*Mucor*, *Rhizopus*, *Rhizomucor*) is characterized by later onset (after day 90 of transplant) and a longer median duration of survival. Sinus disease with erosion through tissue planes is a feature of zygomycete infections but also may occur with *Aspergillus* infection. The mortality rate is approximately 80% for transplant recipients with proven infection. In up to 60% of those colonized, progression to invasive infection will occur.[111] Other, less common molds, including *Fusarium*, *Scedospoarium*/*Pseudaollescheria*, and *Trichosporon*, appear to be more susceptible to voriconazole than to amphotericin B. Of note, however, one report recently indicated successful treatment of *Fusarium* infection with a combination of both agents.[112]

An increased incidence of infection with voriconazole-resistant molds such as *Rhizopus* or *Mucor* species has recently been described. This increase is hypothesized to be related to more frequent use of voriconazole prophylaxis in high-risk cancer patients.[113,114] Use of amphotericin B products has been standard therapy for infections due to these pathogens, but the recently approved triazole posaconazole has potent in vitro activity against the zygomycetes and has quickly become an important drug in battling infections with these molds. Furthermore, it is available in an oral formulation and has less toxicity than that observed with amphotericin products. Posaconazole has not been evaluated as a first-line agent for treatment of zygomycoses, but reports of its use in salvage therapy are promising.[100] Patients in whom pulmonary lesions with radiologic characteristics suggestive of mold infection (e.g., halo sign, as noted earlier) develop despite voriconazole prophylaxis should receive treatment for zygomycoses with amphotericin B or posaconazole pending microbiologic or histologic diagnosis. Aggressive and repeated surgical débridement is a critically important adjunct to the treatment of zygomycoses of the sinuses.[111]

Hepatosplenic candidiasis is a form of chronic disseminated candidiasis that almost exclusively affects patients undergoing leukemia induction or stem cell transplantation.[101] It generally manifests only on recovery from neutropenia, as persistent fevers unresponsive to antibacterial agents. Patients may have right upper quadrant tenderness and demonstrate a variety of other gastrointestinal signs and symptoms. Consistent laboratory findings include marked elevation of alkaline phosphatase, with normal or mildly elevated bilirubin and transaminases, and a rebound leukocytosis after neutrophil recovery. Blood cultures are almost always negative for fungal growth, as are liver biopsy specimens. Suspected hepatosplenic candidiasis is confirmed by the presence of multiple characteristic well-defined lesions in the liver or spleen, and occasionally in the kidneys on CT scan or ultrasound examination. A prolonged course of therapy, initially with amphotericin B or a lipid formulation and then with fluconazole for a number of months, has been advocated. Echinocandins also may be effective.[100] For patients with acute leukemia and hepatosplenic candidiasis, repeated cycles of chemotherapy may be given once the infection is stabilized, and the antifungals are continued through the courses of cytotoxic therapy.

Gastrointestinal Infections

Upper Gastrointestinal Tract

Mucositis of the oral cavity and alimentary mucosa is a common consequence of cytotoxic cancer therapies. Disruption of the gastrointestinal mucosa causes erosions and inflammation that can provide a portal of entry for colonizing organisms. Esophageal symptoms of odynophagia, dysphagia, and retrosternal or epigastric discomfort do not point to a specific etiology, and it often is difficult to discriminate between drug-induced and infection-induced mucositis. The most common organisms causing local oral or esophageal infection are herpes simplex virus and *Candida* spp., although gram-negative and anaerobic bacteria rarely are responsible. The treatment of presumed esophagitis during a period of neutropenia often is based on the empirical administration of antacids or systemic antifungal or antiviral therapy with acyclovir. For patients who do not respond to empirical therapy with these agents, careful upper endoscopy may be considered to obtain a more precise diagnosis based on direct visualization of the lesions, as well as on tissue biopsy for histopathologic and microbiologic examination. Of note, esophageal endoscopy may be associated with substantial morbidity in patients who are profoundly neutropenic or thrombocytopenic, and it often is advisable to wait until counts recover before proceeding.

Lower Gastrointestinal Tract

Enteritis, clinically manifested by diarrhea, is common in cancer patients. Diarrhea may be due to chemotherapy-induced mucositis or infection-induced. *C. difficile* is the most common pathogen to cause diarrhea in the cancer patient. Over the past few years, the emergence of an epidemic strain of *C. difficile* has resulted in a dramatic increase in the incidence and severity of *C. difficile* infection at many centers.[115,116] The epidemic strain is resistant to fluoroquinolones, and use of this class of antibiotics has been implicated as a risk factor in institutional outbreaks.[117] Because of an increased rate of failure of oral metronidazole noted in recent studies, some experts recommend oral vancomycin for patients with evidence of severe disease (e.g., white blood cell count above 20,000 cell/μL, shock, renal failure, need for transfer to the intensive care unit),[115] and some advocate the addition of metronidazole. For patients unable to tolerate oral therapy (because of ileus or toxic megacolon, for example), intravenous metronidazole and vancomycin adminstered by nasogastric tube or by enema should be considered. Colectomy may be necessary in seriously ill, nonresponding patients. Relapse rates are high.[118] Although no proven approach is recognized, a slowly tapering course of oral vancomycin or metronidazole over 6 weeks often is used for patients with multiple relapses. Outpatients must be alerted to the possibility of recurrence so that retreatment can be instituted quickly.

Other bacterial causes of diarrhea are uncommon in patients with cancer unless exposure to such pathogens has occurred. CMV infection can cause protracted or hemorrhagic diarrhea, especially in children or in patients undergoing allogeneic HSCT. Adenovirus may cause severe diarrhea in allogeneic transplant recipients, and stool culture techniques and plasma PCR assay aid in diagnosis.

Typhlitis, also known as neutropenic enterocolitis, is a unique and potentially life-threatening syndrome occurring in febrile neutropenic patients, particularly those with leukemia or who have had intensive cytotoxic therapy.[119–122] Abodominal pain, especially in the right lower quadrant, often with attendant rebound tenderness, and decreased bowel sounds, fever, and diarrhea are typical presenting features. Typhlitis may be limited to the cecum but can involve the entire intestine. CT scan is the diagnostic study of choice and usually demonstrates thickening of the bowel wall, sometimes with pneumatosis coli.[122] *C. septicum*, *P. aeruginosa*, enteric gram-negative organisms, and anaerobes are the most common pathogens associated with this syndrome. *C. difficile* occasionally is associated with typhlitis, so treatment for *C. difficile* infection (i.e., with oral vancomycin or metronidazole) should be included in the initial antibiotic regimen for typhlitis, along with a broad-spectrum intravenous antimicrobial cocktail. Severe sepsis, bowel perforation, and hemorrhage may accompany or follow typhlitis. Therapy consists of nasogastric suction, bowel rest, intravenous fluids, and broad-spectrum antibiot-

ics to cover gram-negative organisms and anaerobes (e.g., piperacillin/tazobactam, a carbapenem). Antifungal agents also should be part of the initial treatment regimen for typhlitis. In approximately 5% of patients with typhlitis, complications develop that require surgical intervention, including uncontrolled sepsis, lower gastrointestinal tract bleeding, and perforation.[121]

Perirectal infection occurs primarily in patients with acute leukemia and especially among those with monocytic and myelomonocytic leukemia, although it is relatively uncommon. The usual symptoms are fever, pain on defecation, and persistent rectal discomfort. Although anaerobes are thought to play a role in these infections, the associated bacteremias are most likely to be caused by *P. aeruginosa*, *E. coli*, and other enteric gram-negative bacteria. Therapy consists of broad-spectrum antibiotics, warm compresses, and stool softeners. Although few abscesses develop in the absence of neutrophils, some patients will benefit from surgical incision and drainage.

Central Nervous System Infections

In the patient with cancer who demonstrates new mental status changes, focal neurologic signs, or neck stiffness, evaluation for central nervous system (CNS) infection is necessary, because infection is a common cause of neurologic complications.[123] The initial evaluation begins with cerebral magnetic resonance imaging (MRI) or contrast-enhanced CT, followed immediately by lumbar puncture. Empirical treatment with antibacterials with adequate CNS penetration, such as cefepime or meropenem at high doses, is indicated. Of note, neutropenic patients may have few white cells in the cerebrospinal fluid (CSF), even in the setting of meningitis. Impaired T-cell function (e.g., corticosteroids, purine analogs, GVHD, alemtuzamab) but not neutropenia is a risk factor for *Listeria* meningitis. Ampicillin should be added if *Listeria* infection is suspected in a patient with T-cell impairment. Patients with varicella-zoster virus (VZV) or HSV meningoencephalitis may have suggestive skin lesions; if such infection is suspected, then acyclovir 10 mg/kg every 8 hours should be added and a CSF sample sent for PCR testing for both viruses. Cryptococcal meningitis often manifests with subtle mental status changes over several days, and very low CSF cell counts often are seen; serum and CSF crytococcal antigens are senstive diagnostic tests. False-positive test results at low titers may occur in patients with plasma cell dyscrasias. Treatment is with amphotericin B preparations combined with 5-fluorocytosine (monitor for thrombocytopenia, leucopenia, and diarrhea) initially. A repeat spinal fluid examination must be done after 2 weeks of therapy to determine if the CSF is culture-negative; if it is, then the patient may be switched to oral fluconazole. Heavily immunosuppressed patients (e.g., recent recipients of allogeneic HSCT, patients with chronic extensive GVHD) are at risk for meningoencephalitis from reactivation of pathogens such as HHV-6, EBV, or *T. gondii*, although such cases are very rare. CSF PCR assay for these specific herpesviruses or *Toxoplasma* is used to make the diagnosis; CSF culture typically is negative. Ganciclovir or foscarnet generally is used to treat HHV-6 infection. *T. gondii* reactivations often are rapidly fatal despite combination therapy with pyrimethamine and sulfadiazine or clindamycin treatment.[124]

Patients with ring-enhancing CNS lesions may have infection with bacteria, *Toxoplasma*, *Nocardia*, mycobacteria, or fungal organisms, including cryptococci. Post-transplantation lymphoproliferative disorder (PTLD) and other malignancies also may manifest as mass lesions. Typically, a brain biopsy is required to make the diagnosis if obvious concurrent infection at a more accessible site is not present (e.g., *Nocardia* growth from blood cultures or conincident diagnosis of pulmonary invasive *Aspergillus* infection). First-line therapy for CNS nocardiosis includes high-dose TMP-SMX (15 to 20 mg/kg daily) given in three or four divided doses, usually in combination with a second agent such as meropenem. Sensitivity testing should be performed to further refine therapy.

Treatment of CNS mold infections (other than those due to with zygomycetes) should include voriconazole, which attains CSF and brain tissue levels of approximately 22% and 100%, respectively (as indicated by data for a small number of samples).[125] The alternative treatment for CNS mold infection (intraventricular amphotericin accompanied by systemic amphotericin) is very toxic and very rarely used. Limited information suggests that posaconazole may be an effective agent for treatment of CNS fungal infections caused by *Cryptococcus neoformans* and invasive molds.[126]

Vascular Access Devices

Indwelling venous access devices are commonly required in cancer patients for the administration of chemotherapy, blood products, and parenteral nutrition, as well as for withdrawal of blood for therapy monitoring and microbiologic evaluation. Infection is a common complication of venous access devices. The risk of infection varies with the device used, duration of placement, and extent of the patient's immunosuppression. Local signs and symptoms, such as erythema and tenderness, are unreliable indicators of catheter infection even in the immunocompetent patient. The evolution of these signs over time, however, is suggestive of infection. Venous access device infections are categorized as entry site infections, tunnel or pocket infections, and catheter-associated bloodstream infections.[24,127]

Entry-site infections can be treated effectively with appropriate antimicrobial therapy, without the need for catheter removal. Tunnel (i.e., erythema, induration or tenderness beyond 2 cm from the entry site) and pocket infections necessitate catheter removal, as well as the immediate initiation of an empirical antimicrobial therapy that includes vancomycin to cover methicillin-resistant *S. aureus*, until culture results are available.

It often is difficult to determine whether a bloodstream infection is related to the venous access device because frequently, no evidence of local catheter inflammation is seen. Recently, however, the concept of "*differential time to positivity*" has been used to distinguish venous access device–related infections from other types of infection, as follows: If the times at which blood cultures become positive (by machine detection in the clinical microbiology laboratory) are more than 2 hours apart for simultaneously obtained catheter and peripheral vein blood cultures, the catheter is then strongly implicated as the source of infection.[127] Although this differentiation may help determine whether a catheter can be retained or must be removed, most indwelling catheter-related infections will respond to antimicrobial therapy alone, without catheter removal. Certain exceptions are notable: Catheter removal is advisable for patients with bloodstream infections caused by fungi (yeasts and molds) and nontuberculous mycobacteria (*M. chelonae*, *M. fortuitum*, *M. abscessus*). For other bacteria, the decision concerning the need for catheter removal will depend on the severity of the clinical picture, the degree of immunosuppression, and the availability of an alternative vascular access site in a given patient. *S. aureus* may cause endocarditis, and the value of the transesophageal echocardiography in the setting of any *S. aureus* bloodstream infections has been well demonstrated to determine duration of therapy.[128] In general, if blood cultures remain positive despite appropriate antimicrobial therapy for more than 48 hours, or if the patient is clinically unstable, the catheter should be removed independent of the etiology.

Viral Infections

The incidence of herpes simplex virus (HSV) reactivation infections has been reduced with the widespread use of acyclovir prophylaxis. Reactivations not involving the CNS are treated with lower doses of intravenous acyclovir (e.g., 5 mg/kg every 8 hours) or similar drugs given orally, whereas VZV infections are treated with higher doses (e.g., intravenous acyclovir 10 mg/kg every 8 hours or oral valacyclovir 1000 mg every 8 hours). Acyclovir resistance is very uncommon among cancer patients. HSV infections that break through acyclovir

prophylaxis, however, should be considered to be acyclovir-resistant until viral sensitivity testing can be performed, and consideration should be given to initiating treatment with foscarnet or cidofovir. Reports of acyclovir-resistant varicella are extremely rare.[129]

Patients at highest risk of CMV reactivation include recipients of allogeneic bone marrow transplants in the early period after engraftement (i.e., days 30 to 100 after transplantation) during which invasive CMV disease will develop in approximately 2% of patients.[130] Also, patients receiving alemtuzumab and those receiving high-dose corticosteroids for GVHD are at high risk. Universal prophylaxis and preemptive strategies using ganciclovir or valganciclovir have markedly reduced the incidence of CMV disease in these patient groups.[131] Asymptomatic CMV viremia or "CMV syndrome" (fever, leukopenia) without end-organ disease is common in the absence of universal prophylaxis, and is often a trigger for starting an antiviral preemptively, as described later.

End-organ CMV disease most commonly involves the lungs, gastrointestinal tract, or liver.[132,133] Definitive diagnosis requires histopathologic evidence, but compatible clinical findings (e.g., colonic ulcers, interstial pattern on chest radiography) in the setting of CMV viremia diagnosed by PCR or antigen testing is suggestive of invasive disease. CMV treatment is initiated with induction doses of the antiviral agent for at least 2 weeks, followed by a variable course of maintenance dosing, which is one-half the induction dose. The total duration of treatment depends on clinical response, the results of viremia or antigenemia assays that reflect viral replication activity, and the patient's overall state of immunosuppression. Intravenous ganciclovir generally is used for the initial antiviral course (induction dose of 5 mg/kg every 12 hours, maintenance dose of 5 mg/kg once daily) when end-organ disease is documented, although some centers are increasingly using oral valganciclovir in patients who can reliably absorb the drug. The valganciclovir dose in patients with normal renal function is 900 mg twice daily for at least a 2-week induction and then 900 mg once daily to complete 1 to 3 months of treatment. Foscarnet and cidofovir are options, albeit somewhat toxic, for patients who are intolerant of or unresponsive to ganciclovir or valganciclovir.

When the end-organ manifestation of CMV infection is pneumonitis, intravenous immune globulin (IVIG) given at a dose of 500 mg/kg typically is added on an every-other-day basis for the duration of induction.[94,132] When CMV infection manifests in an end organ other than the lungs, the use of IVIG is not so clearly delineated. For other end-organ manifestations of CMV disease, IVIG can be added if the patient's total immunoglobulin G (IgG) level is below 400 mg/dL. No clear advantage favors CMV hyperimmune globulin over regular IVIG.[94,132]

HHV-6, a virus acquired by 95% of humans during childhood, reactivates asymptomatically in up to 50% of patients after allogeneic HSCT.[134,135] Clinical disease is uncommon but may include interstitial penumononitis, encephalitis, rash, cytopenias, and delayed engraftment.[134,135] PCR assay performed on plasma, tissue biopsy material, or CSF can be useful in suggesting HHV-6–associated disease. HHV-6 has 60% DNA homology with CMV, and treatment of documented infection usually is initiated with induction doses of foscarnet or ganciclovir, although responses are variable and it is unclear which drug is more effective.[136]

Respiratory syncytial virus (RSV) and influenza virus infections generally are seasonal; parainfluenza and adenovirus infections may occur year round. Upper respiratory infections may progress to pneumonia, with mortality rates between 6.6% and 80% in heavily immunosuppressed patients.[137,138] A neuraminidase inhibitor commonly is used to treat influenza and may prevent progression from upper respiratory infection to pneumonia, but prolonged shedding and the development of resistance may occur.[139] Inhaled ribavirin reduces RSV shedding, but clinical efficacy has not been demonstrated[140]; furthermore, difficulty of administration and occupational exposure issues limit use of this agent.

Adenovirus may cause pneumonia, colitis, hemorrhagic cystitis, hepatitis, or disseminated disease with a sepsis-like presentation in patients undergoing allogeneic HSCT.[141] Asymptomatic reactivaton is common in adults, but rising levels of viremia or isolation from multiple sites has been associated with an increased risk of severe disease. No standard treatment has been validated, but cidofovir (1 mg/kg three times a week or 5 mg/kg weekly) has been associated with a reduction in levels of viremia.[142]

Reactivation of BK virus in the uroepithelium may lead to hemorrhagic cystitis in the allogeneic transplant recipient, and quantitative PCR assay for BK virus in urine and plasma may be helpful both diagnostically and in assessing response to treatment.[143,144] Low-dose cidofovir (1 mg/kg weekly) has been used for treatment, but its efficacy is unknown.[145]

PREVENTION OF INFECTIONS IN SELECTED RISK GROUPS

General guidelines for prevention of infections are shown in Table 47-5.

Low-Risk Patients

Patients categorized at low risk for complications during fever and neutropenia include most with solid tumors. These patients are at lower risk for serious infections, so they do not generally require any prophylaxis against bacteria, fungi, or viruses. Although one recent large randomized study demonstrated that levofloxacin prophylaxis led to a statistically significant decrease in febrile episodes, hospitalizations, and possible infections in a group of largely low-risk patients (e.g., those with breast cancer, testicular cancer, or small cell lung cancer), the reductions seen were of marginal clinical significance. Consequently, this practice is discouraged by most experts.[146–148] The absolute risk reduction for a first febrile episode was only 4.4%, documented infections were rare, and mortality was unaffected by prophylaxis.[147] Concerns for antimicrobial resistance and for increasing incidence of severe *C. difficile* with widespread fluoroquinolone use are also reasons to limit the use of these agents. Furthermore, because fluoroquinolone-based outpatient treatment of fever during neutropenia is an option for many low-risk patients, routine fluoroquinolone prophylaxis in these patients would eliminate that attractive possibility. Routine fungal or viral prophylaxis also is not required for low-risk patients, with the exception of HSV prophylaxis in patients with a history of HSV reactivation.

Patients who receive autologous transplants may be considered to be at intermediate risk for severe infections in that the associated period of neutropenia is relatively long, often at least 10 days, but they typically experience few complications. The role of prophylaxis in these patients varies with the center and the preparative regimens used; consistent recommendations are lacking.

Patients with Acute Leukemia

Patients undergoing induction or consolidation therapy for acute leukemia have a prolonged period of neutropenia, and the use of routine antibacterial prophylaxis during the period of neutropenia has been controversial. A recent large trial randomized patients with expected duration of neutropenia longer than 7 days to receive either treatment with 500 mg of levofloxacin daily or placebo. Among patients with acute leukemia, a reduction in febrile episodes, microbiologically documented infection, and bacteremia was observed with levofloxacin treatment; however, no mortality benefit was seen.[149] A meta-analysis of clinical trials of fluoroquinolone prophylaxis in high-risk patients did show a survival advantage.[150] The NCCN curently recommends antibacterial prophylaxis with a fluoroquinolone (levofloxacin preferred) for patients with acute leukemia with expected duration of neutropenia of greater than 7 days.[2] Potential problems

Table 47-5 Prophylaxis for Selected Risk Categories

Risk Category	Bacterial	Duration	Viral*	Duration	Fungal	Duration	PCP†
Most solid tumors	None	—	None‡	Neutropenic period	None	—	None
Acute leukemia/MDS	Fluoroquinolone	Neutropenic period	HSV, VZV	Neutropenic period	Posaconazole	Neutropenic period	Only patients with ALL
Autologous HSCT (neutropenic period)	None	—	HSV, VZV	Neutropenic period and 30 days after	Fluconazole	Neutropenic period	For 90–180 days after transplantation
Allogeneic HSCT	Penicillin	Minimum 1 year after transplantation	HSV, VZV, CMV	HSV and VZV during neutropenia, some centers continue for up to 1 year, CMV monitoring to day 100 minimum	Fluconazole (some centers use mold-active agent)	75 days after transplantation	For at least 6 months after transplantation
GVHD	Penicillin	Until resolution of GVHD and off immunosuppression	HSV, VZV, CMV	Until resolution of GVHD and off immunosuppression	Posaconazole	Until off significant immunosuppression	Until resolution of GVHD
Alemtuzumab	None	None	HSV, VZV, CMV	At least 2 months and $CD4^+$ ≥100 cells/μL	Consider	None	At least 2 months and CD 4^+ ≥200 cells/μL
Purine analogs§	None	None	HSV, VZV	At least 2 months	None	None	At least 2 months and $CD4^+$ ≥200 cells/μL

ALL, acute lymphoblastic leukemia; CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSCT, hematopoietic stem cell transplantation; HSV, herpes simplex virus; MDS, myelodysplastic syndrome; PCP, *Pneumocystis* pneumonia; VZV, varicella-zoster virus.

*HSV or VZV prophylaxis with acyclovir, valacyclovir, or famciclovir; see text (under Prevention of Infections in Selected Risk Groups) for CMV prophylaxis strategy.

†Agents used for PCP prophylaxis include trimethoprim-sulfamethoxazole, dapsone, atovaquone, and inhaled pentamidine.

‡HSV prophylaxis for patients with a history of HSV reactivation.

§Fludarabine, cladribine, pentostatin.

associated with routine antibacterial prophylaxis include *C. difficile* colitis, fungal superinfections, and the development of antimicrobial resistance.

Similarly, in patients with acute leukemia, a recent trial suggested a morbidity and mortality benefit with the use of antimold prophylaxis with posaconazole. This trial, conducted in more than 600 patients with acute leukemia or myelodysplastic syndrome, randomized patients to prophylaxis with itraconazole, fluconazole, or posaconazole until recovery from neutropenia and complete remission of disease were obtained.[151] Patients who received treatment with posaconazole experienced significantly fewer invasive mold infections and had a survival benefit. Based on this data, posaconazole should be considered the agent of choice for antifungal prophylaxis in neutropenic patients with acute leukemia. Many centers use voriconazole for this purpose because its activity against *Aspergillus* spp. also is potent, but no comparative study has been done to show equivalence of voriconazole and posaconazole for this purpose.

HSV reactivations in seropositive cancer patients are frequent after chemotherapy and are associated with increased mucosal damage, resulting in increasing pain, limitation of the patient's ability to maintain oral hydration and nutrition, and an increased risk of bacterial and fungal superinfections. Therefore, HSV prophylaxis with acyclovir, valacyclovir, or famciclovir is recommended during the period of neutropenia for patients with acute leukemia. Although VZV reactivation is less common than HSV reactivation, life-threatening disseminated disease may occur, and the foregoing agents will serve as prophylaxis for this pathogen as well. CMV disease is not common in this population, and no routine preventive strategy is required. With the exception of patients with acute lympocytic leukemia (ALL), routine prophylaxis against PCP is not required.

Patients Undergoing Allogeneic Hematopoietic Stem Cell Transplantation

Bacterial infections may cause over 25% fevers in the pre-engraftment phase of allogeneic HSCT, so antibacterial prophylaxis (usually with a newer fluoroquinolone) is often used during this period[152] (Fig. 47-2). This practice has been shown to reduce the incidence of infections, particularly those due to gram-negative organisms, in other high-risk groups (see earlier section), but has not been consistently associated with a decrease in mortality.[149,150] Because of the risk of resistant organisms and *C. difficile* infection, some centers choose not to use routine prophylaxis for allogeneic transplant recipients.[153,154] After engraftment, prophylaxis against encapsulated organisms is indicated. Penicillin prophylaxis has decreased the incidence of infection-related morbidity and mortality from *S. pneumoniae*, *H. influenzae* type b, and *N. meningitidis* significantly. Prophylaxis generally is discontinued 1 or 2 years after transplantation, or later if immunosuppression is ongoing at the 2-year point. Prophylaxis with TMP-SMX (or atovaquone, dapsone, or aerosolized pentamidine, if intolerant) for 6 months after transplanation is indicated to prevent PCP.

Fluconazole prophylaxis has been clearly demonstrated to prevent candidemia and hepatosplenic candidiasis among allogeneic transplant recipients, with treatment generally continuing to day 75 after transplantation.[155–158] Fluconazole, however, does not have activity against yeasts such as *C. glabrata* (some strains) and *C. krusei*, or molds such as *Fusarium*, *Aspergillus*, and the zygomycetes. Some centers use prophylaxis with a mold-active agent such as voriconazole in high-risk patients (i.e, mismatched or matched unrelated donor transplants), and a recent trial demonstrated voriconazole to be equivalent to fluconazole for the prevention of fungal infections when administered for the first 100 days (180 days for those receiving prednisone at a dose of ≥1 mg/kg/day or for recipients of T-cell depleted grafts with $CD4^+$ counts <200 at day 100) after transplant.[159]

Prevention of CMV disease after allogeneic HSCT can be effectively accomplished using either universal prophylaxis or preemptive therapy with ganciclovir or valganciclovir.[160,161] The preemptive strategy employs weekly or twice-monthly blood antigenemia or PCR viral load monitoring tests to guide initiation of antivirals, whereas universal prophylaxis involves providing the drug to all patients at risk (all but seronegative donors and recipients). A majority of transplant recipients will initially manifest CMV reactivation silently; this typically is detected by the weekly monitoring test before the development symptoms (e.g., fever) or end-organ disease. Severe end-organ disease can occur if subclinical reactivations are not treated. The preemptive strategy is preferred to universal CMV prophylaxis for two reasons: First, it decreases exposure to this marrow-toxic drug, and, second, allowing for some low-level replication of CMV, recovery of CMV-specific immunity may be enhanced. Both strategies, however, appear to shift the timing of CMV reactivations to later (after day 100, when monitoring often stops) in the postengraftment course, after it is discontinued in those transplant recipients at higher risk.[159] Strategies for preemptive therapy vary; typically, intravenous valganciclovir or ganciclovir is administered at induction dosing for 7 to 14 days and then reduced to maintenance dosing if reduction in viremia or antigenemia is observed.[162] Treatment may be continued for 2 to 3 weeks after a negative result on a viremia or antigenemia test, and then weekly monitoring is resumed. In most centers, weekly monitoring is continued for at least 100 days, and longer if immunosuppression for GVHD is needed.

For patients seropositive for HSV and VZV, most centers use antiviral prophylaxis with acyclovir or an equivalent agent (valacyclovir, famciclovir) during the neutropenic period, and some continue for up to a year to prevent VZV reactivation. These agents should be stopped if a patient is receiving ganciclovir or valganciclovir.

Vaccination after allogeneic HSCT should be initiated once cellular immunity is thought to be reconstituted. Typically, this occurs at approximately 1 year after transplantation, provided that the patient is not on continued immunosuppression for GVHD. Table 47-6 shows a standard vaccination schedule for after allogeneic transplantation.

Patients with Graft-versus-Host Disease

GVHD and its treatment result in significant suppression of the cell-mediated immune system and high risk of certain infections. The use

Table 47-6 Vaccine Schedule after Hematopoietic Stem Cell Transplantation

Vaccine	12 mo	14 mo	24 mo
INACTIVATED-ORGANISM VACCINES			
Begin reimmunization at 1-year anniversary visit.			
Diphtheria, tetanus, pertussis*	×	×	×
Haemophilus influenzae type b conjugate	×	×	×
Hepatitis B	×	×	×
Pneumococcal 23-valent	×		Optional
Inactivated polio	×	×	×
Influenza	Seasonal if >6 months after transplantation		
LIVE-VIRUS VACCINES			
Reimmunize at 2-year anniversary visit if no active graft-versus-host disease or immunosuppressive therapy.			
Mumps-measles-rubella			×
Varicella			×

*One of these three boosters should be the Tdap tetanus–diphtheria–acellular pertussis vaccine.

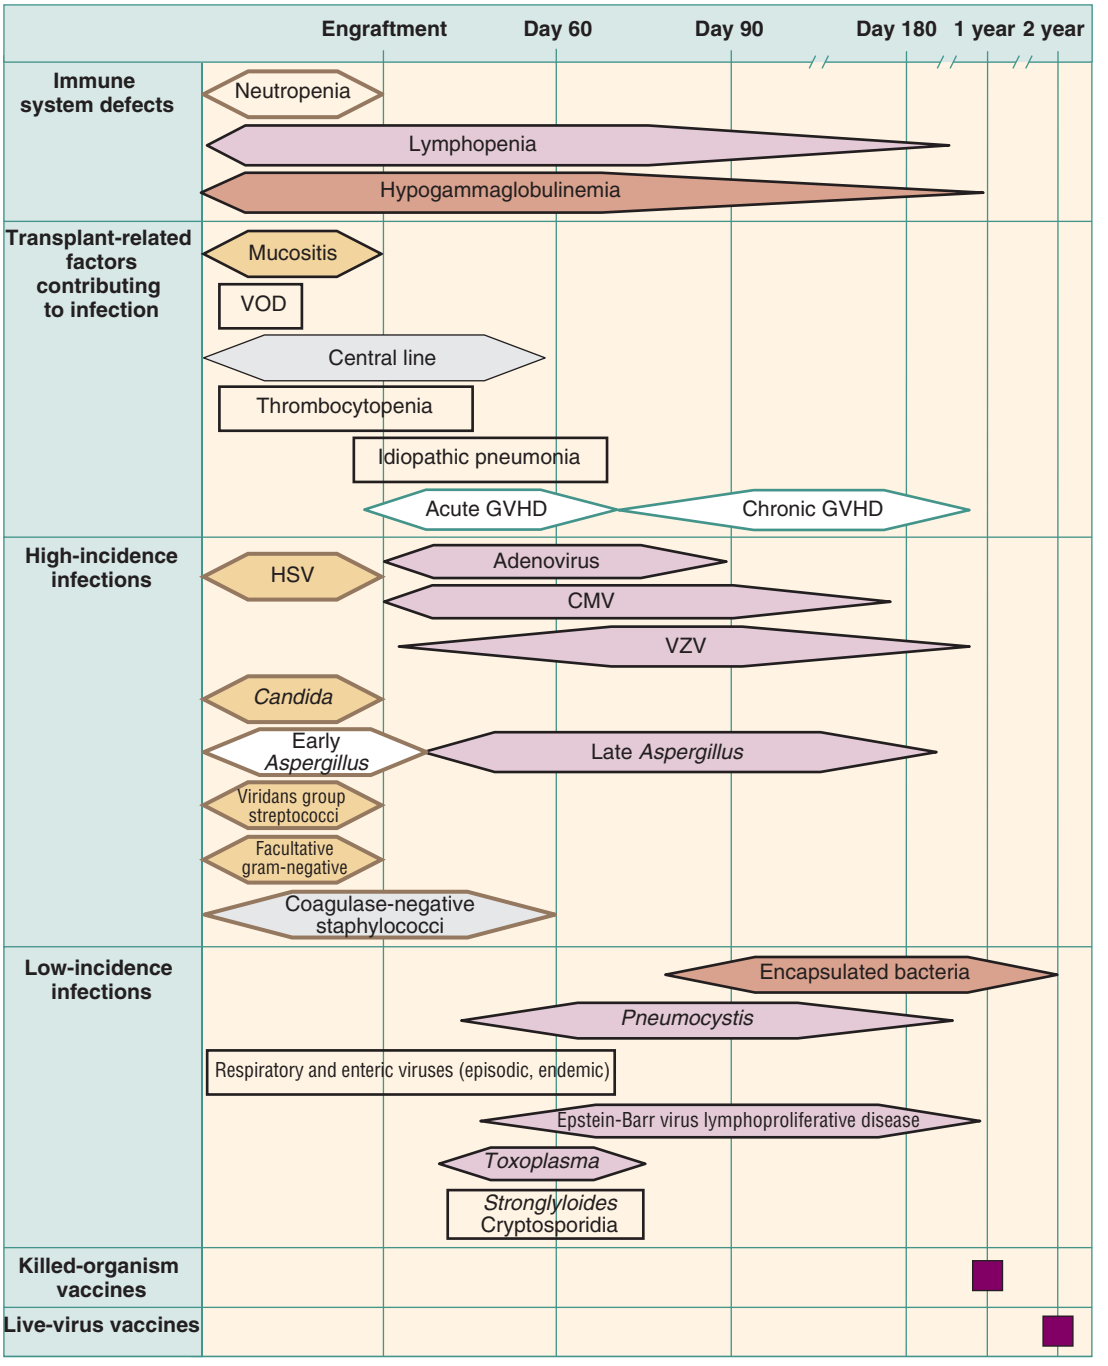

Figure 47-2 • Phases of predictable immune suppression with characteristic opportunistic infections among allogeneic hematopoietic stem cell transplant recipients. CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSV, herpes simplex virus; VOD, veno-occlusive disease; VZV, varicella-zoster virus.

of penicillin to prevent infection with encapsulated organisms (e.g., *Streptococcus pneumoniae*) is widely accepted,[2,161] despite the fact that *S. pneumoniae* is increasingly resistant to this agent.

Although invasive mold infections, particularly invasive aspergillosis, constitute a serious threat during GVHD, few studies have evaluated fungal prophyalxis until recently. A large randomized trial comparing the new triazole posaconazole with fluconazole in patients with grade II or IV acute GVHD or chronic extensive GVHD has now demonstrated a reduction in overall breakthrough invasive fungal infections including invasive *Aspergillus* infections.[163] No effect on mortality was observed, however. Based on this trial, the NCCN recommended posaconazole prophylaxis in patients who are undergoing immunosuppressive treatment for severe GVHD.[2] Posaconazole currently is available only as an oral suspension that must be taken three times daily with a high-fat meal, which is critical for adquate absorption of the drug. Patients with GVHD of the gut may not be able to tolerate this regimen. Voriconazole and echinocandins are potential alternatives but are not well studied for prophylaxis in this setting.

Antiviral prophylaxis with acyclovir or an equivalent drug (e.g., valacyclovir, famciclovir) is widely used to prevent HSV- or VZV-related disease. Most centers have adopted a preemptive monitoring approach, as discussed previously (see earlier section, Patients Undergoing Allogeneic Hematopoietic Stem Cell Transplantation) to

decrease the incidence of CMV-related disease. TMP-SMX or an alternative agent for intolerant patients (e.g., dapsone, inhaled pentamidine, atovaquone) is routinely used as prophylaxis against PCP while patients remain on immunosuppression.

Prophylaxis with Other Immunosuppressive Therapies

Alemtuzumab (Campath) has been used with increasing frequency in patients with a variety of lymphoproliferative disorders, with the primary effect being prolonged suppression of cellular immunity. In one study of patients with B-cell CLL, the median time to reach a $CD4^+$ count greater than 100 cells/μL was 4 months, and the median $CD4^+$ count was less than 25% of baseline at 9 months.[164] A high frequency of CMV reactivation and bacterial infections has been reported during alemtuzumab therapy, and opportunistic infections similar to those seen in patients with late-stage AIDS (e.g., PCP, progressive multifocal leukoencephalopathy, cryptococcosis, disseminated histoplasmosis, cerebral toxoplasmosis) also have been described.[165,166] Prophylaxis against PCP with TMP-SMX or an alternative agent should be given for at least 2 months after completion of alemtuzumab therapy and probably should be continued until the $CD4^+$ count is above 200 cells/μL. Weekly monitoring for CMV infection (i.e., antigenemia or PCR) should be instituted until a $CD4^+$ cell count is greater than 100 cells/μL, and positive results should be treated (see Viral Infections). Acyclovir or an equivalent agent also should be considered throughout the course of cellular immunosuppression to reduce the risk of HSV or VZV reactivation. Although serious bacterial and fungal infections also appear to be increased with alemtuzumab, it is thus far unclear what type of prophylaxis should be undertaken in these patients.[167]

Purine analogs (e.g., fludarabine, cladribine, pentostatin) also cause a depletion of T-cell populations and an increased risk of opportunistic infections compared with traditional therapy with alkylating agents. The rate of opportunistic infection varies considerably, but patients who have received previous therapy, partially or nonresponding patients, and patients receiving other agents (e.g., alkylating agents, corticosteroids) are at higher risk for such infections.[12,168] Prophylaxis against PCP for 2 months and until the $CD4^+$ count is above 200 cells/μL is recommended. Antiviral prophylaxis with acyclovir or an equivalent drug should be considered in these higher-risk patients. The role of antifungal prophylaxis with fluconazole or a moldactive agent in this population is unclear.

PRETRANSPLANTATION MEASURES TO PREVENT INFECTION

Pretransplantation Serostatus Blood Work

The serostatus of herpesviruses (HSV, VZV, CMV, and EBV) that may be present in latent form in the body should be checked before transplantation to determine if the patient is at risk for reactivation. Current testing of both donor and recipient before the transplant-preparative regimen begins includes not only herpesvirus antibodies but also hepatitis virus panels, human T-cell lymphotrophic virus (HTLV-I and HTLV-II) antibodies and human immunodeficiency virus (HIV), and syphilis serology.

The only test result that could lead to immediate cancellation of the transplantation procedure would be a positive result on HIV testing in a patient not known to be seropositive. If the screening test for HIV is positive from either the donor or the recipient, a Western blot study should be completed to confirm the result before informing the affected person of the screening test result. Any time a positive HIV test result is conveyed to a patient, appropriate counseling must be provided.

Several serostatus test results, if positive, would not constitute an indication to cancel the transplant but would lead to a different action plan.[169] If the indirect screening test for syphilis, such as the rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) test, yields a positive result, confirmed by a direct test, the fluorescent treponemal antibody (FTA) test, then the patient should receive high-dose penicillin treatment for 10 to 14 days.

Hepatitis B (core antibody, surface antibody, and surface antigen) and C serologic studies are performed in donor and recipient before transplantation; if results are positive, viral load testing should be performed. Hepatic dysfunction from either hepatitis B or C after transplant can lead to life-threatening liver complications.[170–172] Hepatitis occurs within months or the first few years after transplantation in approximately 20% of HBsAg recipients, whereas cirrhosis developing over a period of many years usually is due to hepatitis C.[173] A hepatitis virus-infected person may serve as a donor if no alternative donor is available or if the intended recipient is already seropositive. The risk of transmission is lowest when a hepatitis B- or hepatitis C-positive donor has an undetectable viral load. Accordingly, donors found to have high viral loads on testing for hepatitis B or C should receive treatment with appropriate antivirals to reduce viral loads before transplantation and before donation, in conjunction with hepatology consultation.[174,175] Similarly, transplant recipients with serologic evidence of previous infection with hepatitis B or C, or those who receive cells from a seropositive donor, should have viral load levels monitored before and after transplantation and also may require treatment. Agents with activity against hepatitis B virus include lamivudine, tenofovir, and entecavir. Hepatitis C currently is treated with pegylated (PEG) interferon and ribavirin, with acceptable safety profiles and cure in up to 50% of patients.[176] Regarding hepatitis C, no evident correlation exists between hepatitis C genotype and type or severity of liver disease after transplantation.[177]

CMV, HSV, and VZV serologic studies are routinely performed before transplantation. If either the donor or the recipient is seropositive, a prevention strategy as presented earlier is used. If both the recipient and the donor are CMV-seronegative, seroconversion with blood products is possible, so CMV-seronegative or filtered blood products should be used.[178,179] Patients seropositive for HSV or VZV (or with a reliable history of chickenpox) receive prophylaxis as discussed. VZV-seronegative patients should receive varicella-zoster immune globulin (VZIG) prophylaxis within 96 hours of significant exposure.[160] If VZIG is not available, most experts would treat with acyclovir or valacyclovir for 3 weeks.

Knowing the EBV serostatus before transplantation is not mandatory because 95% of adult patients can be assumed to be seropositive for this virus. EBV-driven PTLD occurring as a consequence of EBV reactivation is in the differential diagnosis for any space-occupying mass after transplantation, but this usually occurs several months after the neutropenic phase.[180] Major risk factors for the development of PTLD include primary EBV infection after transplantation in a seronegative recipient, the use of antithymocyte globulin or anti-CD3 monoclonal antibodies for immunosuppression, and CMV primary infection or reactivation.[181–183] Mismatched or unrelated donor stem cell grafts or T-cell–depleted grafts also are associated with an increased risk for PTLD. Although the incidence of PTLD after allogeneic HSCT is as low as 0.5% in patients without major risk factors, it increases to 22% in patients with three or more risk factors. Routine monitoring of EBV viral load appears to be of limited value after transplantation, however.[184]

Historically, 15% of patients receiving transplants in the United States are seropositive for *T. gondii*, but this percentage may be higher in European centers.[185] The risk of reactivation among seropositive patients is 2%, for an overall incidence of less than 1% of transplant recipients.[185,186] Because serologies for *T. gondi* may be unreliable after transplantation, serologies should be obtained prior to transplant because this information can be useful in evaluating patients who later develop syndromes (e.g., CNS mass lesion) compatible

with toxoplasmosis. It is likely that low-dose sulfa-based regimens such as those used to prevent PCP also are effective in preventing *Toxoplasma* infection.[186,187]

Environmental Measures to Prevent Infection during and after Transplantation

Handwashing or, preferably, the use of alcohol-based hand-rub disinfectant is the mainstay of infection prevention in the hospital or clinic.[188] Persons entering the patient room to perform examination or touch the patient (including visitors as well as health care workers) should wash or disinfect their hands outside the room.[16] During respiratory virus season, infection control teams will often add extra signs to doorways and in other areas of the wards to remind visitors of the importance of handwashing. Staff and visitors without control of body secretions should not be permitted to have direct patient contact. It should be stressed, however, that routine use of gown, gloves, and masks is not required in the presence of a neutropenic patient.

Some infectious situations necessitate use of special isolation procedures.[16] Contact isolation (gloves, gowns) is indicated for encounters with patients with adenovirus, methicillin-resistant *S. aureus*, or *C. difficile* infection. Droplet precautions are added to contact precautions for respiratory virus or varicella infection. Carriers of vancomycin-resistant enterococci are placed in contact isolation until they meet federally determined criteria for discontinuation of isolation, including a negative result on culture from the original site of positive culture, if the site is still available for culture (as in wound or urine), plus three consecutive negative results on culture of rectal swabs taken at least 1 week apart.[189]

High-efficiency particulate air (HEPA) filtration has replaced laminar air flow as the means of prevention of infection through ventilation in most transplant centers.[16] With at least 12 air exchanges per hour, HEPA filters are capable of removing particles larger than 0.2 mm in diameter, such as mold spores. In addition, it is recommended that room air pressure be maintained continuously above that of the corridor (i.e., positive-pressure environment). These environmental measures are recommended for allogeneic transplant recipients; it does not appear that autologous transplant recipients require this level of protection. For individual patients, such as those who will receive T-cell–depleted transplants, "upgrade" to a laminar air flow environment may be considered. Not all centers, however, continue to maintain laminar air flow patient rooms, and the use of these facilities remains controversial.[16]

Patients may ask if portable HEPA filters should be purchased for the home or apartment that will be occupied after hospitalization is over. In the broadest sense, this extra measure can be recommended on an individual basis, but if portable HEPA filters are used, then they should be obtained for each of the rooms that the patient will occupy during the day and night, and each unit should be sized for the individual room.

Review of Commonsense Measures That Will Assist in the Prevention of Infection

After transplantation, questions often arise about the infectious potential of diet, travel, exposure to crowds, and pets.[160] Diet should be reviewed so that both provider and patient recognize whether the patient is taking any restricted foods or herbal supplements.[160] Patients may not realize that such supplements fall in the same category with medications, and that most herbal supplements need to be discontinued after transplantation.[190]

Food-borne infections constitute an increasingly difficult problem in the United States. Ground meat products must be cooked thoroughly so that bacteria distributed onto meat in the grinding process, such as *E. coli* O157 : H7, are killed. Any fruits or vegetables that cannot be peeled must be washed thoroughly before being eaten, and patients should be aware that salad bars are associated with occasional transmission of *Salmonella*, *Shigella*, and *E. coli* infections.[191,192] Food products that inherently contain infectious organisms should be avoided, including undercooked eggs (*Salmonella*), miso soup (*Aspergillus*), and soft cheeses or unpasteurized dairy products (*Listeria*) or blue cheeses (molds). Yogurt containing *Lactobacillus* has been found to cause lung infection rarely, possibly after aspiration events.[193]

No particular restrictions apply to travel, but strategies to minimize transmission of infectious diseases have been summarized.[160] Some social situations, such as sitting in a crowded movie theater or classroom, increase the risk of acquiring a viral illness. Turning away from people who are coughing or sneezing, or even quickly donning a mask, may be helpful in preventing transmission of infection in the first months after transplantation, until immunosuppression is stopped. Patients should be instructed to practice appropriate infection prevention by handwashing as soon as possible after being close to someone with a cold. In view of recent outbreaks of infection with noroviruses (Norwalk-like viruses) on cruise ships, and other types of outbreaks (e.g., staphylococcal infection) commonly associated with the close living quarters typical with this type of vacation, cruise ships should not be high on the list for vacation choices.[194,195]

Healthy dogs and cats are considered acceptable pets. The immunosuppressed patient, however, should avoid any contact with used cat litter, including "scooping" the litter box, because of potential *Toxoplasma* cyst exposure. Similarly, the patient should not play in sandboxes, because these areas may be used by outdoor cats as litter boxes. Because reptiles of many sorts have been reported to be infected with *Salmonella*, the patient should not touch these animals or the inside or outside of their aquarium homes. The heated water of tropical fish tanks may carry *Mycobacterium marinum*. *Cryptococcus* and *Chlamydia psittaci* can be transmitted from large pet birds.

D. METABOLIC AND PARANEOPLASTIC SYNDROMES

48 Hypercalcemia

A. Ross Morton and Allan Lipton

SUMMARY OF KEY POINTS

Incidence
- Hypercalcemia is a major metabolic complication associated with malignant disease.
- It occurs in approximately 10% of patients with cancer.
- It has a specific predilection for squamous carcinoma of the bronchus, carcinoma of the breast, and multiple myeloma.
- It is frequently recognized late and managed poorly.

Etiology of Complication
- Parathyroid hormone-related protein (PTHrP) produces hormonal and paracrine effects.
- Factors released by, or in response to, metastases in bone (receptor activator of nuclear factor-κB ligand [RANKL], PTHrP, transforming growth factor-α, tumor necrosis factor, interleukin-1 [IL-1], and others) cause paracrine effects.
- Final common pathway is osteoclastic bone resorption.
- It is aggravated by renal functional abnormalities or renal effects of PTHrP, or both.

Evaluation of the Patient
- Determination of the stage of disease and subsequent antineoplastic options provides a logical approach to management.
- Patient symptomatology is more relevant than the absolute calcium level.
- The total calcium concentration must be corrected for serum albumin concentration.
- Close attention to volume status and renal function are mandatory.
- Causes of hypercalcemia other than malignancy should be considered.

Grading of the Complication
- Patients with symptoms due to their hypercalcemia should be treated as severely affected irrespective of the absolute calcium level.
- A corrected serum calcium of less than 3.0 mmol/L is considered mild, 3.0 to 3.5 mmol/L is moderate, and greater than 3.5 mmol/L is severe.

Treatment
- Antitumor therapy should be implemented for best long-term results.
- Consideration should be given to active palliation in the face of advanced disease when antitumor options are exhausted.
- Extracellular fluid volume should be expanded to induce a calciuresis.
- Antiresorptive therapy (bisphosphonates with or without calcitonin) should be considered as first-line therapy.

INTRODUCTION

Hypercalcemia is one of the most common metabolic complications of malignancy. Even though it occurs in approximately 8% to 10% of patients with malignant disease, the diagnosis is frequently delayed. A knowledge of the tumor types associated with hypercalcemia, the mechanisms generating the hypercalcemia, and the symptom constellation will lead to prompt diagnosis, timely and appropriate intervention, and amelioration of morbidity.

Hypercalcemia in association with malignant disease was first reported by Zondek and colleagues in 1924,[1] and the first review of a large series was by Gutman and coworkers in 1936.[2] Since then, the syndrome has become increasingly well recognized and characterized. The frequency with which hypercalcemia occurs varies considerably with tumor type, but it is most commonly seen in association with squamous carcinoma of the bronchus, carcinoma of the breast, and multiple myeloma. It is of considerable interest that some tumors that frequently metastasize to bone—for example, small-cell carcinoma of the lung, carcinoma of the prostate, and some other common tumors, such as adenocarcinoma of the colon and stomach—are infrequently associated with hypercalcemia.

ETIOLOGY

Before we discuss the possible etiologies of hypercalcemia in malignant disease, a short review of normal calcium homeostasis is appropriate. (For a more extensive review see Ramasamy.[3]) The adult human body contains approximately 1 kg of calcium, of which all but 10 g is lodged in bone. Most of the extraosseous calcium is found in the extracellular fluid, but the minute concentrations present in cells (10^{-8} to 10^{-7} M) are vital to normal cellular function and control. The total body calcium is dependent on the balance between calcium intake and calcium loss. Figure 48-1 demonstrates the normal calcium metabolism.[4] The normal dietary calcium intake is approximately 1 g per day (25 mmol). Absorption of dietary calcium is incomplete (25% to 50%), and in healthy individuals it is approximately 300 mg (7.5 mmol per day). Bone represents an enormous reservoir of calcium, yet very little transfer of calcium (on the order of 500 mg or 12.5 mmol per day) occurs between bone and the plasma in health. When net calcium balance is zero, the body is required to excrete approximately 150 mg (3.75 mmol) of calcium daily. The kidney filters large amounts (10 g or 250 mmol) of calcium daily. Of this amount, 65% is reabsorbed in the proximal convoluted tubule, 25%

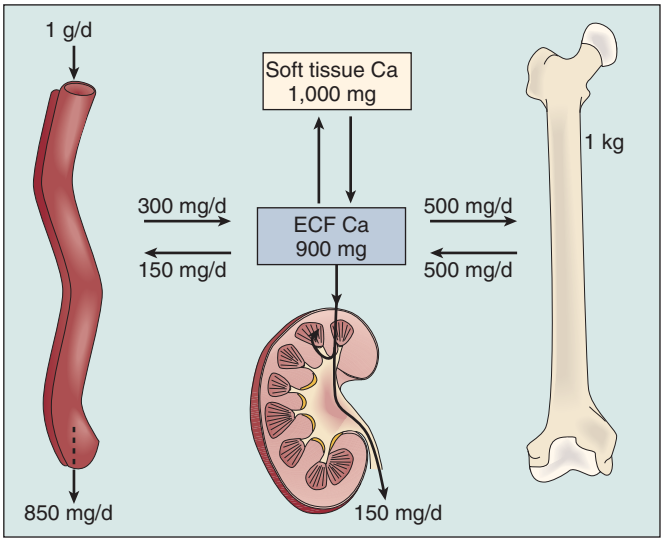

Figure 48-1 • Normal calcium homeostasis. ECF, extracellular fluid. (From Mundy GR: Calcium Homeostasis: Hypercalcemia and Hypocalcemia. Martin Dunitz, London, 1990, p 2, with permission.)

in the ascending limb of the loop of Henle, and a variable amount in the distal convoluted tubule. Calcium reabsorption in the proximal tubule is independent of hormonal control but is closely linked to the reabsorption of sodium, a phenomenon that has important consequences in, and implications for, the treatment of hypercalcemia. Calcium reabsorption from the distal tubule is enhanced in the presence of parathyroid hormone (PTH), and it is at this site that the fine-tuning of calcium homeostasis occurs. The maximal reabsorptive capacity of the kidneys is limited to about 600 mg per day (15 mmol per day); thus, bone resorption can increase by approximately 150% over bone formation before the renal clearance mechanisms are overwhelmed.

The total plasma calcium consists of free plasma calcium (which amounts to approximately 50% of the total) and calcium bound to albumin (and occasionally to other proteins, including paraproteins), which varies with the level of plasma proteins but accounts for approximately 40% of the total. The remaining 10% is in complex with ions such as bicarbonate and citrate (Fig. 48-2). In physiologic terms, the plasma free (or "ionized") calcium carries the greatest

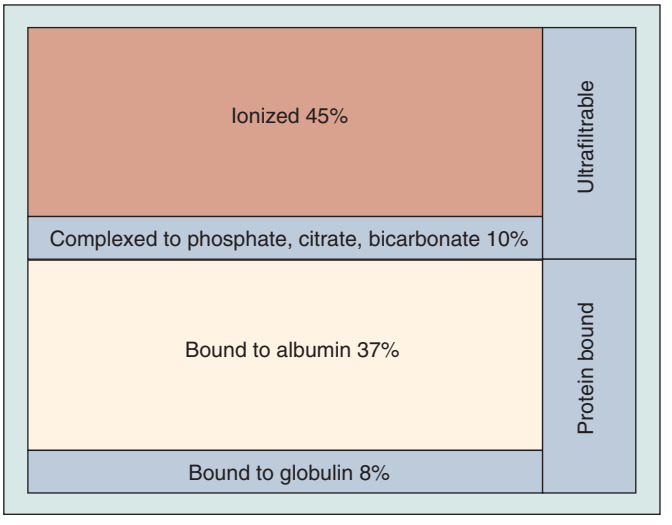

Figure 48-2 • The constituents of total calcium within the serum.

significance. Direct measurement of the plasma free calcium is possible using ion-selective electrodes, but for the most part, total plasma calcium is measured. Because there is a reasonable correlation between serum albumin and serum calcium, algorithms have been suggested to "correct" the total plasma calcium for albumin concentration. Although no algorithm is 100% specific or sensitive for the detection of all true cases of hypercalcemia, the following equation has the merits of accuracy and simplicity.

$$\text{Ca (corrected)} = \text{Ca (measured)} + (0.8 \times [4 - \text{albumin concentration}])$$

Conventional units

$$\text{Ca (corrected)} = \text{Ca (measured)} + (0.02 \times (40 - \text{albumin concentration}))$$

SI units

The serum level of ionized calcium is tightly controlled. The major hormonal determinant of ionized calcium is PTH. This hormone brings about its effects by altering calcium resorption from bone, calcium reabsorption in the kidney, and, via stimulation of formation of active vitamin D (1,25-$(OH)_2D_3$), calcium absorption from the gastrointestinal tract. The active form of circulating PTH is a polypeptide containing 84 amino acid residues; however, only the first 34 amino acid residues are required for activity related to calcium homeostasis. Several larger C-terminal fragments of PTH are found in circulation (most notably in the presence of renal insufficiency). The role of these peptides, and particularly the large PTH(7–84) fragment (which has been postulated to have antagnositic properties to PTH(1–84), which is secreted from the parathyroid glands during hypercalcemia) remains controversial. An excellent review on the topic of PTH has been written by Potts.[5]

PTH release and, to a lesser extent, formation is under the control of the calcium-sensing receptor (CaSR) which is located on the external cell membrane of parathyroid chief cells. This receptor is a G-protein coupled receptor with a large extracellular domain, responsible for calcium binding, seven transmembrane domains, and a smaller intracellular domain responsible for signal transduction. Stimulation of the CaSR by even mild changes in ionized calcium level results in a rapid and profound change in the secretion of PTH as well as more delayed effects on PTH formation.[6]

The parathyroid glands also manufacture the hormone calcitonin. Although pharmacologic doses of calcitonin have effects on plasma calcium levels when given acutely, there remains considerable controversy over its true physiologic role,[7] because in both the absence of calcitonin (following total thyroidectomy) and in the presence of large circulating amounts (seen in medullary carcinoma of the thyroid), gross disturbance of calcium balance is extremely rare.

An understanding of normal calcium homeostasis makes it clear that there are three potential mechanisms that can cause hypercalcemia of malignancy. Calcium can be mobilized from bone in quantities sufficient to overwhelm the renal excretory mechanism, renal reabsorption of calcium can be inappropriately increased (or excretion can be decreased), and gastrointestinal absorption of calcium can be enhanced.

TYPES OF HYPERCALCEMIA OF MALIGNANCY

Humoral Hypercalcemia of Malignancy

In 1980, Stewart and colleagues[8] described a series of 50 patients with hypercalcemia and malignant disease. In their extensive metabolic evaluation they were able to characterize the patients into two groups dependent on their excretion of nephrogenous cyclic adenosine monophosphate (cAMP). Patients with high nephrogenous cAMP shared other features with primary hyperparathyroidism, including a

lowered renal phosphate threshold. There were, however, significant differences between these groups in terms of fasting urinary calcium excretion, 1,25-$(OH)_2D_3$ concentrations, and immunoreactive PTH levels. They concluded that urinary nephrogenous cAMP was a useful marker for identifying hypercalcemia of malignancy associated with a humoral factor—so-called humoral hypercalcemia of malignancy (HHM)—but that this factor was not native PTH.

Parathyroid Hormone-related Protein

Advances in molecular biology, in association with the failure to detect circulating immunoreactive PTH in patients with hypercalcemia, cast increasing doubt on the role of native PTH in HHM. In 1983, Simpson and colleagues,[9] using complementary DNA probes to PTH messenger RNA (mRNA), failed to demonstrate the production of PTH mRNA in many of the tumors considered as prime candidates for ectopic PTH secretion.

In 1987, Burtis and associates,[10] Moseley and coworkers,[11] and Strewler and colleagues[12] published descriptions of a polypeptide hormone isolated from tumors that are associated with the hypercalcemia of malignancy. The primary structure of these peptides shows considerable N-terminal homology with native PTH (Fig. 48-3) and has led to the terminology PTHrP. Although PTHrP is the main humoral factor in patients with hypercalcemia of malignancy, there is increasing information on its normal physiologic roles.[13] Furthermore, PTHrP seems to be under the control of the CaSR, where, in the case of malignant disease, hypercalcemia sensed by the CaSR may actually *increase* the elaboration of PTHrP, thus aggravating the vicious cycle of hypercalcemia. This has led to the suggestion that high calcium levels may actually have a pro-malignant potential mediated by the CaSR, and at least in part due to the actions of PTHrP. This topic has been extensively reviewed by Chattopadhyay.[14]

Vitamin D-linked Hypercalcemia

In the majority of patients with hypercalcemia, levels of 1,25-$(OH)_2D_3$, the active metabolite of vitamin D, are suppressed. Normal vitamin D metabolism is closely controlled at the level of 1α-hydroxylation of 25-hydroxyvitamin D_3 in the proximal convoluted tubules of the kidney. The renal tubular 1α-hydroxylase is stimulated by increased levels of PTH and hypophosphatemia, inhibited by hyperphosphatemia, and decreased in activity as PTH levels fall.

In addition to the well-known association of hypercalcemia in sarcoidosis, abnormal vitamin D metabolism, characterized by a substrate-dependent conversion of 25-hydroxyvitamin D_3 to 1,25-$(OH)_2D_3$, has been described in association with lymphomas. Indeed about half of lymphoma patients presenting with hypercalcemia have abnormal amounts of 1,25-$(OH)_2D_3$, whereas the remainder have elevated concentrations of PTHrP. It seems that the cells responsible for the activation of vitamin D are macrophages in close proximity to the lymphoma cells.[15]

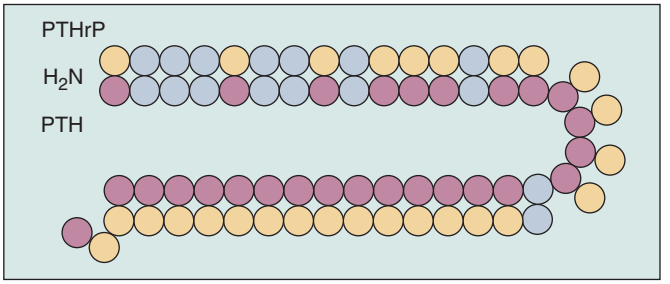

Figure 48-3 • Sequence homology between PTHrP (1–34) and PTH (1–34). Blue circles indicate identical amino acids between the polypeptides; purple and yellow circles indicate that the corresponding amino acids are not identical.

It has become apparent that as many as 50% or more of patients with adult T-cell lymphoma have hypercalcemia. Evidence suggests that the mechanism of hypercalcemia in this lymphoma type is due to overexpression of the receptor activator of nuclear factor-κB ligand (RANKL; see later discussion) in the malignant T cells. Recent work by Okada and associates points to the role of macrophage inflammatory protein-1α as the RANKL-inducing agent, as well as having a recruiting effect on osteoclast precursors.[16]

The role of pharmacologic doses of active vitamin D and its analogs in the treatment of malignant disease is increasing. The major early drawback to this therapy has been the development of drug-induced hypercalcemia. More recently the introduction of intermittent dosing, the combination with dexamethasone or bisphosphonates, and the promise of less calcemic analogs seems to be circumventing this problem. (See reviews.[17,18])

Local Osteolytic Hypercalcemia

In the presence of a large bony metastatic burden, calcium is mobilized from the skeleton by the action of osteoclasts. The osteoclasts seem to be stimulated by local factors produced by the tumor cells. Tumor types in this category (carcinoma of the breast, multiple myeloma, lymphoma, and leukemia) rarely produce hypercalcemia in the absence of significant bony involvement, but it must be remembered that local and humoral factors can interact to aggravate bone destruction.

Multiple Myeloma

Bone resorption, osteopenia, and hypercalcemia are characteristic features of patients with multiple myeloma. The neoplastic cells are in close proximity to bone by the very nature of the condition. Many factors responsible for local osteolysis have been identified, produced by, or in response to, myeloma cells in the marrow. Collectively, these have been called osteoclast-activating factors. They include IL-1, IL-6, IL-11, PTHrP, hepatocyte growth factor, tumor necrosis factor, macrophage inflammatory protein-1α, among others (reviewed by Yeh and Berenson[19]).

The identification of the cytokine system involving RANKL, the target of this polypeptide (receptor activator of nuclear factor-κB [RANK]), and the controlling inhibitor osteoprotegerin (OPG) that acts as a soluble decoy receptor, has represented a major breakthrough in the understanding of local control of bone cell biology (reviewed by Hofbauer[20]). Essentially, RANKL, normally produced by osteoblasts, is responsible for osteoclast differentiation and function. In patients with multiple myeloma the RANK/RANKL/OPG system is deranged. Multiple myeloma cells in the bone marrow increase the presence of RANKL either by direct secretion or by stimulating stromal cell production. Furthermore, there is depression of OPG availability, both at the level of protein systhesis, and after OPG has been secreted as a result of binding to CD-138 (syndecan-1) elaborated by multiple myeloma cells.[21]

The picture of hypercalcemia in multiple myeloma is further complicated by the various renal defects that are a feature of at least 20% of patients with this condition. The major impact is a reduction in glomerular filtration rate, which decreases the kidneys' ability to excrete a calcium load.

Carcinoma of the Breast

It is generally considered that hypercalcemia is uncommon in patients with carcinoma of the breast in the absence of widespread osseous metastases. Bony destruction is again mediated by stimulated osteoclasts. It has been suggested that breast cancer cells themselves might be capable of resorbing bone, but this does not seem to be a major mechanism. Breast cancer cells are able to produce or induce a number of factors in the local bone microenvironmant that could act at a local level to enhance osteolysis (including transforming growth factor-α, IL-8, IL-11, and prostaglandins—particularly of the E series).

Despite this, it is also clear that not all cases of hypercalcemia in carcinoma of the breast are wholly dependent on metastatic disease. Indeed, one of the original tumor types from which PTHrP was isolated was breast cancer.[10] In an early study of 98 women with varying degrees of breast cancer, Bundred and coworkers[22] noted elevated PTHrP levels in 12 of 13 hypercalcemic patients. Furthermore, tumor staining for PTHrP was positive in 22 of 25 patients who had bone metastases and later developed hypercalcemia.

It has become increasingly clear that cell-cell interaction between breast cancer cells and the local bone cells has much to do with the maintenance of the metastatic phenotype in bone. Local production of PTHrP by breast cancer cells can increase osteoclast development and recruitment via RANKL. Enhanced bone resorption can release stored factors including insulin-like growth factor-1 and transforming growth factor-β. These substances support the growth of the malignant cells. Osteoclastic mobilization of calcium increases tumor production of PTHrP (mediated in part by the CaSR), resulting in a vicious cycle. Cellular cross-talk as it relates to bone metastases has been elegantly reviewed by Yoneda and Hiraga.[23]

Special Cases

Pseudohypercalcemia

The phenomenon of psuedohypercalcemia is a rare condition in which excess calcium bound to nonalbumin plasma proteins results in an elevated total serum calcium concentration. These proteins are usually monoclonal proteins associated with multiple myeloma and benign monoclonal gammopathy.[24] The ionized calcium concentration is normal under these circumstances, but correction formulas using albumin give falsely abnormal results.

Multiple Endocrine Neoplasia

The multiple endocrine neoplasia (MEN) syndromes are a group of disorders associated with hyperfunction of two or more endocrine glands. Hyperparathyroidism or parathyroid hyperplasia is a feature of both MEN-1 and MEN-2. Hypercalcemia is usually mild and frequently asymptomatic. The role of parathyroidectomy is unclear in MEN-1 and MEN-2B, but the association with medullary carcinoma of the thyroid in MEN-2A means that it will more frequently be undertaken in this condition. The fact that the hyperplastic parathyroid glands display the CaSR renders them susceptible to treatment using calcimimetics (see later discussion).

Tamoxifen-Linked Hypercalcemia

Hypercalcemia in association with the use of estrogen or antiestrogen therapy for carcinoma of the breast has been recognized for more than 50 years. The severity of the hypercalcemia is variable, but it can be fatal. The mechanism by which tamoxifen and similar agents cause hypercalcemia is unclear. Cell culture studies suggest that prostaglandins could be the main mediators of the response.[25] A role for prostaglandins would be compatible with the clinical picture of a tamoxifen "flare," which, in addition to the hypercalcemia, is frequently associated with bone pain.

EVALUATION OF THE PATIENT

That malignancy is the cause of hypercalcemia is usually not hard to establish. Nonetheless, careful consideration of other causes of hypercalcemia is warranted for all patients. The differential diagnosis of isolated hypercalcemia is a long one (Table 48-1). It is worth noting, however, that immobilization is common in patients with cancer, that primary hyperparathyroidism is not a rare disease, and that the iatrogenic causes of hypercalcemia are easily remedied. An excellent review of rarer causes of hypercalcemia has been written by Jacobs and Bilezikian.[26]

Table 48-1 Causes of Hypercalcemia (Other Than Malignant Disease)

Type	Cause
Endocrine	Hyperparathyroidism
	Hyperthyroidism
	Addison's disease
Iatrogenic	Immobilization
	Vitamins A and D
	Thiazide diuretics
	Lithium
Other	Paget's disease of bone
	Granulomatous disease

Clinical Findings

The syndrome of hypercalcemia of malignancy is often overlooked because many of the symptoms are nonspecific or vague and are ascribed to the underlying malignant process or to its therapy. The symptoms of hypercalcemia are protean. Only parts of the old dictum of "stones, bones, abdominal groans, and psychic moans" used in the description of the symptoms due to primary hyperparathyroidism hold true.

Gastrointestinal symptoms are present in nearly all affected individuals. Nausea, anorexia, and vomiting are early symptoms, but they can easily be confused with the side effects of tumor treatment or with symptoms produced directly by the tumor itself. By inducing dehydration and hence aggravating the hypercalcemia, these complications set up a vicious cycle. Constipation is common, and complete ileus can occur at severely raised calcium levels. Cramping abdominal pains, such as those seen in primary hyperparathyroidism, are encountered occasionally, but acute pancreatitis or peptic ulceration complicating the hypercalcemia of malignancy is extremely rare.

The major effect of hypercalcemia on the kidney is to impair renal concentrating ability. Urine, dilute compared with plasma, is excreted in large volume. As the hypercalcemia and the polyuria persist, volume depletion ensues, with a resultant fall in the glomerular filtration rate. Further impairment of the kidney's ability to handle the abnormal calcium load occurs, and the hypercalcemia is aggravated. Tubular damage continues and manifests as acquired renal tubular acidosis, glycosuria, and aminoaciduria. An important consequence of the tubular malfunction is a natriuresis. This results in a sodium loss that aggravates the hypercalcemia, in that the mechanisms for conserving sodium and calcium within the kidney are similar. A syndrome akin to nephrogenic diabetes insipidus occurs, and polydipsia is therefore an early feature. Unfortunately, the gastrointestinal symptoms of anorexia and vomiting overcome the thirst, and intense dehydration can occur. Nephrocalcinosis and nephrolithiasis require hypercalcemia of a prolonged duration and are therefore atypical of the syndrome.

Neuropsychiatric symptoms of apathy, depression, and fatigue are frequently overlooked and ascribed to the underlying neoplasm. Muscle weakness itself can be profound and can confine the patient to bed. This immobility leads to further calcium mobilization and enhances the hypercalcemia. As hypercalcemia continues to worsen, confusion and finally coma supervene. Focal neurologic symptoms, including ataxia, which resolve on normalization of the serum calcium, also can occur but are rare.

Pruritus is a well-recognized, if infrequent, complication of hypercalcemia, as are various irritating eye symptoms. Their frequency in malignant hypercalcemia is less than in primary hyperparathyroidism.

Bone pain is a frequent symptom of both malignant disease and hypercalcemia. Clearly, this might in part be related to the presence of metastases within bone causing areas of increased intramedullary pressure, ischemia, or microfractures, but the symptom is also present in the absence of demonstrable metastatic disease.

The syndrome of hypercalcemia of malignancy therefore presents insidiously, with anorexia, fatigue, apathy, and polyuria, but it can progress rapidly to obtundation and death.

Laboratory Investigations

From a practical point of view, a few well-chosen, simple investigations are all that are required to aid in the diagnosis, therapy, and monitoring of patients. From the academic point of view, these and less readily available investigations can enhance the understanding of the hypercalcemic process in any given individual.

A complete blood count and estimation of the platelet count are required. Measurements of serum electrolytes, blood urea nitrogen, and creatinine are mandatory. Because of the importance of protein binding on the "free" calcium concentration, serum albumin should always be measured with the serum calcium, and a correction formula (such as the one given previously) should be used. In asymptomatic patients with hypercalcemia and multiple myeloma, a serum ionized calcium should be obtained.

Renal function and the response of the serum calcium to therapy should be monitored daily until the calcium concentration normalizes, and weekly thereafter unless circumstances necessitate more frequent investigation.

Biochemical clues to the presence of HHM due to PTHrP include hypophosphatemia, hyperchloremia, and a mild metabolic alkalosis, although these could not be considered diagnostic. Urinary excretion of calcium is high, as is urinary cAMP. The renal phosphate threshold is low, indicating a renal phosphate leak, and significant hypophosphatemia can result following treatment of the hypercalcemia. Assays for PTHrP are available but currently have limited clinical application in the setting of hypercalcemia of malignancy.

Serum immunoreactive PTH is low or undetectable unless the primary site of malignancy is the parathyroid gland itself, or primary hyperparathyroidism coexists. Vitamin D metabolites are also frequently low in most cases of hypercalcemia, even though PTHrP is capable of stimulating renal 1α-hydroxylase. Measures of osteoblastic function, such as alkaline phosphatase and bone γ-carboxyglutamate (gla) protein (osteocalcin), have little to offer in the diagnosis or management of hypercalcemia.

Radiographs and isotope bone scans might be pertinent for prognostication and follow-up but do not help delineate the cause of the hypercalcemia, nor are they useful in predicting the response to therapy.

GRADING THE COMPLICATION

Although it is possible to grade hypercalcemia according to mild, moderate, and severe categories on the basis of a biochemical value, it is important to note that the development and severity of symptoms do not seem to be strictly related to the serum calcium level. As a general rule, patients with symptoms readily related to hypercalcemia should be treated as severe cases, regardless of the objective degree of elevation of the calcium level. A frequently made but poorly understood observation is that patients with tumor-induced hypercalcemia often have greater symptomatology for any given rise in calcium level as compared with patients with primary hyperparathyroidism. Our approach to the treatment of hypercalcemia of malignancy is based on the following classification of hypercalcemia. It is worth noting that many variables other than the serum calcium level affect the logical choice for therapy.

Mild Hypercalcemia

Patients in this group are asymptomatic and have a serum calcium level of less than 3.0 mmol/L. The abnormality is frequently detected as part of the routine biochemical workup in patients with tumor types known to predispose to hypercalcemia. These individuals are therefore usually outpatients. Although urgent management of the hypercalcemia is not indicated, several considerations must be borne in mind. The natural history of tumor-induced hypercalcemia is for the condition to worsen. A reevaluation of the current antineoplastic regimen and response to treatment is warranted, because the development of hypercalcemia might be an early indication of a diminishing response to therapy. The development of any intercurrent insult to the kidneys is likely to precipitate more severe hypercalcemia. Intercurrent insult includes both any situation in which volume depletion could occur, and the introduction of nephrotoxic agents, such as nonsteroidal anti-inflammatory agents.

Moderate Hypercalcemia

In asymptomatic patients with a serum calcium of 3.0 to 3.5 mmol/L, the situation is more serious. Although this level of calcium might not be life-threatening, little is required to tip the scales toward a more serious problem.

Severe Hypercalcemia

All patients with symptoms attributable to hypercalcemia should be treated as an acute medical emergency. Furthermore, patients with a serum calcium concentration (corrected for albumin) greater than 3.5 mmol/L require urgent treatment.

TREATMENT

The serum calcium concentration can be reduced in almost all patients with tumor-induced hypercalcemia. A variety of antihypercalcemic regimens remains in common use, although the wide therapeutic index and high success rates of the newer bisphosphonates have resulted in their use as first-line management in the majority of cases. Although it has been possible to target osteoclast-mediated bone resorption in a fairly specific way, the same cannot be said for enhanced renal tubular calcium reabsorption or gastrointestinal calcium absorption. The introduction of calcimimetic agents has provided a specific therapy in relationship to parathyroid carcinoma with hypersecretion of PTH.

Selection of therapy should be geared to a knowledge of the individual tumor type (and hence, to the probable mechanism underlying the hypercalcemia) and to the status of the patient's renal function and bone marrow reserve. Any specific antineoplastic therapy that can be used, be it surgical, radiotherapeutic, or chemotherapeutic, will be a powerful adjuvant to antihypercalcemic therapy. An excellent clinical review has been published by Stewart.[27]

Ethical Considerations

The first decision is whether or not to treat this complication. Unless specific antitumor therapy is available, the majority of patients who develop hypercalcemia of malignancy are in the last few weeks of their lives. A recent review of aerodigestive squamous cancer demonstrated a median survival of 35 days and a 2-year mortality of 72%[28] (pulmonary cancers were under-represented in this study at 12% of the total). Similarly, hypercalcemia was predictive of early death in patients presenting with multiple myeloma.[29] Thus, it can be argued that treatment is not indicated for all cases of hypercalcemia associated with malignancy. For some, however, the use of an effective, safe treatment to ameliorate the substantial morbidity of hypercalcemia and to allow patients to return home is clearly warranted.

General Considerations

The best treatment is one directed specifically and effectively at the underlying malignant disease. Early mobilization is a laudable but often unachievable goal in patients with advanced malignant disease. Thiazide diuretics should be avoided because they promote renal tubular calcium reabsorption.

Although dietary restriction of calcium seems intuitively appropriate, gastrointestinal calcium absorption is low in most cases of hypercalcemia associated with malignant disease. A notable exception is among patients whose tumors are associated with a substrate-dependent 1α-hydroxylase, which allows continued production of calcitriol. Patients taking supplemental vitamin D and vitamin A (β-carotene) should be advised of the hypercalcemic effects of these agents.

Extracellular Fluid Volume Expansion

Most patients with hypercalcemia of malignancy have significant depletion of fluid volume (on the order of 5 to 10 L) due to the combined effects of anorexia, vomiting, and nephrogenic diabetes insipidus. In this state, the glomerular filtration rate is reduced, and the response by the proximal convoluted tubule is to increase sodium retention. Concomitantly, proximal tubular resorption of calcium is also increased. The aim of fluid replacement in these circumstances should be to induce a state of mild fluid overload. Restoration of a normal circulating blood volume restores the glomerular filtration rate and increases the fractional excretion of calcium. Further salt loading, on the other hand, induces natriuresis and concomitant calciuresis. Care must be taken to avoid severe congestive cardiac failure in elderly patients or in patients with poor cardiac reserve. Because of the hypoalbuminemia that frequently accompanies advanced malignant disease, dependent edema is to be expected during volume expansion. Care must also be taken to ensure an adequate intake of free water. In the presence of severe hypercalcemia, a resistance to the distal tubular actions of antidiuretic hormone may predispose obtunded patients to significant hypernatremia. After restoration of euvolemia, a maintenance infusion of 3 L/day of 0.9% saline solution will induce continued natriuresis and calciuresis. Patients should be encouraged to drink freely. During such aggressive fluid management, other electrolyte abnormalities are likely to be uncovered or precipitated. Despite impaired renal function, both hypokalemia and hypomagnesemia are frequent findings, and appropriate supplementation could be required.

Although serum calcium can be expected to fall while a patient is on this regimen, restoration of normocalcemia is unlikely. Failure to restore normal fluid balance, however, will greatly detract from the success of subsequent therapeutic measures.

Calciuretic Therapy

Aside from the calciuretic effects of saline overload, two other agents are commonly used to induce renal calcium wasting: furosemide and calcitonin.

Furosemide

Furosemide is a diuretic agent whose main site of action is in the thick ascending limb of the loop of Henle (thus making this agent a loop diuretic), where it completely and reversibly inhibits the $Na^+/K^+/2Cl^-$ cotransporter. In the euvolemic and volume-expanded state, the fractional excretion of calcium can be increased by as much as 30% by loop diuretics. If a patient is volume depleted, however, enhanced proximal tubular sodium and calcium resorption can obviate this response. Thus, the potential exists for loop diuretics to aggravate hypercalcemia if adequate attention is not paid to fluid volume status. In the initial report of the effectiveness of this treatment, the regimen involved the administration of doses of furosemide in the region of 100 mg every 2 hours. Therapy this aggressive would require the facilities of an intensive care unit to ensure adequate fluid monitoring. Although substantial reductions in the serum calcium can be achieved, a rationale for the use of this treatment for other than acute situations is lacking, in that the primary cause of the hypercalcemia—increased bone resorption—is not affected. Given the risks of severe electrolyte disturbances and the availability of potent antiresorptive medication, loop diuretics should be reserved primarily for situations of fluid overload rather than using them as antihypercalcemic agents.

Calcitonin

The renal actions of calcitonin are complex. The calciuretic effect seems to be due to inhibition of calcium reabsorption in the distal tubules. This, in turn, is dependent on an adequate delivery of calcium to the distal nephron, a situation that is compromised by the extracellular fluid volume depletion in hypercalcemia. This renal tubular effect is rapid, however, and the administration of calcitonin can be of great value as an adjunct to more potent antiresorptive therapies.

Antiresorptive Therapy

Given that bone resorption is increased in the majority of cases of hypercalcemia of malignancy, the best treatment after that designed to combat the tumor itself is one directed at bone resorption. The osteoclasts represent the final common pathway for bone resorption in both humoral and local osteolytic hypercalcemia. The following agents, which inhibit osteoclast function, not surprisingly are highly effective antihypercalcemia treatment.

Bisphosphonates

The bisphosphonates are a class of compounds—structural analogs to pyrophosphate—in which the P-O-P bond is replaced by a P-C-P bond stable to enzymatic cleavage. Figure 48-4 shows the structure of some of the available bisphosphonates compared with the structure of pyrophosphate. Pharmacokinetic and pharmacodynamic studies of bisphosphonates indicate that these compounds are absorbed poorly from the gastrointestinal tract after oral administration. Diet has a profound effect on gastrointestinal absorption, reducing the effective bioavailability of the drugs to zero if taken with food.

Although bisphosphonates have a significant physicochemical effect, preventing the formation and dissolution of calcium compounded with phosphate, it has become clear that the major clinical mechanisms of action relate to inhibition of farnesyl pyrophosphate synthase in the case of aminobisphosphonates, and incorporation into adenosine triphosphate–containing compounds resulting in inhibition of cell function in nonaminobisphosphonates. Both mechanisms promote apoptosis in osteoclasts, whereas the aminobisphosphonates also inhibit osteoclast recruitment.[30]

There are strong data to support the use of the intravenous bisphosphonates zoledronic acid (4 mg over 15 minutes), pamidronate (60 to 90 mg over 2–4 hours), ibandronate (4 mg over 1 hour), and clodronate (1500 mg over 4 hours) in the management of hypercalcemia of malignancy. Favorable studies have been reported when comparing bisphosphonates with placebo, calcitonin, glucocorticosteroids, and mithramycin (plicamycin; see an extensive review in Ross and colleagues[31]).

In studies comparing bisphosphonates, pamidronate proved superior to edtironate and clodronate.[32] A pooled analysis of two studies involving 287 patients demonstrated a significantly better response rate for zoledronic acid (4 mg and 8 mg) as compared with pamidronate (90 mg).[33] The complete response rate for both zoledronic acid doses (defined as normocalcemia at day 10) was similar (88.4% for patients given 4 mg; 86.7% for patients given 8 mg), whereas the response rate for pamidronate was 69.7%. Although these studies confirmed the superiority of zoledronic acid to pamidronate in the sample population, it should be noted that the response rate to

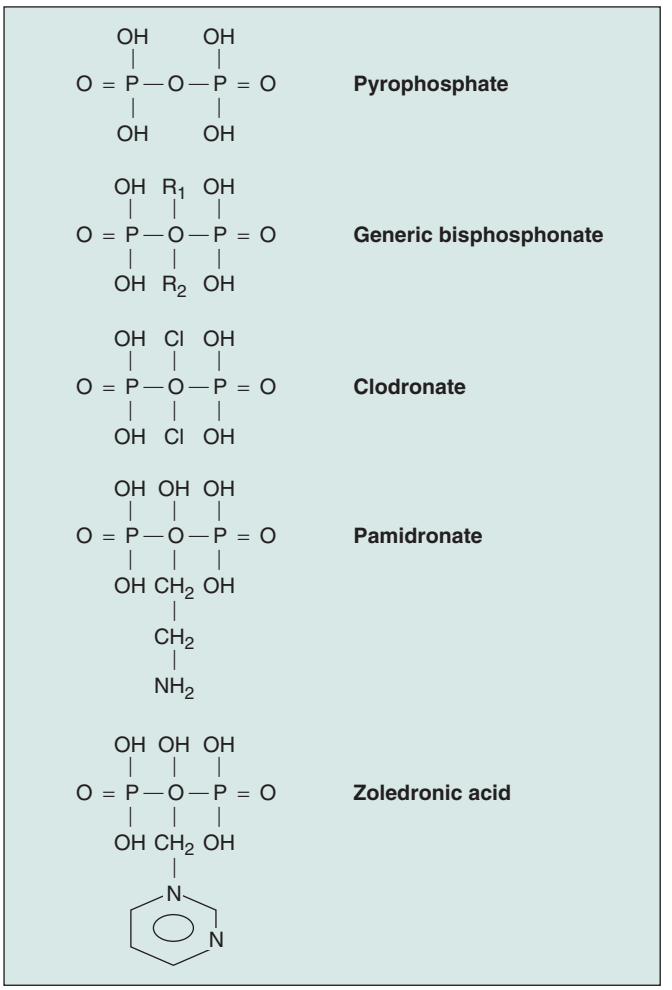

Figure 48-4 • Structural formulas of commonly studied bisphosphonates in relation to the generic bisphosphonate and to pyrophosphate.

pamidronate was lower than has been reported in previous trials. A comparative study between ibandronate and pamidronate has shown that the former is at least equal to the latter in terms of biochemical response and possibly associated with a longer time to recurrence of the hypercalcemia.[34]

The primary mechanism in the generation and maintenance of hypercalcemia in malignant disease is enhanced bone resorption. However, tumors secreting PTHrP also have a significant influence on renal calcium handling, which would not be influenced directly by bisphosphonate therapy. In a review of 147 patients with hypercalcemia of malignancy and available measurement of PTHrP, it was found that, although the hypercalcemia responded well to intravenous ibandronate, the renal tubular calcium index changed only slightly, confirming that the majority of the action of the bisphosphonates was to limit enhanced bone resorption. Although patients with those tumor types associated with higher PTHrP (lung, upper respiratory tract) had the greatest risk of recurrence of their hypercalcemia, this was not statistically associated with PTHrP levels.[35]

The duration of response to bisphosphonates is difficult to determine and varies considerably among individuals. Elucidation of the duration of response is also compounded by the high mortality in this group of patients due to their tumors and by the introduction of specific and effective antineoplastic therapy for patients with cancers such as breast and multiple myeloma. Median time to relapse in the studies comparing zoledronic acid with pamidronate was 30 to 40 days with zoledronic acid and 17 days with pamidronate.[33] Unfortunately, it is not possible to predict the length of time that any specific patient will remain normocalcemic.

In general, bisphosphonate therapy is well tolerated. An acute inflammatory reaction (so-called first-dose effect) with low-grade pyrexia, bone pain, and myalgias is noted in 10% to 30% of patients. The use of rapid intravenous infusions of clodronate and etidronate has been associated with deterioration in renal function in patients with previously diminished renal reserves. Renal dysfunction has been noted with pamidronate (often in the setting of frequent use at doses higher than recommended). The observation of more frequent renal abnormalities in patients receiving 8 mg zoledronic acid has led to the recommendation that 4 mg be the starting dose. Hypophosphatemia sufficient to require supplementation is seen with effective management of hypercalcemia in the setting of bisphosphonate use. The mechanisms of phosphate imbalance are unclear but may include pre-existing nutritional deficiency aggravated by volume expansion, renal phosphate wasting in association with PTHrP activity, and increased native PTH activity as normocalcemia (or even mild hypocalcemia) follows therapy. Osteonecrosis of the jaw has been associated with the use of aminobisphosphonates in the long-term management of skeletal morbidity from cancer and (infrequently) nonmalignant conditions.[36] According to our current understanding of the condition, this side effect would be considered rare after a single treatment for hypercalcemia of malignancy. Infrequently, eye findings including uveitis and scleritis have been associated with aminobisphosphonate use. The management of bisphosphonate side effects has been the subject of a recent review.[37]

Gallium Nitrate

Hypocalcemia was noted as a side effect of therapy among patients receiving gallium nitrate for the management of lymphoma.[38] Thereafter, its effectiveness as an antihypercalcemia agent was confirmed by Warrell and associates[39] The exact mechanism of action of gallium is unknown, although it is clear that urinary calcium excretion is reduced. By implication, bone resorption is reduced, although no histologic changes were noted in explants of fetal long bones exposed to this agent.

Gallium nitrate requires intravenous administration. The best-investigated regimens involve sequential 5-day infusions of 200 mg/m^2/day. At this dose, the drug is relatively free of side effects, although caution is required if other nephrotoxic agents (e.g., aminoglycosides) are being used. Clinical trials using gallium nitrate have shown a superior response (in terms of normalization of calcium and duration of normocalcemia) when compared with calcitonin, etidronate, and pamidronate. Gallium nitrate is effective in tamoxifen-induced hypercalcemia, and it has also been suggested that it may be more effective in cancers associated with higher levels of PTHrP (see review[40]).

The major drawback with this therapy is the need for 5 days of infusion, as compared with the shorter duration of therapy for the bisphosphonates.

Therapy Directed against Humoral Factors

Calcimimetics

Calcimimetics are agonists at, or modulators of, the CaSR. These receptors are abundant on normal parathyroid gland tissue but are also present on malignant parathyroid tissue. A well-documented case report using an allosteric modulator of the CaSR (rendering the receptor more sensitive to the effects of high calcium) showed improved control of hypercalcemia in a patient with parathyroid carcinoma.[41] Parathyroid carcinoma is a rare cause of hypercalcemia of malignancy, and it is equally rare for tumors to manufacture ectopic PTH, thus the clinical impact of calcimimetics in the area of hypercalcemia of malignancy is likely to be limited. Indeed, the effect

of pharmacologic modulation of the CaSR in nonparathyroid cancers is unclear but has the potential to be detrimental by increasing the production of PTHrP as described previously.

Humanized Antibodies to PTHrP

In a murine model antibodies directed against PTHrP were effective in reversing the HHM and improving nutritional status.[42] No human clinical trials have been reported.

Osteoprotegerin and Denosumab

As described previously, OPG, a soluble receptor belonging to the tumor necrosis factor receptor superfamily, is thought to act as a modulator of osteoclast differentation and function by acting as an inhibitory (or decoy) receptor for the polypeptide RANKL. OPG has been shown to reverse hypercalcemia induced by several factors, including IL-1, tumor necrosis factor-α, PTH, PTHrP, and $1,25(OH)_2D_3$, in a mouse model of HHM.[43,44] No human clinical trials in hypercalcemia of malignancy have been reported, although a phase I study using an Fc-OPG construct showed potent antiresorptive effects (including hypocalcemia) of this agent in patients with bone metastases related to myeloma or breast cancer.[45]

Denosumab is a human monoclonal antibody directed against RANKL. It has been shown to reduce markers of bone resorption in patients with multiple myeloma and breast cancer who had normal corrected calcium levels and bony metastases. Mild reductions in calcium levels were seen with this agent, but they were transient.[46] No human data on hypercalcemia of malignancy have been reported.

Potential advantages of these agents include their subcutaneous route of administration and lack of renal side effects. Concerns have been raised about the potential for the development of inactivating antibodies with prolonged use. It is unclear whether human trials specific to hypercalemia of malignancy will occur with these agents.

Other Therapies

The widespread acceptance of bisphosphonates as first-line therapy for the hypercalcemia of malignancy because of their effectiveness, ease of use, and reasonable safety profile has resulted in a dramatic reduction in the use of alternate therapies.

The antitumoral antibiotic mithramycin (plicamycin) has a direct toxic effect on osteoclasts and is effective at restoring normocalcemia in approximately 80% of treated patients. Despite myelotoxicity and exacerbation of renal dysfunction, it remains a useful agent in cases of resistance to bisphosphonates.

Calcitonin has both calciuretic and antiresorptive actions and thus would seem to be an ideal antihypercalcemic agent. The antiresorptive effects of calcitonin are related directly to osteoclast toxicity and possibly to inhibition of new osteoclast recruitment. When used as a single agent, calcitonin's hypocalcemic effect is modest at best, and resistance to the effects of calcitonin develops rapidly. Calcitonin can be used in combination with more powerful antiresorptive agents. Under these circumstances a rapid and enhanced hypocalcemic effect has been documented. In cases of life-threatening hypercalcemia, or when neurologic symptoms are a major feature, we recommend the use of 8 MRC (Medical Research Council) units/kg given intramuscularly every 6 hours for 1 or 2 days in association with an intravenous bisphosphonate. This regimen has the advantage of combining the rapid calciuretic effect of calcitonin with the powerful, prolonged antiresorptive effect of the bisphosphonate.[47]

As discussed previously, prostaglandins (notably prostaglandin E_2) have potent bone-resorbing effects in relationship to certain tumor types. Thus it was hoped that a significant subset of patients might be found who would respond to prostaglandin synthesis inhibitors such as indomethacin. Although well-characterized case reports have shown a good response to these agents, in general they are ineffective for the treatment of tumor-induced hypercalcemia.

Glucocorticoids are commonly used in the management of tumor-induced hypercalcemia despite significant evidence that their usefulness is limited. The mechanism of any hypocalcemic effect produced by these agents is unclear. In patients with multiple myeloma and lymphoid malignancies, glucocorticosteroids may form part of the antineoplastic regimen, thus reducing production of those factors responsible for the hypercalcemia. Furthermore, because glucocorticosteroids block absorption of calcium from the gut, they can be expected to be useful for patients with vitamin D–mediated hypercalcemia where gastrointestinal absorption of calcium is enhanced.

Hemodialysis using a dialysate bath free of calcium can be used in the emergency treatment of hypercalcemia and would be particularly useful in the setting of renal insufficiency, which would preclude aggressive fluid expansion.

Long-Term Treatment

For patients for whom no antitumor therapy is available, long-term survival is unusual. By implication, there are few good long-term studies on the management of hypercalcemia, and most results are anecdotal. Individualization of therapy is the rule. Patients should be advised to drink an adequate volume of fluid (2 to 3 L daily) and to maintain their mobility as long as possible. They should be reminded of the symptoms of hypercalcemia and urged to report for treatment early should those symptoms arise. Table 48-2 shows suggested maintenance treatments for the hypercalcemia of malignancy. It is noteworthy that the effectiveness of antihypercalcemia therapy with bisphosphonates seems to wane with repeated treatments.[48]

The importance of palliative care cannot be overemphasized in the management of these unfortunate individuals.

A logical therapeutic regimen for the acute management of tumor-induced hypercalcemia is shown in Box 48-1. This regimen represents one approach to this problem. Other equally valid regimens are possible, and individualization of regimens is mandatory for long-term therapy.

Table 48-2 Options for Long-term Management of Hypercalcemia of Malignancy

Agent	Dose	Frequency*
Intravenous zoledronic acid	4 mg over 15 min	Every 2–3 weeks
Intravenous pamidronate[†]	60–90 mg over 2–4 hr	Every 2–3 weeks
Oral pamidronate[‡]	200–1200 mg	Daily
Oral clodronate[§]	3200 mg	Daily
Oral etidronate[¶,‖]	20 mg/kg	Daily
Oral phosphate	2–3 g	Daily
Corticosteroids	Variable	Daily
Multiple myeloma		
Carcinoma of the breast		
NSAIDs	Variable	Daily

NSAIDs, nonsteroidal anti-inflammatory drugs.

*Suggested frequencies and doses may be altered to suit individual patients.

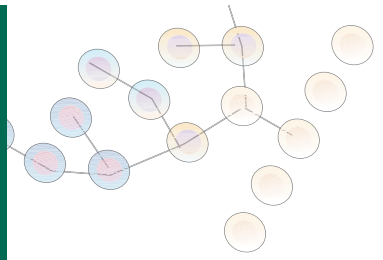
Box 48-1. MANAGEMENT OF HYPERCALCEMIA OF MALIGNANCY

The most effective way to control the hypercalcemia of malignant disease is by therapy aimed at eradicating or reducing the tumor burden. Chemotherapy, radiation therapy, and surgical therapy all have roles to play. In the absence of effective antitumor therapy, the patient's general condition and immediate prognosis should be used to guide the decision to embark on aggressive antihypercalcemic therapy, active palliation, or both. The introduction of agents with high efficacy and few side effects has broadened the oncologist's options.

Our practice is to discuss treatment options with the patients and their families, emphasizing that the drugs used to control the hypercalcemia have little or no impact on the progression of the underlying cancer but will help the symptoms of the hypercalcemia. Volume expansion with 0.9% saline is begun immediately. The rate is determined by the state of hydration of the individual patient as assessed by the clinician. An infusion of intravenous bisphosphonate (zoledronic acid or pamidronate) is begun at the same time as saline volume expansion. In the presence of severe hypercalcemia and neurologic symptomatology, calcitonin 8 MRC units/kg intramuscularly every 6 hours is used in conjunction with the bisphosphonate.

Biochemical response is rapid. The serum calcium can be expected to fall after 24 hours. Most patients reach a nadir calcium value in 5 to 7 days. We maintain natriuresis by continuing the saline infusion until normocalcemia is reached. Volume overload, as shown by an elevation of the jugular venous pressure, the development of a fourth heart sound, pulmonary congestion, or peripheral edema, is treated with furosemide, which has the added benefit of inducing calciuresis. Care is taken to avoid volume depletion during use of the diuretic. Close attention is paid to renal function and electrolyte balance, because hypokalemia, hypomagnesemia, and hypophosphatemia are common sequelae of this treatment approach. Failure to respond to bisphosphonate therapy is a poor prognostic feature, but alternative antiresorptive therapy can be attempted (gallium nitrate, plicamycin).



In the absence of effective antitumor therapy, hypercalcemia is almost certain to recur if the patient survives long enough. The duration of normocalcemia is variable, and further antihypercalcemic therapy must be individualized. Patients are advised to maintain a high fluid intake (3 L daily). Corrected calcium concentration is determined weekly. We treat patients again with intravenous bisphosphonate therapy when the corrected serum calcium exceeds 2.7 mmol/L and at regular intervals thereafter. Repeat treatment is performed on an outpatient basis when possible. The dose of bisphosphonate is based on the last dose that reversed the hypercalcemia.

Often the malignant process is at such an advanced stage that death occurs within a few weeks of the development of hypercalcemia. Because of this, we involve palliative care early in the management of hypercalcemic patients.

49 Hyponatremia

Richard L. Heideman and Nancy H. Heideman

SUMMARY OF KEY POINTS

Incidence
- Hyponatremia is a common problem in many malignancies.
- It occurs in at least 30% of patients in hospitalized, outpatient hospital, and community-based care settings.
- Hyponatremia is present in 10% to 30% of patients with small cell lung cancer.

Etiology
- Hyponatremia has many causes; primary extrarenal sodium loss associated with several medications, as well as cardiac, renal, and hepatic dysfunction. However, diarrhea, vomiting, and hemorrhage are the most common.
- The syndrome of inappropriate antidiuretic hormone (SIADH) is associated with several malignancies, particularly small cell lung cancer.
- Pseudohyponatremia is associated with hyperglycemia, hyperproteinemia, or hyperlipidemia.
- Water overload at surgery, low-sodium intravenous fluids, or polydipsia are other causes.
- Additional causes include edematous states such as malignant peritonitis, heart failure, hepatic tumor, or cirrhosis.
- Thyroid and adrenal deficiencies can result in hyponatremia.
- Renal sodium loss is mediated by diuretics or natriuretic peptides (with central nervous system tumors or injury), the effect of arginine vasopressin (AVP) on the distal tubules, and the renin-angiotensin-aldosterone system.

Evaluation of the Patient
- Start by assessing plasma osmolality and extracellular fluid (ECF) volume.
- SIADH is a common cause but must be a diagnosis of exclusion.

Grading of the Complication
- Many patients are asymptomatic.
- Sodium concentrations below 125 mEq/L and those developing rapidly are most likely to be symptomatic.
- Symptomatic hyponatremia is a medical emergency.

Treatment
- Isotonic saline (0.9%) is an appropriate fluid for most patients.
- Correction of sodium should occur slowly and at a rate that approximates its development; 10 to 12 mEq/L over the first 24 hr is considered safe.
- Overly rapid correction is associated with severe neurologic morbidity.
- Hypertonic saline is appropriate only in symptomatic patients with very low sodium concentrations; discontinue once serum sodium becomes 120 to 125 mEq/L.
- Water restriction is the primary approach to SIADH.

INTRODUCTION

Hyponatremia is among the most common electrolyte disturbances faced in clinical medicine. Recent reports show 30% to 43% of a group of hospitalized, ambulatory hospital, and community-based care patients had hyponatremia (serum sodium below 136 mEq/L), and an additional 3% to 6% had concentrations of 126 mEq/L or less.[1,2] This is particularly sobering in light of the substantial morbidity and mortality that can be associated with hyponatremia. Current studies suggest that the mortality associated with hyponatremia in hospitalized patients is as high as 27%, in comparison with 9% in other patients.[3] Even relatively mild and presumably "asymptomatic" hyponatremia (128 ± 3 mEq/L) is associated with attention deficits and a high incidence of accidental falls and injury.[4] Among patients with cancer, clinical experience suggests that the overall incidence of hyponatremia is perhaps even higher than in other populations. This is because many tumors predispose to the development of hyponatremia (i.e., small cell lung cancer with an incidence as high as 30%) as well as the influences of polypharmaceutical treatments, and chronically ill, debilitated patients.[5]

Sodium (Na^+) is the dominant ion of the extracellular fluid (ECF) and thus the prime contributor to osmolality. Sodium and water balance are tightly linked, and disturbances of one are also generally reflected in the other. This balance is the result of many homeostatic feedback loops that revolve around protection of intravascular volume. Components of this integrated homeostatic system include the hypothalamic osmoreceptors; the adrenals (via the renin-angiotensin-aldosterone cascade); the cardiac, glomerular, and carotid baroreceptors; and changes in renal tubular permeability to water and sodium in response to antidiuretic hormone (ADH, or arginine vasopressin), and natriuretic peptides released from the heart and brain. Thus, there are many paths to hyponatremia.

Definitions

Hyponatremia and hypernatremia are conditions of altered tonicity. To put the physiology of the problem into perspective, it is important to understand the difference between osmolality and tonicity. Osmolality is the concentration of all particles in a fluid. Particles are either "effective" or "ineffective" osmoles. Ineffective osmoles are solutes

that can cross the cell membrane freely and distribute equally in the intracellular fluid (ICF) and ECF yet produce no net movement of water. Examples of physiologically ineffective osmoles include urea and ethanol; their addition to the ECF produces no change in osmolality, because they equilibrate rapidly with the ICF.

Solutes that do not cross the membrane freely or that are kept predominantly to one side by a transporter are referred to as effective osmoles. Only effective osmoles contribute to tonicity. In the physiologic setting, sodium is the major effective osmolar solute. It is relatively restricted to the ECF and is thus the major determinant of ECF tonicity. Other examples of physiologically effective osmoles are glucose and mannitol, two large molecules that are also relatively restricted to the ECF. Potassium and a host of organic compounds that are dominantly restricted to the intracellular milieu are the major osmolar solutes of the ICF and the major determinants of ICF tonicity. Despite the differences in tonicity of these compartments, the osmolality of the ECF and ICF are quite similar as a result of water movement. Even so, the distribution of water in these two spaces is not at all similar; 60% to 75% of total body water resides within the ICF and the remainder in the ECF. Within the ECF, approximately 65% is apportioned to plasma, and the rest is interstitial fluid between cells.

OSMOLAR HOMEOSTASIS: CONTROL OF WATER AND SODIUM

From the perspective of sodium, the job of the osmoregulatory system is to prevent either hyper- or hyponatremia and the secondary movement of water that can change cell volume and disrupt function. Under normal circumstances, plasma osmolality is kept within a relatively constant osmolar range of 275 to 290 mOsmol/kg. The maintenance of this narrow range is primarily the result of ADH, thirst, and renal function.

ADH provides the most sensitive control mechanism. Changes in serum osmolality of as little as 1% to 2% can be sensed by the hypothalamic osmoreceptors and can trigger ADH secretion from the posterior pituitary.[6] At the renal level, ADH acts on receptors in the collecting ducts to initiate a passive reabsorption of water. The threshold for ADH release occurs at a plasma osmolality of 280 to 290 mOsmol/kg; below 280 mOsmol/kg, the secretion of ADH is suppressed.[4,5] Although there is a roughly linear rise in ADH with increases in osmolality, a plateau in its effect occurs at an osmolality of 295 mOsmol/kg or greater. Thus, there is a limit to the ability of ADH to reduce hypertonicity.

Another group of osmoreceptors located in the anterior hypothalamus stimulate thirst; this group is recruited at or near the serum osmolality where ADH begins to show its plateau in effect. Thirst can also be recruited by changes in plasma volume sensed by carotid and cardiac baroreceptors.

Carotid baroreceptors responding to a decrease in effective blood volume can also stimulate ADH release. The sensitivity of this system is significantly less than that of the hypothalamic osmoreceptors, and a change in vascular volume of 8% to 10% or more is required to initiate this nonosmotic stimulus for ADH release. In situations characterized by decreased effective circulating volume or arterial vasodilation (e.g., in anthracycline-induced congestive heart failure, sepsis, or third-space fluid accumulations from malignant ascites or hepatic cirrhosis), nonosmotic baroreceptor-mediated stimulation of ADH can override the osmotic suppression of ADH release that would otherwise be expected as a result of the expanded hypotonic ECF space.[6] The net result can be a spiraling decrease in sodium as more water is retained, and effective volume continues to decline even further.

Although most osmoregulation is affected by water as described previously, sodium also has an active regulatory mechanism. Reabsorption of sodium in the renal tubule is the dominant mechanism of regulation; under normal conditions, about 70% of filtered sodium is reabsorbed. Active excretion of sodium also occurs and is mediated through the actions of a group of related natriuretic peptides that inhibit sodium reabsorption.[7,8] The best described of these, atrial and brain-derived natriuretic peptides, are released from cells in the atrial chambers in response to central volume overload or from the brain as a result of injury. Although there remains much to be learned about the complex physiologic effects of these peptides, their actions in medullary collecting tubules and their inhibitory effect on the renin-angiotensin-aldosterone system result in a sodium diuresis.

Cellular Adaptations to Hyponatremia

In response to hypotonic conditions, water moves from the ECF into the ICF causing an expansion of cell volume that, if unopposed, would eventually lead to cell lysis. Normally, the Na^+,K^+ ATPase pump in the cell membrane maintains cell volume by pumping out the small amounts of sodium that "leak" into cells in exchange for potassium. In the setting of acute hypotonicity, additional mechanisms must come into play; cells adjust initially by losing sodium, potassium, and chloride across stretch-activated membrane channels. However, this process reaches its limit within several hours. In the setting of more slowly developing or chronic hypotonic states, loss of intracellular organic molecules is part of the compensation process.[9,10] In the reverse setting of hypertonicity, adaptations include new synthesis and an increased concentration of these organic osmoles. Because this change requires several days to be complete, these adaptations are not effective in acute events.

The brain is particularly sensitive to changes in tonicity. Hypotonic stresses that lead to cell swelling are tolerated poorly in the central nervous system (CNS) because of the constraints that the skull places on increased volume. The most feared change is increased intracranial pressure; coma and death can occur with as little as a 10% increase in brain volume. Another debilitating and potentially lethal complication is the osmotic demyelination syndrome. This is an uncommon but devastating result of an overly rapid correction of hyponatremia, which leads to demyelination in the pons and extrapontine white matter.[11,12] Thus, both the initiating process and the interventions for hyponatremia can be associated with significant morbidity and mortality.

HYPONATREMIC STATES

Hyponatremia is defined as a serum sodium less than 135 mEq/L. Although hyponatremia is seen most frequently in association with a low plasma osmolality (hypotonic hyponatremia), it also can occur in settings of high or low osmolality. Similarly, hyponatremia can also be associated with normal, increased, or decreased ECF. Identification of the probable etiology and proper approach to hyponatremia begins with evaluating plasma osmolality and ECF volume (Fig. 49-1). In the sections that follow, hyponatremia is characterized and and addressed by these parameters. A graphic representation of many hyponatremic states is shown in Figure 49-2.

Pseudohyponatremia

There are two situations in which sodium can be fictitiously low as a result of the presence of substances that alter the volume of plasma water in which sodium is measured.

Pseudohyponatremia is common in the setting of hyperglycemia or the use of some other restricted solute that causes high plasma osmolality. These situations cause a shift of water from the ICF to the ECF, resulting in sodium dilution. As a general rule, each 100 mg/dL increase in glucose reduces serum sodium by 1.6 mEq/L. The presence of some other nonglucose, active substance (e.g., mannitol) is identified by finding a 10-point or greater difference in the measured vs. the calculated osmoloality (Box 49-1). This "osmolar gap" can also be increased in azotemia and in ethanol and methanol intoxications. Although the plasma osmolality is increased by the

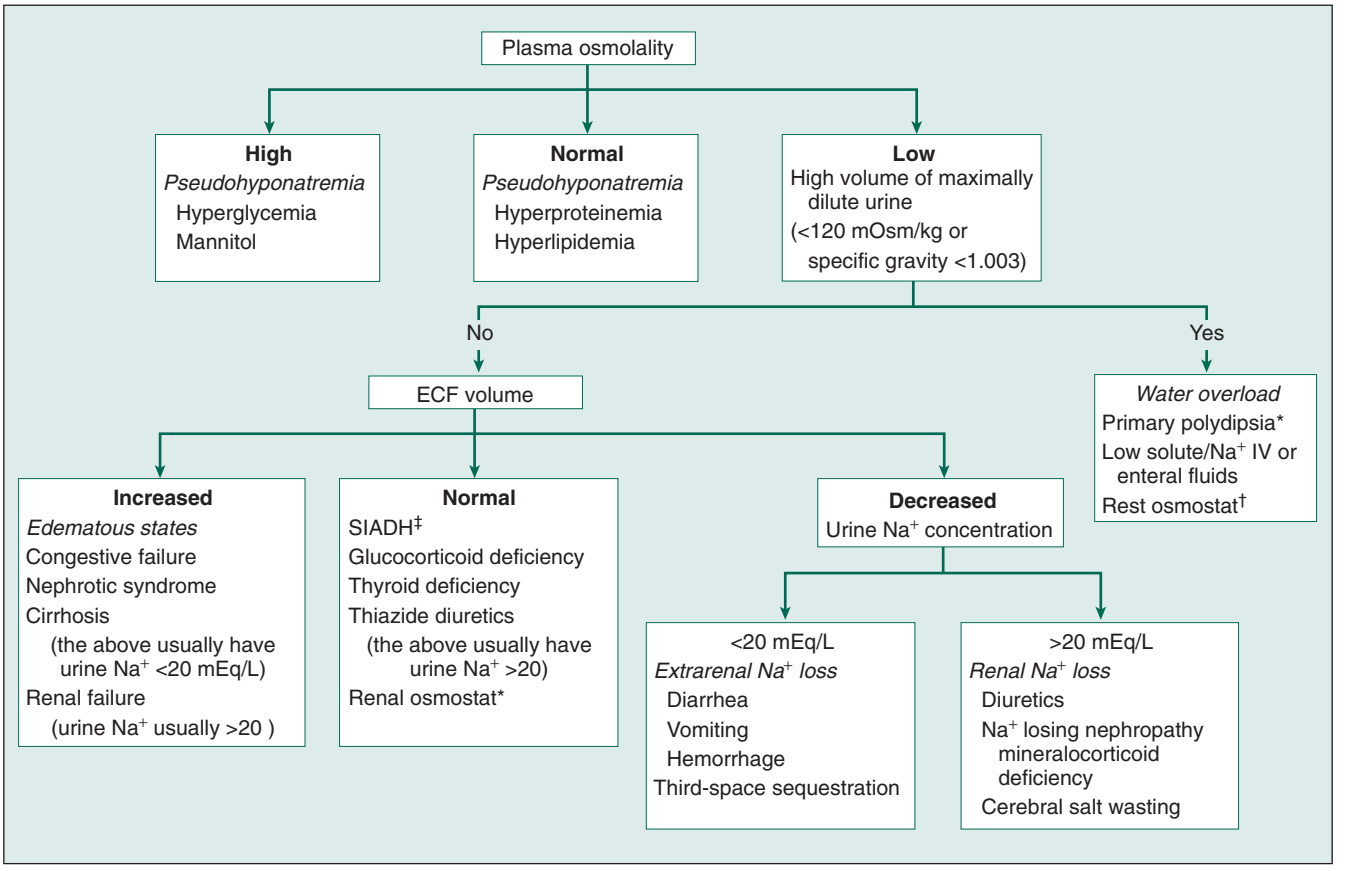

Figure 49-1 • A clinical algorithm for determining causes of hyponatremia using plasma osmolality and extracellular fluid volume. *May be accompanied by increased AVP in some patients. †Rest osmostat usually associated with low plasma osmolality and normal ECF volume. ‡See Table 49-1 for associated etiologies.

addition of these ineffective osmolar substances, there is no shift in water; the true sodium is normal.

Pseudohyponatremia also can occur as a result of an increase in relatively high-molecular-weight substances, such as occurs with Bence-Jones proteins in multiple myeloma or in hyperlipidemia. In these situations, plasma osmolality is normal, but the volume of plasma in which sodium is measured is expanded as a result of compensatory water shifts into the ECF. Thus, if sodium is normalized to the volume of sampled plasma, it will be reported as artificially low. However if sodium is measured using an ion-selective electrode that measures sodium only in the aqueous phase of plasma, its concentration will be reported as normal. Thus, it is important to know how a given laboratory determines sodium concentration.

Patients with pseudohyponatremia are not at risk for complications of low sodium and do not require sodium correction. Their true plasma sodium is normal.

Hypotonic Hyponatremia

Hyponatremia in the setting of hypotonic plasma (hypotonic hyponatremia) is the most common type of low serum sodium and represents a process in which there is an excess of water in relation to sodium.[13,14] Several potential causes of this problem are outlined in the ensuing discussion and summarized in Table 49-1. Most such situations are also characterized by the relative inability to excrete water. Although many patients might be "asymptomatic," even mild hyponatremia is now known to be associated with increased morbidity.[2] Perhaps the most dangerous situation is when hyponatremia develops fairly rapidly (within 48 hours) and in which rapid changes in osmolality may lead to serious and potentially deadly neurologic sequelae.

Hypovolemia

Hyponatremia developing in the setting of either decreased ECF or hypovolemia is a result of both sodium loss and water loss. As adaptations to volume loss occur, however, a relative excess of water over sodium develops.

The most common causes of decreased ECF are a result of extrarenal fluid losses such as diarrhea, vomiting, or third-space sequestrations of body fluid, as in malignant peritonitis. The net effect of these problems is the stimulation of ADH secretion and thirst in an effort to enhance water retention and restore ECF volume. The decreased circulating volume, renal hypoperfusion, and ADH-mediated water retention combine to limit renal water excretion and produce dilutional hyponatremia. The hyponatremia could be made worse by the concomitant depletion of potassium in severe diarrhea or vomiting and by the secondary migration of sodium into cells to compensate. Because the major pathology in these situations is nonrenal, these patients should have a low urine sodium excretion. As a rule of thumb, a urine sodium of less than 20 mEq/L suggests renal sodium conservation. The management of these patients is primarily saline volume expansion. Potassium may be added as necessary.

Hyponatremia associated with the use of thiazide diuretics is a result of sodium, potassium, and volume depletion. Secondary water retention can occur as a result of ADH response to volume loss. Urine sodium is characteristically elevated (>20 mEq/L) in these patients, reflecting increased renal sodium loss. This form of hyponatremia is characterized by hypovolemia or euvolemia with little decrease in effective plasma volume. In contrast, the loop diuretics (e.g., furosemide) rarely cause significant hyponatremia, because they inhibit

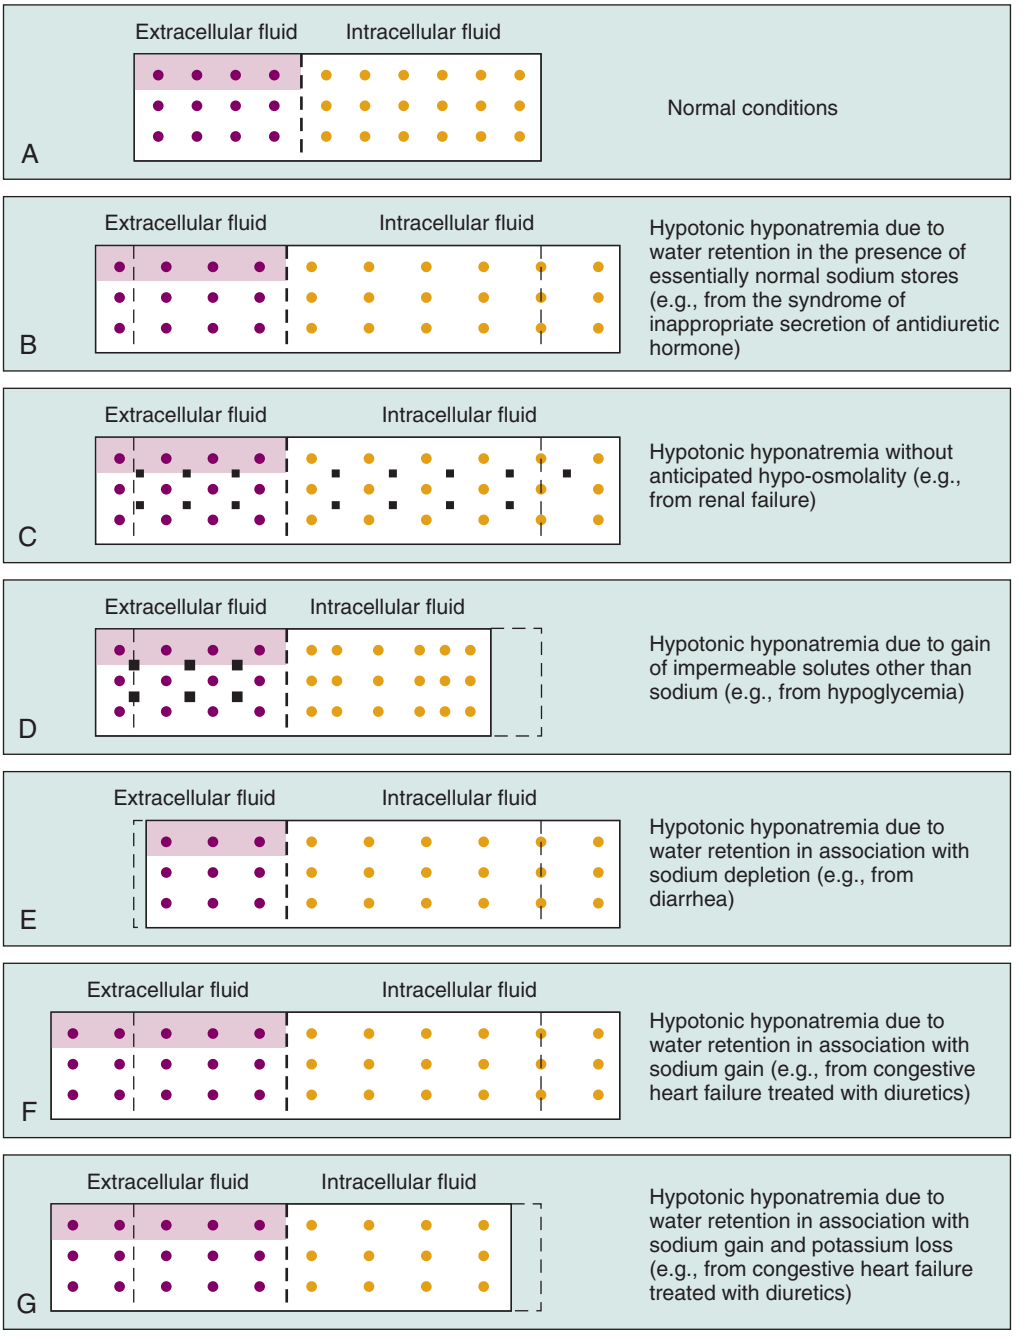

Figure 49-2 • Extracellular and intracellular fluid (ECF, ICF) compartments under normal conditions and during states of hyponatremia. **A,** Normally the ECF and ICF make up 40% and 60% of total body water, respectively. **B,** With the syndrome of inappropriate secretion of antidiuretic hormone, the volumes of ECF and ICF expand (although a small element of sodium and potassium loss, not shown, occurs during inception of the syndrome). **C,** Water retention can lead to hypotonic hyponatremia with the anticipated hypo-osmolality in patients who have accumulated ineffective osmoles, such as urea. **D,** A shift of water from the ICF compartment to the ECF compartment, driven by solutes confined in the ECF, results in hypertonic (translocation) hyponatremia. **E,** Sodium depletion (and secondary water retention) usually contracts the volume of ECF but expands the ICF compartment. At times, water retention can be sufficient to restore the volume of ECF to normal or even above normal levels. **F,** Hypotonic hyponatremia in sodium-retentive states involves expansion of both compartments but predominantly the ECF compartment. **G,** Gain of sodium and loss of potassium in association with a defect of water excretion, as they occur in congestive heart failure treated with diuretics, lead to expansion of the ECF compartment but contraction of the ICF compartment. Box 49-1. CALCULATED PLASMA OSMOLALITY (mOsm/kg)

$$2 \times ([Na] + [K] + BUN/2.8 + glucose/18$$

Note that measured osmolality is generally 10 mOsm/kg higher than calculated osmolality because of the effect of minor solutes such as magnesium, calcium, protein, phosphates, and amino acids. Normal osmolality is 287 ± 4, with a normal range extending from 280 to 290 mOsm/kg.

sodium reuptake and reduce renal interstitial tonicity, which, in turn, limits passive water reabsorption. The management of these patients involves cessation of diuretic medication and volume expansion with saline.

Another cause of hypotonic hyponatremia is salt wasting associated with renal dysfunction.[13,14] This can occur as a result of obstructive uropathy from abdominal and retroperitoneal tumors, loss of renal structure as in polycystic disease, or tubular damage associated with interstitial nephritis. The latter can occur as a result of several chemotherapeutic agents (especially cisplatin, aminoglycosides, or amphotericin) or infection, all of which can limit sodium reabsorption and diminish free-water excretion. As expected, urine sodium is high (>20 mEq/L) in these situations. The management of these situations relies on addressing the underlying problem and on replacing volume with saline.

Table 49-1 Causes of Hypotonic Hyponatremia

ASSOCIATED WITH HYPOVOLEMIA

Extrarenal sodium loss

Diarrhea, vomiting, hemorrhage, fluid sequestration (third space), excessive sweating

Renal sodium loss

Diuretics, *osmotic diuresis (use of mannitol with cisplatin over multiple days)*

Renal tubular acidosis

Salt-losing nephropathy

Interstitial nephritis, urinary tract obstruction, Bartter's syndrome

Hormonal

Adrenal insufficiency (mineralocorticoid deficiency; most common as a late effect of cranial irradiation)

Cerebral salt wasting syndrome

Edematous states

Congestive heart failure, nephrotic syndrome, *malignant ascites,* cirrhosis, renal failure

ASSOCIATED WITH EUVOLEMIA

Distal tubule diuretics

Loop diuretics (furosemide, ethacrynic acid)

Hypothyroidism (early effect of cranial and/or craniospinal irradiation)
adrenal insufficiency (glucocorticoid deficiency; most commonly a late effect of cranial irradiation)

SIADH

Cancer

Small cell carcinoma of lung, Hodgkins disease, leukemia, lymphoma, adenocarcinoma of pancreas and duodenum, breast, and many others

CNS lesions

Tumor, stroke, subarachnoid bleed, hemorrhage, infection

Selected drugs

Opiates, phenothiazines, vincristine, cyclophosphamide, ifosfamide, cisplatin, carbamazipine, tricyclics, NSAIDs, selective serotonin reuptake inhibitors, desmopressin, nicotine, chlorpropamide

Increased intrathoracic pressure

Mediastinal tumor, positive pressure ventilation, pneumonia

Reset osmostat*

Trauma, *pain, and stress (postoperative state)*

AIDS

ASSOCIATED WITH HYPERVOLEMIA

Primary polydipsia†

Excessive dilute or sodium-free irrigants during surgery

Tap water enemas

AIDS, acquired immunodeficiency syndrome; AVP, arginine vasopressin; CNS, central nervous system; NSAIDs, nonsteroidal anti-inflammatory drugs; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Common cancer-associated causes are *italicized.*

*Normal volume accompanied by low plasma osmolality.

†May also be accompanied by decreased water excretion as a result of AVP stimulation.

Hypervolemia

In the disease states listed in this discussion, hyponatremia develops even though total body sodium is generally increased. This is a result of physiologic adaptations to disease that cause an even larger increase in total body water (particularly in the ECF), thus driving sodium down.

Congestive heart failure, ascites associated with malignant peritonitis or cirrhosis, and nephrotic syndrome are edematous states with increased ECF. Despite the edema, however, these diseases are usually associated with decreased effective circulating volume. In these situations, atrial and carotid baroreceptors stimulate ADH release and volume expansion as a compensatory (but physiologically inappropriate) event.[6,13] The management of these situations is centered on improving effective circulating volume by addressing the underlying problem and restricting both sodium and water.

Hypotonic hyponatremia occurring in the setting of volume expansion can also develop in patients with renal failure.[13,14] Accumulation of ineffective osmols (e.g., urea) leads to increased osmolality in both the ICF and ECF, with consequent water retention and an increase in the volume of both compartments. Thus, a dilutional hyponatremia occurs in the setting of increased ECF. As with the edematous states described previously, management is centered on treatment of the primary disease (dialysis) and on restriction of both sodium and water.

Hyponatremic states that are a result of excessive water intake, such as psychogenic polydipsia or low-sodium intravenous or enteral fluids, are examples of hypotonic hyponatremia in the setting of increased ECF.[13,14] Although renal water excretion is usually normal in these patients, the volume of water intake overwhelms the normal ability of the kidney to excrete the maximum of 26 L/1.73 m^2 per day of free water. A moderate to significantly increased ECF usually accompanies these problems. Characteristic of these states is the excretion of large volumes of maximally dilute urine, indicating intact renal function. Depending on how rapidly the problem has evolved, the degree of hyponatremia, and the presence of symptoms, treatment is aimed at net water loss or sodium replacement.

Isovolemia

Patients who develop hyponatremia in the setting of normal or near-normal ECF volume generally have a modest increase in water relative to sodium. This condition generally signals the syndrome of inappropriate antidiuretic hormone secretion (SIADH).[6,15] It is noteworthy, however, that increased ADH by itself is generally insufficient to cause significant hyponatremia; water intake is necessary for the dilutional effect to occur. Although SIADH is often classified as an isovolemic hyponatremia because of the lack of edema and overt signs of volume expansion, most patients have expansion of their ECF, diminished urine output and weight gain. Despite the hyponatremia, an atrial natriuretic peptide-mediated natriuresis can occur in response to the volume expansion. This, and the diminished sodium reabsorption associated with volume expansion, further decrease plasma sodium and limit the formation of edema. Eventually, a new equilibrium between sodium intake and excretion occurs, such that intake and output are matched. Thus, attempts to correct SIADH with the addition of sodium alone are rarely successful; water restriction remains the primary method of management in asymptomatic patients. SIADH is a diagnosis of exclusion. To make the diagnosis, the following criteria should be met:

- Other causes of hyponatremic hyponatremia, particularly hormone deficiencies (e.g., thyroid and adrenal) and a reset osmostat are absent (see related topics covered later in this chapter).
- The patient should be clinically isovolemic or only mildly hypervolemic. The presence of edema or clinical volume overload is not compatible with SIADH.

- The plasma osmolality should be 280 mOsm/kg or less. Higher osmolality does not support the "inappropriate" nature of ADH secretion.
- Urine osmolality must be greater than plasma (≥500 mOsm) and urine sodium must be in excess of 20 to 30 mEq/L; concentrations of 40 mEq/L or greater are not uncommon.

SIADH is associated with a wide variety of clinical settings (see Table 49-1). The most common cause in clinical oncology is the ectopic production of ADH by tumor. Although small cell anaplastic carcinoma of the lung is the most frequent cause, several other neoplasms also can be associated with the problem (see Table 49-1).[1,2] Even though serum ADH is increased in as many as 40% of patients with small cell lung carcinoma, the clinical manifestations may occur in only 10% of such patients. The latter have latent SIADH, which might become evident only in the setting of water loading. It should be noted that ectopic ADH secretion is not steady, nor is it usually at a level that approaches the maximal release by the hypothalamus. Thus, an episode of volume depletion still can produce a nonosmotic ADH release.

Several pharmaceutical products, including several antineoplastic compounds, are also associated with SIADH. Most notable among these is vincristine, which has been associated with acute and severe SIADH. The problem generally develops 2 to 3 days after vincristine administration, is associated with increased ADH levels, and can persist for days to weeks. High-dose (2 g/m^2) cyclophosphamide is also capable of inducing hyponatremia through direct renal tubular effects and possible enhancement of ADH activity.[13] In contrast to hyponatremia due to vincristine, the hyponatremia associated with cyclophosphamide occurs within several hours of administration, and is not associated with ADH secretion. Curiously, we have not identified SIADH associated with the use of ifosfamide, which is structurally similar to cyclophosphamide. Ifosfamide has, however, been associated with significant renal toxicity and a Fanconi-like tubulopathy characterized by the wasting of multiple electrolytes, glucose, and protein. The platinating agents, cisplatin and (less commonly) carboplatin, have also been associated with hyponatremia, although the mechanisms of these agents are probably related in part to direct renal toxicity and not to SIADH. Several other drugs listed in Table 49-1 also can cause SIADH.

The management of SIADH depends on how rapidly the problem has evolved and the degree of hyponatremia; it must include treatment aimed at the underlying disease process. In the asymptomatic patient with SIADH who has a serum sodium greater than 125 mEq/L, water restriction is the primary mode of management. The use of furosemide is appropriate for patients who do not respond well to fluid restriction alone. In the symptomatic patient, partial correction with 3% hypertonic saline and furosemide is indicated (see ensuing discussion).[13,16] Even in these cases, however, treatment must eventually rely on water restriction.

Cerebral salt wasting (CSW) is a cause of hyponatremia associated with intracranial disease or injury.[7,17] It is important to differentiate this process from SIADH, which it can closely resemble and for which it is often mistaken. The approaches to treatment for CSW and SIADH are quite different from one another. CSW is mediated by not yet fully defined physiologic circumstances and is characteristically associated with volume depletion rather than the isovolemic or modestly expanded state of SIADH. At a basic level, primary CNS tumors, subarachnoid hemorrhage, and increased intracranial pressure all seem to be associated with the release of natriuretic peptides from brain, cardiac foci, or both, causing a sodium diuresis and ECF volume loss. Water restriction, the typical approach to SIADH, is contraindicated in CSW, which requires both volume and sodium replacement.

Reset Osmostat

Resetting of the hypothalamic osmostat is generally associated with chronic hyponatremia and has been seen in a variety of malignancies as well as in cachexia, malnutrition, and pregnancy.[6,18] Another common setting is in patients with hypothalamic tumors or hypothalamic injury from trauma or surgery. The mechanism seems to be one in which the set point for ADH release is adjusted downward. Such individuals might have stable plasma sodium concentrations in the range of 125 to 135 mEq/L and are generally asymptomatic. Treatment is unnecessary and even if attempted is generally unsuccessful, because thirst and ADH maintain sodium at the new set point. In isolation, this is a relatively benign problem unassociated with neurologic sequelae. In association with other central water and sodium problems, however (e.g., diabetes insipidus or loss of thirst that could accompany hypothalamic/pituitary tumor or injury), a reset osmostat can become a challenge.

HYPONATREMIA IN ASSOCIATION WITH HORMONE DEFICIENCIES

Hyponatremia also can occur in the setting of a number of primary or secondary hormone deficiencies, such as hypothroidism or hypocortisolism.[7,8,16] Although these are generally associated with a euvolemic state, hypervolemia may occur also. It is important to keep the hyponatremia associated with these deficiencies in mind, because they can be slow to evolve after organ injury and can easily be mistaken for SIADH.

Although the mechanism of hyponatremia in hypothyroidism is not fully understood, the relatively low cardiac output, a decrease in renal perfusion, impaired water excretion, and ADH secretion all seem to be involved. Patients with milder forms of hypothroidism might be euvolemic and have only modestly decreased sodium. Settings commonly associated with hypothyroidism occur in those patients who have received head and neck or craniospinal irradiation. It can take 1 to 2 years for clinically evident hypothyroidism to develop after such events. The treatment of this problem relies largely on thyroid replacement. In patients with advanced disease, temporary sodium, with or without water restriction, may also be helpful.

In the setting of adrenal insufficiency, hyponatremia can be a result of mineralocorticoid deficiency, glucocorticoid deficiency, or both. The mechanisms of hyponatremia in these two settings are entirely independent of each other. Primary and metastatic tumors to the adrenal can reduce both hormones. Isolated glucocorticoid deficiency can occur as a result of hypothalamic or pituitary tumors, surgery, or CNS radiation therapy. Of note, central adrenocorticotropic hormone regulation is relatively radioresistant and generally requires doses exceeding 50 Gy and typically has a 3- to 5-year latency before becoming evident. Glucocorticoid deficiency is generally characterized by hyponatremia in the setting of normal or modestly expanded ECF. Cortisol is necessary for maximum urinary dilution and free water excretion, thus a deficiency results in water retention from increased permeability in the renal collecting tubules. This action seems to be independent of ADH, in that patients with panhypopituitarism who are given cortisol replacement soon exhibit diabetes insipidus. In the setting of an otherwise intact hypothalamic/pituitary axis, cortisol deficiency is also associated with some increase in ADH secretion. Thus, management might require not only cortisol replacement but also desmopressin acetate to control the diabetes insipidus that cortisol has "unmasked."

In mineralocorticoid deficiency the renin-angiotensin system is compromised, and there is generally a contraction of effective circulating volume because of diminished capacity by the kidney to reabsorb sodium. In response to diminished volume, baroreceptor-mediated ADH release and water retention can drive sodium lower.

SYMPTOMS AND MANAGEMENT OF HYPONATREMIA

Most patients with hyponatremia are relatively asymptomatic, and treatment can be aimed at the underlying disease. Symptomatic hyponatremia should be considered a medical emergency. In the

absence of infections and issues related to tumors, congestive failure, and the other edematous states, the symptoms associated with hyponatremia depend on the depth of the sodium concentration and the rapidity of its onset. When hyponatremia develops within a matter of several hours as a result of an acute hypotonic volume load, neurologic findings related to evolving cerebral edema dominate. Those patients in whom hyponatremia develops over an extended period (≥48 hr) might have only mild lethargy, muscular symptoms, and anorexia even though their serum sodium might be the same or even lower than that of patients who develop the problem acutely.

Mild symptoms characterized by vomiting, malaise, and even agitation are usually seen in patients with sodium concentrations above 125 mEq/L. As sodium falls further, muscle cramps and weakness, as well as neurologic symptoms including lethargy, headache, and confusion can occur. Sodium levels below 120 mEq/L are associated with seizures and coma.

In all but the unequivocal acute volume overload state and patients with neurologic signs, it is wise to assume that hyponatremia is a chronic process that has developed over several days. The rationale for this assumption is that chronic hyponatremia must be corrected slowly. Too rapid a correction is associated with severe, life-threatening CNS complications from osmotic demyelination syndrome.

Osmotic demyelination is related to an overly aggressive sodium correction. Rapid but relatively modest degrees of sodium correction can cause ECF to appear hypertonic to the cell (even though sodium is still low). Thus, correction should be limited to no more than 12 mEq/L in 24 hr and 18 to 24 mEq/L in 48 hr.[5,12,19] It should be noted that there is typically a delay of 2 to 4 days (and sometimes as long as 6 days) before the signs of brain injury and demyelination occur. Thus, it is possible to see patients improve initially but have a subsequent neurologic decline some days after the start of correction. Patients with acute hyponatremia have significantly less risk of developing this problem than do those with chronic hyponatremia.[16]

Treatment of Asymptomatic Hyponatremia

Hypovolemic hyponatremia is generally associated with the symptoms of volume depletion, and these patients are not at risk for the neurologic complications related to cerebral edema that accompany acute hyponatremia. They might, however, be subject to osmotic demyelinating syndrome associated with rapid sodium correction. The management of patients with mild hypovolemic hyponatremia from chronic renal sodium loss or overuse of diuretics is best performed by giving isotonic (0.9%) saline or, if tolerated, oral salt tablets. A rate of correction aimed at no more than 12 mEq/L per day over a period of 2 to 3 days is generally sufficient.

In the isovolemic hyponatremias that commonly result from SIADH, treating the underlying disease, stopping any potentially offending drugs, and water restriction are the methods of choice. Rigorous restriction of free water to as little as 30% to 70% of maintenance needs might be necessary and could take 2 to 3 days to become effective. The often attempted use of isotonic saline at a lower than maintenance rate is a doomed strategy, because an isotonic load is excreted quickly with little or no net change in serum sodium. In patients who do not tolerate or who are noncompliant with water restriction or in whom furosemide is contraindicated or ineffective, democycline may be used to induce a nephrogenic diabetes insipidus-like state with increased free-water excretion. Lithium carbonate can produce the same result but is generally not well tolerated.

In relatively asymptomatic hypervolemic hyponatremic patients, modest fluid restriction, sodium restriction, and the use of a loop diuretic to promote renal free-water excretion are appropriate measures. These measures will be ineffective, however, without management aimed at the underlying edematous disease state.

Box 49-2. SODIUM DEFICIT

[Desired Na – measured Na] × 0.6 body weight (kg) = mEq of Na^+ needed.*

*Use 0.5 in elderly and frail.

Treatment of Acute Symptomatic Hyponatremia

Acute hyponatremia—most frequently the result of volume overload with hypotonic fluids—generally manifests by the presence of some neurologic findings as a result of evolving cerebral edema. These patients generally have a serum sodium below 120 mEq/L and are generally hospitalized individuals with iatrogenic hyponatremia (Box 49-2). Common characteristics include: menstruating women (who are more susceptible than males), excessive hypotonic intravenous fluids, recent use of diuretics, particularly thiazides, or seratonin reuptake inhibitors, which can lead to SIADH. Another group are patients who have undergone transurethral prostatectomy with excessive absorption of hypotonic fluids across the organ bed, and those with colonoscopic preparation–induced losses.[12] The goal of treatment for these patients should be to raise the serum sodium sufficiently to stop any seizure activity and to correct cerebral edema; changes in serum sodium of as little as 5% can diminish cerebral edema, and increases of as little as 3 to 6 mEq/L can stop most seizures.[13] With this in mind, a rate of correction of about 1 to 1.5 mEq/hr during the first 4 to 6 hr is often sufficient to manage the acute neurologic problems. Anticonvulsants might be necessary for those with seizures. This initial correction might use 3% hypertonic saline (Box 49-3). Acute, symptomatic hyponatremia is the only condition in which the use of a hypertonic saline solution is unequivocally an appropriate intervention. Although patients with acute hyponatremia have a lower risk of osmotic demyelination than those who develop low sodium on a more chronic basis (>48 hr), the use of hypertonic saline should be limited to achieving an initial increase of 3 to 6 mEq/L or a serum sodium of 120 to 125 mEq/L. After the initial period of correction, the rate of sodium rise should be limited to 0.5 mEq/L using 0.9% (isotonic) saline. Correction rates of 10 to 12 mEq/L during the first 24-hr period and 18 mEq/L over the first 48 hr are safe.[5,12,19]

The addition of furosemide during the initial correction period has been advocated as a method of encouraging free-water excretion by the kidney. Furosemide diminishes interstitial renal medullary tonicity, impairs urinary concentrating ability, and leads to a hypotonic urine with a concentration of about 0.45% saline (75 mEq/L). Although this often seems to be helpful, it should probably be limited to a single dose, thus minimizing too rapid a correction. Furosemide is particularly useful in a frail patient with diminished cardiac reserve, in whom the use of hypertonic saline could incite congestive failure.

Management of Chronic Hyponatremia and SIADH

The management of these patients relies on treating the underlying disease. Examples include the treatment of malignancies, hormone replacement, removal of drugs associated with SIADH, providing adequate sodium (and water) needs for patients receiving enteral feeding, and compensating for disordered thirst. Preventive measures, such as the preference for the use of isotonic saline in "at risk" patients

Box 49-3. SODIUM CONTENT OF COMMON INTRAVENOUS SOLUTIONS

Solution	Na^+ (mEq/L)	Na^+ (mEq/mL)
3% saline	513	0.513
0.9% saline	154	0.154
Ringer's lactate	130	0.130

(malignancy, chemotherapy, positive pressure ventilation, and other states noted in Table 49-1) who require hydration, are equally important. It is important to remember that correction of chronic hyponatremia must be executed slowly to avoid the potential of osmotic demyelination. Asymptomatic patients who have slowly developed sodium concentrations as low as 105 to 110 mEq/L have been corrected successfully using an initial rate of 0.5 mEq/L/hr or less to bring them to serum levels of 120 mEq/L. After this, the rate of correction may be liberalized, keeping in mind the risk factors for demyelination noted earlier. Although it is permissible to initiate treatment with 3% saline solutions in these severely hyponatremic patients, the need to do so and the potential risks of too rapid a correction in a relatively asymptomatic patient suggest isotonic saline as a safer alternative. For unstable patients and those with neurologic symptoms, the approach to treatment should be similar to that noted earlier for acute symptomatic hyponatremia, but at a slower pace; a planned initial rise in sodium of 4 to 6 mEq/L over 12 hr, followed by a more gradual correction at a rate not to exceed 12 mEq/L during the first 24 hr, is considered safe (including the initial 4- to 6-mEq/L correction). During the second 24 hr, the rate of correction should be even more gradual than for the acutely symptomatic patient. A rate of 0.5 mEq/L or less, with the plan of limiting sodium rise to no more than 18 mEq/L over the initial 48 hr, is appropriate. Some authors suggest an even slower rate of correction, limiting sodium rise to no more than 8 mEq/L in any 24-hr period.[13] Furosemide may be used during the initial correction phase but should probably be limited to a single dose to minimize too rapid a correction, particularly in the setting of hypertonic saline use.

A more challenging situation is that of a patient with severe hyponatremia associated with a malignancy. Such patients should have at least a partial correction to a serum sodium above 125 mEq/L (and preferably above 130 mEq/L) before proceeding with chemotherapy and hydration.

A caution is that the correction of a hypovolemic hyponatremia associated with excessive use of thiazide diuretics might occur more rapidly than anticipated. As volume is replaced, these patients might quickly regain the ability to excrete a hypotonic urine that could cause an unintended acceleration of sodium correction. Likewise, other hypovolemic patients are at risk for rapid correction. As their volumes are expanded and the nonosmotic stimulus of ADH decreases, accelerated sodium correction can occur. Again, the use of isotonic rather than hypertonic saline for correction, as well as frequent evaluations of volume and sodium status, limits the potential for too rapid a rate of correction.

An important, more elegant and selective treatment of hyponatremia is now emerging as a result of the development of antagonists to the renal arginine vasopressin (ADH) receptors. Some amount of impaired water excretion is common in virtually all the hypervolemic and isotonic hyponatremic states. Thus, antagonists to the renal AVP receptors (V2 receptor antagonists; tolvapatan and conivaptan) which mediate free-water reabsorption from the distal tubules can promote free-water excretion. These agents have no effect on the excretion of sodium or other electrolytes; the effect is pure aquaresis. Though not yet in common use outside of the management of congestive heart failure, these agents will undoubtedly become a part of the primary treatment of hyponatremias, as adjuvants or replacements for management by water restriction.[20–22]

EXAMPLE CASES

Postoperative Symptomatic Hyponatremia

A 56-year-old woman who had an uncomplicated resection of a breast tumor 48 hr ago is reported by her family to be more lethargic and somewhat confused compared with the day before. She has a tonic-clonic seizure that is controlled rapidly with lorazepam. Serum chemistries reveal a serum sodium of 115 mEq/L, a serum potassium of 3.3 mEq/L, and a serum osmolality of 245 mOsm/kg. Her urine osmolality is 125 mEq/L, and urine sodium is 20 mEq/L. On examination, she has a heart rate of 90 beats/min, is normotensive, and has no peripheral edema. Her preoperative weight was 65 kg. Based on the foregoing data, a probable diagnosis is hypotonic hyponatremia in what seems to be a euvolemic patient. The differential diagnosis includes SIADH from the pain and stress of surgery and/or from the use of morphine for postoperative discomfort, or dilutional hyponatremia from hypotonic volume overload. SIADH would be expected to be associated with a more concentrated urine and a urine sodium well in excess of 20 mEq/L. Her record indicates that she received 2.5 L of D5W during surgery. Additionally, it is noted that she has had several glasses of water over the last 12 hr, the exact amount unknown. The highly dilute urine, the relatively low urine sodium in the setting of a low serum osmolality, and her history are characteristic of acute hypotonic fluid overload. Because the patient is symptomatic, the initial plan should be to increase her serum sodium by 3 to 6 mEq/L over the course of 3 to 6 hr. Based on her weight and gender, the appropriate factor for determining the volume of ECF in need of correction is 0.5, thus giving a volume of 32.5 L (0.5×65 kg). An initial correction of 5 mEq/L over the course of 6 hr is planned using 3% saline. The total amount of sodium needed is 163 mEq (32.5 kg × 5 mEq/L). Given over 6 hr, this equates to 27 mEq/hr. Using 3% saline, which contains 0.513 mEq/mL of sodium, her hourly fluid rate becomes

$$\frac{27 \text{ mEq Na}}{0.513 \text{ mEq Na/mL 3\% saline}} = 53 \text{ mL/hr for 6 hr}$$

If furosemide is given at the start of the initial correction, the time to correction might be somewhat longer as a result of both free-water and sodium loss (furosemide produces a roughly 0.45% saline diuresis). Thus, sodium should be monitored every 2 hr, and the infusion rate should be adjusted accordingly (Box 49-4).

At the end of the initial 6 hr the serum sodium is 119 mEq/L, and there have been no further seizures. The patient remains unresponsive, however. Based on this, an additional 5 mEq/L sodium correction is planned. Even though patients with acute volume overload are not at high risk for osmotic demyelination associated with rapid correction, it is wise to assume that the problem occurred slowly to minimize the potential for development of this condition. Thus, the second-phase correction should be done at a much slower rate of 0.5 mEq/L/hr, with the goal of not exceeding a total correction of more than 12 mEq/L over the first 24 hr. Another 163 mEq of sodium will be required (32.5 kg × 5 mEq/L) over the next 18 hr. Because the patient is still unresponsive, it is appropriate to use 3% saline for correction. The hourly rate of correction now changes to 163 mEq/18 hr, or 9 mEq/hr. Using 3% saline, this becomes

$$\frac{9 \text{ mEq Na}}{0.513 \text{ mEq Na/mL 3\% saline}} = 17 \text{ mL/hr for 12 hr}$$

At the end of 24 hr, the patient's serum sodium is 125 mEq/L, and she is somewhat lethargic but arousable. At this point, it is appropriate to switch to isotonic saline (0.9%) for further correction. The goal is now to continue correction, limiting the total amount of correction in the first 48 hr to 18 mEq/L. Thus, an additional 8 mEq/L of sodium will be given over the second 24-hr period, for

Box 49-4. CALCULATING THE RATE OF FLUID ADMINISTRATION

Na^+ deficit/Na^+ mEq/L = rate (mL/hr)

a total of 260 mEq of sodium (8 mEq/L × 32.5 L) or 11 mEq/hr. Using isotonic saline, the rate becomes

$$\frac{11 \text{ mEq Na}}{0.513 \text{ mEq Na/mL 3\% saline}} = 39 \text{ mL/hr}$$

At the end of the first 48 hr the patient's serum sodium is 132 mEq/L, and she is alert and responsive. Further correction with 0.9% saline at a rate of no more than 0.5 mEq/L/hr over the next 12 to 24 hr will result in a normal serum sodium having been achieved over a period of time long enough and at a slow enough rate to minimize the potential for CNS demyelination.

Hypotonic Hyponatremia Associated with Euvolemia

A 72-year-old man with recently diagnosed small cell lung carcinoma is noted to have become increasingly confused and lethargic over the last 72 hr. He has not yet started chemotherapy. Notably, he has been on replacement therapy for hyperthyroidism for several years. His wife is not sure whether he has been taking his thyroid replacement over the last several days. Laboratory evaluation reveals a serum sodium of 112 mEq/L, serum potassium at 3.6 mEq/L, and a serum osmolality of 225 mOsm/kg. The urine osmolality is 590 mOsm/kg. His blood pressure and heart rate are normal, and there is no evidence of edema, suggesting that he is euvolemic. His urine sodium is 50 mEq/L. His weight is 66 kg. Although the temptation to make the diagnosis of tumor-related SIADH is strong, this must be a diagnosis of exclusion. Other possible causes of euvolemic hypotonic hyponatremia include overuse of a diuretic and glucocorticoid or thyroid deficiency (see Fig. 49-2). He has not been taking any diuretics, and cortisol deficiency seems unlikely because his potassium is normal and he has been an otherwise healthy, active man except for recent events. Although known to have primary hypothyroidism, it is unlikely that missing 2 to 3 days of replacement therapy would put him at risk for hyponatremia. Thus, tumor-related SIADH is the most likely diagnosis. He is given 1 L of normal saline (0.9%), and 2 hr later his serum sodium is 110 mEq/L and his urine osmolality remains at 590 mOsm/kg. Although this might initially be surprising, recall that patients with SIADH have a relatively fixed urine osmolality due to tonic ADH secretion, and they retain the ability to excrete sodium despite their hyponatremia. Thus, the net effect of isotonic saline was to produce further dilution of serum sodium, as a concentrated sodium-containing urine is excreted, leaving a relative free-water gain.

The approach to this symptomatic patient involves raising his sodium to a level of 120 mEq/L and then restricting free water. The goal is to provide an initial sodium increase of 3 to 6 mEq/L. Knowing that the hyponatremia has developed over a period of at least 72 hr based on the patient's history, the rate of correction should be similar to minimize the potential for osmotic demyelination, for which he is at significant risk. Based on this information, the goal is an increase in serum sodium of no more than 10 to 12 mEq/L over the first 24 hr at a rate of no more than 0.5 mEq/L/hr. Because he is an elderly man, the factor for determining his total body water is 0.5, thus making his total ECF volume 33 L (0.5 × 66 kg). Although the use of isotonic saline is often a better plan for correcting hyponatremia in patients who have developed the disorder chronically, 3% saline is acceptable for this patient because he is symptomatic.

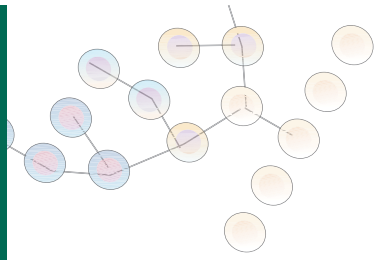
Raising his sodium by 10 mEq/L to 120 mEq/L over the next 24 hr requires 10 mEq/L of sodium by 23 L, for a total of 230 mEq of sodium.

$$\frac{230 \text{ mEq Na}}{0.51 \text{ mEq/mL/3\% saline}} = 450 \text{ mL 3\% saline at 19 mL/hr}$$

This correction rate is only 0.4 mEq/L/hr and within the guidelines for minimizing the risk of osmotic demyelination discussed earlier in the chapter. Also, keep in mind that the rate of correction should be limited to 18 mEq/L within the first 48 hr. If furosemide is used at the start of the initial correction, the rate of correction might even be somewhat slower, as noted in the previous case example. At 24 hr, the patient's serum sodium is 119 mEq/L; he is lethargic but arousable and less confused, and the objective of bringing his sodium close to 120 mEq/L has been achieved. If he had not been clinically improved, it might have been prudent to increase his sodium another 5 mEq/L over the next 12 hr, to about 125 mEq/L. At this point, with signs of improvement in the patient and a serum sodium of 119 mEq/L, it is appropriate to begin water restriction, limiting water and anything that becomes water at body temperature (e.g., gelatin and ice cream) to 1 L/day. Over the next 48 to 72 hr, one should expect to see his sodium increase to 130 mEq/L or more. At this point, it is appropriate to begin management of his tumor.

Hyponatremia with Diminished Extracellular Fluid

A 12-year-old 50-kg male underwent resection of a large temporal lobe tumor 48 hr previously; the tumor has been associated with significantly increased intracranial pressure. He is irritable but lucid, complaining of leg cramps; he has a moderate hypotension of 100/60 mm Hg and a moderate sinus tachycardia of 120 beats/min and has developed significantly increased urine output of 6 mL/kg/hr over the last 12 hr. Serum chemistries reveal a sodium of 124 mEq/L, potassium of 4.5 mEq/L, blood urea nitrogen (BUN) of 17, and creatinine of 1.2. His serum osmolality is 300 mOsm/kg, urine osmolality is 350 mOsm/L, and urine sodium is 155 mEq/L. Review of his record shows that he received 0.5 g/kg dose of mannitol before surgery and 1 L of normal saline during surgery. Over the last 24 hr he has been drinking ad lib and seems to have increased thirst. His examination suggests some degree of hypovolemia, and the elevated urine sodium is compatible with either a primary salt-wasting process or SIADH. The urine sodium and moderate urine concentration are not consistent with diabetes insipidus. The latter is unlikely given his increased serum osmolality, excessive urine output, and signs of hypovolemia. A hypovolemic hyponatremia characterized by excessive renal sodium loss in a neurosurgical setting is characteristic of cerebral salt wasting.



Recognizing that the serum sodium has probably developed acutely and is likely to quickly drop even further given the amount of sodium he is excreting and the fact that he is developing some mild symptoms (irritability and muscle cramps), the decision is to make a partial correction of his sodium to diminish the potential of more severe symptoms. At the same time, his hypovolemia must be treated, and his ongoing losses must be replaced. The plasma volume for this adolescent male is 30 L (0.6 × 50 kg). Because the sodium loss has been rapid, the decision is taken to raise his sodium by 4 mEq/L over 6 hr. Thus, a total of 120 mEq of sodium over 6 hr will be needed at a rate of 20 mEq/hr using 3% saline.

$$\frac{20 \text{ mEq Na}}{0.513 \text{ mEq Na/mL 3\% saline}} = 39 \text{ mL/hr}$$

Simultaneously, it is necessary to replace his urine output, volume for volume, with isotonic saline. To this it is necessary to add an amount calculated to represent his current volume deficit with the intent of correcting it over 24 hr. After 24 hr, the patient appears euvolemic with a normal blood pressure and heart rate. Having replaced his volume deficit, it is now prudent to decrease the rate of isotonic saline correction to match urine output. The natriuresis continues for several days, but isotonic saline keeps the serum sodium at 138 mEq/L. At this point the patient is stable, is able to drink, and appears to have a normal thirst. He can be discharged on oral NaCl supplements approximating his renal sodium loss. Two weeks later he appears well, and his urine output has diminished to 3 mL/kg/day. He is on a normal diet, and urine osmolality has increased to 550 mEq/L with 50 mEq/L of sodium. The serum sodium is 138 mEq/L. At this point NaCl supplements are stopped, and the patient's serum sodium remains normal.

50 Tumor Lysis Syndrome

Jessica Hochberg, Mitchell S. Cairo, and Peter F. Coccia

SUMMARY OF KEY POINTS

Incidence and Epidemiology

- The exact incidence of tumor lysis syndrome is unknown; incidence in high-grade non-Hodgkin's lymphoma is approximately 40%.
- Tumor lysis syndrome is most commonly associated with acute lymphocytic leukemia and "high-grade" non-Hodgkin's lymphoma; however, it has been observed in a variety of hematologic and solid malignancies.
- Tumor lysis syndrome has been observed with the administration of chemotherapy, corticosteroids, radiation, hormonal agents, and biologic response modifiers. Tumor lysis syndrome can rarely occur spontaneously before the initiation of therapy.

Etiology

- Tumor lysis syndrome results from the spontaneous release of intracellular ions and metabolites from malignant cells before or after the initiation of cytotoxic therapy.
- The body's inability to handle the increased concentrations of ions and metabolites results in the characteristic metabolic abnormalities associated with tumor lysis syndrome, including hyperuricemia, hyperphosphatemia, hyperkalemia, hypocalcemia, and/or uremia.
- The metabolic disturbances associated with tumor lysis syndrome can lead to life-threatening complications including arrhythmias, acute renal failure, and sudden death.

Evaluation of the Patient

- Patients with tumors with a high proliferative rate and sensitivity to cytotoxic therapy, large tumor masses, pre-existing renal insufficiency, and high serum lactate dehydrogenase levels are at highest risk for the development of tumor lysis syndrome.

Management and Treatment

- Recognition of patients at risk for the development of tumor lysis syndrome is the most important management issue.
- Establishing central venous access and administration of intravenous fluids and allopurinol or rasburicase should begin before the initiation of tumor therapy.
- Alkalinization of urine with sodium bicarbonate or acetazolamide is not recommended.
- Prompt initiation of hemodialysis may aid in the reversal of severe complications associated with renal failure and metabolic abnormalities.

INTRODUCTION

Tumor lysis syndrome (TLS) describes the metabolic derangements that occur from rapid tumor breakdown associated with the initiation of cytotoxic therapy of malignancy in both children and adults. The syndrome is characterized by a tetrad of abnormalities including hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia; it should be considered an oncologic emergency.[1–5] The abrupt release of intracellular ions, nucleic acids, proteins, and their metabolites results from the rapid destruction of malignant cells and the release of their intracellular contents into the extracellular space after the initiation of therapy. Cell lysis can overwhelm the body's normal homeostatic mechanisms and cause severe metabolic disturbances that require immediate clinical intervention (Fig. 50-1).

TLS has been primarily observed in patients with acute lymphocytic leukemia and high-grade non-Hodgkin's lymphomas, in particular Burkitt's lymphoma. However, TLS has also been recognized in a variety of other malignancies, both hematologic and solid. These malignancies share the characteristics of a high proliferative rate and a relative sensitivity to cytotoxic therapy.[6–14] Other hematologic malignancies associated with TLS include acute myeloid leukemia, chronic lymphocytic leukemia, chronic myeloid leukemia, and low-grade and intermediate-grade non-Hodgkin's lymphomas. TLS has also been reported to occur in a number of solid tumors such as breast cancer, ovarian and testicular cancer, neuroblastoma, and small cell carcinoma of the lung.[15–24]

The overall incidence of TLS is not well established and has only been closely studied in high-grade non-Hodgkin's lymphomas.[25] In a retrospective study of 102 patients with high-grade non-Hodgkin's lymphoma, the incidence of TLS was reported to be 42% as determined by serial laboratory testing. The incidence of clinically significant TLS was only 6% in the same group of patients. Part of the difficulty in obtaining the true incidence of TLS is that there is no unifying definition or grading system. Recent proposals define TLS by both laboratory (LTLS) and clinical (CTLS) criteria and use these criteria to develop a grading system (Tables 50-1 through 50-3).[1,2,5]

The development of TLS is not limited to the administration of chemotherapy alone. Reports of TLS have been associated with the administration of radiation therapy, corticosteroids, hormonal agents, biologic response modifiers, monoclonal antibodies, and more recently, the low-molecular-weight inhibitor, imatinib mesylate, better known as Gleevec.[15,20,24,26–41] TLS is not limited to systemic administration of agents; it has been observed with intrathecal administration of chemotherapy and with chemo-embolization. It is extremely important clinically to note that TLS can occur spontaneously, before the initiation of any intervention. The identification of

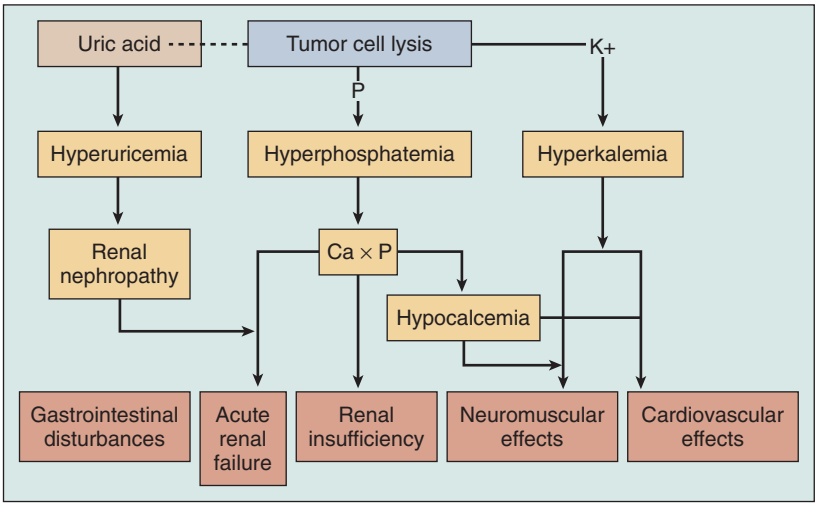

Figure 50-1 • Schematic of the metabolic abnormalities associated with the development of tumor lysis syndrome and the clinical complications stemming from these metabolic derangements.

patients at risk for the development of TLS is the most important aspect of management, so that prophylactic measures can be initiated before the initiation of therapy. Most of the complications can be readily managed when they are recognized early; however, delay in recognition and initiation of treatment of TLS can be life-threatening. In addition, a recent cost analysis looking at acute renal failure, length of stay, and total cost demonstrated that those patients who went on to develop acute renal failure requiring dialysis had up to two to three times the length of stay and more than five times the cost.[42,43]

PATHOPHYSIOLOGY

The majority of agents that are used in the treatment of malignancies are dependent on the proliferative rate of malignant cells for their activity. In tumors with a high proliferative rate, a relatively large mass, and a high sensitivity to cytotoxic agents, the initiation of therapy often results in the rapid release of intracellular anions, cations, and the metabolic products of proteins and nucleic acids into the bloodstream. The increased concentrations of uric acid, calcium, phosphates, potassium, and urea can overwhelm the body's natural mechanisms to process and excrete these materials and result in the clinical spectrum associated with TLS.

Hyperuricemia and its associated complications are the most frequently recognized manifestations of TLS, and more importantly, predispose to many of the other clinical derangements. Hyperuricemia results from rapid release and catabolism of intracellular nucleic acids. Purine nucleic acids are catabolized to hypoxanthine, then xanthine, and finally to uric acid by xanthine oxidase. In humans, who lack urate oxidase, uric acid is the final endpoint of purine catabolism (Fig. 50-2). Uric acid clearance is renal, and in normal circumstances approximately 500 mg of uric acid are excreted through the kidneys each day. Uric acid has a pKa of 5.4 to 5.7 and is poorly soluble in water. At normal concentrations and at physiologic blood pH, more than 99% of uric acid is in the ionized form.[44] The concentration of uric acid has been noted to be elevated in patients with acute leukemias and lymphomas before the initiation of therapy.[45] The high concentrations of uric acid increase the risk for urate crystal precipitation in the renal collecting ducts and distal tubules, which are sites of urinary acidification.[46,47] General clinical manifestations of hyperuricemia include nausea, vomiting, diarrhea, and anorexia. Uric acid crystal precipitation within renal tubules results in a decline in glomerular filtration and the subsequent development of acute renal failure. The risk of acute renal failure caused by uric acid precipitation may be increased by dehydration, which is often present at the time of diagnosis; ureteral obstruction by tumor; a history of renal insufficiency; and the possible need for nephrotoxic antibiotics, such as aminoglycosides, in patients with active infections. If the hyperuricemia results in acute obstructive uropathy, other clinical manifestations may include hematuria, flank pain, hypertension, azotemia, acidosis, edema, oliguria, anuria, lethargy, and somnolence.

Table 50-1 Cairo-Bishop Definition of Laboratory Tumor Lysis Syndrome

Uric acid	≥8.0 mg/dL or 25% increase from baseline
Potassium	≥6.0 mEq/L or 25% increase from baseline
Phosphorous	≥6.5 mg/dL (children)
	≥4.5 mg/dL (adults) or 25% increase from baseline
Calcium	≤7.0 mg/dL or 25% decrease from baseline

Laboratory tumor lysis syndrome (LTLS) is defined as either a 25% change or level above or below normal, as defined above, for any two or more serum values of uric acid, potassium, phosphate, and calcium within 3 days before or 7 days after the initiation of chemotherapy. This assessment assumes that a patient has or will receive adequate hydration and a hypouricemic agents(s).

Modified from Hande and Garrow (1993).

Table 50-2 Cairo-Bishop Definition of Clinical Tumor Lysis Syndrome

1. Renal failure (creatinine*: ≥1.5 ULN† [age >12 yr or age adjusted])
2. Cardiac arrhythmia/sudden death*
3. Seizure*

Clinical tumor lysis syndrome (CTLS) assumes the laboratory evidence of metabolic changes and significant clinical toxicity that requires clinical intervention. CTLS is defined as the presence of laboratory tumor lysis syndrome (LTLS) and any one or more of the above-mentioned criteria.

*Not directly or probably attributable to a therapeutic agent (e.g., rise in creatinine after amphotericin administration).

†Patients will be considered to have elevated creatinine if their serum creatinine is 1.5 times greater than the institutional upper limit of normal (ULN) below age/gender defined ULN. If not specified by an institution, age/sex ULN creatinine may be defined as: >1 <12 years, both male and female, 61.6 µmol/L; ≥12 <16 years, both male and female, 88 µmol/L; ≥16 years, female, 105.6 µmol/L; ≥16 years, male, 114.4 µmol/L.

Modified from Hande and Garrow (1993).

Table 50-3 Cairo-Bishop Grading System for Tumor Lysis Syndrome

	Grade 0*	Grade I	Grade II	Grade III	Grade IV	Grade V
LTLS	–	+	+	+	+	+
Creatinine†‡	≤1.5 × ULN	1.5 × ULN	>1.5–3.0 × ULN	>3.0–6.0 × ULN	>6.0 ULN	Death§
Cardiac arrhythmia‡	None	Intervention not indicated	Non-urgent medical intervention indicated	Symptomatic and incompletely controlled medically or controlled with device (e.g. defibrillator)	Life-threatening (e.g. arrhythmia associated with CHF, hypotension, syncope, shock)	Death§
Seizure‡	None	—	One brief generalized seizure; seizure(s) well controlled by anti-convulsants or infrequent focal motor seizures not interfering with ADL	Seizure in which consciousness is altered; poorly controlled seizure disorder; with breakthrough generalized seizures despite medical intervention	Seizures of any kind which are prolonged, repetitive or difficult to control (e.g. status epilepticus, intractable epilepsy)	Death§

Clinical tumor lysis syndrome (CTLS) requires one or more clinical manifestations along with criteria for laboratory tumor lysis syndrome (LTLS).
Maximal CTLS manifestation (renal, cardiac, neuro) defines the grade.
*No LTLS.
†Patients will be considered to have elevated creatinine if their serum creatinine is 1.5 times greater than the institutional upper limit of normal (ULN) below age/gender defined ULN. If not specified by an institution, age/sex ULN creatinine may be defined as: >1 <12 years, both male and female, 61.6 µmol/L; ≥12 <16 years, both male and female, 88 µmol/L; ≥16 years, female, 105.6 µmol/L; ≥16 years, male, 114.4 µmol/L.
‡Not directly or probably attributable to a therapeutic agent (e.g. rise in creatinine after amphotericin administration).
§Attributive probably or definitely to CTLS.
(This research was originally published in Cairo MS, Bishop M: Tumour lysis syndrome: New therapeutic strategies and classification. Br J Haematol 2004;127:3–11. © Blackwell Publishing Ltd.)

Hyperphosphatemia results from the rapid release of intracellular phosphates from malignant cells, which may contain as much as four times the amount of organic and inorganic phosphates as normal cells.[1–5,25] Initially, the kidneys are able to respond to the increased concentration of phosphorus from tumor lysis by increased urinary excretion and decreased tubular absorption of phosphorus. Eventually, however, the tubular transport mechanism becomes saturated and is unable to maintain normal serum phosphorus concentrations. The development of hyperphosphatemia may be further exacerbated by acute renal insufficiency associated with uric acid precipitation, resulting in obstructive uropathy or other complications of tumor therapy. Hyperphosphatemia can lead to the development of acute renal failure after precipitation with calcium in renal tubules during TLS. Hyperphosphatemia may be associated with nausea, vomiting, diarrhea, lethargy, and seizures. More importantly, hyperphosphatemia may result in tissue precipitation of calcium-phosphate crystals, resulting in hypocalcemia, metastatic calcification, intrarenal calcification, nephrocalcinosis, nephrolithiasis, and additional acute obstructive uropathy. The serum concentration of calcium rapidly decreases as precipitation with phosphate occurs. Hypocalcemia is one of the most serious clinical manifestations of TLS and has been associated with the development of severe muscle cramping, tetany, and cardiac arrhythmias. In addition to the kidneys, other tissues such as muscle may be sites of precipitation of calcium and phosphorus.[8]

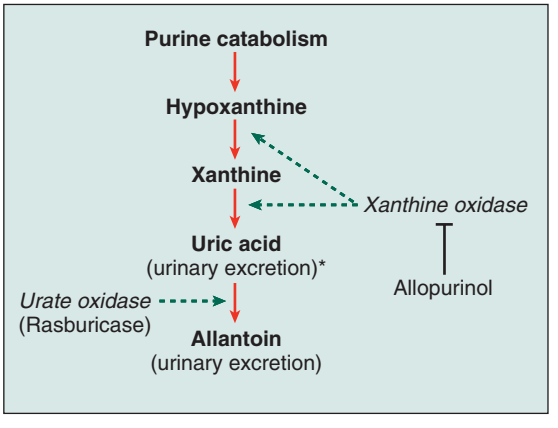

Figure 50-2 • Mechanism of action: rasburicase and allopurinol. Depicted is the pathway of purine catabolism. Rasburicase is a recombinant form of urate oxidase, an enzyme that converts uric acid to allantoin. Allopurinol in comparison acts by inhibiting the endogenous enzyme xanthine oxidase, thereby inhibiting formation of uric acid. *A normal endpoint of purine metabolism in humans. (This research was originally published in Goldman SC, Holcenberg JS, Finklestein JZ, et al: A randomized comparison between rasburicase and allopurinol in children with lymphoma or leukemia at high risk for tumor lysis. Blood 2001;97:2998–3003. © The American Society of Hematology.)

Hyperkalemia may also be a life-threatening consequence of TLS.[8,37,48] Hyperkalemia results from the kidneys' inability to clear the massive load of intracellular potassium released by lysed tumor cells. General clinical manifestations of hyperkalemia may include nausea, anorexia, vomiting, and diarrhea. More specific complications include neuromuscular and cardiac abnormalities. Neuromuscular signs and symptoms may include muscle weakness, cramps, paresthesias, and possible paralysis. Cardiac manifestations may include asystole, ventricular tachycardia or fibrillation, syncope, and possible sudden death.[1–5,25]

Increases in blood urea nitrogen and creatinine levels occur as a result of renal impairment associated with acute uric acid crystal nephropathy, calcium-phosphate crystals and nephrocalcinosis, or a combination of both, leading to an acute obstructive uropathy syndrome. A correlation with the pretreatment serum lactate dehydrogenase (LDH) concentration and the development of azotemia has been reported, and the blood urea nitrogen level will generally rise in parallel with the rise in the serum phosphorus concentration. Acute clinical manifestations may include uremia resulting in nausea, vomiting, and lethargy; oliguria or anuria leading to fluid retention; edema, hypertension, congestive heart failure, metabolic disturbances, and exacerbations of hyperphosphatemia and/or hyperkalemia (see previous discussion); flank or back pain; hematuria; and severe acidosis. Extreme elevations in blood urea nitrogen concentrations can

result in a platelet function defect, cellular immunodeficiency, and inflammatory pericarditis.[49,50] Furthermore, acute obstructive uropathy may precipitate acute renal failure (anuria), confusion, somnolence, seizures, and/or coma.

TREATMENT

The management of TLS can be classified into preventative and immediate treatments. The ability to prevent TLS is highly dependent on the immediate recognition of patients at risk for its development (Table 50-4). Patients at high risk include those with tumors with a high proliferative rate, large tumor masses including elevated leukocyte counts, extensive adenopathy and splenomegaly, preexisting renal insufficiency, and elevated levels of phosphorus, uric acid, or both before the initiation of therapy (Table 50-5). The elevation of the serum LDH level before the initiation of therapy has also been associated with the recognition of patients at risk for TLS.[1,2,4] Cytotoxic therapy should be delayed in patients at high risk for development of TLS until prophylactic measures can be initiated. Unfortunately, a delay in therapy is not possible for many patients because of the aggressive nature of their underlying malignancy. In this clinical situation, a decision must be made regarding the relative risks in the delay of tumor therapy versus the risk of development or exacerbation of TLS and its associated complications including acute renal failure.[51,52] Regardless of time constraints, the patient should have reliable venous access and be treated in an intensive care or oncology special care unit with personnel who are trained and familiar with the complications associated with TLS. The unit should have, at a minimum, the capability of continuous cardiac monitoring and preferably the capacity for hemodialysis.

The patient's vital signs, weight, urinary output, and fluid intake must be carefully monitored. Serum creatinine, blood urea nitrogen, sodium, potassium, calcium, phosphorus, LDH, and uric acid concentrations should be determined before therapy and every 4 to 6 hours for the first 48 to 72 hours after the initiation of tumor therapy. The LDH concentration serves as an excellent marker for tumor proliferation and response to therapy. Patients should have a baseline electrocardiogram and continuous cardiac monitoring until the completion of treatment. Ideally, all patients should receive intravenous hydration 24 to 48 hours before the initiation of tumor therapy.[4,53]

Table 50-4 Risk for Tumor Lysis Syndrome by Tumor Type

Burkitt's lymphoma	Frequent cases
Lymphoblastic lymphoma	
Acute leukemia	
Large cell lymphoma	
Low-grade lymphoma treated with chemotherapy, radiotherapy or steroids	Recognized complication but few occurrences
Breast carcinoma treated with chemotherapy or hormonal therapy	
Small cell lung carcinoma	
Seminoma	
Neuroblastoma	
Low-grade lymphoma treated with interferon	Case reports only
Merkel's cell carcinoma	
Medulloblastoma	
Adenocarcinoma of the gastrointestinal tract	

Table 50-5 Initial Management of Patients at Risk for Tumor Lysis Syndrome

1. Identification of the patient at risk (see Table 50-4).
2. Admit to intensive care or hematology/oncology unit.
3. Alert dialysis team of existence of patient and potential emergent need of assisted renal support.
4. Establish adequate venous access.
5. Perform baseline electrocardiogram and continuous cardiac monitoring.
6. Determine baseline and serial WBC, serum LDH, uric acid, Na^+, K^+, creatinine, BUN, phosphorous, and Ca^{++} levels. Repeat every 4–6 hours.
7. Provide intravenous hydration with hypotonic or isotonic saline solution at 2500 to 3000 mL/m^2/24 hours.
8. Given allopurinol, 300 mg/m^2/day orally, or rasburicase, 0.20 mg/kg/day intravenously, over 30 minutes for up to 3 days.

Intravenous hydration, preferably with a hypotonic or isotonic saline solution at 2500 to 3000 mL/m^2/24 hr, should ideally begin 24 to 48 hours before the initiation of therapy and continue for 48 to 72 hours after completion of chemotherapy. Care must be taken to prevent severe hyponatremia, especially when hypocalcemia is present, because the risk of seizures is increased. A hypotonic saline solution should be used when the urinary sodium concentration is less than 150 mEq/L, to reduce the risk of uric acid supersaturation. The rate and amount of fluid is dependent on each patient's cardiovascular function. Administration of mannitol may be considered if sufficient diuresis cannot be achieved with intravenous hydration alone. A test dose of 200 to 500 mg/kg may be given intravenously and discontinued if an appropriate increase in urine output is not observed. Careful attention must be given to the administration of both intravenous fluids and mannitol to avoid fluid overload and the potential for congestive heart failure.

In addition, it is necessary to administer a hypouricemic agent, either allopurinol or rasburicase, before the initiation of therapy. Allopurinol is a potent inhibitor of xanthine oxidase and blocks the conversion of hypoxanthine and xanthine to uric acid.[47] Whereas hypoxanthine is more soluble than uric acid is at physiologic pH, xanthine is less soluble than uric acid. This may result in the formation of xanthine crystals in the kidney and lead to obstructive uropathy. Although allopurinol prevents new uric acid formation, it does not reduce the amount of uric acid already present. Thus allopurinol requires administration for 2 to 3 days before the serum uric acid concentration begins to fall and therefore needs to be initiated 2 to 3 days before the initiation of cytotoxic therapy. Allopurinol is generally given at a dose of at least 300 mg/m^2/day.[54] Allopurinol is known to interfere with the degradation of 6-mercaptopurine, 6-thioguanine, and azathioprine through inhibition of the P450 pathway; thus, the dose of allopurinol should be reduced 50% to 75% in patients receiving these chemotherapeutic agents. Allopurinol should be used with caution in patients with underlying renal insufficiency, because it can cause a syndrome consisting of rash, hepatitis, eosinophilia, and worsening renal function. A previous limitation of allopurinol has been the requirement for administration by the oral route. For some critically ill patients or young infants who may be unable to tolerate oral medications during the prevention or treatment of TLS, there is an intravenous preparation of allopurinol available.[53,55] Previously, urine alkalinization was recommended to increase uric acid solubility and promote uric acid excretion in patients treated with allopurinol. However, alkalinization is not currently recommended because of the risk of decreasing ionized calcium concentrations, decreasing phosphate excretion, and increasing serum phosphate concentrations.

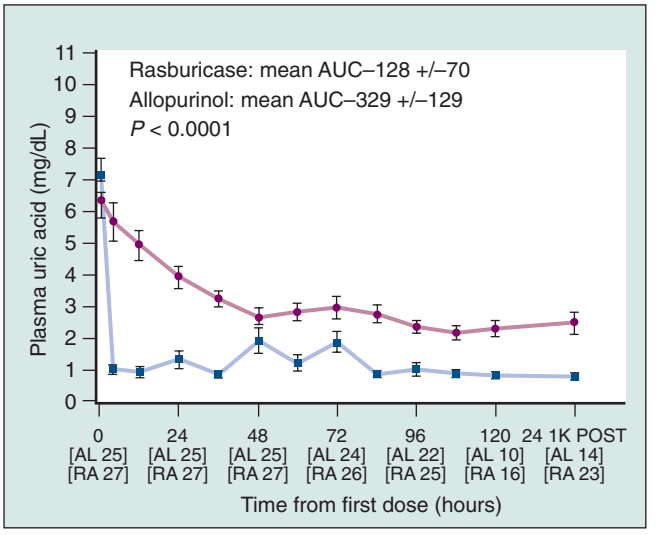

Figure 50-3 • Mean (± SE) plasma uric acid concentrations over time for all patients. Squares denote patients who received rasburicase ($n = 27$) and stars allopurinol ($n = 25$). The 24-hour post levels reflect 24 hours after the last dose of study drug. Patients who received rasburicase demonstrated more rapid decline and maintained lower plasma uric acid levels throughout the study period. The area under the serial plasma uric acid concentration curve (AUC) through the first 96 hours of therapy was significantly less for patients receiving rasburicase ($P < 0.0001$). (This research was originally published in Goldman SC, Holcenberg JS, Finklestein JZ et al: A randomized comparison between rasburicase and allopurinol in children with lymphoma or leukemia at high risk for tumor lysis. Blood 2001;97:2998–3003. © The American Society of Hematology.)

An alternative to inhibiting uric acid formation by competitively inhibiting xanthine oxidase is to promote the catabolism of uric acid to allantoin by uric acid oxidase. Allantoin is 5 to 10 times more soluble in the urine than uric acid. Urate oxidase is an endogenous enzyme commonly found in many mammalian species but not in humans. Urate oxidase, extracted from *Aspergillus flavus,* has been demonstrated to rapidly and significantly reduce uric acid levels in patients at high risk for TLS. Recently, the gene encoding urate oxidase was identified and expressed in yeast to yield large quantities of the pure recombinant form of urate oxidase (rasburicase).[54,56–63] In a multicenter trial, 52 pediatric patients with hematologic malignancy at high risk for TLS were randomly assigned to receive allopurinol or rasburicase. Uric acid levels significantly decreased by 85% with rasburicase as compared with 12% with allopurinol within 4 hours of drug administration (Fig. 50-3).[64] Pui and colleagues administered rasburicase IV at doses up to 0.2 mg/kg in 131 pediatric patients with newly diagnosed leukemia or lymphoma. They found a rapid drop in uric acid levels from 9.7 to 1 mg/dL within 4 hours of treatment in patients with hyperuricemia and further reductions to 0.5 mg/dL within 24 hours after rasburicase administration. Serum phosphorus and creatinine concentrations also decreased significantly within 1 to 3 days.[65] The same investigators went on to review data on 173 children and 72 adults with malignancy who were treated with rasburicase. All patients had a dramatic decrease in uric acid concentration with median post-treatment concentrations of 0.5 to 0.7 mg/dL. There were very few adverse reactions after administration, and all of these were mild, making this an excellent therapeutic option.[66,67] Coiffier and associates investigated the safety and efficacy of rasburicase in 100 adult patients with non-Hodgkin's lymphoma over a 1-year period. Of these patients, 66% had elevated LDH levels and 11% were hyperuricemic with concentrations higher than 7.56 mg/dL. Rasburicase was given to all subjects and uric acid levels then measured at 4 hours. All of the patients responded to rasburicase with normalization of uric acid, and none exhibited increased creatinine levels or required dialysis.[56]

Attempts should be made to correct fluid overload, dehydration, and electrolyte and acid-base abnormalities, and to establish adequate urinary output before the initiation of therapy. Hyperkalemia should be treated expediently with standard measures such as the administration of sodium polystyrene sulfonate, a potassium-binding resin, at a dose of 15 to 60 g/day given orally or rectally. There should be little hesitation about initiating hemodialysis to correct this electrolyte abnormality. Aluminum hydroxide, given orally or through a nasogastric tube at a dose of 15 mL (50–150 mg/kg/24 hr) every 4 to 6 hours, should be used to treat hyperphosphatemia. The degree of tumor lysis declines after the first 48 to 72 hours of treatment, and a decline in the serum LDH level serves as an excellent marker for a decrease in tumor lysis. However, close monitoring of the patient should continue until treatment is completed.[1,2,54] Treatment of asymptomatic hypocalcemia is generally not recommended. In patients with symptomatic hypocalcemia, intravenous calcium gluconate (50–100 mg/kg per dose) may be administered to correct the clinical symptoms; however, this may increase the risk of calcium and phosphorus deposition and acute obstructive uropathy.

For patients who have acute renal failure, significant uremia, or severe electrolyte abnormalities associated with TLS, the general consensus is that hemodialysis should be initiated as soon as possible. Continuous hemofiltration has been used to correct fluid overload and electrolyte abnormalities associated with TLS in children.[68] The failure to promptly initiate hemodialysis for acute renal failure may turn a potentially reversible clinical situation into an irreversible one (Table 50-6).

CONCLUSIONS

Successful management and treatment of TLS is highly dependent on the prompt identification of clinical and laboratory characteristics, signs, and symptoms of patients at risk. Establishment of vascular access and the initiation of prophylactic measures, especially hydration and administration of allopurinol or rasburicase, are vital. The early recognition and treatment of metabolic abnormalities usually prevents the severe and life-threatening complications associated with TLS.

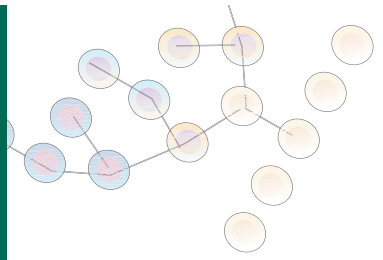

Table 50-6 Approach to the Management and Treatment of Tumor Lysis Syndrome

	Decreased Urinary Output (< 50 mL/h)	Hyperkalemia	Uremia	Hypocalcemia	Hyperuricemia	Hyperphosphatemia
Primary intervention	Mannitol challenge	K^+ binding resin	Diuretic	Cautious replacement	Allopurinol or rasburicase	Aluminum hydroxide (200–500 mg/kg)
Clinical manifestation	Renal insufficiency or fluid overload	Arrhythmia	Pericarditis or platelet dysfunction	Arrhythmia or tetany	Renal insufficiency	Renal insufficiency
Secondary intervention	Hemodialysis	Treat arrhythmia	Hemodialysis	Treat arrhythmia	Hemodialysis	Hemodialysis

51 Paraneoplastic Neurologic Syndromes

Josep Dalmau and Myrna Rosenfeld

SUMMARY OF KEY POINTS

- The paraneoplastic neurologic syndromes include an extensive group of disorders that can affect any part of the central or peripheral nervous system.
- Evidence indicates that many of these syndromes have an immunopathogenesis and are mediated by immunologic responses triggered by the presence of a cancer.
- Antibodies directly mediate some disorders of the neuromuscular junction and peripheral nervous system, such as myasthenia gravis, the Lambert-Eaton myasthenic syndrome, and neuromyotonia. For these disorders and a few paraneoplastic neurologic syndromes of the central nervous system, immunotherapy may result in neurologic improvement. However, for most paraneoplastic neurologic syndromes of the peripheral and central nervous system the response to any type of therapy is, in general, disappointing. The physician's main concern should be to rule out other diagnostic entities and to uncover the presence of the associated neoplasm.
- The treatment approach should be aimed at the tumor, because stabilization and, less often, improvement of neurologic symptoms after tumor treatment have been reported for almost all syndromes. In a few cases, depending on the syndrome and if the patient is in the early stages of the neurologic disease, treatment with immunosuppression may have some effect on the paraneoplastic neurologic syndrome.

INTRODUCTION

Clinically significant paraneoplastic neurologic syndromes occur in fewer than 1% of all cancer patients. Paraneoplastic syndromes may affect any part of the neuraxis. In some, a single cell type, such as the Purkinje cells in paraneoplastic cerebellar degeneration (PCD), is predominantly involved, whereas in others any neuron of the central or peripheral nervous system may be affected, as occurs in paraneoplastic encephalomyelitis (PEM) and sensory neuropathy (PSN). Due to this variable distribution of pathological involvement, patients with these disorders may present with symptoms of unifocal or multifocal involvement of the nervous system.

Most paraneoplastic neurologic syndromes are thought to have an immunopathogenesis. One hypothesis is that the expression of neuronal antigens by the tumor triggers an immune response against the tumor that affects the nervous system. An immune-mediated pathogenesis has been demonstrated for the Lambert-Eaton myasthenic syndrome (LEMS).[1] Patients with LEMS have serum antibodies against voltage-gated calcium channels that are expressed by the tumor, which usually is a small cell lung cancer (SCLC). These antibodies block the entry of calcium necessary for the release of quanta of acetylcholine and result in neuromuscular weakness. Removal of the serum antibodies results in improvement of symptoms. In paraneoplastic myasthenia gravis (MG), a thymoma triggers an immune response against the acetylcholine receptor at the postsynaptic level of the neuromuscular junction, resulting in weakness and fatigability.[2] A similar antibody-mediated mechanism directed against voltage-gated potassium channels has been reported in paraneoplastic neuromyotonia.[3] Antibodies directed to mGluR1 and voltage-gated calcium channels may be pathogenic in a small subgroup of patients with paraneoplastic cerebellar degeneration.[4] Autonomic dysfunction, sometimes associated with cancer, may result from immunity to the nicotonic acetylcholine receptor.[5]

Aside from these syndromes and cancer-associated and melanoma-associated retinopathy (CAR, MAR), the immune origin of other paraneoplastic neurologic disorders has not been proven but is supported by a number of findings[6]:

- Patients with these disorders have high titers of antibodies that react with antigens restricted to the nervous system and tumor.[7,8]
- The antibodies are specific markers of characteristic syndromes and tumors and are produced intrathecally.[9,10]
- Similar antibodies are not found in other inflammatory disorders of the central nervous system (CNS) associated with neuronal destruction, or with tumors that do not express the specific antigen.
- A pathogenic effect of antibodies has been shown in animals for some of these disorders (anti-Hu and paraneoplastic gut dysmotility and anti-amphyphysin and paraneoplastic stiff-man syndrome).[11,12]
- Recent data indicate that in some paraneoplastic neurologic disorders of the CNS in which the antibodies target cell surface rather than intranuclear antigens, the antibodies may mediate the neurologic dysfunction.[13,14]

For some paraneoplastic syndromes of the CNS, circumstantial evidence suggests that T-cell-mediated mechanisms play a major pathogenic role. Autopsies of patients with paraneoplastic syndromes of the CNS show intense inflammatory infiltrates of mononuclear cells, including CD4+ and CD8+, which predominate in the areas of the nervous system that are symptomatic.[10,15] The mechanism whereby CD4+ or CD8+ cytotoxic T-cells recognize antigens expressed in neurons which normally lack expression of the antigen presenting MHC class I and II molecules is unknown.

Identification of the paraneoplastic origin of a patient's symptoms is important because in more than two thirds of patients the neurologic symptoms develop before the cancer is detected. Because similar

Table 51-1 Immune Associations in Paraneoplastic Neurologic Disorders

Antibody	Syndrome	Most Common Tumor Association(s)
Anti-Hu	PEM/PSN	SCLC
Anti-Yo	PCD	Ovary, breast
Anti-Ma	Brainstem encephalitis/PCD	Several
Anti-Ma2	Limbic/brainstem encephalitis	Testicular
Anti-Ri	Opsoclonus-ataxia	Breast, gynecologic
Anti-Tr	PCD	Hodgkin's lymphoma
Anti-amphiphysin	Stiff-man syndrome	Breast, SCLC
Anti-CV2/CRMP5	PEM/PCD, peripheral neuropathy, uveitis	SCLC, several
Anti-recoverin	Retinopathy	SCLC
Anti-bipolar cells of retina	Retinopathy	Melanoma
Anti-NMDAR	Limbic encephalitis, seizures, psychiatric symptoms	Teratoma
Anti-VGCC*	LEMS, PCD	SCLC
Anti-AChR*	Myasthenia gravis	Thymoma
Anti-VGKC*	Peripheral nerve hyperexcitability	Thymoma, others

*These antibodies may occur with or without a cancer association and therefore are not markers of paraneoplasia.

AChR, acetylcholine receptor; CRMP, collapsin response-mediator protein; LEMS, Lambert-Eaton myasthenic syndrome; NMDAR, N-methyl D-aspartate receptor; PCD, paraneoplastic cerebellar degeneration; PEM, paraneoplastic encephalomyelitis; PSN, paraneoplastic sensory neuropathy; SCLC, small-cell lung cancer; VGCC, voltage-gated calcium channel; VGKC, voltage gated potassium channel.

disorders may occur without cancer, the diagnosis of the paraneoplastic origin of a disorder depends heavily on the index of suspicion. This is based in part on the syndrome, since some syndromes have a paraneoplastic origin more frequently than others. For example, the likelihood that LEMS or subacute cerebellar degeneration in a middle-aged or elderly patient is paraneoplastic is probably more than 50%.[16] In contrast, subacute sensory neuropathy or dermatomyositis probably is paraneoplastic in origin in less than 20% of patients.[17,18] In most paraneoplastic syndromes, symptoms develop acutely or subacutely and may resemble a viral process. Symptoms evolve over weeks or months and then stabilize, differentiating them from the more chronic and progressive degenerative diseases of middle age and adulthood.

The finding that some paraneoplastic neurologic syndromes of the central or peripheral nervous system are associated with specific antineuronal antibodies has had a major impact on the ability to diagnose and manage these disorders.[19] These antibodies serve as markers of the paraneoplastic origin of neurologic symptoms and as markers for the presence of specific types of tumors (Table 51-1). Criteria have been proposed to facilitate the diagnosis of paraneoplastic disorders that take into consideration the type of neurologic syndrome, the detection of an associated tumor, and the presence or absence of paraneoplastic antibodies[20] (Box 51-1 and Fig. 51-1).

PARANEOPLASTIC SYNDROMES OF THE CENTRAL NERVOUS SYSTEM

Paraneoplastic Encephalomyelitis

Patients with PEM develop symptoms of multifocal involvement of the nervous system resulting in several syndromes that may occur in isolation or in various combinations.[21,22] These include limbic encephalitis, cerebellar degeneration, brainstem encephalitis, myelitis, and sensory and autonomic neuropathies.

Paraneoplastic encephalomyelitis has been described in association with many tumors, but in 70% of patients the underlying tumor is an SCLC. Most tumors are diagnosed within 2 years of the first neurologic presentation. Most patients with PEM and SCLC have high titers of anti-Hu antibodies in their serum and CSF, as do some patients with PEM associated with other types of cancer.[8,23] Antibodies to CV2/CRMP5, with or without anti-Hu antibodies, also occur at a lower frequency and most commonly are associated with thymoma.[21,24] A subset of patients with PEM and antibodies to CV2/CRMP5 also develop paraneoplastic chorea and uveitis.[25]

The onset of symptoms in PEM is subacute. Sensory neuropathy is the most common initial manifestation, followed by brainstem and limbic encephalopathy.[21,26,27] The progression of symptoms usually is relentless, or, less frequently, intermittent, until stabilization. Spontaneous improvement is rare but has been described in patients with limbic encephalitis.[28] For most patients the neurologic deficits are severe and incapacitating. Respiratory or autonomic failure due to neurologic dysfunction is commonly the cause of death.[26]

About one third of patients with PEM develop symptoms of cerebellar and/or brainstem dysfunction.[8,21,29] Motor weakness, muscle atrophy, and fasciculations are found in 20% of patients with PEM.[26] When spinal cord involvement predominates, a diagnosis of subacute motor neuron dysfunction or atypical motor neuron disease may be entertained until other areas of the nervous system become involved.[30,31] Autonomic dysfunction affects about 30% of patients. Symptoms include orthostatic hypotension, gastrointestinal paresis, and pseudo-obstruction.[32,33] Hypothermia, hypoventilation, sleep apnea, and cardiac arrhythmias may be the cause of sudden death in these patients.

About 75% of patients with anti-Hu-associated PEM develop an asymmetric pansensory neuropathy, called *paraneoplastic sensory neuronopathy* (PSN; see later discussion).[21,26] Often associated with painful dysesthesias, PSN results from inflammation of the dorsal root ganglia and neuronal degeneration. For patients in whom motor weakness and a sensory neuropathy develop subacutely, the initial diagnosis may be that of acute inflammatory polyneuritis (Guillain-Barré syndrome).[34]

Limbic Encephalitis

Symptoms of paraneoplastic limbic encephalitis may develop alone but more often are found in association with brainstem dysfunction, cerebellar symptoms, or PSN (see Paraneoplastic Encephalomyelitis).[26]

Box 51-1. DIAGNOSTIC STRATEGIES

The diagnosis of a paraneoplastic neurologic syndrome is relatively straightforward for patients who develop symptoms of a well-defined syndrome that typically is associated with cancer. The specificity of paraneoplastic antineuronal antibodies for paraneoplastic neurologic syndromes or some types of cancer makes them useful diagnostic tools. Therefore, in the right clinical context, the detection of a paraneoplastic antibody in the serum or cerebrospinal fluid (CSF) helps to establish the diagnosis and focus the search of the neoplasm. If the detected antibody usually does not associate with the patient's neurologic syndrome, other etiologies for the neurologic dysfunction should be considered. Similarly, if the detected cancer is not the histologic type typically found in association with the patient's antibody (e.g., anti-Yo with lung cancer rather than breast or ovarian cancer), the presence of a second neoplasm should be suspected. A search for another neoplasm definitely is indicated if the tumor cells do not express the target antigen of the paraneoplastic antibody. If paraneoplastic antibodies are present but a cancer is not discovered, the patient should be assumed to harbor an occult neoplasm unless proven otherwise. Whole-body positron emission tomographic scans may detect tumors that escape detection by other standard imaging methods. In patients with a history of cancer or who have recently gone into tumor remission, the development of a paraneoplastic neurologic syndrome frequently heralds tumor recurrence.

The diagnosis of paraneoplastic neurologic syndromes is more difficult in patients who develop less characteristic symptoms (e.g., brainstem dysfunction, myelopathy), especially if no antibodies are found in the serum or CSF. In this case and if other non-cancer-associated etiologies have been ruled out, analysis for serologic markers of cancer (e.g., carcinoembryonic antigen, CA-125, CA-15-3, prostate-specific antigen) may provide evidence for the presence of cancer. The CSF may show evidence of inflammation with pleocytosis, elevated protein concentration, intrathecal synthesis of immunoglobulin, and oligoclonal bands. Immunoelectrophoresis may disclose M-proteins in serum or urine, suggesting a plasma cell dyscrasia. A skeletal survey to rule out lytic or osteosclerotic myeloma should be considered for patients with peripheral neuropathy associated with a monoclonal gammopathy. CT of the chest is the study of choice to demonstrate a suspected lung cancer. Due to the common association of breast and gynecologic cancers with paraneoplastic disorders, mammogram and pelvic CT scan or ultrasound should be carried out in all women with a suspected paraneoplastic neurologic syndrome. Symptoms of limbic and brainstem encephalitis should cause men to be examined with testicular ultrasound and young women to be checked for an ovarian teratoma that may appear as a benign cyst. Whole-body PET scans are useful when other tests are negative. The best approach to treating paraneoplastic neurologic syndromes is to discover and treat the tumor promptly and provide supportive care for the neurologic deficits with symptomatic treatment and physical therapy.

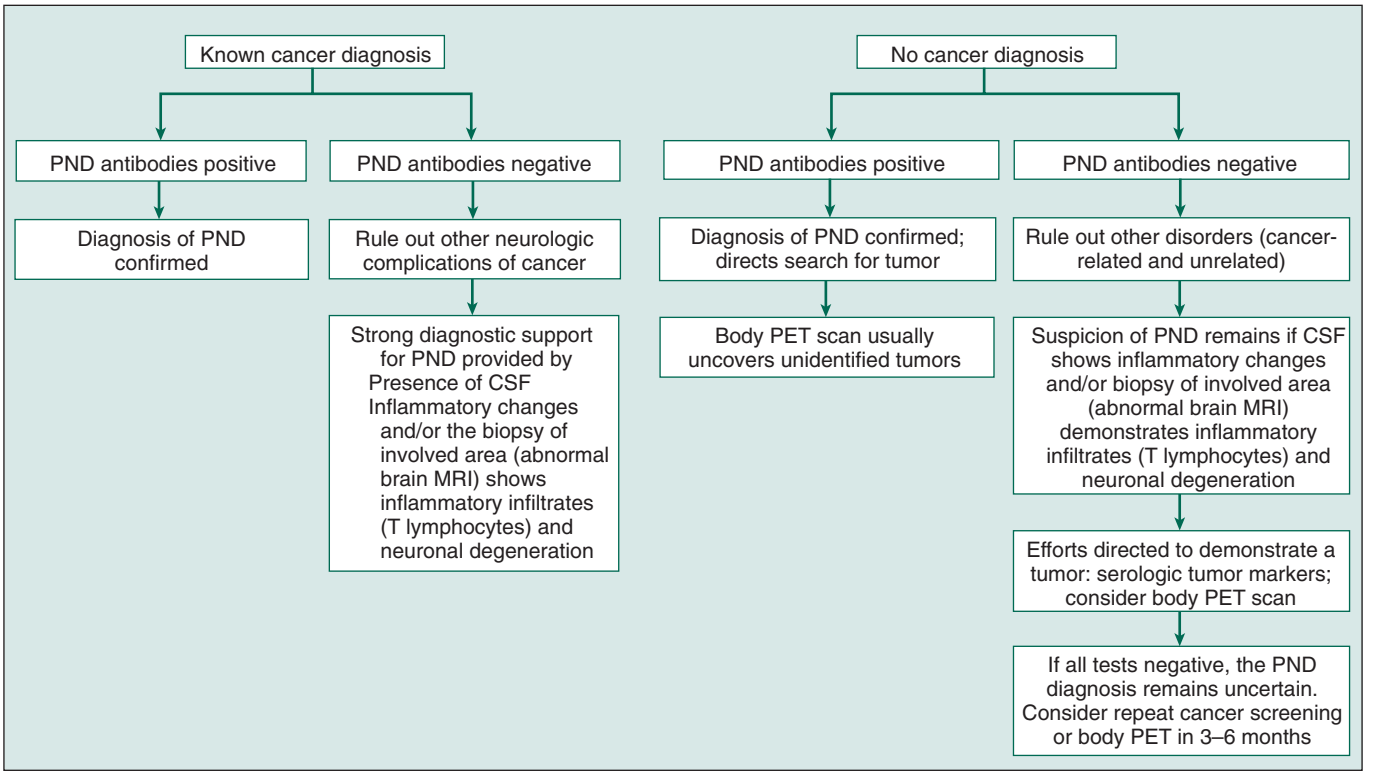

Figure 51-1 • Approach to the patient with a suspected paraneoplastic neurologic disorder (PND) of the central nervous system (CNS). CSF, cerebrospinal fluid; PET, positron emission tomography.

The most common underlying tumor is SCLC, followed by testicular cancer. Regardless of the tumor type, the neurologic dysfunction usually precedes the diagnosis of cancer.

The most characteristic finding is short-term memory deficits with relative preservation of other cognitive functions.[35,36] Memory deficits often become evident after several weeks of depression, personality changes, irritability, and seizures. Partial complex temporal lobe seizures with or without motor involvement of face and extremities are common. Some patients develop signs of diencephalic-hypothalamic dysfunction, including drowsiness, hyperthermia, hyperphagia, and, less frequently, pituitary hormonal deficits. The disorder may resemble a viral encephalitis or a rapidly developing dementia due to a primary neurodegenerative disorder.

Paraneoplastic limbic encephalitis is one of the few paraneoplastic neurologic disorders in which neuroimaging may be useful. Typical MRI findings include unilateral or bilateral mesial temporal lobe abnormalities best seen on T2-weighted and FLAIR images (Fig. 51-2).[28,37,38] On T1-weighted sequences, the temporal–limbic regions may be hypointense and sometimes may enhance with contrast injection. Patients with herpes simplex encephalitis may have similar MRI findings in the early stages of the disease. However, these patients usually develop prominent signs of edema and mass effect involving one or both inferomedial temporal lobes, inferior frontal lobes, and cingulate gyrus often associated with gyral enhancement and signs of hemorrhage.[39,40]

The major pathological findings are from the hippocampus, parahippocampal gyrus, cingular cortex, insular cortex, and diencephalon.[36] Almost all patients have mild abnormalities in other areas of the nervous system in a pattern of distribution resembling PEM, suggesting that paraneoplastic limbic encephalitis should be regarded as PEM with predominant involvement of the limbic structures.

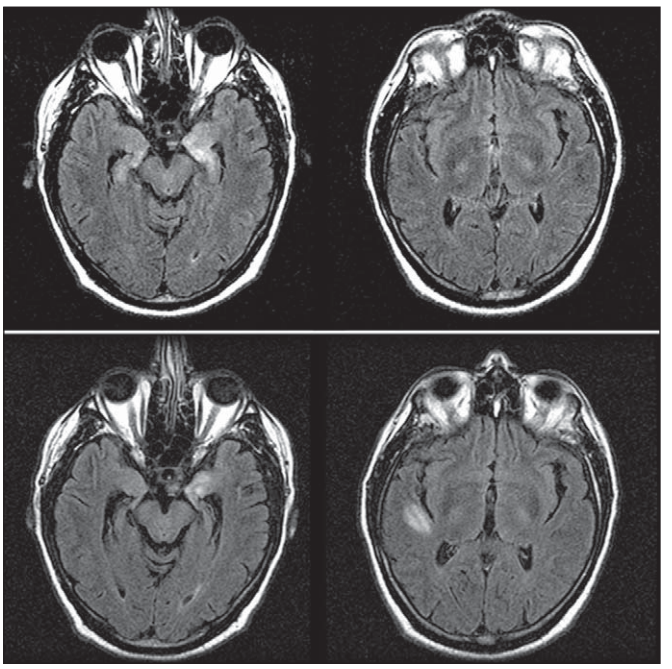

Figure 51-2 • MRI abnormalities in a patient with limbic encephalitis. Fluid-attenuated inversion recovery (FLAIR) sequences of two MRI studies of a patient with paraneoplastic limbic encephalitis associated with a papillary thyroid carcinoma that was confined to the thyroid gland. *Upper panels,* Bilateral hyperintensity of the medial aspect of the temporal lobes (hippocampi) is seen, with the left greater than the right. *Lower panels,* Another MRI obtained 6 months later shows atrophy of the hippocampi and new signal abnormality in the right posterior insular region. The patient had severe short-term memory loss that did not significantly change between the two MRI studies.

Antineuronal antibodies, when present in serum and cerebrospinal fluid (CSF), facilitate the diagnosis of PLE and often allow for early detection of the associated tumor. In patients with SCLC, the anti-Hu antibody is present in about 50% of cases with predominant or isolated symptoms of limbic encephalitis.[41] A few patients have been reported with limbic encephalitis and anti-CV2 antibodies. In these patients the underlying tumors are SCLC and thymoma.[42] Limbic encephalitis in association with antibodies to voltage-gated potassium channel antibodies is paraneoplastic in about 20% of patients; the most common cancers are thymoma and SCLC.[43]

Anti-Ma2 antibodies may be found in the serum and CSF of patients with limbic and/or brainstem encephalopathy. These patients usually have testicular cancer (either seminomatous or nonseminomatous germ cell tumors), but other tumors have been reported.[10] Patients with anti-Ma2 antibodies often have additional involvement of the hypothalamus and brainstem and are more likely to have abnormal MRI findings than are other patients with paraneoplastic limbic encephalitis.[44]

A paraneoplastic limbic encephalitis recently has been described in young women with ovarian teratoma (in one patient the tumor was a teratoma of the mediastinum). All patients had serum and CSF antibodies to the NR1/NR2 subunits of the NMDA receptor that are highly enriched in hippocampus. These patients often present with acute change in behavior and personality, with delusional thinking, paranoid thoughts, and aggressive behavior, and may be misdiagnosed with acute psychosis, or suspected malingering or drug abuse. Others can have a picture more typical of limbic encephalitis with short-term memory loss and seizures. Most will progress to decreased level of consciousness, with autonomic dysfunction and central hypoventilation, requiring prolonged ventilatory support.[14,45]

When limbic encephalitis is part of PEM or PSN, it usually responds poorly to treatment. Symptom stabilization or improvement may occur if the tumor is recognized and treated early.[10,22,46] A study of patients with SCLC and paraneoplastic limbic encephalitis suggested that the presence of anti-Hu antibodies was associated with a decreased likelihood of improvement.[41] In contrast, about 35% of patients with limbic encephalopathy associated with antibodies to Ma2 improve with immunotherapy and treatment of the tumor (most of these 35% have a testicular germ-cell tumor).[47] The encephalitis of patients with antibodies to NR1/NR2 subunits of the NMDA receptor and teratomas usually responds to removal of the tumor and corticosteroids, intravenous immunoglobulins (IVIg), or plasma exchange.[45]

Paraneoplastic Cerebellar Degeneration

Paraneoplastic cerebellar degeneration (PCD) is characterized by the subacute development of rapidly progressive cerebellar dysfunction, which stabilizes after a few months, leaving the patient severely disabled.[48] Postmortem studies demonstrate near or total loss of Purkinje cells with relative preservation of other cerebellar neurons, and Bergmann astrogliosis (Fig. 51-3). Almost every type of tumor has been reported in association with PCD; the most common neoplasms are gynecologic tumors, breast and lung cancers, and lymphomas.[49,50] In about 60% of patients the neurologic symptoms precede detection of the tumor.

Presenting symptoms of PCD include dizziness, visual problems, nausea, vomiting, and dysarthria. Within days or even hours the patient develops ataxia of gait and of the extremities, usually accompanied by dysphagia. Some patients with PCD who have gynecologic or breast tumors have serum and CSF antibodies called anti-Yo that react with 34- and 62-kd proteins expressed by Purkinje cells and the underlying tumor.[51] Other patients develop PCD that is not associated with anti-Yo antibodies. Some of these patients have PCD in

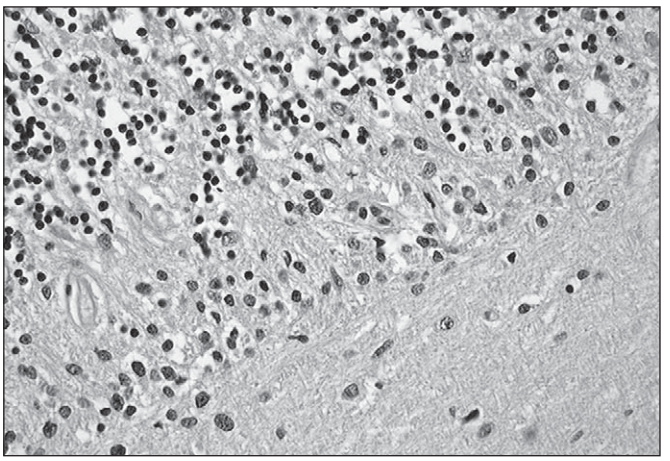

Figure 51-3 • Paraneoplastic cerebellar degeneration. Section of cerebellum from a patient with adenocarcinoma of the ovary and paraneoplastic cerebellar degeneration associated with anti-Yo antibodies. Note the Bergmann gliosis and the absence of Purkinje cells, which normally are located between the granular cell layer *(top left)* and the molecular cell layer *(bottom right).*

association with Hodgkin's disease, in which case an antibody called anti-Tr usually is found (Fig. 51-4).[52]

For patients with SCLC, PCD may develop in association with LEMS.[49,53] Because LEMS symptoms often are treatable, suspicion of LEMS should prompt an appropriate investigation with electrophysiologic testing or measurement of antibodies directed against P/Q type voltage gated calcium channels. Recent studies demonstrate that these antibodies also are present in some patients with SCLC and PCD without symptoms of LEMS.[4]

A distinctive clinical syndrome occurring predominantly in women is characterized by the subacute onset of ataxia and opsoclonus.[54] The ataxia predominates in the trunk, causing severe gait difficulty and frequent falls. In half of these patients the neurologic symptoms develop before the tumor is diagnosed. The tumor usually

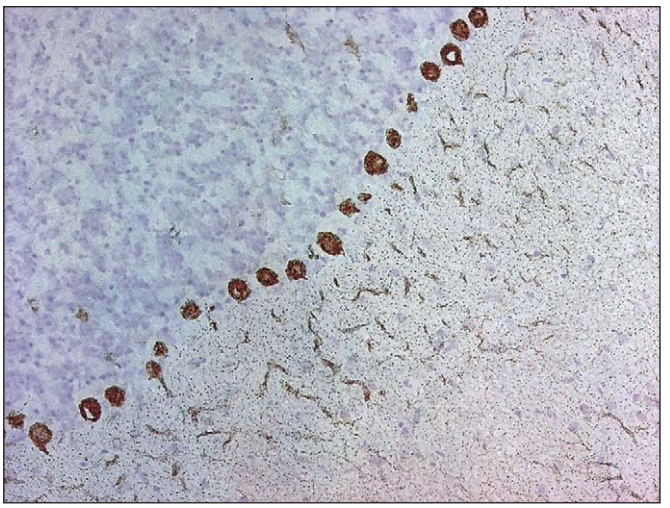

Figure 51-4 • Detection of an anticerebellar antibody (anti-Tr) in the serum of a patient with paraneoplastic cerebellar degeneration. A frozen section of rat cerebellum incubated with the serum of the patient shows a characteristic dot-like reactivity with the cytoplasm of Purkinje cells and molecular layer of the cerebellum. This antibody, known as anti-Tr, is a specific marker of paraneoplastic cerebellar degeneration associated with Hodgkin's lymphoma.

is a breast cancer or, less frequently, gynecologic cancers or SCLC. The serum and CSF of these patients contain an antibody called anti-Ri, which is expressed by neurons and the associated tumor.[54,55]

In patients with SCLC, the development of PCD may be the presenting symptom of PEM. In such cases, anti-Hu or anti-CV2/CRMP5 antibodies usually are present, and the patients eventually develop signs and symptoms of multifocal neurologic disease. Patients whose symptoms remain restricted to the cerebellum and who do not harbor anti-Hu antibodies may have antibodies to voltage-gated calcium channels.[56]

One subset of patients develop PCD in the setting of brainstem dysfunction. These patients have serum and spinal fluid antibodies against Ma1 and Ma2 proteins expressed in neurons and spermatogenic cells of testis. These patients have a variety of associated cancers, including those of the lung, breast, parotid, colon, and testis.[57]

Most patients with PCD do not improve, although there are isolated reports of improvement with treatment of the tumor, corticosteroids, IVIg, plasma exchange, rituximab, or cyclophosphamide.[58–60]

Motor Neuron Syndromes

The existence of paraneoplastic motor neuron dysfunction is based on reports of patients with typical amyotrophic lateral sclerosis (ALS) who improved after treatment of the underlying tumor, suggesting more than a coincidental relationship.[61,62] In patients with cancer and symptoms of motor neuron disease the most common neoplasms are carcinoma of the lung, breast, kidney, and lymphoma. For these patients, the neurologic syndrome and laboratory studies are similar to those seen in typical patients with ALS.

Patients with PEM may develop symptoms resembling motor neuron disease.[26,30] These patients almost always develop signs of involvement of other areas of the nervous system, which, along with the presence of the anti-Hu antibody, helps to rule out typical ALS.

Patients with Hodgkin's and non-Hodgkin's lymphoma may develop a subacute lower motor neuronopathy.[63] Typically, these patients have a subacute, progressive, painless, and asymmetric involvement of the extremities, with the legs more affected than the arms. In contrast to typical ALS, fasciculations are rare, bulbar muscles usually are spared, and upper motor neuron signs are absent. Examination of the CSF is normal or shows mildly increased proteins, and electrophysiologic studies demonstrate denervation with normal or mild slowing of motor nerve conduction velocities. Neurologic stabilization or spontaneous improvement may occur. Paraneoplastic subacute lower motor neuronopathy must be distinguished from the lower motor neuron dysfunction that patients may develop after radiation therapy of the spinal cord.[64]

Peripheral Nerve Hyperexcitability and Stiff-Man Syndrome

Peripheral nerve hyperexcitability (PNH) is characterized by muscle cramps, stiffness, myokymia, and delayed muscle relaxation (neuromyotonia) due to spontaneous and continuous muscle fiber activity of peripheral nerves. It often is found in association with a sensorimotor polyneuropathy and has been described most often in patients with thymoma and SCLC.[3,65] An autoimmune etiology for neuromyotonia is supported by the presence of serum antibodies that interfere with the function of voltage-gated potassium channels.[66] Electrophysiologic studies reveal large numbers of bizarre, high-frequency motor unit discharges during voluntary contraction that persist during relaxation, in contrast to patients with stiff-man syndrome (discussed in the following paragraph), who have continuous but relatively normal motor unit activity.[67] Treatment with phenytoin, carbamazepine or plasma exchange may be effective in some patients.

The stiff-man syndrome is an unusual disorder characterized by progressive muscle stiffness, aching, muscle spasms, and rigidity. The stiffness develops over a period of months and is most prominent in the paraspinal muscles and lower limbs. The muscle spasms are painful and are triggered by a variety of stimuli. They are severe enough to produce limb deformities and fractures.[68] There are no other associated neurologic abnormalities; the CSF may show oligoclonal bands, and increased IgG index and neuroradiologic studies are usually normal. The tumors most commonly involved include breast cancer, SCLC, thymoma, and Hodgkin's disease. A subset of patients with paraneoplastic stiff-man syndrome and breast cancer or SCLC have antibodies that react with amphiphysin, a neuronal synaptic protein.[68–70] When stiff-man syndrome occurs in patients who do not have cancer, the disorder is associated with antibodies against glutamic acid decarboxylase (GAD).[71–73] These patients usually develop diabetes and other endocrine deficits. Treatment of the tumor and use of corticosteroids may result in improvement. Patients with nonparaneoplastic stiff-man syndrome respond to IVIg, and this approach may be useful for patients with the cancer-associated syndrome.[74,75] Drugs that enhance GABA-ergic transmission (e.g., diazepam, baclofen, sodium valproate, tiagabine, vigabatrim) improve symptoms of most patients.

A rare disorder seen in patients with cancer is progressive encephalomyelitis with rigidity.[72,76] In this disorder, most often associated with SCLC, patients usually develop brainstem dysfunction, rigidity, and spinal myoclonus due to widespread dysfunction of the CNS. The cervical portion of the spinal cord is affected most commonly.[77]

Paraneoplastic Opsoclonus-Myoclonus

Opsoclonus is a disorder of ocular motility characterized by the presence of spontaneous, arrhythmic, large-amplitude conjugate saccades occurring in all directions of gaze without a saccadic interval.[78] In patients with cancer, opsoclonus can have a paraneoplastic origin, in which case it often is associated with myoclonus of head, trunk, or extremities (paraneoplastic opsoclonus-myoclonus). The differential diagnosis includes viral, toxic, metabolic, and vascular disorders.

In children, paraneoplastic opsoclonus-myoclonus is a well-known complication of neuroblastoma.[79,80] In half of the patients, the opsoclonus precedes diagnosis of the neuroblastoma, but it also may develop after tumor diagnosis, during remission, or at recurrence. The onset is subacute, with frequent fluctuations of symptoms; in some patients symptoms may resolve spontaneously. Treatment with corticosteroids, adrenocorticotropic hormone, plasma exchange, IVIg, or rituximab, or treatment of the tumor, results in improvement in one half to two thirds of patients.[81] Despite an initial response, about 60% of patients are left with permanent neurologic deficits, including language and cognitive dysfunction.[82]

Paraneoplastic opsoclonus-myoclonus also has been described in adult patients with cancer. Most have an underlying SCLC, although there are individual case reports associated with other tumors, including carcinoma of the uterus, fallopian tube, breast, bladder, thyroid, thymus, chondrosarcoma, and Hodgkin's disease.[78,83–85] A small number of women with breast cancer, anti-Ri antibodies, and opsoclonus have been reported.[54,86] Patients with anti-Ri antibodies often have other symptoms, suggesting a more diffuse involvement of the brainstem, whereas patients without anti-Ri antibodies tend to have limb or truncal myoclonus and encephalopathy.

Compared to the idiopathic form of opsoclonus-myoclonus, from which patients often recover, paraneoplastic opsoclonus-myoclonus in adults has a more severe clinical course, even when aggressively treated with IVIg or corticosteroids. For those patients who develop an associated encephalopathy, one series noted improved outcomes when the tumor (usually SCLC) was identified and treated promptly.[87] Currently, no immunologic markers have been found that identify most cases of adult or pediatric paraneoplastic opsoclonus-myoclonus. Recent studies have found a high incidence of autoimmune responses to a variety of neuronal autoantigens but did not identify a specific antibody marker.[88,89]

Paraneoplastic Syndromes of the Visual System

In patients with cancer, visual symptoms and blindness usually are related to metastatic infiltration of the optic nerves by tumor and neurotoxicity from chemo- and radiation therapy.[90–93] Paraneoplastic visual syndromes can result from retinopathy and optic neuritis. Paraneoplastic optic neuritis is very rare, and while it may develop in isolation, it usually is associated with PEM.[94] The onset is subacute with painless bilateral visual loss.[95,96]

The paraneoplastic retinopathies are a heterogeneous group of syndromes including CAR and MAR. These two syndromes have specific clinical, electrophysiologic, and pathological characteristics and distinct immunologic associations. Patients with cancer-associated retinopathy develop acute or subacute visual loss due to degeneration of the retinal photoreceptor or ganglion cells.[97,98] The onset usually is unilateral, but progresses to become bilateral over days or weeks. Initial symptoms include photosensitivity, light-induced glare, color vision deficits, intermittent visual obscurations, and central or ring-like scotomas. For most patients the underlying tumor is SCLC, but a few case reports have been associated with breast or gynecologic cancers. Visual symptoms usually precede diagnosis of the tumor. Visual evoked responses usually are normal, but electroretinograms demonstrate reduced or flat responses to photopic and scotopic stimuli, suggesting dysfunction of cones and rods. Examination of the CSF may reveal a mild pleocytosis; neuroimaging studies are normal.

The serum of some patients with CAR contains antibodies that react with antigens expressed by photoreceptors and ganglion cells. The most common antibody is against recoverin, a 23-kd photoreceptor calcium-binding protein,[99] and the presence of antirecoverin antibodies indicates that the associated tumor almost always is an SCLC.[100] These antibodies cause apoptotic retinal cell death, suggesting a direct pathogenic role.[101] Other antigens that are targets of immune responses in some patients include tubby-like protein 1 and the photoreceptor-specific nuclear receptor (PNR).[102,103] The role of the latter antibodies in the pathogenesis of the retinopathy is unknown, but it is of interest that mutations of the PNR gene have been identified in a cohort of patients with enhanced S-cone syndrome, a disorder of retinal cell fate that progresses to retinal degeneration.[104,105] This finding suggests a mechanism whereby antibodies interfere with autoantigen function, resulting in retinal cell death.

Melanoma-associated retinopathy has been described in patients with metastatic cutaneous melanoma. These patients present with acute visual loss, years or months after the diagnosis of the metastatic disease,[106,107] and have serum antibodies that target unidentified proteins localized in the bipolar cells of the retina.[108,109] The electroretinogram shows selective loss of the photopic "b" wave with relative preservation of the "a" and "d" wave forms. Intraocular injection of serum from patients with MAR reproduces the retinal abnormalities, demonstrating that the antibodies are pathogenic.[107]

For both CAR and MAR, the visual loss usually is irreversible. Treatment with immunosuppression, plasma exchange, or corticosteroids is mostly ineffective, but in rare cases may result in symptom stabilization.[110,111]

PARANEOPLASTIC SYNDROMES OF THE PERIPHERAL NERVOUS SYSTEM

Paraneoplastic Sensory Neuronopathy

Paraneoplastic sensory neuronopathy (PSN) resulting from dorsal root ganglia dysfunction may develop in isolation but most often is

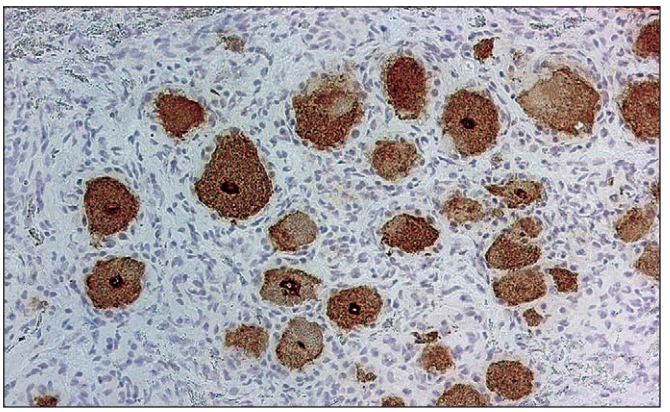

Figure 51-5 • Detection of an antineuronal antibody (anti-Hu) in the serum of a patient with paraneoplastic sensory neuronopathy. A frozen section of rat dorsal root ganglion incubated with the serum of the patient shows intense immunolabeling of the neurons, with reactivity predominantly involving the nuclei. This antibody, known as anti-Hu, usually is associated with paraneoplastic sensory neuronopathy (or dorsal-root ganglionitis) and encephalomyelitis. Patients with anti-Hu antibodies usually harbor a small cell lung cancer.

a fragment of PEM.[26] Patients typically develop asymmetric pain and paresthesias that can mimic radiculopathy or multineuropathy.[112] Symptoms usually progress over weeks or months to involve other extremities and, sometimes, the trunk.[26] Cranial nerves may be affected, resulting in loss of taste, facial numbness, and sensorineural deafness. Eventually, there is severe involvement of all modalities of sensation, resulting in pseudo-athetotic movements of the hands, a debilitating sensory gait ataxia, and neuropathic pain that are difficult to control.

In more than 80% of patients with PSN the associated tumor is SCLC. Sensory symptoms usually precede diagnosis of the tumor. Electrophysiologic studies confirm the isolated or predominant involvement of the sensory nerves, but in some patients the motor conduction velocities may be affected.[113] These patients had evidence of both demyelination and axonal degeneration in association with loss of neurons in the dorsal root ganglia, and circulating anti-CV2/CRMP5 antibodies in association with anti-Hu antibodies.

Patients who develop PSN as a component of PEM often have anti-Hu antibodies, and the associated cancer almost always is an SCLC (Fig. 51-5).[21,26] In patients with PSN without anti-Hu antibodies, associated cancers include SCLC, non-SCLC lung tumors, and breast cancer. Except for the detection of anti-Hu antibodies in patients with SCLC, laboratory studies of patients with PSN are nonrevealing. The CSF may show increased proteins and a mononuclear pleocytosis.

There is no specific treatment for PSN. Studies have suggested that patients with PSN associated with SCLC and anti-Hu antibodies whose tumors responded to therapy were more likely to have stabilization of improvement of the PSN compared with those whose tumors were not treated or did not respond to treatment.[21,22] Some patients may have partial improvement with corticosteroids. The effects of IVIg, cyclophosphamide, and rituximab are unclear.[60,114,115]

Sensorimotor Neuropathies

Many patients with cancer, particularly those with advanced disease and significant weight loss, develop signs and symptoms of peripheral neuropathy. In most patients, an identifiable cause such as a nutritional deficit, hepatic or renal failure, the use of chemotherapeutic agents, or leptomeningeal metastases can be found. Mononeuropathies and plexopathies in patients with cancer most often are secondary to compression of nerves by tumor or hemorrhage and infarction secondary to leukemic infiltration.[116,117] A paraneoplastic brachial neuritis may occur with increased frequency in patients with Hodgkin's disease.[118,119] The clinical presentation is similar to that of brachial neuritis observed in patients without cancer, with the initial pain complaints followed by the development of paresthesias and weakness.

A subacute or chronic sensorimotor neuropathy may occur with any malignancy but most commonly is associated with lung cancers.[116,120] The onset usually follows the cancer diagnosis but may precede it by several months or years. Lower extremities are predominantly involved, with symptoms spreading proximally over the course of the disease with rare involvement of cranial nerves. Weakness occurs late, and most patients have slowly progressive disease.

An acute rapidly progressive sensorimotor polyneuropathy can be seen in association with Hodgkin's lymphoma.[121] The syndrome is clinically indistinguishable from Guillain-Barré syndrome (GBS). A similar syndrome also has been reported in patients with solid tumors. Treatment is the same as for patients with idiopathic GBS and includes plasma exchange and IVIg. There is evidence, however, that cancer-associated GBS has a worse outcome than GBS alone.[122]

Approximately 10% of patients with multiple myeloma will develop a clinically significant neuropathy. The neuropathy, most often sensorimotor, commonly precedes diagnosis of the myeloma and is slowly progressive.[123] Treatment of the myeloma usually does not alter the course of the neuropathy. Other causes of peripheral nerve or nerve root involvement include deposits of amyloid and root compression by spine metastases.

Osteosclerotic myeloma represents about 3% of all cases of myeloma. More than 50% of patients with osteosclerotic myeloma develop a predominantly motor paraneoplastic peripheral neuropathy, which often is the initial presentation of the myeloma.[124] The clinical picture is similar to that of chronic inflammatory demyelinating polyneuropathy.[125] Resection or radiation of the sclerotic lesions, or chemotherapy, often results in neurologic improvement.[123]

Ten percent of patients with Waldenström's macroglobulinemia develop a peripheral neuropathy with predominant sensory involvement. In some, the monoclonal IgM has activity against myelin-associated glycoprotein or gangliosides.[126]

The POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal proteinemia, and *s*kin changes) is a rare disorder that can develop in association with all forms of myeloma but is seen predominantly with osteosclerotic myeloma.[125,127,128] Patients develop a severe, symmetric, sensorimotor neuropathy that is associated with muscle atrophy.

Castleman's disease is a rare disorder that overlaps with POEMS. Patients commonly develop neuropathies, including a painful sensorimotor neuropathy, a chronic relapsing sensorimotor neuropathy, and a predominantly motor neuropathy.[129] Treatment of the Castleman's disease along with plasma exchange or immunosuppression may result in improvement of the neuropathy.[130]

Vasculitic Neuropathy

Paraneoplastic vasculitis may be systemic or confined to nerve and muscle. When systemic, the small vessels of the skin commonly are affected, and the most commonly associated tumors are lymphomas and leukemias.[131,132] A paraneoplastic microvasculitis of the muscle and nerve without systemic vasculitis has been reported in older patients with solid tumors, particularly carcinoma of the prostate, kidney, lung, endometrium, and lymphoma.[133] These patients develop symptoms of symmetric or asymmetric painful sensorimotor neuropathy. As a result of the muscle vasculitis, patients can develop proximal muscle weakness. The diagnosis is suggested by the presence of elevated proteins in CSF and an elevated erythrocyte sedimentation rate and is confirmed by biopsy of nerve and muscle. This disorder may respond to corticosteroids and cyclophosphamide or other types of immunosuppression.

Autonomic Neuropathy

Paraneoplastic autonomic neuropathy usually occurs as a component of other disorders, such as LEMS and PEM, but it may occur rarely as the predominant symptom.[26] Patients with paraneoplastic autonomic neuropathy can develop several life-threatening complications, such as gastrointestinal paresis with pseudo-obstruction, cardiac dysrhythmias, and postural hypotension. Additional symptoms include dry mouth, erectile dysfunction, anhidrosis, and sphincter dysfunction. Paraneoplastic autonomic neuropathy has been reported in association with several tumors, including SCLC, cancer of the pancreas, cancer of the testis, carcinoid tumors, and lymphoma. When the autonomic dysfunction is a component of PEM, serum anti-Hu and anti-CV2/CRMP5 antibodies may be positive. Serum antibodies to ganglionic acetylcholine receptors have been reported, but they also may occur without a cancer association.[134]

PARANEOPLASTIC SYNDROMES OF THE NEUROMUSCULAR JUNCTION

Myasthenia Gravis

Myasthenia gravis (MG) results from an immune response directed against the acetylcholine receptor at the neuromuscular junction. Thymic abnormalities are reported to occur in approximately 75% of patients with MG. Of these, 15% have microscopic or gross evidence of thymoma, and 85% have evidence of thymic hyperplasia. Patients develop weakness of the extremities and the ocular and bulbar muscles; a few patients have pure ocular involvement.[2,135] The most common presenting signs are ptosis and intermittent diplopia. Proximal muscles tend to be more affected than distal muscles, and muscle atrophy is rare. Deep tendon reflexes are preserved. Pain usually is not reported, although some patients complain of paresthesias. Aspiration secondary to dysphagia and ventilatory paralysis secondary to respiratory muscle involvement may be causes of death.[136]

The initial approach to treatment should be directed at the underlying tumor. Additional therapeutic strategies, including symptomatic treatment (i.e., anticholinesterase drugs), immunomodulation (e.g., plasma exchange, IVIg), and immunosuppression (e.g., corticosteroids, azathioprine) are similar for patients with and without cancer.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is a disorder of the neuromuscular junction in which the presence of autoantibodies against P/Q type voltage-gated calcium channels results in a defect in the presynaptic quantal release of acetylcholine.[137–139] Approximately 60% of patients with LEMS have an associated SCLC.[16] In most patients (70%), the neurologic symptoms develop before the tumor diagnosis is made; in 25% of patients the symptoms develop at the same time the tumor is diagnosed.[140]

Patients present with lower extremity weakness, increased fatigability, and difficulties walking, rising from a chair, or climbing stairs. Some patients report a brief increase in muscle strength following a period of activity. Nerve conduction studies show a very-low-amplitude compound muscle action potential that increases progressively (>200%) in response to fast rates (20–50 Hz) of repetitive stimulation or after a short period of maximum voluntary contraction (Fig. 51-6). Detection of antibodies against the P/Q type voltage gated calcium channel currently is used as a serologic test for LEMS.[138]

At least 50% of patients have evidence of autonomic dysfunction, such as dry mouth, impotence, constipation, or impaired sweating.[16,141,142] Mild and usually transient cranial nerve dysfunction occurs in most patients.[143] Although rare, respiratory muscle weakness may occur, even to the point of requiring assisted ventilation. In contrast to MG, where the deep tendon reflexes usually are spared, in LEMS they are reduced or absent, especially in the lower extremities. In some patients, LEMS may develop in association with PCD or PEM.[4,49]

When LEMS is associated with cancer, most patients will have neurologic improvement with combined cancer treatment and therapy directed to LEMS. The latter includes medications that increase the presynaptic release of acetylcholine and immunomodulation. The use of 3,4-diaminopyridine results in moderate to marked neurologic improvement in 80% of patients.[144] If 3,4-diaminopyridine is not available, a combination of pyridostigmine and guanidine may be beneficial.[145] Plasma exchange and IVIg are useful for treating patients with severe weakness.[146] Neurologic improvement occurs within days or weeks but is transient. For patients who are refractory to these treatments, long-term immunosuppression with prednisone or azathioprine may be effective. Patients whose neurologic symptoms relapse should be evaluated for tumor recurrence.

PARANEOPLASTIC MYOPATHIC SYNDROMES

Polymyositis–Dermatomyositis

About 9% of patients with polymyositis develop cancer. Since the neoplasm often is diagnosed several years before or after diagnosis of the polymyositis, this may represent a coincidental occurrence and casts doubt on the role of cancer in the pathogenesis of the neurologic disorder.[17] In contrast, 15% of patients with dermatomyositis develop cancer, and in most patients the tumor is diagnosed by the time the myopathic symptoms develop.[17] Cancer of the breast, lung, ovary, and stomach are the most commonly associated tumors.

Clinical symptoms are similar for patients with and without cancer.[147] Patients with dermatomyositis may present with a reddish or purplish skin rash that often precedes the onset of proximal muscle weakness. Serum creatine kinase levels usually, but not always, are elevated. Respiratory muscle weakness may lead to ventilatory failure and contribute to death. Other symptoms include arthralgias and muscle contractures, myocardial inflammation leading to congestive

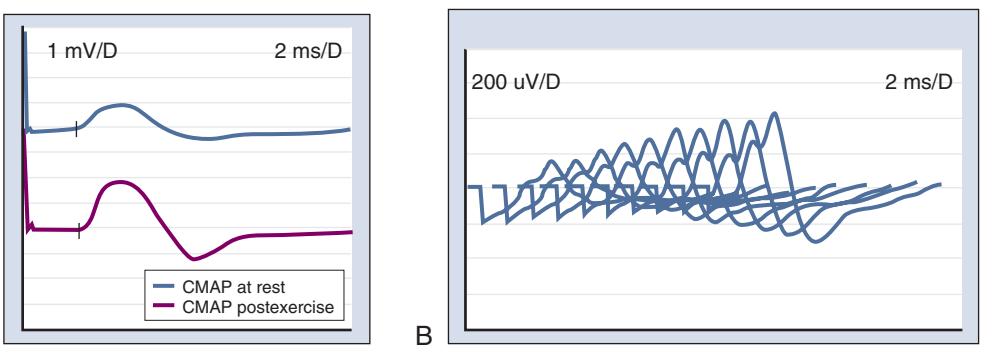

Figure 51-6 • Electrophysiologic study of a patient with small cell lung cancer and the Lambert-Eaton myasthenic syndrome. **A,** Facilitation of the compound motor action potential (CMAP) after 10 seconds of maximal voluntary contraction. **B,** Progressive increase of the CMAP amplitude with high-frequency repetitive stimulation. These are the classic electrophysiologic findings in patients with LEMS.

heart failure, and interstitial lung disease.[148] Reflexes and sensory examination usually are normal.

Several autoantibodies have been identified in patients with polymyositis and dermatomyositis. Jo-1 antibodies are identified in a group of patients with either disorder and are associated with interstitial lung disease.[149,150] Antinuclear antibodies typical of other connective tissue diseases also can be detected.[151] There are no specific markers indicative of the paraneoplastic origin of dermatomyositis. Dermatomyositis and polymyositis usually respond to corticosteroids and other types of immunosuppression (e.g., azathioprine). High-dose IVIg has proved to be effective for dermatomyositis.

Acute Necrotizing Myopathy

Acute necrotizing myopathy has been described in patients with cancer of the lung, bladder, breast, and gastrointestinal tract.[152] Patients present with symmetric weakness of the extremities associated with pain and a marked increase of serum muscle enzymes. Symptoms rapidly progress to involve pharyngeal and respiratory muscles, often resulting in death. The electrophysiologic studies are consistent with myopathy, and pathology studies demonstrate extensive muscle necrosis with little or no inflammatory infiltrates. It has been suggested that acute necrotizing myopathy represents a severe and more rapid form of polymyositis, but this remains unproven.[153]

Treatment and Prognosis

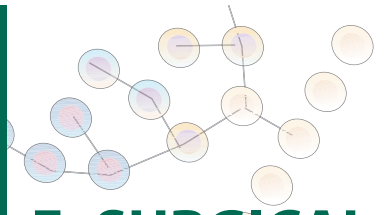
In general, paraneoplastic syndromes of the CNS have a subacute, progressive course that results in severe deficits or death in weeks or months.[26,51] Spontaneous improvement has been observed in some patients with opsoclonus-myoclonus, mostly children with neuroblastoma,[154] or patients with PCD associated with Hodgkin's disease,[52,155] subacute motor neuronopathy,[63] and sensorimotor neuropathies, which usually fulfill the criteria of acute or chronic GBS.[121,156,157] Progression to severe disability is seen less often in the neuromuscular disorders that develop after the diagnosis of the tumor, such as some sensorimotor neuropathies. A few patients with anti-Hu-associated sensory neuronopathy, and patients with PCD, particularly those without anti-Yo antibodies, may have a mild, indolent clinical course or even stabilize with only moderate neurologic deficits.[49,158] A classification of the paraneoplastic neurologic disorders by expected treatment response is given in Table 51-2.

Improvement of neurologic symptoms after tumor treatment has been reported for almost all the paraneoplastic syndromes.[159] However, the actual impact of antineoplastic therapy on the paraneoplastic symptoms is difficult to assess. This is due, in part, to the low incidence of neurologic paraneoplastic syndromes and the lack of effective treatment for some neoplasms. The rapid and apparently irreversible neuronal damage that is characteristic of many paraneoplastic symptoms may allow potentially effective treatments to arrest, but not reverse, the neurologic symptoms. Despite these limitations in assessment, some patients with limbic encephalitis have neurologic improvement, which appears to relate to tumor treatment. In particular, limbic encephalitis in young men with anti-Ma2 antibodies and germ cell tumors and young women with anti-NR1/NR2 antibodies and teratomas improves with treatment of the tumor and immunotherapies.[28,45]

For those paraneoplastic disorders of the peripheral nervous system associated with pathogenic antibodies (e.g., MG, LEMS, neuromyotonia), removal of the antibodies,[160] treatment of the tumor (removing the source of antigen), or immunosuppression often is effective.[161] For other paraneoplastic disorders, the symptoms sometimes evolve independently of the course of the tumor. An exception is osteosclerotic myeloma, in which treatment of the myeloma can result in dramatic improvement of an associated sensorimotor neuropathy.[162–164] Immunosuppressive treatments including corticosteroids, IVIg, and plasma exchange have been used in paraneoplastic syndromes that appear to result from immune-mediated mechanisms.[159,165] These include demyelinating sensorimotor neuropathies, vasculitic neuropathy,[166] and dermatomyositis.[167,168] In these disorders, clinical improvement can be expected after treatment, because the area of the nervous system involved is not irreversibly damaged. Large series examining plasma exchange and IVIg in paraneoplastic disorders of the CNS have not shown any significant benefit.[169,170] There are, however, individual case reports of improvements.[87,171–173]

Table 51-2 Treatment Response of Paraneoplastic Neurologic Disorders

Disorder	Treatment
DISORDERS THAT USUALLY RESPOND TO TREATMENT	
Myasthenia gravis	Tumor, plasmapheresis, IVIg, immunosuppression
Lambert-Eaton myasthenic syndrome	Tumor, plasmapheresis, IVIg, 3,4-diaminopyridine
Dermatomyositis	Corticosteroids, IVIg, immunosuppression
Opsoclonus/myoclonus (pediatric)	Tumor, corticosteroids, ACTH
Limbic encephalitis with anti-Ma2 antibodies and testicular tumors	Tumor, corticosteroids, IVIg
Encephalitis with anti-NMDAR antibodies and ovarian teratoma	Tumor, corticosteroids, plasmapheresis, IVIg, cyclophosphamide
Carcinoid myopathy	Tumor, cyproheptadine
Neuropathy (osteosclerotic myeloma)	Tumor, radiation
DISORDERS THAT MAY RESPOND TO TREATMENT	
Vasculitis (nerve/muscle)	Corticosteroids
Opsoclonus/myoclonus (adults)	Tumor, corticosteroids, protein A column, clonazepam, diazepam, baclofen
PCD (Hodgkin's disease)	Tumor
Opsoclonus/ataxia (anti-Ri associated)	Corticosteroids, plasmapheresis
Guillain-Barré (Hodgkin's disease)	Tumor, plasmapheresis, IVIg
Stiff-man syndrome	Tumor, corticosteroids, diazepam, baclofen, IVIg
Neuromyotonia	Plasmapheresis



ACTH, adrenocorticotropic hormone; IVIg, intravenous immunogbbulin; NMDAR, N-methyl D-aspartate receptor; PCD, paraneoplastic cerebellar degeneration.

E. SURGICAL PROBLEMS

52 Establishing and Maintaining Vascular Access

John C. Mansour and John E. Niederhuber

SUMMARY OF KEY POINTS

- More than 750,000 vascular access devices are used in the United States each year.
- Placing the catheter tip in the superior vena cava or inferior vena cava provides large lumen and high flow.
- Types of central access systems are traditional central line for short-term use, tunneled central lines for long-term use, surgically implanted infusion ports, and peripherally inserted central catheters (PICC lines).
- Three questions to ask in selecting a catheter system are: (1) What device best meets the patient's therapy needs? (2) How is the device most safely inserted and maintained? (3) What are the likely immediate and long-term complication risks?
- Vascular access devices can be placed using a number of anatomic sites to access the superior vena cava or inferior vena cava: subclavian vein, internal jugular vein, external jugular vein, and femoral vein.
- Insertion can occur via Seldinger technique (closed) or by operative exposure of vein (open) technique.
- Complications include vascular laceration, arterial puncture, pneumothorax (2%), hemothorax, and air embolus (overall placement complications should be <5%).
- Long-term complications include catheter exit site or tract infection, catheter-associated sepsis, cardiac arrhythmias, catheter colonization, catheter thrombus (~30%), fibrin sheath, extravasation, occluded catheter, and shearing of catheter.
- Factors that increase the risk of catheter-associated infection include prolonged duration of indwelling time, multiple-lumen catheters, femoral or internal jugular vein locations, non-catheter-related bacteremia (neutropenic patient), number of times the system is accessed, difficult catheter placement, and poor technique in catheter or port-site care.

INTRODUCTION

During the course of disease, many patients with cancer require intravenous chemotherapy, frequent blood sampling, transfusion of blood products, or total parenteral nutrition. Many of these intravenously administered therapies—especially chemotherapies—are inflammatory to small peripheral veins. Over the past three decades, techniques for obtaining and maintaining central vascular access have been developed and refined. Managing the treatment of patients with cancer requires a thorough familiarity with the special use of vascular access devices. This chapter provides a review of the pros and cons of various devices, insertion methods, and catheter maintenance techniques.

Although it would be ideal to base vascular access decisions on solid clinical information, few randomized controlled trials have examined the clinical controversies that are involved with chronic vascular access for the patient with cancer. In addition, many of the larger studies regarding central vascular access were performed in the inpatient intensive care unit (ICU) setting. Comparing ICU patients with patients with cancer who receive chemotherapy or weekly blood draws on an outpatient basis could lead to inaccurate conclusions. It is important, however, to review the available randomized trials, a number of carefully performed retrospective analyses, and pertinent ICU literature to address some of the questions concerning vascular access for the patient with cancer.

When managing a patient who requires vascular access for treatment of a malignancy, there are three important questions: (1) What device will best meet this patient's therapeutic needs? (2) How can we most safely insert and maintain central venous access? (3) What are the immediate and delayed complications of vascular access procedures that are unique to the oncology patient population?

CHOOSING THE RIGHT DEVICE

Clinical oncologists use the vascular access devices that are discussed in this chapter to aspirate blood and centrally infuse agents into central veins, such as the superior vena cava (SVC) or the inferior vena cava. Many chemotherapeutics and parenteral nutrition formulations act as vesicants to the venous intima, causing inflammation and thrombosis of smaller veins. By infusing this type of product into the higher-flow, less thrombogenic cardinal veins, the durability and safety of vascular access can be extended, and patient comfort can be enhanced significantly.

Percutaneous Central Lines

Traditional central lines are placed by using the Seldinger technique, which is described in detail later in this chapter. The subclavian vein, internal jugular vein, or femoral vein is cannulated percutaneously, and the catheter is placed by using guide-wire assistance. There is a very short distance between the skin and the catheter's entry point into the vein. Theoretically, this proximity to skin flora increases the risk of subsequent central line infection.

These central lines are in common use throughout most hospitals for oncology patients, for critically ill patients who require central access, or for any patients who require infusions that are poorly

tolerated via peripheral intravenous access. Such central lines provide excellent short-term access to the central venous system. In general, percutaneous central lines are considered only for short-term use, and after the first 7 to 10 days, percutaneous central lines have a markedly higher incidence of infection despite optimal skin entrance site dressing techniques. Obviously, prolonged patient neutropenia and episodes of bacteremia could result in shorter life spans of such catheters.

Patients could benefit from these traditional central venous catheters if the patients require a relatively short course of infusion or need a bridge to placement of a more long-term catheter. Meticulous sterile dressing changes are an absolute necessity for outpatients who need short-term therapy via these lines. Patients without the resources or dexterity to care for percutaneous central lines are at a prohibitively increased risk of line infection, bacteremia, or thrombotic event and should be provided with a long-term form of central access. Certain comorbid conditions (e.g., burns, open wounds near the line site, or tracheostomy) preclude placement of this type of vascular access.

Surgically Tunneled Central Lines

Most oncology patients need a long-term form of central venous access rather than a traditional central line. Surgically tunneled central lines were developed to increase the distance between the skin entrance site and the puncture of the vein. The hypothesis was that by increasing this distance, the life span of the central access would be increased by decreasing the incidence of infection and thrombosis. Tunneled central lines are commonly referred to by the name of the first brand marketed, Hickman. Other examples include Broviac, Quinton, and Groshong (Fig. 52-1). These polymeric silicone rubber venous access catheters are placed via a subcutaneous tunnel that is described in detail later in this chapter. Clinical studies have supported the hypothesis that increasing the distance between the catheter exit site in the skin and the hole in the vein decreases the incidence of externally derived infection.[1,2] Studies suggest that the incidence of bloodstream infections associated with tunneled catheters is approximately 1 to 2 per 1000 catheter days.[3] The frequency of bacteremia among nontunneled catheters has been reported at between 1.0 and 13.0 per 1000 catheter days.[4]

A Dacron cuff 3 to 4 cm from the exit site encourages scar formation to fix the catheter in place. This exaggerated scarring eliminates the need for long-term sutures holding the catheter in place to the skin. Avoiding these fixation sutures can decrease the incidence of stitch reactivity and associated localized skin infections. One drawback of this type of central access device is the inconvenience of placing and removing the lines. In most instances, surgeons insert these lines in the operating room under local anesthetic and intravenous sedation. Therefore, these procedures require coordination of the patient, the surgeon, the anesthesia staff, and the operating room staff. They are also more uncomfortable to remove than are nontunneled lines owing to the Dacron cuff scar reaction. Removal requires intravenous sedation and local anesthesia but can be accomplished outside of the operating room.

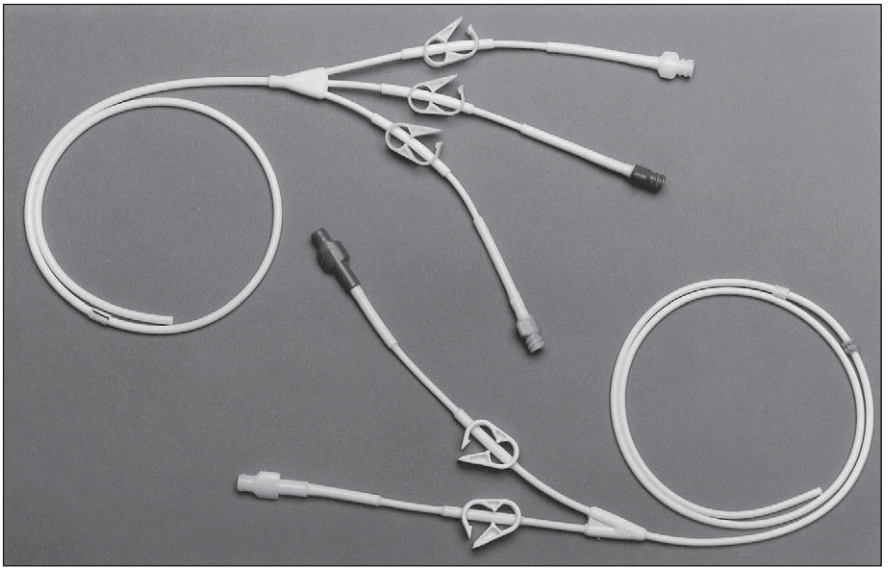
Surgically Implanted Infusion Ports

Implantable ports consist of a small injection reservoir with a self-sealing membrane; they are placed entirely beneath the skin. There is no external catheter. An internal catheter runs from the reservoir into the subclavian or internal jugular vein to provide central access. The internal catheter is essentially identical to those used for tunneled central lines. A noncoring (Huber) needle can pass directly through the skin into the reservoir for infusion or aspiration.[5] The self-sealing rubber cap on the reservoir prevents leakage from the reservoir after withdrawal of the Huber needle. The gauge of the noncoring needle—not the catheter—typically limits flow through the port system (Fig. 52-2). The ports can also be used for continuous drug infusion, as shown in Figure 52-3.

The theoretical concern that bacteria more easily traverse the short distance between the skin and the "neo-vein" or reservoir and cause increased rates of infection does not prove true.[6–11] Sterile technique and site care lead to an infection risk comparable to that of tunneled catheters. With adequate care, the rate of infection could be fourfold to fivefold less than that for tunneled catheters.[3] The low rates of infection and extravasation make infusion ports ideally suited for patients with cancer who need long-term single-lumen access and a low-maintenance catheter. Experience has shown, however, that patients with prolonged periods of neutropenia or significant risk of cutaneous eruptions might not be good candidates for port devices. The visible lump of the port could bother extremely thin patients; however, the port is hidden from plain view in most people.

Long-Line Central Access

Also known as a peripherally inserted central catheter (PICC line), this vascular access device is becoming increasingly popular. The catheter is inserted into a brachial, cephalic, or antecubital vein and advanced into the subclavian vein or higher. Successful placement



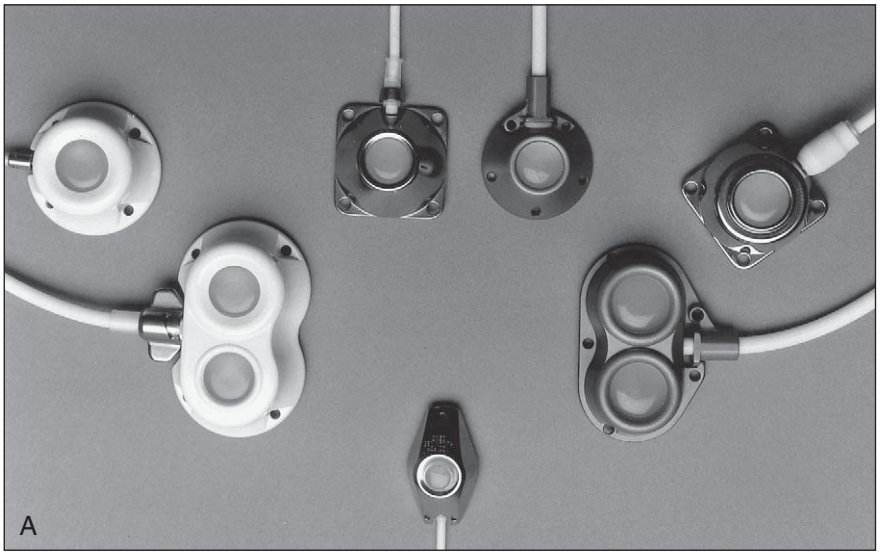


Figure 52-1 • Examples of standard double- and triple-lumen Hickman catheters. The double-lumen catheter has both the standard Dacron cuff and an additional antibacterial barrier cuff.

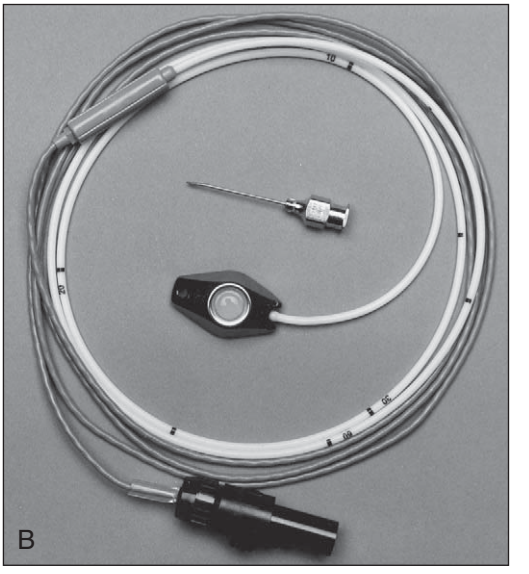

Figure 52-2 • **A,** Examples of implantable infusion devices: Low-profile titanium ports (*top center*), peripheral access port used in the arm (*bottom center*), single and dual polysulfone-titanium ports (*left*), single- and double-lumen standard profile ports (*right*). **B,** Peripheral access catheter for placement of a small port in the forearm. This system utilizes a fluoro-free thermosensor (gray wire) initially inside the white silicon catheter. An external wand over the chest determines the site of catheter top placement.

rates of 75% might be improved by the addition of ultrasound guidance.[12–14] These lines can be placed simply and easily in the outpatient office setting and are well tolerated by patients, with minimal risk. Many oncology patients have poor arm veins after multiple peripheral infusions and are therefore poor candidates for this technique. The 50% risk of catheter-related thrombosis is the greatest drawback to more widespread use of PICC lines in oncology patients. This problem is secondary to the presence of a long length of catheter within the vein and to the catheter tip in the relatively low flow subclavian vein. Advancing the catheter tip into the SVC can reduce the incidence of thrombosis by more than half.[15] Accurate placement of the catheter tip in the SVC can be complicated by the large displacement of the catheter tip (up to 8 cm) with normal arm range of motion.[16]

INSERTING VASCULAR ACCESS DEVICES

Providing patients who are undergoing treatment for cancer with appropriate vascular access requires not only a thorough knowledge of available devices but also technical expertise in the procedures for placing these catheters. Although these procedures are sometimes viewed as routine, the risks of poor technique can be devastating for the patient. Before undertaking the procedure, one should carefully consider everything from choosing the site of insertion to selecting the dressing to be used at the end of the procedure (Table 52-1).

Choosing Insertion Location

Vascular access devices can be placed by using a number of different access points, including the internal jugular, subclavian, external jugular, and femoral veins. The vast majority of catheters that are used for long-term vascular access in patients with cancer are placed in the internal jugular and subclavian veins. We will limit this discussion to these most common access sites.

The most frequent site for insertion of vascular access devices in the oncology population is the subclavian vein. Clavicular fracture or previous median sternotomy can alter the anatomy of this location. For a patient with such a history, an alternative site should be considered. Even for patients with standard venous anatomy, the acute angle at the confluence of the subclavian and internal jugular veins at the brachiocephalic vein can complicate the passing of the guide wire into the SVC. There is a higher incidence of pneumothorax, hemothorax, and catheter malposition among inexperienced operators, and there is a higher incidence of vein stenosis with

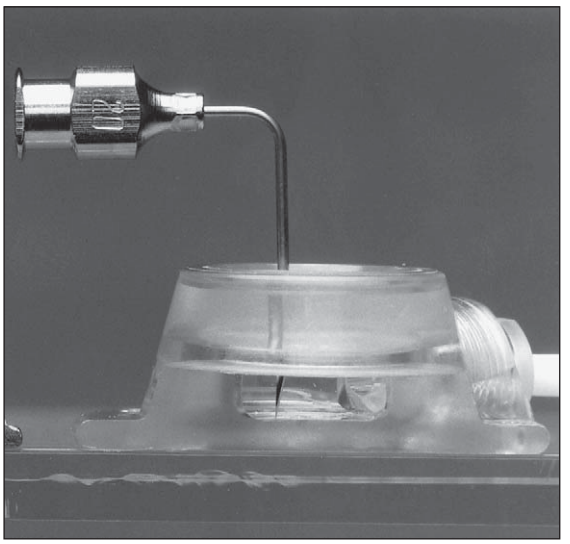

Figure 52-3 • Placement of a deflected point (Huber) needle in a port. The lower portion of the port has been cut away to show the needle tip in the reservoir. This example of a bent needle shows how the needle can be taped and secured at the skin surface for protracted infusion using an external pump.

subclavian vein placement than with internal jugular placement.[17–19] A subclavian artery puncture during line placement can be difficult to control, owing to the position of the artery posterior to the clavicle. A catheter placed on the anterior chest wall is more comfortable and easier to cover with clothing, however, than is a line in the neck. Additionally, some authors have concluded that with lines that are in place for more than 4 days, the risk of line infection is less for subclavian catheters than for internal jugular catheters.[17,18]

In many ways, the internal jugular vein is the ideal location with regard to ease of placement of a central catheter. The path of the guide wire during placement is straight, thereby limiting many guidewire complications and catheter malposition. In the event of carotid artery puncture, arterial bleeding can be controlled safely with the application of direct pressure. This advantage is especially important in the thrombocytopenic patient. The incidence of central venous occlusion is decreased, which could be important for patients who are likely to need an arteriovenous fistula for hemodialysis in the future. Unfortunately, patients often complain of pain with neck and shoulder movements after placement of an internal jugular catheter.

Preparing to Place the Vascular Access Device

Adequate preparation for placing a central venous catheter for oncology patients includes several steps before the actual line insertion. The surgeon must make several decisions that can limit the incidence of both immediate and delayed complications and ensure optimal line function.

Studies suggest that providing a single dose of prophylactic antibiotic to cover common skin flora before inserting the vascular access device reduces central line infection. It is difficult, however, to determine how this small benefit affects antibiotic resistance and subsequent infections. Using central venous catheters impregnated with antibiotics could be more effective in dealing with infectious complications and will be discussed later in this chapter.[20,21]

Table 52-1 General Guidelines for Catheter and Port Use

Type	Advantages	Uses	Dressings	Flushing	Comments
Central line	Placed at bedside Easy removal One or multiple lumens Can change over wire	Hospital use only	Sterile transparent dressing Change dressing twice weekly	5 mL heparinized saline (10 units/mL) in each lumen daily or after each use	Antibiotic ointment may promote resistance
PICC catheter	Safe to insert and remove	1 week to 6 months of IV access	Transparent antimicrobial foam dressing Change every 6 days	3 mL heparinized saline bid or after each use	Flush and draw blood slowly to avoid catheter migration
Hickman catheter	Multiple sizes and lumens Tunneled under skin	Continuous infusion therapy Long-term access	Newly placed: antimicrobial dressing for 7 to 10 days Gauze or transparent dressing changed 2 times per week	5 mL heparinized saline daily or after each use	Clean with chlorhexidine during dressing change After 4 weeks may clean with antimicrobial soap
Groshong catheter	Slit valve requires no heparin flushes Smaller, more flexible catheter	Single- or double-lumen catheter for long-term use			
Port	Completely under skin Minimal care	One lumen access and low maintenance	None	5 mL heparinized saline daily or after each use 20 mL saline after blood draw Monthly flush with 5 mL heparinized saline (100 units/mL)	Clean with chlorhexidine before use, access with noncoring needle Use no needle >20 gauge to access EMLA cream helpful

A sterile surgical field with mask, gown, cap, gloves, and a large sterile drape should be used to minimize the risk of line infection.[22] The skin of the entire anterior neck and chest should be prepared with chlorhexidine, which is superior to povidone-iodine or alcohol in limiting line infections.[23–26]

The choice to use ultrasound guidance to identify the vein during cannulation should be addressed before beginning the procedure. Less experienced operators will likely benefit from the use of ultrasound guidance as an adjunct to the anatomic landmarks technique.[13,27] Ultrasound can decrease the incidence of arterial puncture and placement failure. Although a few reports in the literature exist regarding the advantage of these techniques, such superiority is often judged when compared with high rates of complications using the landmark approach as the control group.

The operator must also decide where to position the catheter tip within the central vein. Clearly, catheters that are positioned with the tip in the right atrium will function longer as a source for aspirating blood samples than will those with the tip positioned in the SVC.[28,29] A case review of thrombosed catheters documents that the position of the tip of the catheter at the time of thrombosis seems to be the most important contributing factor.[30–33] The closer the catheter tip is to the right atrium, the lower is the frequency of thrombosis and infection. The risk of a catheter tip in the right atrial position is primarily that of cardiac arrhythmias when the tip is near the tricuspid valve. An additional risk of right atrial catheter placement is right atrial thrombus or right atrial erosion.[32] These risks have led the Food and Drug Administration to publicly warn operators to avoid placement of the catheter tip within the right atrium. Instead, the catheter tip should sit at the junction of the SVC and the right atrium.

Insertion Technique

After informed consent is obtained, a rolled towel is placed directly under the vertebral column at the shoulders to extend the clavicles. A peripheral line is established, and the patient is connected to an EKG monitor and a pulse oximeter. Intravenous sedation is typically established by using small doses of benzodiazepines. The fluoroscopy operating table and patient are placed in the Trendelenburg position. The skin of the neck and entire upper anterior thorax is prepared, and sterile drapes are positioned. The skin and deep tissues are anesthetized with 1% lidocaine using a 25-gauge needle for the skin followed by a 22-gauge needle for the anticipated insertion tract (Fig. 52-4A).

For subclavian vein puncture, the site of skin puncture is usually 1 cm below the angle of the lateral third of the clavicle. The long insertion needle, as depicted in Figure 52-4A, is slowly inserted below the clavicle, aiming for a point approximately one fingerbreadth above the sternal notch. During insertion, a small amount of negative pressure is maintained on the syringe. With experience, the physician develops a feel for the actual puncture of the vein, and when this occurs, the syringe fills easily with venous blood.

As the position of the needle is being carefully maintained, the syringe is removed, and the guide wire is inserted (Fig. 52-4B). If the patient experiences discomfort in the neck, the guide wire is partially withdrawn. Turning the patient's head away from the site of insertion and exerting a downward pull on the ipsilateral arm could facilitate entrance of the catheter or guide wire into the SVC. Cardiac ectopy indicates that the guide wire has entered the right atrium, and the wire should be withdrawn slightly.

Fluoroscopy may be used to pass the wire when difficulty is experienced. The correct position of the catheter is confirmed by fluoroscopy or chest x-ray before the catheter is secured with a 3–0-nylon suture at the skin exit site. The tip of the catheter is positioned 1 cm above the SVC-atrial junction when the patient is in the Trendelenburg position. A chest x-ray is obtained to document the absence of pneumothorax and accurate placement of the catheter within the SVC.

When it is necessary to use the veins in the neck, the right internal jugular provides more direct access to the SVC and right atrium. In this case, the patient's head is turned to the opposite side. The insertion site is located just lateral to the carotid artery and approxi-

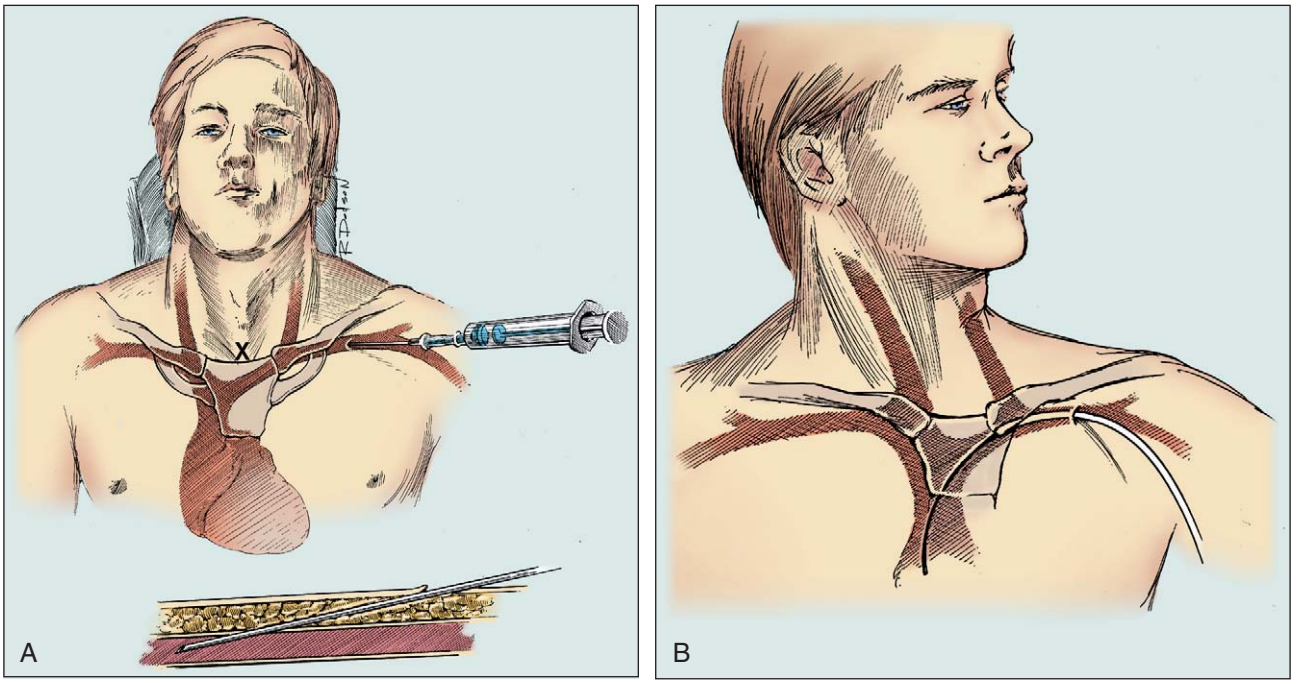

Figure 52-4 • **A,** Placement of a catheter using the Seldinger technique. The long insertion needle is shown entering the vein through skin and subcutaneous tissues. **B,** Demonstration of a catheter passing over the guide wire.

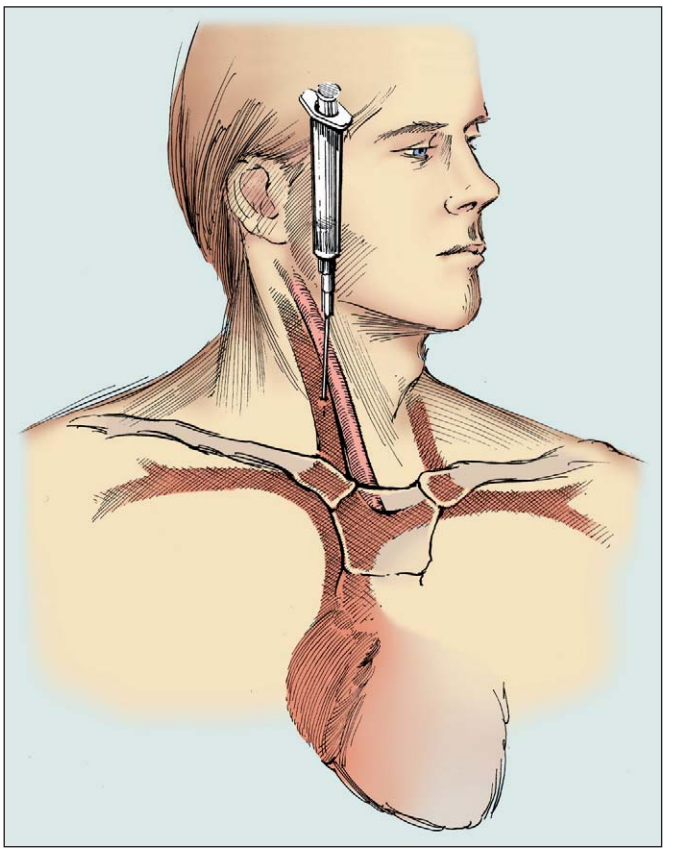

Figure 52-5 • Demonstration of catheter insertion technique when utilizing a vein in the neck (right internal jugular).

mately two fingerbreadths above the head of the clavicle. Another useful landmark for the insertion site is the angle formed by the sternal and clavicular heads of the sternocleidomastoid muscle (Fig. 52-5).

Placement of a permanent Silastic catheter, such as a Hickman, is depicted in Figure 52-6. Placement of the introducing needle and guide wire is as described in previous figures except that a 1-cm incision is made before insertion of the introduction needle. A prophylactic antibiotic is given before the procedure. It is often beneficial to provide the patient with intravenous sedation.

A second 1-cm incision is placed lower on the anterior chest, usually at the level of the fourth or fifth interspace. The skin and subcutaneous tissues are first anesthetized with 1% lidocaine. The projected course of the tunneled catheter is also infiltrated with lidocaine. A tunneler is passed from the lower incision to the upper incision, where the guide wire is exiting. A heavy suture is tied to the end of the tunneler and brought down through the tract. The suture is tied to the end of the catheter and used to pull the catheter up through the tract, securing the cuff 3 to 4 cm from the skin exit site. The catheter is trimmed to the correct length that will position it about 1 cm above the SVC-RA junction with the patient in Trendelenburg position. This location is approximately four fingerbreadths below the sternal notch.

Care is taken to cut the catheter squarely and smoothly. An introducer and a tear-away sheath are passed over the guide wire into the vein (Fig. 52-7). A slight rotary motion facilitates the introduction of the sheath and avoids crimping. To avoid developing a false passage, the guide wire should be withdrawn occasionally as the introducer is inserted. The guide wire is then removed, and a syringe is attached to the introducer to confirm that blood can be aspirated. The introducer is removed, and the thumb is used to control bleeding or air intake through the sheath. It is important to have the catheter tip poised to insert as the introducer is removed. The passage of the catheter could meet some resistance as it is passed between the clavicle and first rib.

Fluoroscopy or a chest x-ray is obtained to confirm correct positioning and the absence of pneumothorax. The catheter is aspirated and flushed to confirm function. Care should be taken to avoid any angulations of the catheter through the subcutaneous tract, especially at the bend toward the subclavian vein. The incision below the clavicle is closed with a subcutaneous absorbable suture. The catheter is secured at the exit site with a 3-0 nylon suture, which is maintained for approximately 3 weeks to allow the fibrous tissue ingrowth into the subcutaneous cuff. The exit site is covered with a sterile gauze dressing.

Similar techniques apply to the use of neck veins. The catheter is tunneled over the clavicle, the exit site being the same as for subclavian vein placement. When other sites are required (e.g., the femoral vein with the catheter tip in the inferior vena cava), direct cut-down exposure of the saphenous vein or other large femoral branch is preferred.

Figure 52-8 illustrates the placement of an implanted injection port. A 1-cm incision is placed below the clavicle at the site planned for subclavian venipuncture. A second, 3-cm incision is placed lower on the chest in a position that provides a relatively flat surface and stability for the port chamber. Local anesthesia is 1% lidocaine with 1 : 200,000 epinephrine. A subcutaneous pocket just large enough to accommodate the port is dissected inferior to the incision. Ideally, the level of this pocket is over the underlying pectoral fascia. The skin coverage needs to be thick, but the port must be percutaneously accessible. A tunneler is passed subcutaneously from the pocket through the infraclavicular incision. A suture is tied to the tunneler and brought down through the tract. The suture is tied to the end of the port catheter and used to pull the catheter through the tract to the intraclavicular incision. Care should be taken to position with a gentle curve and to avoid catheter angulation. The port is secured in the pocket with three sutures of 0-prolene. It is necessary to anchor the port adequately to prevent flipping or rotation of the device.

The guide wire is inserted as described, and the dilator and sheath are passed over it. The catheter is cut to the desired length. The dilator and guide wire are removed, and the catheter is inserted through the sheath as described. The incision for the port pocket is closed with interrupted 3-0 absorbable sutures placed in the subcutaneous layer. The skin is approximated with a running subarticular 4-0 absorbable suture. A transparent nonpermeable dressing is used at the port incision.

Open insertion methods are quite safe in a skilled surgeon's hands. The major complication of the open technique is the possibility of air embolus during the actual catheter insertion. This is most likely to occur in patients who are hypovolemic, cachectic, or unable to tolerate positioning in Trendelenburg position. An air embolus happens most frequently when the internal jugular vein is used, and extreme care with the use of the purse-string suture around the insertion site and venous occlusion with vascular clamps should limit the possibility of introduction of air into the vascular system. With open direct surgical placement, although it takes considerably longer than the closed Seldinger technique, complications should be much lower than 5%.[33–35] In the Hopkins series, the open method results in a complication rate of less than 1%. Although this is a safer technique, it requires more training, more experienced operative personnel, and larger incisions. Any patient who has had repeated problems with closed insertions should be approached in an open fashion, however, as this is the most controlled and safest format for that patient. Sometimes, previous operations or radiation therapy in the region of the cardinal veins makes the open operative approach more difficult, but generally such problems are limited.

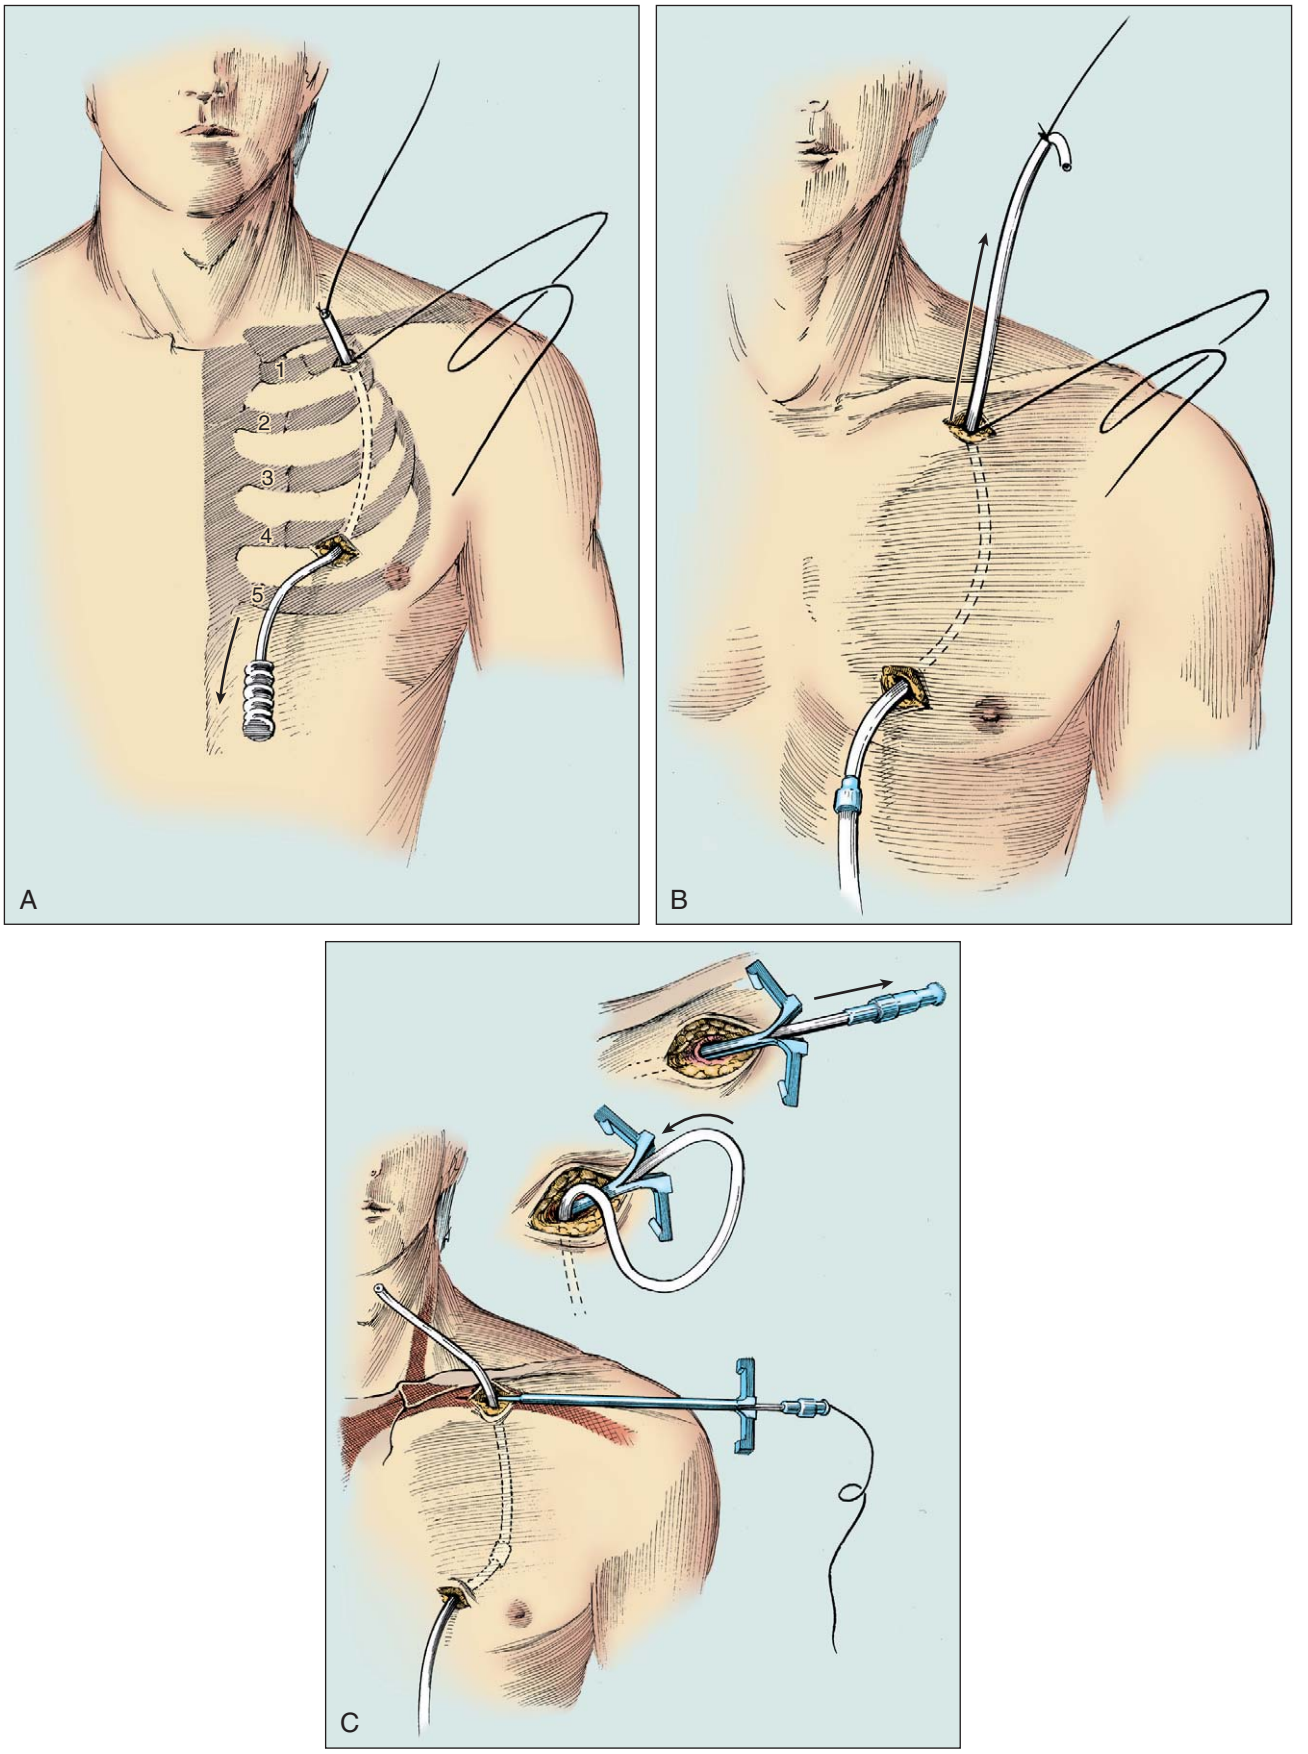

Figure 52-6 • **A,** Placement of a permanent Silastic catheter (such as a Hickman). The first and second incision sites are shown, as is the path of the tunneler. **B,** The catheter is pulled through the tract by using a heavy suture. The catheter cuff is secured 3 to 4 cm from the skin exit site. **C,** The catheter is trimmed and positioned 1 cm below SVC-RA junction. The introducer and tear-away sheath are shown passing over the guide wire. The catheter is inserted into the sheath, and the sheath and introducer are removed.

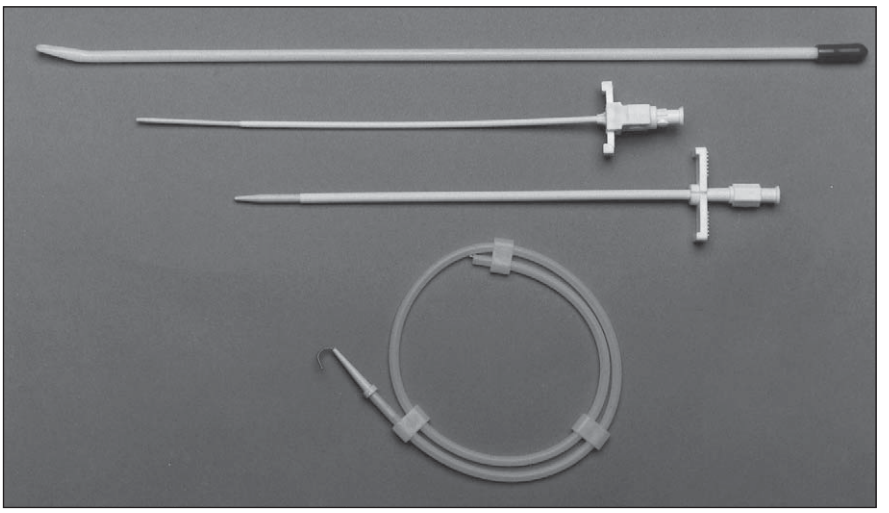

Figure 52-7 • Example of an introducer kit. The kit includes a guide wire and introducer (dilator) with tear-away sheath (two different sizes shown). The upper, longer blunt object is a tunneler, which is included in some kits.

COMPLICATIONS OF VASCULAR ACCESS DEVICES

When complication rates are examined as a whole, certain patient factors, catheter factors, and operator factors seem to predict the occurrence of complications. Patient-related factors that predict higher complication rates include the presence of multiple comorbid conditions, atherosclerosis, abnormal anatomy, thrombocytopenia, immunocompromise, prior radiation therapy to insertion area, recent myocardial infarction, and patient restlessness.[36] In addition, multiple-lumen or stiffer catheters carry increased risks of complications.[37–40] Factors related to the person performing the insertion of the catheter also influence risk of complications. Risk increases if the operator has inserted fewer than 50 central venous catheters, if more than two tries at cannulating the vein are required, or if the insertion of the catheter is difficult.[16,41,42] Risk factors for specific complications are discussed in the sections that follow.

Immediate Complications

Pneumothorax

Published complication rates for pneumothorax after jugular vein central line placement are approximately 0.5% and up to four times higher for subclavian vein procedures.[16,37,38,43] The risk of this technical complication can be reduced dramatically among experienced operators or physicians who have experienced supervisors.[36]

Bleeding

Many patients with cancer are at increased risk of bleeding complications owing to thrombocytopenia, uremia, other platelet dysfunction,

or anticoagulant therapy. Bleeding complications are associated most frequently with thrombocytopenia.[39] For patients with platelet counts less than 50 or International Normalized Ratio greater than 2.0, we consider administration of platelets or fresh-frozen plasma. Experienced physicians should perform these procedures with access to ultrasound guidance if necessary.

Cardiac Arrhythmias

Disruptions in the normal cardiac conduction pathway can be caused by contact between the catheter and the right atrium. Most of these arrhythmias are short-lived and self-limiting.[16] These problems are more common with insertion of pulmonary artery catheters than with catheters that are typically inserted for oncologic vascular access. They are associated with more significant sequelae in patients who have recently suffered a myocardial infarction or who have a history of left bundle branch block.[40,44]

Delayed Complications

Infectious Complications

Infectious complications are the most common complications of long-term vascular access devices in the oncology patient population. Two factors make the interpretation of this relatively well-studied topic challenging. First, many of the large randomized controlled trials that have studied central line infections have concentrated on ICU patients. The ICU population has different risk factors and susceptibilities from those of the outpatient population of people with cancer. Nevertheless, by carefully reviewing the available data, we can make some conclusions regarding the pathogenesis, prevention, and treatment of line-related infections among oncology patients. In studies of ICU patients with central lines, factors that predispose to line infection have included malignancy, neutropenia, extended duration of indwelling time, and coincident parenteral nutrition. All of these factors can contribute to the incidence of infection among patients with vascular access for oncologic treatment.[45,46]

Second, the confusing terminology regarding line-related infections can make the literature on this topic difficult to interpret. *Local infection* is a positive culture at the catheter insertion site. *Catheter colonization or infection* is the positive culture of a segment of removed catheter. *Catheter-associated bacteremia* is evidenced by a positive blood culture from a site other than the catheter and the positive culture of a segment of removed catheter with the same pathogen.

Understanding the pathophysiology of catheter-associated bacteremia can help to limit the incidence of this complication. Up to 50% of catheter-associated bacteremia is caused by coagulase-negative staphylococcus. This common skin flora can colonize the catheter during insertion or later. A thrombus that forms at or along the catheter tip can become a nidus for bacterial proliferation, with resultant bacteremia. Thrombosis significantly increases the risks of colonization and infection.[47] Bacteria can also be introduced into the bloodstream by hub contamination, by hematogenous seeding from another focus of infection, and, rarely, by the infusate itself.

Factors that increase the risk of catheter infection include prolonged indwelling time, multiple-lumen catheters, femoral or internal jugular vein location, difficult catheter placement, and non-catheter-related bacteremia.[45,48] As was mentioned previously, nontunneled catheters are at increased risk of catheter infection compared with tunneled catheters, and totally implantable devices are even less susceptible than tunneled catheters.[49,50]

Multiple-lumen catheters have demonstrated higher infection rates than single-lumen catheters. The addition of each lumen exponentially increases incidence of infection.[51–54] There are two possible explanations for this observation. First, the increased internal lumen diameter of the line is associated with a higher thrombosis rate and accumulation of loose thrombus at the catheter tip. Thrombosis causes more breaking of the line and more line manipulation when attempting to declot, leading to subsequent infection. Second, the multiple ports invite multiple interruptions of the line for access and result in a greater likelihood of introduction of bacteria. Despite their greater risk of iatrogenic infection, multiple-lumen catheters have great appeal for patients who need multiple simultaneous infusions of incompatible drugs. Very strict nursing guidelines must be followed in the management of multiple-lumen catheters to prevent iatrogenic infections and thrombosis.[55,56]

Diagnosis and management of catheter-related infection differs between nontunneled and tunneled catheters. However, some diagnostic principles apply to both tunneled and nontunneled catheters. Routine surveillance blood cultures should not be performed. When a catheter-related infection is suspected due to fever, chills, or purulence around the catheter site, percutaneous and catheter blood samples should be submitted for culture.[57–60] Qualitative culture with continuously monitored differential time to positivity compares the time to positivity for catheter blood cultures to percutaneous peripheral-blood cultures. This technique has demonstrated excellent specificity and sensitivity for detecting catheter-related infection in tunneled catheters.[61,62]

In most patients with nontunneled central venous catheters, the line should be removed if the patient demonstrates signs of site infection or sepsis or if blood culture results from the catheter and percutaneous blood samples are positive.[61,62] Seven to 10 days of narrow-spectrum antibiotic therapy is generally recommended. In certain cases of clinically stable patients with a single episode of coagulase-negative staphylococcus, a trial of antibiotic therapy might salvage the catheter.[53] For any patient with persistent bacteremia despite antibiotic therapy and removal of the infected catheter, a thorough investigation of possible septic sources, such as endocarditis or septic thrombus, is warranted.

Tunneled catheters or infusion ports should be removed in cases of sepsis, complicated infections, tunnel tract infections, or port abscesses.[63] A thorough evaluation confirming the surgically implanted catheter as the source of infection should precede the removal of any of these vascular access devices. In the absence of complicated infection, catheter salvage could be indicated. Antibiotic lock therapy is a reasonable approach for attempting to salvage lines with common coagulase-negative staphylococcus, *Staphylococcus aureus,* or gram-negative bacilli intraluminal infections. This therapy consists of instilling the catheter lumen with high concentrations of antibiotics and leaving them there for several days.[64–67] If salvage therapy fails, a new tunneled catheter can be placed after removing the infected catheter, treating with an appropriate course of antimicrobial therapy, and repeating blood cultures with negative results.

Catheter Thrombus

Thrombus of central vein access devices predisposes to both line malfunction and line infection. The most common site of thrombus formation with prolonged indwelling central catheters is where the catheter enters the vein. At this point, a fibrin sleeve progresses distally toward the tip of the catheter. The precipitating event is likely local trauma from line insertion with subsequent endothelial damage and disruption of intraluminal laminar flow. The venous intima exposed to blood flow activates the coagulation cascade. Understanding this pathophysiology helps to explain why difficult line placements often lead to shorter catheter survival and increased rates of infection.

The incidence of central venous catheter-related thrombus as demonstrated by ultrasound is greater than 30% for catheters that are in place longer than 7 days.[68] This problem typically presents as progressive difficulty in flushing the catheter. A change in posture or the Valsalva maneuver could allow aspiration of blood. Occasionally, thrombosis can present as extremity edema. This can be especially devastating after axillary nodal resection or axillary irradiation. Management of a nonfunctioning catheter is discussed later.

Acute line obstruction can also be caused by precipitation of incompatible medications. Common offenders include total

Table 53-2 Management of a Suspected Clot

Complications	Cause	Gravity Flow Observation	Corrective Action
Fibrin sheath*	Fibrin collects on the tip or encases the catheter	Excellent in all positions but no blood return in any position	May be declotted following the declotting procedure
Occluded catheter*	Fibrin and platelets collect inside catheter	Inability to infuse solutions and draw blood	May be declotted following the declotting procedure; drug precipitate cannot be corrected with tPA or heparin

*These are the only two instances in which it is safe to declot after checking the chest x-ray for proper placement.

parenteral nutrition, etoposide salts, lipid emulsions, calcium salts, antibiotics, and sodium bicarbonate. Infusion of a solution specifically matched to the precipitated material might flush the line.[69]

Extravasation

Extravasation is defined here as the leaking of infusate into the subcutaneous tissue surrounding a central venous catheter. This complication can be caused by needle displacement from an implanted port, a defect in the catheter tubing, or withdrawal of the catheter from the vein due to inadequate fixation. Additionally, "backtracking" can occur when the catheter is partially occluded and infusate tracks up along the fibrin sleeve and into the subcutaneous tissue. Findings that are suggestive of extravasation include sudden swelling at the line site, increased patient discomfort during infusion, and sudden loss of blood return.[70]

Clavicular–First Rib Compression

This infrequently discussed complication may occur up to 1% of the time in long-term indwelling catheters.[71] When the subclavian vein is cannulated more medially than usual in the narrow space between the clavicle and first rib, the line can be compressed between the first rib and the clavicle. Patients who report difficulty infusing while in the sitting position or when the ipsilateral arm is elevated or abducted should be suspected of this compression. This malposition can be observed on chest x-ray as kinking of the line over the first rib. The catheter can break free and embolize if the line is not promptly removed. An interventional radiologist using a percutaneous retrograde femoral catheterization approach can retrieve an embolized section of catheter.

MANAGEMENT OF NONFUNCTIONING CATHETERS

When a central venous catheter does not return blood or infuse solution, the malfunction should be assessed systematically to maximize catheter durability and to minimize the incidence of catheter-related complications. The first step in this assessment is reviewing the most recent chest x-ray to confirm appropriate placement. The next step is checking for gravity flow. Connecting a bag of normal saline to gravity flow and asking the patient to change position, cough, and breathe deeply will demonstrate whether flow is positional. If the catheter is patent to gravity flow, lower the bag below the catheter and assess for blood return. With this information, one can make a decision as to whether to remove, reposition, or declot the catheter (Tables 52-2 and 52-3).

Two conditions are appropriate for thrombolysis of the catheter with alteplase or tissue plasminogen activator (TPA): fibrin sheaths and intraluminal thrombus occlusions. Contraindications for declotting procedures include high bleeding risk and known recent or current episode of bleeding.

Catheter malfunction caused by fibrin sheaths usually demonstrates good gravity flow and no blood return because the sheath acts as a one-way valve, allowing outflow but not inflow through the catheter. When intraluminal fibrin and platelets occlude the catheter, the catheter will demonstrate neither gravity flow nor return, regard-

Table 52-3 Management of an Unknown Clot

Complications	Cause	Gravity Flow Observation	Corrective Action
Do not attempt to declot any of the following conditions.			
Malposition	Catheter cut short and abutting vessel wall	Positional; no blood return in any position	Must be removed; do not attempt declot, which may erode vessel wall
Pinch-off syndrome	Insertion site too close to first rib and clavicle	Excellent when lying down but absent when standing	Must be removed to avoid catheter breakage
Transverse catheter	Catheter crosses into opposite subclavian	Positional flow, slow blood return, position noted on chest x-ray	Interventional radiology can reposition via femoral vein access
Arrhythmia	Catheter in right atrium	Positional; position noted on chest x-ray	Catheter must be pulled back into SVC or removed
Flipped up	Catheter tip in jugular vein; can occur in association with vomiting or coughing	Positional, blood return may be positional, patient complaint of tinnitus or headache with catheter flushing, position noted on chest X-ray	Interventional radiology may be able to reposition if catheter not cut too short
Major vessel thrombus	External thrombus within vessel due to insertion trauma	No change; good blood return; arm, hand, or neck swelling	Documentation of thrombus with ultrasound or venogram, treatment with thrombolytics after consultation with hematology

less of any positional changes. If the caregiver is convinced that the catheter malfunction fits one of these categories and appropriate catheter position is confirmed on chest x-ray, catheter thrombolysis is indicated. Contrast venography is not necessary before using TPA to open nonmechanical catheter occlusions.

Techniques for declotting catheters vary from institution to institution but follow the same general principles. We recommend instilling 500 μg of TPA and allowing the infusate to dwell for 1 hour. If patency is not restored after 1 hour, instill an additional milligram of TPA and allow the infusate to dwell for another hour. Using a very similar technique, the authors of the Cardiovascular Thrombolytic to Open Occluded Lines Trial (COOL-2) studied nearly 1000 patients with occluded central venous catheters. These patients in a predominantly oncology population did not undergo prethrombolysis contrast studies. No deaths or major bleeding episodes were directly attributable to the thrombolysis. More than 87% of the catheters were opened with the TPA. At 3-month follow-up, nearly 75% of the catheters were still patent.[72] A similar study in the oncologic population reported a success rate greater than 80%.[73]

VASCULAR ACCESS DEVICE MAINTENANCE

The risk of complications with a long-term vascular access device does not end with insertion of the device. Proper care and maintenance of each type of central catheter can dramatically reduce the incidence of catheter-related bacteremia, catheter thrombosis, and line failure.[74] Maintenance is performed not only by qualified staff of oncology centers but also by patients and family members in the outpatient setting. In Table 52-1 and Box 52-1, we have detailed our recommendations for central catheter care after a thorough review of the best available literature.

SUMMARY

Patients and physicians have a large variety of vascular access devices from which to choose, and no individual catheter is the ideal solution for all clinical situations. By understanding the strengths and weaknesses of each catheter system, insertion site, and maintenance technique, we hope to minimize the morbidity associated with these commonly used devices. Clearly, having a great deal of experience in placing vascular access devices in the oncology population minimizes the number of problems. Line care is the joint responsibility of the health care team and can be a major source of patient morbidity if each and every member of the oncology team does not maintain the highest quality of care.

More than 750,000 vascular access devices are used in the United States each year. We must continue to conduct clinical studies to make the safest, most cost-effective choice for each cancer patient.

Box 52-1. PROBLEM SOLVING IN CATHETER USE

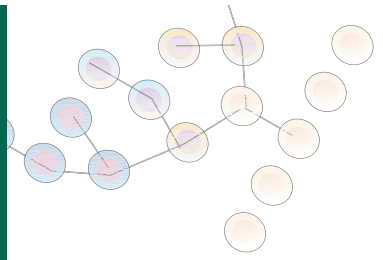
Troubleshooting Guidelines

If a catheter does not have a blood return or will not infuse solution, perform the following troubleshooting techniques to diagnose the problem before proceeding with the declotting procedure:

1. Connect a flush bag of NS or D5W to the catheter and open the roller clamp to allow the fluid to flow to gravity.
2. Have the patient change position, take deep breaths, and cough while the drip rate is observed.
3. When the fluid infuses at the fastest rate, lower the bag and observe for a blood return.
4. If a blood return is observed, use the catheter as indicated, making a note that it is positional.
5. If no blood return is observed in any position, if gravity flows freely in all positions, and if the last chest x-ray verifies that the catheter tip is in the SVC, proceed to declot the catheter with a likely fibrin sheath obstruction.
6. If the x-ray shows that the catheter tip position is questionable, obtain a dye study to verify the exact location of the catheter tip, integrity of the catheter, and flow of solution.

Declotting Procedure

See the preceding guidelines before proceeding to declot, as follows:



1. Using a 1-mL syringe, create a vacuum by aspirating back on the plunger (at the hub) and clamp. Repeat once.
2. Instill 2 mL 1 : 1000 U heparin solution (in each lumen) and let dwell for 1 hour. Assess for a blood return.
3. If the line remains clotted, instill the appropriate amount of alteplase to fill the catheter (listed following) using the same technique as with the heparin.
4. Let dwell for 30 minutes to 1 hour and then assess for a blood return.

Catheter Type	Alteplase (mL)
Central line, 14 gauge	0.7
Central line, 16 gauge	0.5
Hickman, 12 F	1.6
Hickman, 10 F	1.3
PICC	0.5
Groshong	1.6
Plasmapheresis	1.4

53 Acute Abdomen, Bowel Obstruction, and Fistula

Sandra L. Wong and Alfred E. Chang

SUMMARY OF KEY POINTS

Gastrointestinal Perforation
- Perforation affects approximately 20% of patients with acute abdominal emergencies.
- Bowel perforation can be due to spontaneous tumor rupture, tumor necrosis secondary to chemotherapy, radiation therapy, drugs (e.g., steroids), or inflammatory conditions.
- Operative intervention is mandated unless the patient's overall prognosis is poor.

Gastrointestinal Bleeding
- Bleeding affects approximately 15% of patients with acute abdominal emergencies.
- Bleeding is more commonly seen in patients with leukemia or lymphoma who are undergoing chemotherapy.
- Endoscopy is critical to identify the source of bleeding and can even be therapeutic.
- Nonoperative therapy is successful for many patients.

Neutropenic Enterocolitis
- Also termed *necrotizing enterocolitis,* neutropenic enterocolitis typically affects the terminal ileum, cecum, and ascending colon in patients with chemotherapy-induced neutropenia.
- Most patients respond to conservative management with broad-spectrum antibiotics and bowel rest.
- Surgical intervention should be considered for perforation, uncontrolled sepsis, or persistence of symptoms despite correction of neutropenia.

Bowel Obstruction
- Obstruction affects approximately 40% of patients with cancer who experience acute abdominal emergencies.
- One fourth to one third of patients who require surgical intervention have a benign cause of their obstruction.
- Partial bowel obstruction can initially be treated nonoperatively, which is successful 25% of the time.
- Clinical suspicion of bowel ischemia or complete obstruction mandates urgent surgical intervention.

Fistulae
- Presenting symptoms rarely match those of intra-abdominal malignancy and more commonly represent complications after surgery or radiation therapy or both.
- Fistulae occur most often as a result of treatment of gynecologic malignancies.
- Medical management consisting of nutritional support and bowel rest allows spontaneous closure of most enterocutaneous fistulae.
- Causes for persistence of a fistula include undrained infection, luminal obstruction distal to the fistula, prior radiation, epithelialization of the fistulous tract, cancer within the tract, presence of a foreign body, and malnutrition.

INTRODUCTION

General surgical problems in the cancer patient require special attention. This chapter reviews common abdominal complications and emergencies that are encountered in patients with a cancer diagnosis. In some cases, these problems might not be related to the cancer itself. For other patients, clinicians must be cognizant of the potential complications associated with progression or treatment of disease. The management of cancer patients has undergone significant changes with the increasing utilization of multimodality therapy. Combined approaches, including surgery, radiation therapy, chemotherapy, and immunotherapy, are now commonplace. Topics having to do with the "acute abdomen" include intestinal obstruction, gastrointestinal (GI) bleeding, and perforation. Other related presentations, such as gastrointestinal inflammatory conditions and fistulae, are also reviewed in this chapter. In addition, unique abdominal problems that are seen in patients undergoing bone marrow transplantation (BMT) are covered.

ACUTE ABDOMEN: GENERAL CONSIDERATIONS

The classic general surgery approach to a patient with acute abdominal pain entails identification of a potentially life-threatening problem and evaluation for emergency exploratory laparotomy. In patients with cancer, the etiology of acute abdominal pain may be directly related to a malignant process, but seemingly unrelated processes must be considered as well. Some GI cancers can present as abdominal emergencies that require surgical intervention. Problems that require surgical consultation include obstruction, perforation, hemorrhage, inflammatory processes, and other miscellaneous problems such as fistulae (Box 53-1).[1,2] In a recent prospective analysis of over 1000 consecutive palliative procedures in patients with cancer, over 50% were performed on the GI system, with obstruction and bleeding making up over 75% of the presenting symptoms. Interestingly, surgical intervention resulted in symptom resolution in over 80% of patients.[3] The decision to intervene with surgical therapy is often

Box 53-1. ACUTE ABDOMINAL EMERGENCIES IN CANCER PATIENTS

  - Appendicitis
  - Pancreatitis
  - Neutropenic enterocolitis

difficult because of abnormal physiologic responses to injury and inflammation, complications associated with previous cancer therapies, and competing risks due to extent or stage of the underlying cancer. In some instances, medical management or utilization of palliative measures make up the mainstay of therapy.

Abdominal pain is the most common symptom in the patient with an acute abdomen. In patients with a diagnosed intra-abdominal malignancy who are undergoing chemotherapy and/or radiation therapy, abdominal pain must be investigated carefully. Care must be taken not to automatically attribute these complaints to cancer progression. Important considerations in the evaluation of the patient with an acute abdominal process include hemodynamic stability and deterioration of symptoms during the course of examination and workup. Patients taking corticosteroids or who have an altered sensorium warrant special attention because of a potentially unreliable physical examination. Other abdominal complaints, such as vomiting, distention, lack of flatus, and fever, should raise the examiner's index of suspicion that an emergent problem is present.

On physical examination, tenderness to palpation is the most common finding. Peritonitis almost invariably produces tenderness as a localized or diffuse finding, since abdominal pain is transmitted by both visceral and somatic sensory pathways. There is no substitute for a thorough history and physical examination. A careful and thoughtful differential diagnosis is important in directing the course of subsequent evaluation and action. Laboratory tests and diagnostic imaging studies can help to narrow the nature of the problem. Standard laboratory studies should include a complete blood count and electrolyte panel. Leukocytosis will normally be evident if an intra-abdominal infection is present. Unfortunately, chemotherapy-induced neutropenia or immunosuppression might prevent the white cell count from adequately reflecting an inflammatory process. Liver function studies and a serum amylase are helpful in patients with upper abdominal complaints when hepatobiliary or pancreatic etiology is suspected. Patients with evidence of GI bleeding require serial hemoglobins to assess the severity and magnitude of the bleeding; thrombocytopenia and coagulopathy should be corrected when possible.

If an intra-abdominal process is suspected and time permits, diagnostic imaging with plain abdominal films, ultrasonography, and/or computed tomography (CT) could be helpful in making a more definitive diagnosis. With increasing sophistication of CT studies, their importance in identification of abdominal processes, including free fluid, free air, intestinal pneumatosis, portal venous gas, transition points for gastrointestinal obstruction, and localization of abdominal inflammatory processes, is well defined.[4] Importantly, rapid tumor progression and/or metastases can often be assessed at the same setting. Localization of the bleeding source by endoscopy or arteriography can be helpful, and these can often be used as therapeutic modalities as well.

Ultimately, the surgeon must make the determination as to whether the patient has an acute abdominal process that requires surgical intervention. Decisions to operate on acutely ill patients with cancer are difficult and often require a high level of surgical decision making. Due consideration must be given to the stage and prognosis of the cancer itself, since the surgeon's ability to offer a procedure with curative intent versus palliation only may alter the decision-making process. The role of palliative procedures has increased tremendously, with as many as 6% to 21% of cancer operations being classified as palliative in nature.[3,5–6] Even without curative intent, surgeons have a great deal to offer in terms of symptom relief and overall improvement in quality of life. However, attempts at successful palliation must be balanced with inappropriately aggressive attempts, which may carry unacceptable rates of morbidity and mortality.

GASTROINTESTINAL PERFORATION

Perforation of the GI tract mandates operative intervention unless the patient's condition is judged to be extremely poor. Excluding iatrogenic causes of bowel perforation, the causes of perforation can be categorized into the following subgroups: spontaneous tumor rupture or erosion into bowel, drug-induced or associated perforations, and inflammatory conditions. GI tract cancers may present with perforation as the precipitating event, but this is rare and associated with high mortality rates. Primary colon cancers can present as localized perforations or can cause obstruction with subsequent perforation. The perioperative mortality rate following presentation with colon cancer perforation, either at or proximal to the tumor site, ranges from 17% to 48%.[7] Even after accounting for stage, patients tend to have a poorer prognosis.

Spontaneous perforation of GI tumors is more common in patients with lymphomas involving the gastrointestinal tract, although this diagnosis is rare. Large malignant retroperitoneal lymphomas, renal cell carcinomas, and testicular cancers metastatic to aortocaval nodes can invade the adjacent duodenum and cause perforation. Patients with GI lymphomas can have symptoms at presentation or can develop symptoms related to regression of their primary tumor during treatment with chemotherapy and/or radiation therapy. Perforation or bleeding from treatment-induced tumor lysis occurs in approximately 3% and 5% of patients, respectively. Although resection of larger, higher-grade GI lymphomas can be associated with increased morbidity, the mortality rate is greater than 50% when surgical intervention is urgently required for perforation or bleeding in the setting of neutropenia and thrombocytopenia.[8–10]

Surgical management of bowel perforations varies with the site and etiology. Infectious causes of perforation, such as colitis secondary to cytomegalovirus or *Clostridium difficile,* have been described but are rare. Treatment includes proper control of the infection and usually necessitates resection with possible enteric diversion. For gastric perforations secondary to benign ulcers, surgical intervention is indicated. For perforated duodenal ulcers, various surgical options can be employed, depending on the patient's underlying disease and clinical status (e.g., hemodynamic stability). Small bowel perforations should be resected with primary anastomosis if possible. Colonic perforations, especially in the setting of the unprepped bowel and in the immunosuppressed patient, should be treated with resection and diversion. One-stage procedures to include primary anastomosis in these situations must be used cautiously and are generally not advised. Aggressive supportive care with control of intra-abdominal infection and sepsis are paramount in the immediate perioperative period.

GASTROINTESTINAL BLEEDING

The true incidence of significant gastrointestinal (GI) bleeding in patients with cancer is not well defined. An estimated 10% to 15% of patients with abdominal emergencies requiring operative intervention had abdominal hemorrhage, most of them secondary to intralu-

minal bleeding.[1] Patients with lymphoma or leukemia treated with combination chemotherapy regimens can experience GI tract bleeding. While a GI tumor itself could be the source of bleeding, differential diagnosis should include non-tumor-related sources as well. The most common causes of upper GI tract bleeding in patients with cancer are peptic ulcer disease or stress ulceration and complications of anticoagulation or thrombocytopenia.[2,11–12] Rates are likely to be lower in clinical practice, given the availability and increasingly widespread use of H2-receptor blockers and proton pump inhibitors.[13] Other, less common, causes of bleeding include Candida esophagitis, Mallory-Weiss mucosal tears, hemorrhage from inflammatory conditions (e.g., neutropenic enterocolitis), or radiation-associated complications (e.g., arterial-enteric fistulae, radiation enteropathy).

The pathogenesis of upper GI bleeding can be multifactorial. Gastritis or peptic ulcers can be associated with a variety of agents, such as aspirin, alcohol, steroids, indomethacin, or phenylbutazone. Chemotherapeutic agents can depress platelet production as well as damaging or irritating the mucosal surfaces. While the correlation between thrombocytopenia and bleeding is well described, it is difficult to predict which patients might develop transfusion-requiring bleeding or life-threatening hemorrhage. Overall, the incidence of bleeding is low, with one group reporting bleeding episodes with 9% of chemotherapy cycles.[12,14] The vast majority of episodes were mild (e.g., epistaxis), but major hemorrhage (including GI bleeding) was seen in approximately 3% of cycles. In that study, administration of certain chemotherapy agents (cisplatin, carboplatin, carmustin, and lomustine) was noted to be significantly related to bleeding episodes:. Others have more recently reported thrombocytopenia, hemorrhage, and hemolysis with oxaliplatin.[15] Prophylactic platelet transfusions should be considered on a case-by-case basis, especially if bleeding has occurred previously.

Hepatic arterial infusion of fluorodeoxyuridine utilizing an implanted pump for the treatment of liver tumors has been reported to result in a significant incidence of upper GI toxicity with biliary sclerosis, gastritis, peptic ulcers, and intra-abdominal bleeding due to catheter displacement.[16–18] Other unusual causes of bleeding include hemobilia secondary to presence and/or treatment of hepatobiliary tumors. Arterial-enteric fistulalization may result in severe intraluminal hemorrhage, and operative management should be approached with joint vascular surgery consultation. Communication with vascular structures should always be considered in previous surgical sites and areas of prior radiation treatment.

Intra-abdominal hemorrhage is usually seen as a result of tumor rupture (Fig. 53-1), but spontaneous splenic rupture in patients with hematologic malignancies can be seen as well. Rapid tumor necrosis with subsequent hemorrhage has been reported during chemotherapy and is most commonly seen in patients with GI lymphomas. The incidence of significant GI bleeding in this patient population secondary to tumor lysis from therapy is approximately 5%.[19] Surgical resection of GI lymphoma before systemic or radiation therapy could be beneficial for lesions that are amenable to resection with minimal morbidity.

Treatment of upper GI tract bleeding requires defining its source. Early endoscopic examination should be performed for diagnosis. In most patients, nonoperative treatment is successful. Supportive measures with antacids, proton pump inhibitors, and blood products will control the bleeding in most patients with gastritis or ulceration. Endoscopic injection with sclerosing agents or endoscopically guided use of coagulative laser or electrocautery can sometimes control bleeding from isolated ulcerations or tumors. If medical management fails to stop bleeding from erosive gastritis or if there is intractable bleeding necessitating ongoing packed red cell transfusion, operative management should strongly be considered. Indications to proceed with surgery should also be predicated on the patient's quality of life and disease prognosis. For erosive gastritis, total or near-total gastrectomy is the most effective means of controlling hemorrhage but is associated with a high morbidity and mortality because of the underlying

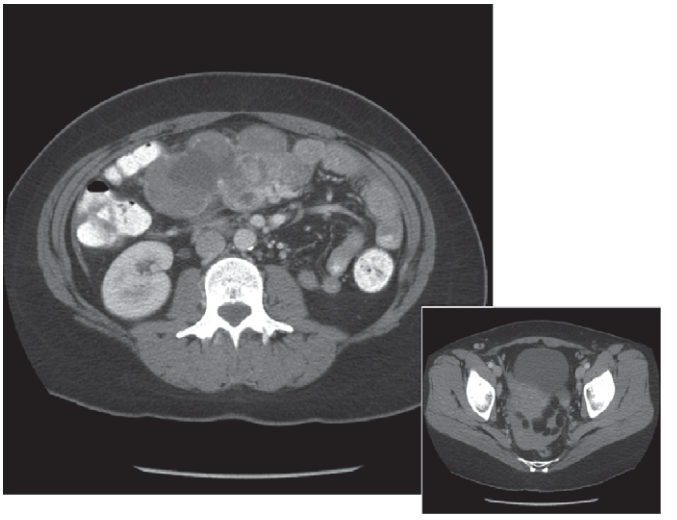

Figure 53-1 • Intra-abdominal hemorrhage from gastrointestinal stromal tumor (GIST). CT scan of the abdomen demonstrating a 10.5-cm proximal jejunal GIST on initial presentation with intra-abdominal perforation and subsequent hemorrhage (*inset photo,* blood in the pelvis).

medical condition of these patients. Bleeding from duodenal ulcer disease in a patient with cancer is probably best treated by oversewing the ulcer and performing a truncal vagotomy with pyloroplasty. When extensive bleeding occurs from a tumor, operative resection might be the only recourse.

Lower GI tract bleeding is infrequently seen from primary cancer sites. Endoscopy, radionuclide imaging, or mesenteric angiography might be required to identify the source. Colonoscopy should be performed as the initial diagnostic study for lower GI bleeding, followed by consideration of upper GI endoscopy. Brisk bleeding can make endoscopic examinations difficult. For GI bleeding at a rate greater than 1 mL/minute, selective mesenteric arteriography might be the most accurate method for localization. Technetium-labeled red blood cell scans can be helpful in localizing the site of hemorrhage when bleeding is more intermittent. Small bowel sources should be entertained if upper and lower endoscopic examination is negative. Primary small bowel tumors (e.g., carcinoids, adenocarcinomas, gastrointestinal stromal tumors) and metastatic lesions (e.g., melanoma, lung) to the small bowel may initially present with an episode of lower GI bleeding. Bloody diarrhea can be seen as a sequelae of radiation treatment for rectal cancer. Radiation enteropathy resulting in bleeding can usually be managed nonoperatively, but in the setting of acute hemorrhage, resection with intestinal diversion might be required.

Operative management of lower GI bleeding is necessary when modalities such as vasopressin infusion or embolization are not indicated or are unsuccessful. In poor-risk patients, these nonoperative therapies are associated with a definitive risk of bowel infarction. Prior localization of the bleeding source is necessary to identify the segment of bowel to resect. When it is not possible to localize the source of colonic bleeding either preoperatively or intraoperatively with inspection or on-table endoscopy, subtotal colectomy should be performed.

ADVERSE EVENTS WITH CYTOTOXIC AGENTS LEADING TO BLEEDING OR PERFORATION

Special consideration should be given to patients receiving targeted molecular therapy agents. Bevacizumab (Avastin), a monoclonal antibody targeting the vascular endothelial growth factor (VEGF)

receptor, has been shown to significantly improve overall and progression-free survival rates in patients with metastatic colorectal cancer when used with combination chemotherapy compared to chemotherapy alone[20,21] Results of these randomized trials have led to the widespread use of bevacizumab in patients with metastatic colorectal cancers and in selected patients with other solid-organ cancers. Because this drug targets tumor angiogenesis, rare but serious complications, such as bowel perforation, can occur in about 1.5% of patients during treatment.[22] Risk factors for perforation are difficult to define but include longer length of treatment, prior radiation, carcinomatosis, and bowel inflammation from entities such peptic ulcer disease, tumor necrosis, diverticulitis, and chemotherapy-induced colitis.[20,22] Bowel perforation can occur at sites that are not affected by malignant disease; perforations were reported in 8% of patients treated with gemcitabine and bevacizumab for pancreas cancer.

Another targeted molecular agent associated with bowel perforation and gastrointestinal bleeding is imatinib (Gleevec), a tyrosine kinase receptor inhibitor that is commonly used in the treatment of chronic myelogenous leukemia and gastrointestinal stromal tumors (GIST). In an early Phase II study of metastatic and/or unresectable GISTs, 5% of patients had hemorrhages into the GI tract or tumor sites.[23] Some of the cases might have been related to tumor rupture. However, episodes were not correlated to imatinib dosing, tumor burden, treatment duration, or platelet count.

With the expanding indications for use of immunotherapeutic agents such as interleukin-2 (IL-2) for metastatic melanoma and renal cell cancer, clinicians should be alert to occasional cases of colonic infarction and perforation.[24] The causes of these perforations are unknown, but it has been postulated that they arise from impaired perfusion due to hypotension, tissue edema, and vasoconstriction secondary to the use of pressor agents. A recent report suggests that bowel perforation might be more commonly seen when IL-2 is used in combination with anti-CTLA 4 antibody and that association can be seen in conjunction with autoimmune colitis.[25]

Bowel necrosis with perforation has been described with the use of cytosine arabinoside. In 50 patients treated for leukemia, seven patients were found to have bowel necrosis and peritonitis at autopsy.[26] Paclitaxel (Taxol), which is commonly used to treat patients with ovarian, breast, and non-small-cell lung cancers, has also been reported as a chemotherapeutic agent that can cause bowel perforation unrelated to tumor lysis.[27] In patients with advanced ovarian cancer, this is a rare but serious complication, and its presentation is associated with a 43% mortality rate.[28] Noncytotoxic drugs are the presumed cause of perforation when bowel wall injury cannot be associated with tumor necrosis or other specific factors in patients with cancer who are undergoing drug therapy. Immunosuppressed patients have a blunted inflammatory response and may have a more subtle presentation of GI perforation. The drugs that are most commonly implicated are corticosteroids, which can give rise to ulcers and perforations in various portions of the GI tract.

INFLAMMATORY CONDITIONS IN THE CANCER PATIENT

Increasingly, aggressive chemotherapeutic regimens are being employed in the treatment of patients with cancer. These treatments can expose patients to life-threatening complications related to bone marrow suppression and neutropenia. The incidence of acute illnesses necessitating surgical intervention in the setting of the neutropenic patient with cancer is approximately 7%.[29] Unique inflammatory abdominal problems in patients with cancer receiving aggressive therapies are reviewed in this section.

Neutropenic Enterocolitis

Neutropenic enterocolitis is a clinicopathologic syndrome that involves the gastrointestinal tract of patients receiving chemotherapy for hematologic and solid malignancies. The clinical condition has been given a variety of names in the past, including typhlitis, ileocecal syndrome, and necrotizing enteropathy. Most commonly seen in pediatric patients who are undergoing treatment for leukemia, neutropenic enterocolitis is still a relatively rare occurrence in adults, with an incidence of less than 5% in this patient population.[30–32]

The pathophysiologic basis of this clinical entity has not been established clearly and is undoubtedly multifactorial. Neutropenic enterocolitis characteristically affects the terminal ileum, cecum, and ascending colon in patients with chemotherapy-induced neutropenia. Although any part of the GI tract can be involved, the cecum appears to be the most severely affected, with mucosal ulceration, gangrene, and perforation. The presence of microorganisms such as *Clostridium difficile, Pseudomonas, Escherichia coli, Klebsiella,* and *Candida* in areas of necrotic bowel and in blood cultures suggests that enterocolitis is primarily an infectious process in an immunocompromised host. The invasion of bacteria itself can cause further necrosis of the bowel wall, leading to full-thickness infarction and perforation of the intestine.

The clinical presentation of neutropenic enterocolitis is extremely variable, and there are no specific criteria on which to make the diagnosis. Furthermore, the symptoms are nonspecific and can be similar to those of a number of other GI processes. Affected patients typically present with fever, abdominal pain and distension, and diarrhea. Abdominal tenderness is frequently localized to the right lower quadrant but can also be diffused. Peritonitis suggests intestinal perforation. Portal venous gas, low serum bicarbonate levels, and generalized peritonitis are ominous findings and suggest a poor outcome.[33,34] A right lower quadrant mass might be palpable, indicating a dilated cecum or a focal inflammatory phlegmon or abscess. Advanced cases can present with systemic sepsis and multiorgan failure.

No specific laboratory or radiologic findings are diagnostic for neutropenic enterocolitis. Pneumatosis intestinalis is often seen and is not itself an indication for surgical intervention.[35] The initial treatment for neutropenic colitis is supportive, with the administration of broad-spectrum antibiotics, nasogastric decompression, intravenous fluids, bowel rest, and serial abdominal examinations.[36] In most patients, these measures are sufficient, and symptoms resolve after correction of the neutropenia. Surgical intervention is rarely helpful, but sound surgical judgment should be exercised in determining which patients require an operation (Box 53-2). Specific situations that dictate surgery include uncontrollable GI bleeding, intestinal perforation, and deteriorating clinical course on medical management.

Appendicitis

Other intra-abdominal inflammatory conditions, such as appendicitis, can be indistinguishable from neutropenic enterocolitis in patients receiving chemotherapy. In large series of children with leukemia or other malignancies, the incidence of appendicitis has been reported to be between 0.2% and 2%, which is equivalent to the incidence in the general pediatric population.[37] Typically, acute appendicitis presents with right lower quadrant pain and localized tenderness. "Classic"

Box 53-2. CONDITIONS FOUND AT SURGERY IN NEUTROPENIC PATIENTS WITH CANCER UNDERGOING EMERGENCY LAPAROTOMY

- Neutropenic enterocolitis

- Hemorrhage (e.g., tumor site, gastritis, gastric ulcers)
- Other (appendicitis, cholecystitis, incarcerated hernia, etc.)
- No disease

symptoms and clinical findings of appendicitis can be followed by a CT scan to confirm diagnosis.[38] Whereas the treatment of neutropenic enterocolitis is primarily medical, the treatment of acute appendicitis is surgical. Nonoperative management of appendicitis (e.g., intravenous antibiotics with interval appendectomy) is associated with high mortality in patients with leukemia. Delay in treatment results in a higher incidence of perforation, peritonitis, and death. Appendectomy is the treatment of choice for appendicitis. Cases that are complicated by perforation or abscess formation could necessitate the placement of drains, and the surgical incision should be left to close by secondary intention.

Pancreatitis

Pancreatitis in the patient with cancer is likely to be caused by the same factors that are implicated in the general population, such as gallstones or alcohol abuse. However, pancreatitis can also be a complication of either medical or surgical therapy. Primary adenocarcinoma of the pancreas is seldom a cause of acute pancreatitis. Metastases to the pancreas have been reported from a variety of tumors, including renal cell carcinoma, melanoma, some types of soft tissue sarcoma, and cancers of the prostate, breast, and lung. However, the vast majority of these metastases are asymptomatic.

Pancreatitis is a recognized complication of a number of antineoplastic chemotherapeutic agents, although the drug with which it is most commonly reported is L-asparaginase. Other antineoplastic drugs that are known to induce pancreatitis are corticosteroids, didanosine, and, less commonly, cytarabine, cisplatin, interleukin-2, vincristine, methotrexate, mitomycin C, cyclophosphamide, doxorubicin, and ifosfamide.[39,40] The clinical course of patients with chemotherapy-induced pancreatitis is most often mild and self-limiting but can progress to necrotizing pancreatitis or pseudocyst formation. Pancreatitis is also a complication of other cancer treatments. Associated procedures, such as endoscopic retrograde cholangiopancreatography, pancreatectomy, or splenectomy, can also result in pancreatitis. Transarterial embolization of the liver for primary or metastatic tumors can cause pancreatitis by misperfusion of chemotherapeutic agents.

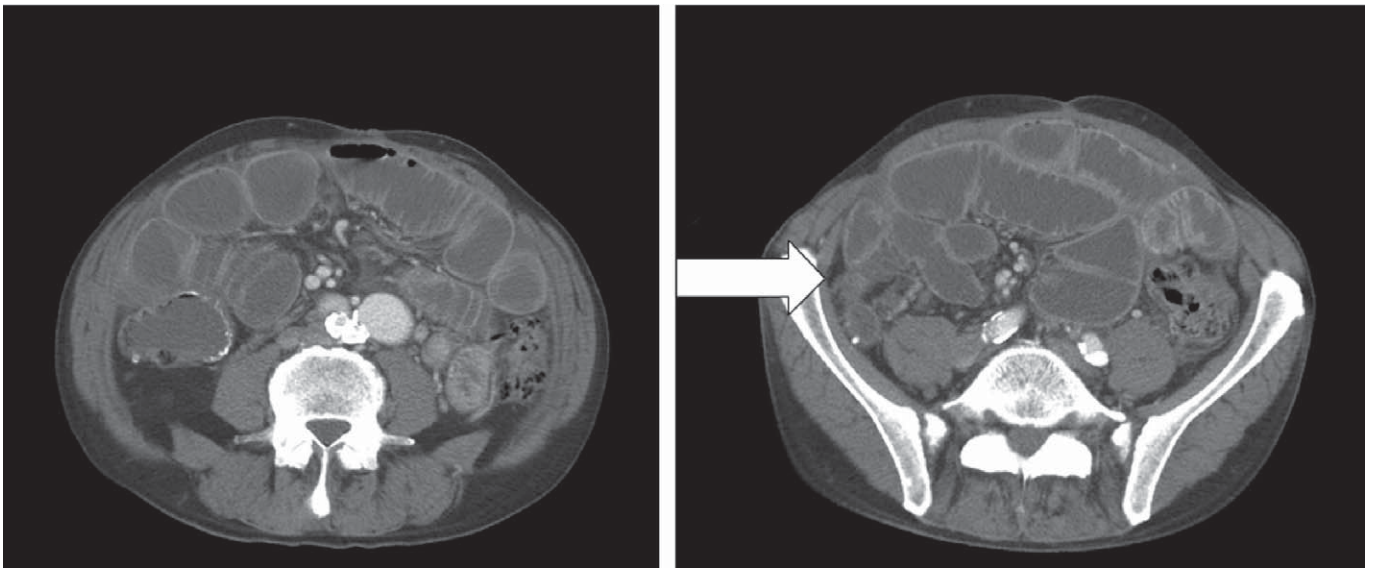
The clinical presentation of pancreatitis includes epigastric pain, nausea, vomiting, generalized ileus, tachycardia, and fever. The diagnosis is usually confirmed by elevations in the serum amylase and lipase levels. CT of the abdomen with intravenous contrast is useful to confirm the presence of pancreatic inflammation or phlegmon and to document necrosis or pseudocyst. The treatment of pancreatitis is generally supportive and includes bowel rest, hydration, and intravenous hyperalimentation. If possible, the causative agent should be eliminated or discontinued, if it can be identified. Necrotizing pancreatitis warrants consideration of pancreatic debridement if there is overwhelming infection.

Perianal and Perirectal Infections in Patients with Cancer

The exact pathogenesis of perianal infections in the patient with cancer is not well defined, though most patients have an underlying neutropenia or immunosuppression. Many patients have a history of pre-existing anorectal problems, including previous perianal or perirectal abscesses, fistula in ano, anal fissures, or hemorrhoids. Once established, the infection can spread into the ischiorectal fossa, supralevator space, retroperitoneum, or perineum. Perianal and perirectal infections develop most frequently in patients with acute leukemia who are being treated with chemotherapy but can also be encountered in some patients with solid tumors or following BMT. In most series in the literature, the incidence of perianal infections in patients with leukemia is between 2% and 8%.[41,42]

The most common presenting symptoms are perianal pain and fever. On examination, the perianal region could be erythematous, indurated, and extremely tender to palpation. Often, an abscess does not develop owing to the patient's profound neutropenia or immunosuppression. Spontaneous drainage of an abscess can result in ulceration, purulent discharge, or bleeding. Spread of the infection in the perineum can lead to a fulminant necrotizing fasciitis. The initial course of therapy is administration of broad-spectrum antibiotic and supportive measures such as sitz baths, warm compresses, stool softeners, and analgesics. Most patients can be managed successfully using a nonoperative approach. However, early surgical intervention for complete drainage of pus and debridement of necrotic tissue may be required and should not be delayed when indicated.

INTESTINAL OBSTRUCTION



Complete or partial obstruction of the GI tract is a common problem in patients with cancer.[43] Typical presentation includes abdominal pain, nausea, and vomiting. Intestinal obstruction is one of the most common indications for emergency laparotomy.[1,3] Intestinal obstruction can occur at any site along the GI tract, and symptoms are often dictated by the level of obstruction. Initial symptoms may be identical to those of adynamic ileus, a condition that needs to be distinguished from obstruction. Adynamic ileus in patients with cancer can be related to chemotherapeutic agents or can be secondary to other metabolic problems. Vincristine sulfate and the vinca alkaloids are known to produce peripheral neuropathies and a paralytic ileus. Drug-induced ileus is estimated to occur in 10% of patients receiving these agents and could be due to their neurotoxic effects.[44] Clinical presentation and radiologic studies are very helpful in differentiating adynamic ileus from a mechanical obstruction. With an adynamic ileus, generalized small bowel and colonic distension is apparent on plain films without the multiple air-fluid levels and absence of colonic gas that are seen with mechanical obstruction. Cross-sectional imaging with CT is now the adjunctive study of choice, since it can provide information simultaneously about the presence, level, severity, and cause of obstruction.[4,45]

Therapeutic options include nasogastric decompression with bowel rest (e.g., NPO with intravenous fluid support). Adjunctive treatment with analgesics, antiemetics, somatostatin, or motility agents have been used with varying success. Patients with a history of previous malignancy who present with bowel obstruction should be treated like any other patient with intestinal obstruction.[43] In the case of a first presentation with obstructive symptoms, the etiology is benign (e.g., due to adhesions or herniation) in up to one third of patients. Many patients who require laparotomy to treat their obstructions are found to have benign disease, and some even have a new primary malignancy.[46] Given a good baseline performance status, surgical exploration for benign causes of obstruction have a high rate of success.

Recurrence of cancer, either locally or as diffuse peritoneal disease, is a more common problem and, unfortunately, is more difficult to treat. Surgical intervention is required if bowel strangulation and infarction are suspected because of fever, leukocytosis, and localized peritoneal tenderness. Radiographic evidence of complete bowel obstruction with loss of air in the distal large bowel and absence of flatus may likewise prompt an urgent laparotomy. Patients with partial obstructions can be managed expectantly. Further evaluation to include CT scan or other contrast studies may be helpful in delineating level(s) or extent of obstruction (Fig. 53-2).

Successful nonoperative management of malignant bowel obstruction is reported in up to 29% of cases; however, recurrent episodes of obstruction are commonplace.[43] Operative mortality and successful intervention rates for patients with cancer undergoing exploratory laparotomy for intestinal obstruction are difficult to measure, since patient selection bias tends to skew the reported results. The extent of disease and failing performance status are associated with high perioperative morbidity and mortality.[43,47] Even with early relief of symptoms, durability of palliation can be short.

Retrospective studies have identified presence of ascites and multiple sites of obstruction as factors predictive of unsuccessful surgical

A B

Figure 53-2 • Small bowel obstruction in a patient with metatstatic appendiceal carcinoma. **A,** CT scan of the abdomen demonstrating a widely patent–stapled anastomosis from a prior right colectomy; **B,** Decompressed bowel distal to the point of obstruction *(arrow).* Findings at laparotomy were consistent with intractable bowel obstruction due to adhesions from small tumor implants.

intervention. Conversely, long disease-free interval, good nutritional status (albumin >3.0 mg/dL), and good performance status are predictive of successful laparotomy. However, each patient must be approached on an individual basis, and it is of paramount importance to combine surgical decision making with basic principles of palliative care in forming a treatment plan. The reported results of surgical treatment for intestinal obstruction in this patient population vary significantly. The site of the primary tumor may also influence the clinician's approach to management, since the natural history of a cancer should also be taken into account.

Stomach and Duodenum

The most common causes for upper GI obstruction involving the stomach or proximal duodenum in patients with cancer are benign peptic ulcer disease, primary carcinoma of the gastric antrum, and gastric outlet obstruction secondary to an upper GI, pancreatic, or biliary tract cancer. Symptoms due to obstruction at this level include nonbilious vomiting, postprandial pain, and epigastric fullness. On physical examination, a succussion splash or palpable mass is present in approximately one third of cases, reflecting ascites and tumor burden. Endoscopy is helpful for defining the site and cause of upper GI obstruction.

Benign, obstructive ulcer disease is uncommonly seen in the modern era of H2-receptor blockers and proton pump inhibitors. Operative therapy is generally required after initial stabilization with fluid resuscitation and nasogastric decompression in uncontrolled cases. Vagotomy with pyloroplasty is the treatment of choice, particularly for patients with cancer who might be debilitated. For obstructing primary gastric carcinomas, a curative resection with gastrojejunostomy reconstruction is recommended if the patient is stable and if the procedure is technically feasible. In cases of advanced disease, gastrostomy tube placement, with or without gastrojejunostomy (intestinal bypass), may be the best course of action. When gastric outlet obstruction is due to an unresectable pancreatic or biliary tract neoplasm, prognosis is typically poor owing to the extent of disease. Creation of a gastrojejunostomy via an open or laparoscopic approach can be considered for bypassing the obstruction and maintaining gastrointestinal continuity, but outcomes are not uniform. Many patients have poor emptying of stomach contents even with a mechanically patent anastomosis. Therapeutic endoscopic options are in their infancy, and success has been seen with endoscopically deployed metal endoluminal stents. This procedure is gaining widespread acceptance, and reports show 70% relief of symptoms with low complication rates. Common complications include perforation (0% to 15%) and stent migration (0% to 40%).[43,48] In patients with concomitant biliary obstruction from a cancer in the head of the pancreas, an endoscopic retrograde cholangiopancreatography can be performed at the same setting to accomplish biliary stenting with plastic or metal prostheses.

Small Intestine

Most malignant obstructions of the small intestines are a result of metastatic deposits from other cancers; primary tumors of the small bowel are rare. The most common malignancies that give rise to obstructive metastatic deposits are intra-abdominal tumors, such as colorectal, ovarian, pancreatic, and gastric cancers.[49] Carcinomatosis with resultant malignant bowel obstruction from appendiceal primaries (including pseudomyxoma peritonei) are seen less commonly. Symptoms of small bowel obstruction include crampy abdominal pain, distension, nausea, and vomiting. Physical examination usually reveals percussion tympany and high-pitched bowel sounds. Plain films of the abdomen reveal multiple air-fluid levels within the small intestine. A contrast study of the large bowel should be performed to determine whether distal obstruction is present, as carcinomatosis can involve multiple sites. If a partial small bowel obstruction is diagnosed (e.g., presence of gas in the large bowel), then nonoperative management is generally recommended.

During an exploratory laparotomy when intestinal bypass is being considered, it is preferable to perform the simplest procedure with maximal conservation of bowel length. Ileostomy or colostomy might be unavoidable, depending on the level of obstruction. At least one third of patients with symptomatic relief of malignant small bowel obstruction experience recurrence of the obstruction at a later point in time. Survival after bypass surgery for malignant obstruction is often short, and is a marker of advanced malignancy.

Colon and Rectum

Obstruction of the colon and rectum occurs approximately half as frequently as small bowel obstruction in the cancer patient population. Large bowel obstruction is more often a result of malignancy (i.e., primary or recurrent tumor) than of benign causes such as volvulus or diverticulitis. Symptoms include vomiting, crampy abdominal pain, bleeding, lack of flatus or stool, or change in bowel habits. Flat and upright abdominal films are important in the initial assessment of these patients. Follow-up contrast studies are helpful in delineating the site of obstruction.

Initial treatment should consist of nasogastric tube decompression and fluid resuscitation. If a total colonic obstruction is present, dilation of the proximal colon can lead to perforation of the cecum, especially if a competent ileocecal valve is present. Cecal dilation of 12 to 14 cm is associated with a high risk of perforation, and a decompressive procedure should be performed urgently to avoid this complication. A diverting colostomy may be the surgical therapy of choice if there is evidence of peritoneal carcinomatosis. If the obstruction is related to a primary colon cancer, resection with primary anastomosis or ostomy should be performed. Obstructive tumors of the rectum are often a harbinger of locally advanced primary rectal tumors or recurrent carcinomas after a previous low anterior resection. These tumors are often associated with evidence of distant metastatic disease or a high local recurrence rate if resection is performed. Therapeutic endoscopy with colonic stenting offers an alternative to surgical diversion, providing excellent palliation and allowing an elective procedure to be performed following bowel decompression and other treatments if necessary. There is no apparent difference in long-term survival rates with stents compared to an emergent operation.[50]

Palliation Issues in Bowel Obstruction

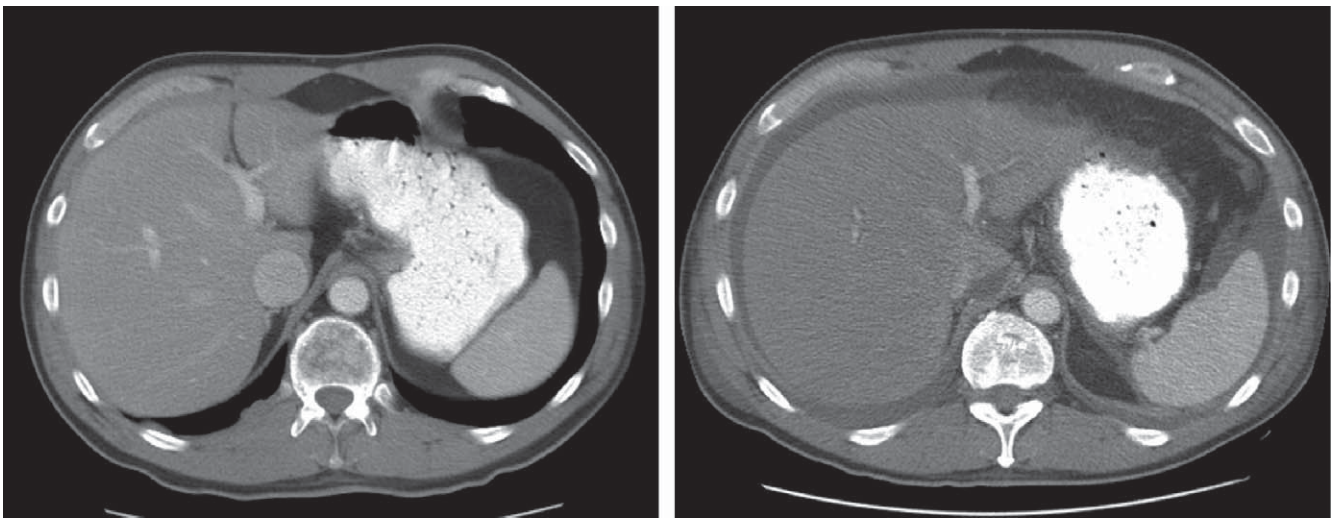
Heterogeneity of patient populations, coupled with lack of evidence-based medicine in this area, makes appropriate patient selection one of the biggest challenges in palliative surgery. End-stage cancer patients are diverse in multiple facets: symptoms experienced, tumor biology, extent of underlying disease, previous treatments received, type of palliative procedure performed, and psychosocial circumstances, to name a few. Deterioration of a patient's general medical condition can make operative treatment of bowel obstruction prohibitive or inappropriate. A patient might also wish to avoid further operative interventions in the face of terminal disease. In these patients, optimal medical management should be considered to help alleviate suffering from abdominal pain, nausea, vomiting, and dehydration.

Because of the nature of the underlying disease process, surgical resection and/or bypass might not yield durable palliation. Proper patient selection is paramount to successful palliative efforts. Recent series have reported effective palliation in up to 80% of patients with obstruction.[3] Another approach that has been described for the therapy of these patients is the use of a decompressive gastrostomy tube in conjunction with either enteral or parenteral fluids. Management of malignant bowel obstruction has to be coordinated with end-of-life care in some patients. Time to mortality with malignant bowel obstruction is short; small series report mean durations of survival ranging from 35 to 64 days regardless of intervention.[43,48,51,52]

GASTROINTESTINAL PROBLEMS FOLLOWING BONE MARROW TRANSPLANTATION

Evaluation of acute abdominal complaints in patients who have had BMT represents a major diagnostic challenge for the surgeon. Virtually all patients who have undergone BMT will experience gastrointestinal problems at some point in the post-transplant period; these can include nausea, vomiting, alterations in liver function tests, diarrhea, and abdominal pain.[39] Such findings in an acutely ill patient following BMT may herald a broad spectrum of acute abdominal processes. There are, however, several disease entities that are unique to the BMT patient, and these warrant special consideration.

There are three common causes of abdominal complaints in the BMT patient that are unique:



1. High-dose induction chemotherapy or chemoradiation therapy given before transplantation
2. Acute intestinal graft-versus-host disease (GVHD) in recipients of allogeneic transplants
3. Infections of the gut that occur before bone marrow recovery

The post-transplant period at which each of these potential complaints becomes problematic differs. Injury to the gastrointestinal tract and liver after high-dose chemotherapy and radiation is usually present by day 10; the process is transient and usually resolves after several weeks. Acute GVHD appears between 2 and 8 weeks after allogeneic BMT, while chronic GVHD is manifest from 3 to 15 months after BMT. In patients receiving HLA-mismatched marrow, the onset of acute GVHD could be as early as 7 days. Lower GI tract involvement with acute GVHD is characterized by diarrhea and abdominal cramping and is often severe in its presentation. GVHD affecting the upper GI tract is characterized by anorexia, dyspepsia, nausea, and vomiting. Biopsies of affected portions of the GI tract for histologic examination are diagnostic, though diagnosis is often made on clinical grounds. Immunosuppression with combination therapy is the cornerstone of treatment.

Infections of the gut caused by bacteria and fungus are most often seen before post-transplant day 30, while viral infections are usually seen after 30 days, although there are reports of late (5 months to 1 year) reactuation of varicella zoster infection associated with acute abdominal pain, hepatitis and pancreatitis, or disseminated disease. Mortality rates are from 50% to 100%.[53,54]

GVHD is a process in which donor T-cells react to recipient cells; it develops in 30% to 50% of patients receiving allogeneic grafts.[55,56] Despite the prominence of intra-abdominal organs and symptoms in the manifestations of GVHD, it is rare that surgical intervention is necessary. The most common indications for abdominal surgery in patients with GVHD are gastrointestinal bleeding and obstruction.[56,57] Perforation of the bowel is uncommon. The finding of pneumatosis intestinalis on abdominal radiography has been reported to be present in as many as 18% of BMT patients with acute GVHD;[58] the majority of these cases do not require operation.[54,59–61] Although usually an indication for surgery, free air in the peritoneal cavity need not be associated with a frank bowel perforation, and there are reports of managing this problem without an operation.

Another intra-abdominal complication of BMT that presents with abdominal pain is venoocclusive disease (VOD) of the liver.[39,62] The etiology of VOD is thought to be damage to the endothelium of hepatic venules and centrilobular hepatic necrosis, leading to fibrosis and occlusion of the central hepatic veins. VOD is associated with significant mortality. The differential diagnosis of VOD is lengthy and includes any disorder that could result in right upper quadrant pain, jaundice, or ascites. A partial list would include such disorders as hepatitis, drug- or parenteral nutrition-induced liver dysfunction, acute cholecystitis, cholangitis, or liver abscess; careful work-up should be undertaken. The diagnosis of VOD can usually be made on clinical signs, liver biopsy being reserved for patients in whom the diagnosis is not certain (Fig. 53-3). Because of underlying hematologic disorders, liver biopsies are associated with acute bleeding and must be performed with care. The treatment of VOD is supportive, with emphasis on maintaining intravascular volume and renal

A B

Figure 53-3 • Venoocclusive disease following bone marrow transplant. **A,** CT scan of the abdomen demonstrating no abnormalities of the liver. **B,** Following allogeneic peripheral stem cell transplant for refractory large B-cell lymphoma, this patient developed increasing fatigue, abdominal distention, and elevated liver function tests. CT scan showed new findings of ascites and low-density diffusion of the liver. Subsequent laparoscopic biopsy of the liver confirmed venoocclusive disease.

perfusion while limiting the amount of sodium and extravascular fluid accumulation.

In summary, BMT has become a proven and accepted treatment for a number of hematologic and solid malignancies. Transplant-related complications, such as GVHD and VOD, remain a major cause of morbidity and mortality. The presentation and sequelae of both these disease entities present difficult diagnostic and management challenges for the clinician. Although the management of GVHD and VOD is primarily medical, surgical consultation could be required for evaluation of abdominal pain and distension, nausea, vomiting, diarrhea, hyperbilirubinemia, or other gastrointestinal complaints. An understanding of the manifestations of these complications, together with vigilant clinical evaluation, is paramount to determine when surgical intervention is necessary in this complex patient population.

FISTULAE

A fistula is an abnormal connection between two epithelialized surfaces, and fistula formation is an important complication of cancer and its treatment. Fistulae that complicate cancers have been reported between the stomach and pericardium, the biliary and bronchial trees, the portal and systemic circulations, and the alimentary canal and vascular system, to name a few. This overview concentrates on the more routine fistulae connecting the skin, alimentary canal, and genitourinary tract in various combinations.

Fistulae are seen as complications in patients with cancer because multiple risk factors for fistula development are often present in these patients.[63] Fistulae are rarely the presenting symptom of an intra-abdominal malignancy; they most often present as complications during or after treatments. Most clinicians agree that contributing factors include prior abdominal surgery, inflammatory bowel disease, use of radiation therapy, cancer, malnutrition, and intra-abdominal sepsis. Unfortunately, many of these factors are prevalent in patients with cancer and are not often reversible. Despite the use of total parenteral nutrition, enteral nutrition, antibiotics, and highly sophisticated bioengineered wound care adjuncts, mortality and morbidity rates from gastrointestinal fistulae remain high. Although mortality rates as low as 7% are reported, numbers in the range of 10% to 30% are more representative.[64,65] The exact incidence of GI fistula formation in patients with cancer is not known but is likely quite low.

Enterocutaneous fistulae commonly occur in patients who have received radiation therapy. Direct invasion with subsequent tumor necrosis can result in an abnormal connection between viscera and the skin. Ischemic necrosis secondary to neoplastic vascular invasion or secondary to small vessel occlusion from host reaction and sclerosis likewise can lead to fistula formation. Finally, tumor-induced perforation with abscess and subsequent erosion can result in fistula formation. This latter mechanism is particularly troublesome, as it can lead to diagnostic confusion and can complicate management. Ionizing radiation could have both acute and chronic effects on the GI tract. The acute effects—a result of the depletion of rapidly proliferating mucosal cells causing diarrhea, nausea, vomiting, abdominal pain, and GI tract bleeding—are generally self-limiting. However, chronic radiation damage can become evident as early as 1 month after radiation therapy, or it might not be clinically apparent for as long as 30 years after treatment.[66,67] Although radiation injury to the bowel can arise as a complication in as many as 15% of patients receiving treatment to abdominal fields, fistulae occur more rarely. Factors related to the incidence of radiation-induced injury include the total radiation dose and fractionation, the sensitivity of exposed normal organs within the radiation port, anatomic considerations, the presence of comorbid conditions, and concomitant administration of other drugs.

Bowel tolerance of radiation therapy is limited. The small bowel, stomach, and colon are the least tolerant organs, with a maximum tolerated dose of 45 Gy. The greater the amount and extent of exposure to the radiation beam, the greater is the risk of injury.[68] Factors that tend to fix the bowel in a single location, such as postoperative adhesions, increase the likelihood of radiation enteritis. Pre-existent large-vessel atherosclerosis and small-vessel diabetic vasculopathy can increase sensitivity to radiation injury. Finally, the effects of many chemotherapeutic agents—especially doxorubicin, 5-fluorouracil, gemcitibine, and mitomycin-C—can potentiate the effects of radiation therapy, increasing its toxicity. In this regard, pyrimidine analogs

such as bromodeoxyuridine and iododeoxyuridine are being studied as tumor-selective radiation sensitizers.[69] Many techniques have been developed to limit GI tract exposure to radiation, including the use of shielding and conformal mapping techniques as well as intra-operative radiation therapy, whereby normal visceral structures can be better shielded from the radiation ports.[70]

Fistulae that complicate cancer generally occur during active treatment or subsequent follow-up. To reduce the risk of fistula formation following surgical procedures, adherence to good surgical principles and techniques is thought to be helpful. Systemic antibiotics might help to prevent complications (including fistulae) in these situations. Intra-operative risk factors for fistula formation include active infection, extensive adhesions, creation of serosal injuries, prior radiation therapy, prior fistulization, and presence of ischemic tissue. Thorough drainage of all intra-abdominal infection and debridement of all devitalized and ischemic tissue can reduce the incidence of fistulae. Protection of sites of anastomosis or extensive dissection could also be important, particularly in the previously irradiated abdomen. Vascularized flaps, including serosa, omentum, and muscle, have all been described to fill soft tissue defects and exclude small bowel from areas of dissection.[71] Many investigators have demonstrated the relationship of nutritional status to operative morbidity and mortality, including fistulae. In patients with cancer who developed postoperative gastrointestinal fistulas, an albumin level of less than 3.0 g/dL was a poor prognostic factor for fistula closure.

GI fistulae occur commonly during the treatment of gynecologic malignancies. Although less common, they also occur in the settings of bladder and rectal cancer. Postoperative irradiation after the extensive pelvic operations exposes the bowel to high doses of ionizing radiation. Fistulae resulting from the treatment of other cancers are much less common.

A number of factors decrease the likelihood of spontaneous closure of a fistula. The most common are undrained infections and luminal obstruction distal to the fistula. Other factors include prior radiation or chemotherapy, epithelialization of the fistula tract, cancer within the tract, granulomatous disease (e.g., inflammatory bowel disease or mycobacterial infection) within the fistula, presence of a foreign body, and malnutrition. Although predictive of morbidity due to fistulae, fistula output does not necessarily appear to be related to the probability of spontaneous fistula closure. Given proper nutritional support and attention to these factors, as many as 60% of GI fistulae can close spontaneously.[64,65]

Complications that are routinely encountered with GI fistula include fluid and electrolyte disorders, sepsis, malnutrition, and impaired skin integrity. The frequency and severity of these complications relate to the daily volume of fistula output and to the composition of the output. High-output fistulae (>1 L/day) tend to originate more proximally in the GI tract. Because of the specialized composition of gastric juice, bile, and succus pancreaticus, these more proximal fistulae not only tend to lead to dehydration but also are more prone to cause electrolyte and acid-base imbalances. Low-output fistulae generally originate more distally in the alimentary canal, resulting in low-volume outputs that are generally isotonic. For these reasons, the classification of fistulae according to their daily output volume can help to predict the likelihood and kinds of complications to be expected.

Resuscitation of patients with GI fistulae follows the principles of general fluid and electrolyte assessment and management. A urinary catheter and, if necessary, central venous pressure monitoring are quite helpful. Specific fluid, electrolyte, and acid-base disturbances, organ dysfunction, and nutritional status should be identified with the initial bloodwork and treated appropriately. Subsequent diagnostic and therapeutic maneuvers must await completion of the resuscitation phase, so these issues must be dealt with promptly, over the initial 12 to 48 hours after presentation.

Patients who exhibit signs of sepsis must be evaluated aggressively to identify the source. Intra-abdominal and perifistular abscesses are common and must be identified quickly. Thorough physical examination (including digital examination of the rectum, vagina, stomas, and wounds) is absolutely necessary. CT scanning of the abdomen and pelvis using intravenous and enteric contrast and contrast in the rectum, fistula tract, and drainage tubes is often the most enlightening radiologic study (Fig. 53-4). Any undrained foci of infection must be addressed aggressively and drained either percutaneously or operatively. Once the acute electrolyte imbalances have been corrected and the fistula output has stabilized, intravenous fluid and nutritional infusions may be combined to simplify fluid management. Definitive treatment of fistulae ultimately requires the reestablishment of normal skin integrity; macerated skin and large open wounds complicate and delay spontaneous or operative closure. Techniques such as sump drainage, stoma bag application, and barrier protection of the skin using special adhesives or pastes should be used liberally.

Malnutrition either pre-exists or will develop in nearly all patients with GI fistulae unless specific, aggressive nutrition support is initiated early in the treatment course. Either enteral or parenteral nutrition support can generally be started as soon as the initial resuscitative and stabilization measures have been accomplished. Formal nitrogen balance studies and indirect calorimetric measurement of energy expenditure are the gold standards for adjusting protein and calorie intake to meet needs. Once requirements have been determined, the route of administration that is chosen depends on overall patient status and the nature of the fistula. In general, early initiation of parenteral nutrition is helpful to ensure adequate support without delay. Subsequent aggressive attempts should be made to meet some or all of the patient's nutritional requirements enterally.

Fistulae can be managed appropriately only when their anatomic features are well defined. Reversible causes for fistulae failing to close spontaneously must be identified. Careful examination of the fistula with appropriate biopsies is necessary to rule out epithelialization or the presence of cancer. Generally, the entire GI tract should be investigated with radiographic contrast studies to rule out distal obstruction, to determine the origin of the fistula accurately, and to identify all involved organs and poorly drained associated abscesses. A fistulogram, obtained in the presence of an experienced surgeon, can provide valuable anatomic information and can help in the formulation of surgical plans. In patients with cancer, a thorough search for recurrent and metastatic disease is also important.

In patients who are stable and in whom no factors preventing spontaneous fistula closure are present, a trial period of nonsurgical management is generally indicated. The availability of parenteral and enteral nutrition support programs should be coordinated with home care services to allow for spontaneous closure. In some patients, adequate stabilization cannot be achieved. Ongoing fistula output or sepsis in these patients precludes nutritional repletion, adequate skin care, and protection of end-organ function. In this setting, early operation is mandatory.

The operative goals for treating intestinal fistulae are to effect excision of the fistula tract and associated diseased tissue, restore continuity of the GI tract, and prevent recurrent fistulae. Use of vascularized omental, mesenteric, bowel, or muscular flaps to fill inflamed cavities and protect anastomoses is often helpful and should be planned for in conjunction with appropriate consultants preoperatively. The definitive operation is a good opportunity to simplify subsequent management of the patient through the insertion of enteric tubes for feeding and GI drainage. Bypass of fistulae can be a useful palliative technique when definitive resection is technically impossible or is thought to be associated with prohibitive morbidity.

Figure 53-4 • Arterioenterocutaneous fistula. Patient with a multiply recurrent high-grade liposarcoma of the spermatic cord treated with radical surgical resection and radiation therapy. After the most recent surgery, the patient developed an enterocutaneous fistula that was managed conservatively. He later presented with brisk bleeding from the fistula and per rectum. **A,** CT scan of the pelvis demonstrating recurrent tumor and tract *(arrows)* of enterocutaneous fistula. **B,** Arteriogram with contrast extravasation from the left external iliac artery and communication of the bowel *(arrow).*

F. LOCAL EFFECTS OF CANCER AND ITS METASTASIS

54 Superior Vena Cava Syndrome

David H. Johnson, Janessa Laskin, Anthony Cmelak, Steven Meranze, and John Robert Roberts

SUMMARY OF KEY POINTS

Etiology
- Superior vena cava (SVC) syndrome is usually due to neoplastic process—predominantly primary lung carcinoma, with a disproportionate number of patients having small cell histology; non-Hodgkin's lymphoma and metastatic tumors are the next most common.
- SVC syndrome can be iatrogenic—sometimes seen as a complication of central venous line or cardiac surgery.

Anatomy and Physiology
- Junction of the brachiocephalic veins forms the thin-walled, low-pressure SVC, which is subjected to obstruction from a variety of mediastinal components.
- External compression often precedes direct tumor invasion or thrombus formation.
- The SVC has an extensive collateral network.

Clinical Features
- Usual symptoms are head "fullness," dyspnea, cough, and chest pain, typically with insidious onset.
- More severe symptoms are infrequent, and life-threatening, neurologic symptoms are rare.
- Diagnosis is based on clinical findings.

Evaluation
- Chest radiograph typically shows mediastinal widening; a mass is often seen in the region of the SVC.
- Small-dose cavagrams can be safely accomplished to define exact location and routes of collateral flow.
- Computed tomography (CT) scanning identifies the mass and collateral flow and is the most helpful study to guide treatment.
- Treatment of an identified mass before histologic diagnosis is rarely justified unless prior diagnosis is established.
- Methods used to define histology are sputum cytology, bronchoscopy, lymph node biopsy, thoracentesis, percutaneous biopsy, mediastinoscopy, and thoracotomy; previously reported high risks associated with these procedures are not borne out in current data.

Treatment
- Radiation therapy with or without chemotherapy is the preferred treatment in most malignant causes of SVC obstruction, particularly small cell lung cancer (SCLC) and non-Hodgkin's lymphoma.
- Radiation therapy fractionation schedule depends on tumor histology, stage, prognosis, patient's general condition, and whether obstruction is acute or subacute.
- Surgery is usually reserved for selective patients with benign causes of obstruction and consists of a bypass procedure.
- Percutaneously placed, self-expanding intravascular wire stents provide an option or adjunct to other procedures in the palliative treatment of patients (usually with malignant disease).

INTRODUCTION

Obstruction of the superior vena cava (SVC) may occur as an acute or subacute process producing a syndrome with characteristic features including facial edema and plethora, dilation of chest wall and neck veins, mild to moderate respiratory difficulty, and, less commonly, conjunctival edema, central nervous system complaints such as headache, or, more rarely, visual disturbances and signs of altered states of consciousness.[1–4] The first recorded description of SVC obstruction (SVCO) occurred in 1757 when William Hunter described the entity in a patient with syphilitic aortic aneurysm.[5] For nearly two centuries thereafter, nonmalignant processes such as aortic aneurysms, syphilitic aortitis, or chronic mediastinitis due to tuberculosis were the predominant etiologic factors.[1,3,6,7] However, these diseases are now quite rare, and cancer has become the leading cause of SVCO primarily because of the rapid increase in the incidence of bronchogenic carcinoma after World War II.[1,3,6,8–10] Although SVCO was once considered a medical emergency, it is now well established that patients with SVCO rarely experience immediate, life-threatening complications.[6,11–13] Consequently, in cases in which a diagnosis is not known, it is appropriate to proceed with a biopsy to establish the underlying cause, because optimal management is dependent on etiology.[14]

ANATOMY AND PATHOPHYSIOLOGY

The SVC is formed by the junction of the brachiocephalic veins, which in turn are formed by the joining of the internal jugular and subclavian veins. Thus, the SVC represents the major drainage system of venous blood from the head, neck, arms, and upper thorax.[15] The right and left brachiocephalic veins join at about the level of the sternal angle to form the SVC. The SVC descends on the right side of the ascending aorta and empties into the right atrium, with its distal 2 cm lying within the pericardial sac (Fig. 54-1).

Because of its mediastinal location surrounded by several rigid structures including the sternum, trachea, pulmonary artery, right main-stem bronchus, and numerous lymph nodes, the SVC is particularly vulnerable to obstruction. Despite being a relatively large

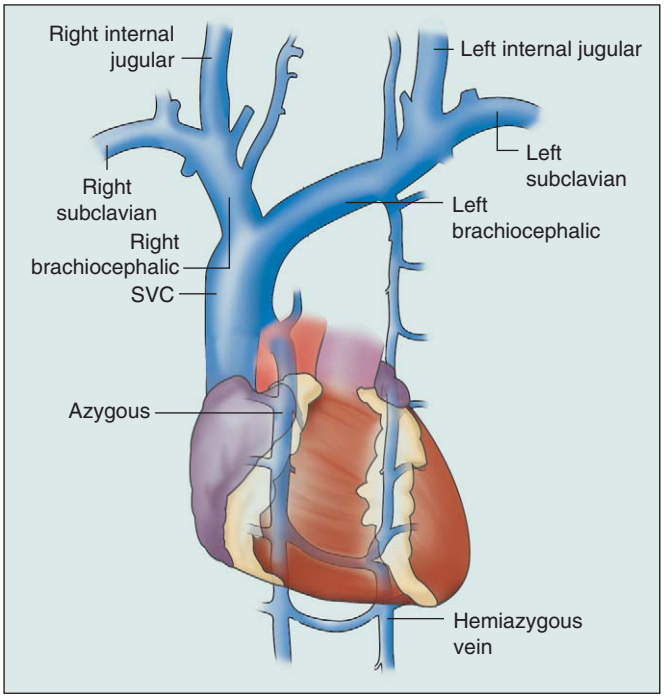

Figure 54-1 • Normal anatomy and drainage pattern of the superior vena cava.

vessel, its thin vascular walls and low intravascular pressure contribute to the ease with which the SVC can be obstructed.[15] SVCO can be caused by external compression due to tumor or by lymph nodes enlarged by inflammation or metastases (Fig. 54-2). SVCO also can be caused by direct tumor invasion or by a thrombus. Secondary thrombus is reported to occur in up to 50% of cases[2] and may contribute to the lack of response to appropriate therapeutic maneuvers.

The azygous vein represents an important collateral system of the SVC and is formed by the junction of the right subcostal and right ascending lumbar veins. Additional routes of collateral flow include the mammary, vertebral, lateral thoracic, paraspinous, and esophageal vessels. The azygous vein ascends through the posterior and superior mediastinum, arches over the hilum of the right lung, and ends in the SVC. Fortunately, extensive anastomoses are formed between the SVC, azygous, and vertebral systems, providing multiple routes of collateral blood flow. Therefore, an obstruction of the SVC above the orifice of the azygous vein is better tolerated than is blockage below this level, because blood can be diverted through chest-wall veins into the thoracic and iliac veins and enter the heart by way of the inferior vena cava and azygous systems.[9,15,16] Blood from the head and neck also can return to the heart via the vertebral plexus. If the SVC is obstructed between the azygous vein and the heart, the only route of blood return is via the inferior vena cava.

ETIOLOGY

Since the middle part of the 20th century, cancer has been the principal cause of SVCO, with bronchogenic carcinoma accounting for up to 85% of cases (Table 54-1).[1–3,8,11,17–21] The two most frequent lung cancer histologic types associated with SVCO are small cell and

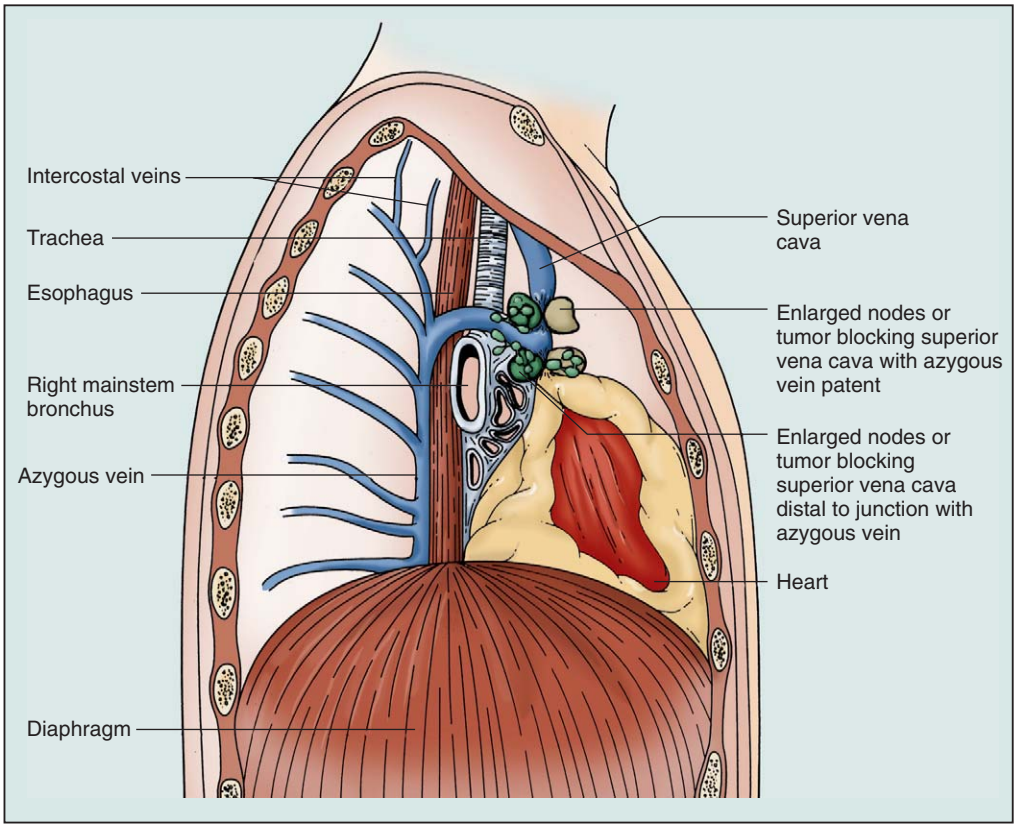

Figure 54-2 • Lateral view of the thorax with superior vena cava obstruction.

Data compiled from references 1–3, 11, 17–19, and 21.

squamous cell carcinoma.[1,15,22–24] Although small cell lung cancer (SCLC) accounts for just 15% to 20% of newly diagnosed lung cancers, it is the underlying cause of up to 65% of all cases of SVCO.[6,9,22,25,26] The tendency of SCLC to occur centrally within the lung, as well as its high incidence of mediastinal lymph node metastases, most likely accounts for this consistent observation. Although lung cancer is the leading cause of SVCO, the incidence of this syndrome in patients with lung cancer ranges from 3% to 30%, with most series tending toward the lower figure.[4,12,27]

Non-Hodgkin's lymphoma is the second most common cause of SVCO.[3,6,28,29] Perez-Soler and colleagues[29] identified 36 cases among 915 lymphoma patients treated at the M.D. Anderson Cancer Center (University of Texas, Houston). SVCO was most commonly observed with diffuse large cell and lymphoblastic lymphomas.[29] The frequency of mediastinal presentations with the latter histologic types may account for this association, because up to 65% of patients with lymphoblastic lymphomas are first seen with a mediastinal mass. The incidence of SVCO in these categories of non-Hodgkin's lymphoma is reported to be 7% and 20%, respectively.[29]

Metastatic cancers account for approximately 5% to 10% of SVCOs (see Table 54-1).[1,3,8,11,18,21,30–32] The most common primary tumor sites are, in approximate order of frequency: breast cancer, germ cell malignancies, and gastrointestinal cancers. Less common primary sites include sarcomas (including primary sarcomas of the great vessels),[33–35] transitional cell carcinoma, prostate cancer, and melanomas.[32] However, virtually any cancer capable of metastasizing to the mediastinum can result in SVCO.

Nonmalignant causes of SVCO account for up to 5% of cases. An increasingly common benign cause of SVCO is central venous catheter-induced thrombosis, which may occur with cardiac pacemakers, LaVeen shunts, hyperalimentation lines, and Swan-Ganz catheters, as well as those used for chemotherapy administration.[8,36–43] SVCO seems to be more common when the tip of the catheter is placed in the left subclavian vein in the upper part of the vena cava.[40] The incidence of catheter-related thrombosis may be reduced with the administration of very-low-dose warfarin (1 mg/day) before insertion of the catheter and continuation afterward.[44,45] Additional rare benign causes of SVCO include chronic mediastinitis secondary to histoplasmosis, retrosternal goiters, *Nocardia* infection, and congestive heart failure.[3,46–50]

In children, SVCO is most frequently related to iatrogenic causes secondary to cardiovascular surgery for congenital heart disease or ventriculoatrial shunts for hydrocephalus.[51–53] The most common malignant causes of SVCO in children are non-Hodgkin's lymphoma, acute lymphoblastic leukemia, Hodgkin's disease, neuroblastomas, and yolk sac tumors.[51,53]

CLINICAL FEATURES

Although the duration of symptoms may range from a few days to several weeks, a majority of patients have symptoms of 4 weeks' duration or less.[1] The physical findings accompanying SVCO are diagnostic (Fig. 54-3). Patients frequently complain of a sense of head "fullness," mild dyspnea, cough, chest pain, and occasionally dysphagia (Table 54-2).[1,3,13,21,25,53] Less frequently arm edema, stridor, upper body cyanosis, and neurologic symptoms (e.g., headaches or lethargy) may occur. All symptoms may be aggravated by positional changes, particularly those associated with lowering of the head, for example bending to put on shoes.

The prospect of catastrophic neurologic events has led to the characterization of SVCO as an "oncologic emergency."[4,9,53] However, experimental studies in dogs as well as several recent reviews have conclusively demonstrated that life-threatening neurologic symptoms such as seizures, syncope, or coma rarely occur.[6,8,13,14,16]

RADIOGRAPHIC FINDINGS AND DIAGNOSTIC STUDIES

Imaging Studies

A standard chest radiograph is the first radiographic procedure performed when SVCO is suspected, with the most common abnormality being mediastinal widening. Typically, a mass is found in the superior mediastinum, right hilum or perihilar region, or right upper lobe[3,4]; however, a normal chest radiograph is not inconsistent with the diagnosis of SVCO.[3]

A contrast-enhanced chest computed tomography (CT) scan provides visualization of extravascular and intravascular tumor, as well as thrombus formation within the SVC, and also demonstrates collateral flow.[54–61] A CT diagnosis depends on diminished or absent contrast opacification of central venous structures such as the innominate vein or the SVC inferior to the obstruction, and opacification of collateral venous routes,[59] especially anterior subcutaneous collaterals (Fig. 54-4).[54] Because dilution of the contrast medium by unopacified blood or the displacement of blood by laminar flow may simulate an intraluminal filling defect, both criteria must be present for the diagnosis of SVCO to be made.[59] The anatomy defined by CT scan may help to guide a fine-needle aspiration biopsy or another diagnostic procedure if a histologic diagnosis has not been previously established. The current-generation helical CT scans also have been used to diagnose SVCO with results that correlate well with regular contrast CT scans.[58] In addition, helical scans can potentially reveal more information regarding the site and extent of disease

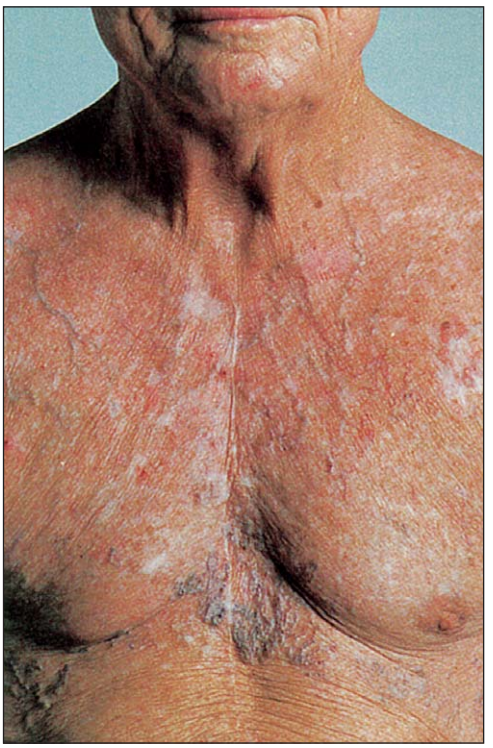

Figure 54-3 • A patient with characteristic venous dilation and facial edema.

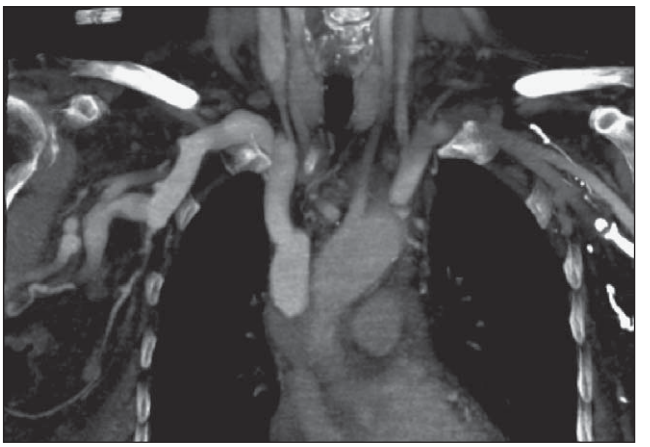

Figure 54-4 • Chest computed tomography venogram scan of a patient with superior vena cava obstruction. Note the abrupt blockage of contrast dye indicative of the superior vena cava obstruction.

and the collateral pathways involved, as well as define soft-tissue abnormalities.

Contrast venacavograms may still play an occasional role in determining management strategy, particularly when surgical bypass or stenting is being considered.[62] Current techniques using low-osmolarity contrast involve the positioning of a small catheter in the desired vascular location under fluoroscopic guidance with injection of only small amounts of contrast dye necessary to define the pattern of venous flow and degree of SVCO.[62] Collateral circulation is usually identified readily, and complications are uncommon. Cavography also is possible by using nuclear medicine techniques.[63–66]

In the majority of cases of SVCO, a contrast CT scan will be the most useful radiographic study; noncontrast studies are of limited value, because the vessels are difficult to distinguish. However, occasionally other imaging studies may also provide helpful data.[56,57] For example, transesophageal echocardiography can be used to distinguish thrombus formation from extrinsic compression of the SVC.[67] Single-photon emission CT has been used to identify obstruction of the SVC by an intravascular metastasis from an adenocarcinoma.[68]

DIAGNOSTIC APPROACH

In the absence of a known cause of SVCO, every effort should be made to obtain a histologic diagnosis before the initiation of any therapy (Box 54-1) for two reasons.[6,8,13,14] First, a definitive diagnosis is necessary to plan therapy, and second, even a brief course of radiation therapy before establishing a diagnosis can make histologic diagnosis difficult or even impossible.[14,69,70]

The least invasive diagnostic technique should be performed initially, followed by more invasive procedures as necessary (Box 54-2). Procedures commonly used to establish a tissue diagnosis include

Box 54-1. HISTOLOGIC CONFIRMATION OF UNDERLYING CAUSE OF SUPERIOR VENA CAVA OBSTRUCTION

In most cases the distinction between carcinoma and lymphoma is readily accomplished with routine hematoxylin and eosin stains. Special studies sometimes required to distinguish these entities include the following:

1. Immunoperoxidase stains
   a. Common leukocyte antigen; positive in lymphoma, negative in carcinomas
   b. Epithelial membrane antigen or keratin; positive in carcinomas, negative in lymphomas
   c. Surface immunoglobulins; positive in B-cell lymphomas, negative in carcinomas
2. Electron microscopy
   a. Desmosomes and intracellular junctions typical of carcinomas
   b. Microvilli typical of adenocarcinomas
   c. Dense-core granule (neurosecretory) present in neuroendocrine tumors (e.g., small cell lung cancer)
   d. Transformed lymphocytes, identified from a paucity of organelles, abundant free ribosomes, prominent nucleoli, and occasional presence of nuclear blebs

Immunoperoxidase studies can usually be obtained relatively quickly and are most helpful in distinguishing a lymphoma from a carcinoma. However, expensive pathology studies are avoided unless necessary to help guide therapeutic decisions.

Box 54-2. APPROACH TO PATIENTS WITH SUPERIOR VENA CAVA OBSTRUCTION

Diagnosis is established by physical examination and clinical presentation (see text).

- Respiratory status should be assessed promptly. Only patients in extremis should be treated urgently with radiation without a histologic diagnosis. Emergency radiation therapy is necessary in fewer than 5% of all SVCO cases. Stent insertion can also be considered as first-line therapy for patients with malignant cases of SVCO.
- Diagnostic evaluation should proceed with least invasive procedures performed initially followed by more invasive procedures as needed to obtain histologic diagnosis:
  - Chest radiograph
  - Sputum cytology
  - Thoracentesis with cytologic evaluation of fluid
  - Node biopsy if palpable node is present, avoid fine-needle aspiration if lymphoma suspected
  - Fiberoptic bronchoscopy
  - Mediastinoscopy
  - Thoracostomy
  - Evaluation may vary depending on the age and sex of the patient.
- In older adults (i.e., ≥50), the most common cause of SVCO is lung cancer; lymphoma or metastatic cancer are less common and benign processes are uncommon.
- In young adults (<50 years old), the most common cause of SVCO is lymphoma (usually large cell lymphoma or lymphoblastic lymphoma; rarely Hodgkin's disease); lung cancer or rare thoracic malignancy are less common, and germ cell cancer (almost never in females) and benign causes all uncommon. The preceding evaluation should be modified to include the following studies before more invasive procedures:
- Serum tumor markers (i.e., β-human chorionic gonadotropin, α-fetoprotein, lactate dehydrogenase)
- Bone marrow aspiration and biopsy

sputum cytology, bronchoscopy, lymph node biopsy, thoracotomy, and mediastinoscopy, although the diagnosis is sometimes obtained through other means such as thoracentesis and percutaneous lung biopsy with or without ultrasound guidance.[6,17,71–73] The complication rate of invasive procedures in the face of SVCO is fairly modest. Schraufnagel and associates[13] reviewed the outcome of 93 invasive procedures in 62 patients with diagnostic problems, and none of the procedures, including bronchoscopies and mediastinoscopies, was associated with a fatal outcome. Yellin and coworkers[21] performed 27 invasive diagnostic procedures in 63 patients with SVCO. No mortality or major bleeding episodes were observed, and diagnostic material was obtained in 89% of patients. Ahmann[6] reported that complications of bronchoscopy and lymph node biopsies are virtually nonexistent and that contrast studies, such as nuclear medicine venography, are remarkably safe in the presence of SVCO. Of the various invasive procedures used to obtain tissue in patients with SVCO, mediastinoscopy seems to be the most risky. However, even this procedure has a relatively low complication rate. Mineo and colleagues[73] reviewed the outcome of 80 patients who underwent diagnostic mediastinoscopy for SVCO by a single surgeon over a 23-year period. Five patients had significant bleeding, but only one required an urgent sternotomy, and no perioperative mortality was recorded. A definitive diagnosis was made in all of the patients; therefore, mediastinoscopy should be considered if less invasive procedures are unsuccessful at determining a diagnosis (Table 54-3).[17,72,74,75]

Special pathologic studies may be needed to establish a diagnosis when routine histologic assessment is unclear or available tissue is scant. Other laboratory studies such as serum tumor marker (e.g., β-human chorionic gonadotropin and α-fetoprotein) determination may be useful in selected cases. For example, the presence of an

Table 54-3 Diagnostic Procedures, Yield, and Complication Rate in Superior Vena Cava Obstruction

Procedure	No. Performed	No. Diagnostic	Complications
Sputum cytology	30	8	0
Bronchoscopy	84	39	1
Thoracotomy	22	21	0
Mediastinoscopy	132	124	13
Lymph node biopsy	44	30	0
Bone marrow	13	3	0

Data compiled from references 13, 21, 31, 55, 73, 75, and 147.

elevated β-human chorionic gonadotropin and/or an abnormal α-fetoprotein in a young male patient with SVCO is virtually diagnostic of an underlying germ cell malignancy. In the latter situation, no further workup is needed before initiation of chemotherapy.

The diagnostic yield from various noninvasive and invasive procedures ranges from approximately 20% for cytologic studies to virtually 100% with thoracotomy and mediastinoscopy (see Table 54-3).[73,75] Although these findings may reflect publication bias, the existing data argue against the need for immediate irradiation without a histologic diagnosis in most cases. In rare circumstances, a definitive tissue diagnosis cannot be made in a timely manner. In such cases it is appropriate to proceed with radiotherapy or placement of an endovascular stent, because either therapy is effective for most underlying causes of SVCO. Prudence dictates that prolonged attempts to establish a histologic diagnosis should be discouraged in the presence of severe dyspnea due to tracheal compression or rapidly progressive neurologic symptoms. Furthermore, in circumstances in which SVCO occurs in an individual with an established diagnosis of cancer or other known cause, an attempt to reestablish the histology of the underlying cause clearly is not a productive exercise.[13]

TREATMENT

Radiotherapy

Radiotherapy is the most commonly used treatment modality for SVCO after a malignant etiology has been established. Three factors must be considered before radiation delivery: (1) dose fractionation (fraction size and timing), (2) total dose to be delivered, and (3) volume to be irradiated, or "field size."[9]

Dose Fractionation

Considerable controversy is found in the radiation oncology literature over the past 40 years regarding fractionation in patients with SVCO. Before 1960, treatment of SVCO generally consisted of low-dose (i.e., 50–100 cGy) fractions to avoid inducing "radiation edema," which was assumed to cause further compromise of SVC patency and worsen associated symptoms.[76] In reality, however, the fear of producing further SVC compromise by radiation-induced edema was largely unfounded, and symptoms previously ascribed to radiation edema were predominantly due to inadequately treated tumor, causing progressive obstruction.[23]

Rubin and associates[23] undertook a retrospective comparison of a high-fraction regimen (400 cGy/day) with historical controls treated with lower fraction schedules (200 cGy/day). They noted more prompt relief of facial swelling after an initial high-dose-per-fraction schedule. The apparent superiority of high-dose-per-fraction regimens in providing faster symptom relief has been corroborated in several other retrospective nonrandomized studies.[1,2,13,14,16,19,22,77] In contrast, Perez and colleagues[4] found the high-dose-per-fraction regimen only slightly better than conventional fractions. It is our belief that for the management of potentially curable patients, 300-cGy fractions for the first 2 to 3 days is reasonable therapy for those experiencing rapidly progressive and distressing SVCO. Thereafter, the daily fraction size can be safely reduced, and the total dose adjusted to compensate for the number of initial high-dose fractions. Patients with subacute SVCO treated with curative intent should be managed with conventional (e.g., 200 cGy) fractions throughout their treatment course. Effects on surrounding normal tissues treated to tolerance doses are more predictable with standard fractions. Appropriate oblique fields with spinal cord shielding can later be used to boost the target volume.

In patients with extrathoracic disease who are treated with palliative intent, total radiotherapy doses will probably be lower, and the use of higher fraction sizes (e.g., ≥300 cGy) for the entire course of radiation is appropriate. With two hypofractionated regimens with 8-Gy fractions, Rodrigues and associates[77] concluded that 24 Gy given once weekly in 8-Gy fractions using spinal cord sparing after the first fraction produced better relief of symptoms, more durable responses, and better median survival than did 16 Gy given in 1 week.

Total Dose

In the individual with SVCO, the planned total radiation therapy dose should take into account the specific type and extent of underlying malignancy and normal tissue tolerance. Other considerations include prognosis and performance status, the speed at which SVCO symptoms developed, and whether chemotherapy is to be included in the treatment program. The radiation oncologist must also decide if the goal of treatment is curative or palliative and treat accordingly. If radiation alone is to be used for the curative treatment of lymphoma in adults, 3600 to 4400 cGy is commonly recommended.[78,79] More commonly, however, combined-modality treatment is given, and total radiation dose can then be reduced.[80] In SCLC, typically 4500 cGy twice daily or 6000 cGy given daily with concomitant chemotherapy is recommended,[81,82] and for non-SCLC, 6000 cGy to 7000 cGy is usually used sequentially or, more commonly, simultaneously with chemotherapy.[83,86]

Field Size

Radiation field size is determined by the extent of disease, baseline pulmonary reserve as determined by pulmonary function tests and split perfusion-ventilation scans, and the type of chemotherapy, if any, the patient will receive. Toxicity of treatment, in particular radiation pneumonitis, pericarditis, and fibrosis, can carry significant morbidity and mortality if severe. Mortality from severe radiation pneumonitis approaches 50% in some reports.[87] Therefore, efforts to minimize radiation field size carry considerable importance in the treatment of SVCO. Risk of pneumonitis is a function of many patient- and treatment-related factors: pretreatment performance status, gender (women more likely than men), forced expiratory volume in 1 second, low PaO_2 (<80 torr), mean lung dose, and volume of lung irradiated to 20 Gy.[88–90] To reduce the risk of pulmonary and cardiac toxicity, some groups have used induction chemotherapy followed by thoracic irradiation with a reduced treatment volume. With bronchogenic carcinoma, retrospective and prospective studies have shown that the postchemotherapy tumor volume can be treated without significantly compromising local control or survival.[91,92] In addition, CT scan-based treatment planning, particularly with intensity-modulated radiation therapy, provides better assurance of the target volume and allows a reduction in the lung volumes irradiated.[93–96] Volumes should be constricted if high total doses are used (>4000 cGy) or if methotrexate, mitomycin C, doxorubicin, or bleomycin is used concomitantly.

Patients with lymphoma will need chemotherapy for control of systemic as well as local disease. Fraction size and total dose to the spinal cord should be carefully considered in these patients who may subsequently undergo a bone marrow transplant requiring total body irradiation.

Response to Radiotherapy

Clinical response of SVCO signs and symptoms to various radiotherapeutic dose-fractionation schedules is high (Table 54-4).[2,11,19,21,31] Radiographic and postmortem pathologic studies, however, indicate that reestablishment of vena cava patency is rare, and therefore collateral flow rather than therapeutic intervention may be responsible for symptomatic improvement. Ahmann[6] reported the response to radiation therapy for SVCO based on a literature review of more than 90 publications since 1934. Overall, approximately 50% to 70% of treated patients achieve symptomatic improvement within 2 weeks of initiation of therapy. In circumstances in which serial venograms

Howard[23]	253	86	Use 30-Gy total dose

RT, radiation therapy; SVCO, superior vena cava obstruction.
Data compiled from references 2, 11, 19, 24, and 31.

were obtained, normal venous flow through the SVC was rarely observed after completion of radiation therapy.[19,24,97] In some instances, complete obstruction remained despite clinical improvement in the patient's signs and symptoms.[19,24,97]

SVC patency after radiation also has been assessed in autopsy studies.[6,12] After radiotherapy, the SVC usually is not sufficiently patent to allow adequate blood flow through the vessel. Ahmann's literature review[6] found that among 99 postmortem examinations of which most patients had achieved symptomatic relief after radiation therapy, only 14 patients had complete or partial SVC patency. Although autopsy studies may be less reliable than venography obtained in living patients, these results are entirely consistent with reported radiographic data. Although radiotherapy is associated with improvement or relief of clinical signs and symptoms in most patients, the majority of patients do not actually achieve any measurable increase in vena cava blood flow. The development of collateral blood flow probably contributes to the clinical improvement in some patients and is the sole reason for improvement in others. Thus, the literature does not support the traditional dogma that emergency irradiation is needed in all patients with SVCO.

Chemotherapy

Small Cell and Non-Small Cell Lung Cancer

SVCO has been reported to occur in 7% to 12% of SCLC patients at diagnosis.[26,31,98–101] With rare exception,[31] the literature indicates that the presence of SVCO has little impact on the prognosis of SCLC patients, provided that therapy is appropriately instituted.[26,98,101,102] Even in the presence of SVCO, chemotherapy (with or without thoracic radiotherapy) is the preferred initial treatment of SCLC.[103] The choice of treatment is dictated by the patient's stage and performance status. Those with limited-stage disease, good performance status, and no contraindication to cisplatin are best treated with cisplatin plus etoposide and concurrent chest irradiation.[82] In extensive-stage disease, it is reasonable to proceed with chemotherapy alone—either cisplatin-based therapy or a cyclophosphamide-based regimen in those in whom excessive hydration is to be avoided.[26,98,99,101,102] Alternatively, carboplatin can be substituted for cisplatin if there is a need to avoid aggressive hydration.[104] A majority of patients will experience partial or complete resolution of signs and symptoms within 7 days of initiation of treatment, and in most series, complete resolution of symptoms has occurred within 2 weeks. Although the rapidity of symptom resolution suggests that a direct treatment effect on tumor regression is the principal cause of symptom improvement, the development of collateral drainage undoubtedly plays an equally significant role, as noted earlier. Thoracic radiotherapy does not cause transient worsening of symptoms. Although SVCO reoccurs in approximately 25% of patients, reinstitution of therapy with salvage chemotherapy alone, radiotherapy alone, or a combination of these modalities has resulted in the prompt resolution of symptoms in most cases.[24] Unfortunately, sequential thoracic radiotherapy on completion of chemotherapy has not resulted in a reduction in the incidence of SVCO relapse.[105]

Chemotherapy alone also has been used for the treatment of SVCO in non-SCLC with positive results.[106] However, because of their innate chemotherapy resistance this approach is less effective with non-small cell tumors, and thus radiotherapy or combined-modality therapy remains the preferred initial treatment.[90] Unlike SCLC, the presence of SVCO in non-SCLC seems to have a negative impact on the prognosis of patients with locally advanced disease.[106]

Non-Hodgkin's Lymphoma

Although symptoms can be well controlled with radiotherapy, chemotherapy alone also can effectively palliate the symptoms of SVCO in non-Hodgkin's lymphoma.[29] However, because lymphoma is usually a systemic process and death is rarely due to localized disease, radiotherapy should never be used in isolation except when dealing with recurrent disease. Local recurrences tend to occur primarily in patients with large mediastinal masses and large cell histologic types.[29] Therefore, local consolidation with radiotherapy after a few cycles of chemotherapy can be justified in patients with large cell lymphoma and mediastinal masses larger than 10 cm.[29] Conversely, in lymphoblastic lymphoma, recurrences are uniformly systemic, obviating the need for radiotherapy in this histologic type of non-Hodgkin's lymphoma.[29] As in SCLC, the optimal chemotherapy regimen for treatment for lymphoma-associated SVCO has not been determined and is dictated to a much greater degree by the underlying histologic type, further underscoring the need to establish a tissue diagnosis before institution of therapy. It should be noted that a fine-needle aspiration is insufficient for a complete diagnosis and characterization of a lymphoma and should not be relied on as the sole diagnostic procedure. Lymphoblastic lymphoma is more aggressive than large cell lymphomas and generally requires more aggressive chemotherapy.[54,107,108]

SURGERY

Surgery generally plays a limited role in the management of the patient with SVCO, although reconstruction of the obstructed SVC may be indicated in highly selected patients.[58,109–112] Surgical intervention is reserved most often for patients with SVCO due to a benign cause such as granulomatous disease, aortic aneurysm, or retrosternal goiter.[113] When symptomatic malignant obstruction is refractory to radiotherapy, chemotherapy, or both, and when anticipated survival approaches 6 months, operation may be considered. Surgical intervention also may prove beneficial in the setting of recurrent SVCO after chemotherapy and radiation, and when caval thrombosis is the primary problem and fails to improve symptomatically with anticoagulants or thrombolytic therapy.[95,114–116]

Surgical bypass of the obstructed SVC may be accomplished with synthetic grafts (Dacron or Goretex), autologous pericardium, or autogenous vein graft, with preference for the later because of a better

potential for long-term patency.[109–112,117,118] The spiral vein graft, initially described by Doty and associates,[110,119] is constructed by using the saphenous vein, which is slit longitudinally and wrapped around a stent (usually a chest tube) of the desired diameter. The edges of the vein are joined by using continuous suture, resulting in a large-bore conduit. The bypass is constructed between the brachiocephalic or left internal jugular vein and the right atrial appendage. Long-term relief of symptoms may be achieved.[112,119,120] When SVCO is the result of a primary tumor of the SVC or right atrium, resection (with cardiopulmonary bypass) and reconstruction is recommended. These tumors may be relatively slow-growing sarcomas (angiosarcomas or leiomyosarcomas), and long-term palliation is sometimes possible.[33–35,121]

Stents

Percutaneously placed, self-expanding intravascular wire stents can offer an attractive adjunct to other procedures in the palliative treatment of patients with SVCO in the presence or absence of an underlying malignant disease.[122] These devices have been placed before radiotherapy, during the course of radiotherapy or chemotherapy, and after maximum-tolerance radiation therapy.[20,123–140] This percutaneous treatment option offers the ability to increase the lumen diameter of the SVC and does not usually require general anesthesia (Fig. 54-5). Complete symptom relief is often obtained within 24 to 48 hours in 75% to 95% of patients, depending on the underlying cause of SVCO and type of stent deployed. Dyspnea seems to be the least likely symptom to improve, whereas facial and upper body edema improve within 48 hours in virtually all patients.[123] Possible complications include acute thrombosis, retroperitoneal hemorrhage, and death due to cardiac arrhythmias, and reocclusion may occur (especially in the absence of anticoagulant therapy).[126–128] Because all currently available expandable stents have a metallic composition, their presence may preclude or limit serial follow-up with magnetic resonance imaging. This point should be taken into account before this course of treatment is chosen.

Venous access is accomplished through a femoral, jugular, or subclavian vein. It is necessary to traverse the obstruction with a guide wire to allow deployment of the stent, and in many cases, a preplacement venous angioplasty is indicated. The presence of acute thrombosis superimposed on the chronic SVCO may indicate the need for preprocedure thrombolytic therapy. Although thrombolytic therapy is associated with a known risk of hemorrhage, it may minimize the risk of thromboembolization and permit greater accuracy of stent placement.[122,139] Careful consideration should be given to a preprocedure cerebral CT scan to help rule out the presence of cerebral metastases before the use of thrombolytic therapy.[139]

Whereas a variety of metallic stents is currently available, most reports address one or more of three general device designs, the Gianturco-Rösch (sometimes referred to as the "Z-stent"; Cook, Bloomington, IN), Wallstent (Schneider, Plymouth, MN), and Palmaz stent (Johnson & Johnson Interventional Systems, Warren, NJ). No rigorous comparisons of outcomes have been made among the various stent designs. Each has particular qualities with respect to flexibility and radial strength, which may make one or another particularly well suited under certain clinical circumstances. Although the Wallstent and Z-stent are "self-expanding" devices, balloon dilatation may be required after stent insertion to provide a clinically adequate effect.[141]

Technical and clinical success and long-term venous patency have been demonstrated by several trials summarized in Table 54-5.[122,134–140,142] The overall complication rate is relatively low,

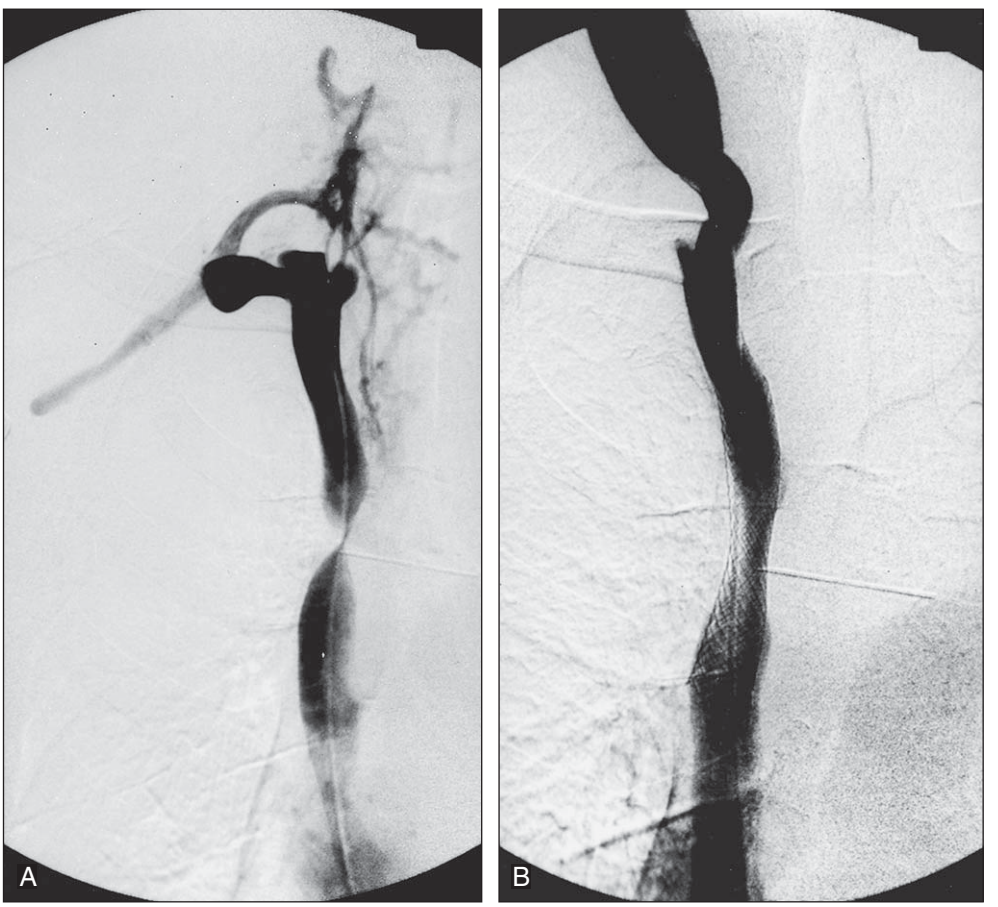

Figure 54-5 • **A,** A 60-year-old man after radiotherapy for lung cancer with recurrent superior vena cava obstruction. **B,** Placement of a Wallstent resulted in immediate relief of symptoms. Radiograph at 6-month follow-up.

Data compiled from references 122, 134–140, and 142.

although considerable variation is found in the reporting of complications, in that some studies include reocclusion as a complication.[136] The majority of the more serious complications involve graft migration. Many patients require more than one stent either to maintain SVC confluence with adjacent vessels or because the vascular lesion is too extensive to be covered by a single stent. Close follow-up is required to monitor venous patency, and stent occlusion can generally be alleviated by a second procedure.

A discrepancy exists in the literature regarding balloon dilation before stent placement. Some studies advocate routine balloon dilation before stent insertion, whereas others limit such dilations to situations necessitated by very tight stenoses.[122,134,135,137] The suggestion is that immediate stenting without dilation traps endothelial clots, thus helping to prevent distant embolic events.[135] Other series reported improved patency rates with balloon angioplasty after stent placement.[140] Some believe that this variation in practice may relate to the type of stent used.

Considerable variation also exists regarding routine anticoagulation after stent placement. Chatziioannou and coworkers[136] recommend oral anticoagulation therapy with coumarin "for life." Kee and colleagues[122] recommend continuous oral anticoagulation for all of their patients with an underlying malignancy. In both the studies of Lanciego and associates[134] and Chacon Lopez-Muniz and coworkers,[123] patients were initially given anticoagulation with heparin and warfarin; however, over time their standard of practice changed to recommend antiplatelet agents alone, with seemingly no adverse effects. Thony and colleagues[140] treated a few selected patients with heparin for up to 3 days after the procedure and otherwise recommend aspirin therapy for 3 months after stent placement. This shift in practice may reflect parallel studies of anticoagulation for coronary artery stents. As no standard recommendations exist now, the risks and benefits of full anticoagulation versus antiplatelet agents must be weighed for individual patients.[143]

Although no randomized trials have been done, two studies directly compared the results of endovascular stenting with radiation with or without chemotherapy for malignant SVCO. Tanigawa and associates[144] reported the results of 33 patients treated with radiation therapy or stents. These patients were selected for a specific therapy and not randomized. Of the 23 patients who underwent a stenting procedure, 11 had undergone ineffective radiation therapy for their obstructions. The majority of patients in the stent group and all 10 of the patients who received radiation therapy had a primary lung cancer. Symptom relief was seen in 78% of the stent group overall: 75% of those who had not had previous therapy and 82% of those who had received prior radiation. Although the rate of improvement (80%) in clinical signs and symptoms in patients who were treated with radiation therapy was similar, the median time to respond was longer at 5.5 days compared with 24 to 48 hours after stenting. No difference was found in the overall survival between the two treatment groups. These authors suggested that stenting be considered first-line therapy and certainly indicated after an ineffective trial of radiation. Nicholson and colleagues[139] reported their experience with malignant SVCO of 76 patients treated with stent insertion and compared the results retrospectively with those of 25 similar patients who had been treated with radiation therapy for malignant SVCO. Of the 76 patients, 26 were treated with stents alone, and the remainder were treated with chemotherapy or radiation before or after stent placement. The report of Nicholson and colleagues confirms the more rapid resolution of clinical symptoms in the stent group versus the radiation-alone group; however, it should be noted that the radiation group was examined retrospectively. The mean asymptomatic time was significantly longer in the stent group at 21.8 weeks compared with 11.7 weeks in the radiation-only group. Although 83% of patients treated with a stenting procedure continued to have minor symptoms of swelling or venous distention, major symptoms were relieved in all 76 patients. In addition, more than 90% of patients in the stent group died without a recurrence of their SVCO symptoms compared with only 12% in the radiation-only group. The figures for the stent group include the patients who were treated with additional therapy, although the trends are the same for the 26 patients who were only stented. Poststent venography was performed on 19 patients. Interestingly, although they were all asymptomatic, seven of these patients had a reoccluded SVC, suggesting that collateral vessels play a significant role in symptom relief. This finding is consistent with the reocclusion after radiation therapy noted in autopsy studies.[6,13]

Although a definite role exists for stents in malignant SVCO, the results of endothelial stent placement for benign causes are more mixed, and few long-term follow-up data are available.[141] Life expectancy for patients with malignant disease is often limited, but the same may not be true with benign SVCO, and therefore in these patients, long-term patency is a critical consideration. The underlying cause of the initial SVCO and the likelihood of recurrence may be more relevant in these situations. Technical success and symptom relief have been reported, primarily for venous catheter-induced SVCO.[137] The gold standard for benign SVCO remains surgical bypass, although, given the variability and rarity of this condition, no studies have been done comparing these two modalities.

Although endovascular stents may provide more rapid relief of symptoms, they are not designed to treat the underlying cause of the obstruction, whereas radiation, chemotherapy, and surgery may function both palliatively and therapeutically. No randomized trials are likely to compare treatments for SVCO, because the goals of each therapeutic modality are somewhat different. However, many studies report that stented patients experience a rapid and almost complete resolution of the symptoms associated with SVCO.[123,126,134,135,137,138,140,144]

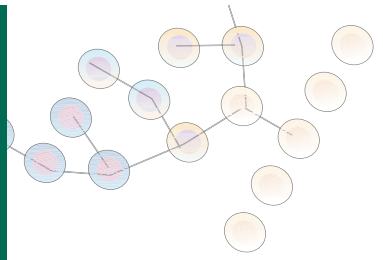
For this reason, several recent studies advocated stent placement as first-line therapy for patients with malignant causes of SVCO.[138,142–144,147] Stent insertion should not interfere with subsequent radiation or chemotherapy and may allow symptom relief while further therapy is being planned and initiated.[145]

SUPPORTIVE MEASURES

Few medical measures are of proven benefit in the management of SVCO, other than therapy directed at the underlying cause. General recommendations include bedrest, head-of-the-bed elevation, and oxygen administration.[9,21] These therapies are designed to reduce venous pressure and cardiac output. Diuretics also have been advocated without clear evidence of efficacy, although they are thought to lessen edema.[9] Steroids also are sometimes administered without good documentation as to their efficacy. These agents have been advocated for their putative benefit in lessening the likelihood of radiation-induced edema. However, in experimental systems, little inflammation or edema has been observed with irradiation.[74] Anticoagulation and thrombolytic therapy may be of benefit when the underlying cause is an indwelling catheter, but otherwise they have not been shown to alter the course of recovery.[32,37,39,109] Furthermore, because anticoagulation may impair diagnostic efforts, it should be avoided until a clear indication for its use is identified.

Survival in the face of SVCO is dependent on the underlying cause and proper treatment.[1,11,29,146] Overall, median survival is around 6 months and is clearly related to the underlying cause. One-year survival may range from as little as less than 1% in non-SCLC to more than 40% in patients with non-Hodgkin's lymphoma.[1,11]

SUMMARY



SVCO is usually not a true oncologic emergency, except in rare situations in which a patient experiences respiratory compromise secondary to tracheal obstruction. Administration of irradiation before histologic confirmation of the underlying cause can lead to inappropriate therapy and should be discouraged. Excessive concern about the risk of invasive procedures in the face of SVCO is likewise without foundation. Numerous reports have demonstrated the relative safety of bronchoscopy, thoracentesis, lymph node biopsy, and similar invasive procedures. In the past 5 years, numerous studies have demonstrated the palliative benefit of endovascular stent placement, particularly for malignant causes of SVCO. Stent placement does not preclude the use of additional therapy such as chemotherapy or radiation. In experienced hands, the procedure has a low rate of complications and often provides rapid and lasting relief of symptoms. Depending on availability, endovascular stenting should be considered early in the treatment of SVCO and certainly when a different primary therapy has failed. In many institutions, radiotherapy remains the treatment of choice, with exceptions made for those causes known to be relatively sensitive to chemotherapy (e.g., SCLC or non-Hodgkin's lymphoma).

55 Spinal Cord Compression

Daniel M. Sciubba, Ali Bydon, and Ziya L. Gokaslan

SUMMARY OF KEY POINTS

Incidence
- Spinal cord compression is diagnosed in more than 30% of all patients with disseminated cancer, and roughly 5% to 10% of all patients experience cord dysfunction.
- Back pain is the most common presenting complaint and almost always precedes neurologic dysfunction.
- Spinal cord compression has a devastating effect on quality of life and is frequently diagnosed late.

Etiology
- Compression occurs from epidurally located tumor or from bony fragments generated by pathologic fractures.
- Constant compression leads to spinal cord arterial compromise, venous occlusion, vasogenic edema, and demyelination with subsequent clinical deterioration.

Evaluation
- Any new or worsening back pain in a cancer patient mandates urgent radiographic evaluation.
- Unfortunately, no characteristics of back pain can safely differentiate cord compression from other benign or malignant spinal diseases.
- Any evidence of myelopathy may signal impending catastrophic loss of cord function.
- A scout sagittal magnetic resonance imaging (MRI) view of the entire spine or a scanning MRI is the most rapid and cost-effective means of diagnosis and should be the first procedure performed.

Treatment
- Corticosteroids, conventional radiation therapy, and decompressive surgery are the mainstays of treatment.
- Although treatment of metastatic spinal lesions is considered palliative, aggressive medical and surgical treatment can significantly improve pain, neurologic function, and quality of life.

INTRODUCTION

Spinal metastases have long been a significant source of morbidity in patients with systemic cancer. Regional pain, pathologic compression fractures, deformity, and spinal cord compression with ensuing neurologic compromise are problems that commonly must be managed in both the patient with advanced cancer and the patient with isolated metastatic vertebral disease. In regard to metastatic epidural spinal cord compression (MESCC), data from the 1970s from Gilbert and colleagues and from Greenberg and colleagues showed that a significant proportion of patients entering the hospital in an ambulatory state left with varying degrees of paresis and paralysis.[1,2] Specialists from that era emphasized the need for earlier diagnosis and improved treatment.[3] Unfortunately, proposed diagnostic algorithms relied heavily on the only available diagnostic tool at the time: myelography.[4] Early opposition existed for using such an invasive test on neurologically intact cancer patients with new onset back pain; however, Rodichok and colleagues demonstrated that roughly 60% of patients with new back pain, abnormal findings on a plain spinal radiograph, and normal findings at neurologic examination who underwent myelography were shown to have epidural cord compression.[4,5] Since that time, diagnosing spinal cord compression prior to clinically apparent neurologic dysfunction has remained paramount in the management of metastatic vertebral disease. Early diagnosis and early, aggressive treatment are the hallmarks of current treatment.

Currently, roughly 30% of patients with cancer develop symptomatic spinal metastases during the course of their illness, and up to 90% of cancer patients have metastatic lesions within the spine at the time of death.[6] With advances in the treatment of systemic oncologic disease, patient survival has increased over the last few decades. This increase, combined with improved imaging modalities of the neurologic and musculoskeletal systems (magnetic resonance imaging [MRI], bone scintigraphy, etc.), will undoubtedly increase the incidence with which physicians encounter spinal metastases. As a result, it is essential that individuals with cancer and those caring for them understand not only the myriad ways in which spinal metastases present, but also the means by which they are currently diagnosed and managed. In this chapter, the authors attempt to address these issues using an evidence-based approach from the most recently compiled literature. In addition, we propose a simple algorithm to aid in deciding which patients are ideally treated medically and which patients could benefit from surgery.

EPIDEMIOLOGY

Over 1.4 million new cases of cancer are diagnosed annually in the United States,[7] and roughly 500,000 of these patients die annually from metastatic disease.[8] Metastases to the skeletal system occur third in frequency behind metastases to the lungs and liver.[9,10] Within the skeletal system, the spinal column is the most commonly affected site. Cadaver studies have shown that as many as 30% to 90% of

terminal cancer patients possess metastatic disease to the spine.[11–15] Although it is estimated that only roughly 10% of cancer patients develop *symptomatic* spinal secondaries,[16] the prevalence of spinal metastases is likely to increase as survival rates for many cancers improve.

The highest incidence of clinically detected spinal metastases occurs during midlife (40 to 65 years of age), which corresponds to the period of increased cancer risk.[17] Primary breast, lung, and prostate represent the most common histologies metastatic to spine, reflecting both their higher prevalences and their tendencies to metastasize to bone.[18,19] A slightly higher incidence in men is related to the slightly higher incidence of prostate cancer over breast cancer.[17] However, as adjuvant treatment for breast cancer improves overall survival, this dissimilarity could vanish.

PATHOPHYSIOLOGY

Figure 55-1 shows the relevant anatomy of the spinal cord, spine, and associated structures and the location of metastatic lesions in these areas. Lesions that cause spinal cord compression usually first invade the epidural space, most often as direct extension of metastatic disease from the vertebral body. Spine metastases are thought to arise by various mechanisms, often predicated on the biologic behavior of the primary.

- *Hematogenous spread.* As the most common means of malignant tumor spread to the skeleton, such dissemination likely occurs by both venous and arterial routes. Batson's venous plexus is the longitudinal network of valveless veins that course parallel and juxtaposed to the spinal column. This plexus communicates with multiple venous systems (spine, vena cava, portal, azygous, intercostals, pulmonary, renal), and the flow direction within the plexus may be variable owing to changes in intrathoracic and intra-abdominal pressures. In this way, tumors in multiple sites of the major body cavities could deposit tumor cells in the spine.[20] Owing to the significant blood flow to the vertebral bodies, the arterial system also is effectively able to deliver tumor cells to these well-perfused bones.[21] Although less common, hematogenous dissemination of tumor cells may also lead to direct metastasis to the cord (intramedullary) or to the epidural space itself.
- *Direct extension.* Primary tumors located in paravertebral soft tissues can often extend into the vertebral column via intervertebral foramina. Lung cancer, for instance, may become locally aggressive and invade the thoracic spine, while prostate, bladder, and colon cancer may invade the lumbar and sacral spine.[20]
- *Cerebrospinal fluid (CSF) spread.* Such spread is usually conferred by "shedding" of tumor cells from cerebral or cerebellar metastatic lesions, often following surgical manipulation of brain metastases.[22]

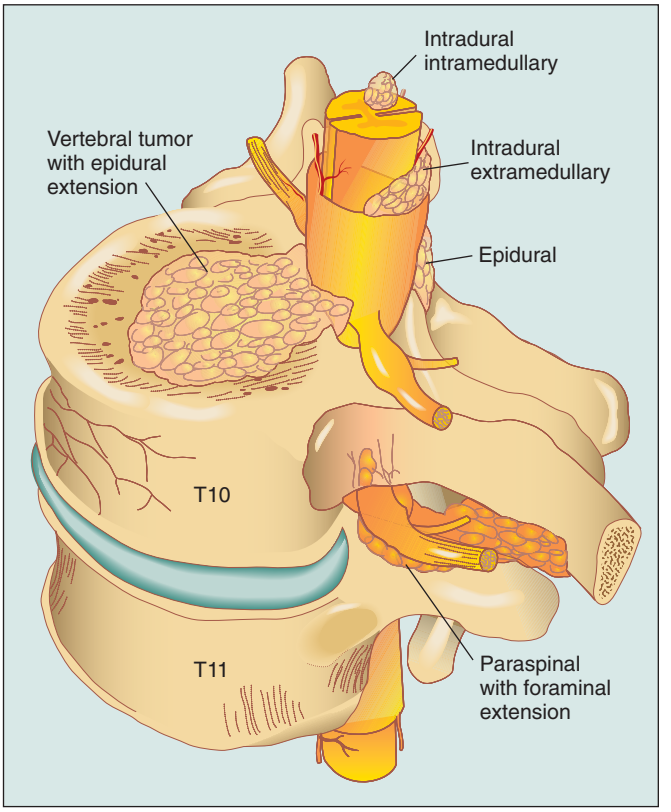

Figure 55-1 • Locations of metastatic lesions of the spine: vertebral body, epidural space, neural foramen, intradural space, and within the spinal cord itself.

After a malignant lesion has begun to grow in the epidural space, it is unclear how or at what point spinal cord compression (as may be seen on MRI or myelogram) leads to clinically apparent spinal cord compromise. Animal models demonstrate that at least three mechanisms may be at play.[23–25] First, direct pressure on the neural structures of the cord may result in subsequent demyelination. Second, compression may also lead to arterial insufficiency with subsequent neural degeneration. Finally, compression may cause venous blockage with secondary vasogenic edema due to disruption of the blood–spinal cord barrier. Interestingly, results of various animal experiments have shown that the spinal cord can tolerate prolonged pressure if the onset of the pressure is slow and the neural degeneration is not irreversible.[26–28] Along these lines, Rades and colleagues found that slower clinical progression of neurologic symptoms before diagnosis led to improved outcome,[29] emphasizing again that early diagnosis is a key to successful management.

CLINICAL EVALUATION

Back Pain

Significant back pain will likely affect over 80% of Americans at some point in their lives.[30] Because the overwhelming majority of such patients suffer from noncancerous musculoskeletal pain, the presenting complaint of back pain may divert many physicians away from patients who will ultimately harbor underlying spinal metastatic disease. However, in roughly 10% of patients with cancer, symptomatic spinal metastases may be the initial presentation.[31] In addition, when vertebral lesions are discovered, pain ends up being the most common presenting symptom, occurring in approximately 83% to 95% of patients.[3,18,32] As a result, a cancer patient who reports back strain from a particular event still needs very close attention and follow-up care.[33]

Three classic pain syndromes affect patients with spinal metastases: local, mechanical, and radicular pain. Patients often present with a combination of these pain syndromes. *Local pain* is usually described by patients as a persistent "gnawing" or "aching" pain emanating from the region of the spine that is affected by metastatic disease. It is hypothesized that growth of the metastatic tumor, most commonly located in the posterior vertebral body, leads to periosteal stretching and/or a local inflammatory process that stimulates the pain fibers within the spinal periosteum. In such patients, percussion over the spinous process may elicit local tenderness. Such pain usually responds well to steroid administration.[34]

Mechanical pain, also known as axial back pain, is aggravated by movement, activity, or simply increasing weight-bearing forces on the spinal segment affected. Spinal metastases that result in vertebral body damage (e.g., deformity, fracture) may result in spinal instabil-

ity, which likely results in muscle, tendon, ligament and/or joint capsule strain and ensuing symptoms of mechanical pain. Unfortunately, such discomfort is usually refractory to narcotics and steroids but responds to recumbency, bracing, and/or internal stabilization. *Radicular pain* may occur when spinal lesions compress or irritate an exiting nerve root, yielding pain in the dermatomal distribution of the involved root that is often described as "sharp," "shooting," or "stabbing." Interestingly, *dysesthetic/neuropathic pain* may also arise when patients have intradural extramedullary disease, creating pain that may be described as an "intense, burning" sensation.[22]

Motor and Autonomic Dysfunction

The second most common presenting complaint of patients with vertebral metastases is motor dysfunction, which can manifest as myelopathy and/or radiculopathy. Although less common than the presentation of pain alone, in patients with MESCC, roughly 60% to 85% of such patients are weak at the time of diagnosis.[2,3,18] In addition, patients often have some level of bladder, bowel, and/or sexual dysfunction related to the MESCC that they will not readily offer to the physician unless an inquiry is made. Bladder dysfunction is the most common autonomic finding and commonly correlates with the degree of motor dysfunction.[8] Although the rate of clinical progression is variable, patients with motor dysfunction inevitably progress to complete paralysis in the absence of intervention.[35] In addition, severe autonomic dysfunction with urinary retention, constipation, and loss of control of bowel or bladder function is a late and particularly ominous finding because full paraplegia can follow within hours.[33]

Neurologic status at the time of diagnosis, particularly motor function, has been shown to correlate with prognosis from MESCC,[21,36] thus reinforcing the concept that diagnosis prior to the development of a neurologic deficit is of paramount importance. Unfortunately, since complaints of chronic back pain in the general population are extremely common,[30] it is likely that a delay in diagnosis of vertebral metastasis occurs frequently in patients who complain merely of new-onset back or neck pain. Levack and colleagues reported, in a study of 319 cancer patients, that a median of 2 months passed from the onset of pain, as reported to their primary care providers, until the diagnosis of metastatic spinal cord compression.[37] For this reason, new-onset back or neck pain in a patient with known cancer must be considered spinal metastatic disease until proven otherwise. Moreover, thoracic pain is less common than is pain originating from the mobile cervical and lumbar regions, where degenerative disease is the precipitating cause of pain; thus, pain in the thoracic region should raise a high level of suspicion for the likelihood of cancer.

Sensory Dysfunction

Sensory disturbances such as anesthesia, hypesthesia, and/or parasthesia typically occur in correlation with motor dysfunction both in location and time of onset. In this way, patients with myelopathy may elicit a sensory level across the chest or abdomen, while patients with radicular pain or weakness may complain of sensory abnormalities in the same dermatomal distribution as their motor dysfunction. Notably, patients with MESCC of the thoracic cord may present complaining only of discomfort around the chest, described as if they were being restricted by a "tight shirt" or "corset," similar to the symptoms of patients with thoracic transverse myelitis.

DIAGNOSIS

In patients with known or suspected malignancy who present with back pain, the first step is a neurologic examination (Fig. 55-2). If the presence of an abnormal finding is in question, assistance should be sought from a neurologist. Any sign of myelopathy should lead to a prompt MRI of the entire spine with institution of high-dose dexamethasone therapy before the patient is sent to the MRI suite. Since a single bolus of steroid is unlikely to cause any significant side effects, waiting for confirmation of spinal cord compression before instituting administration of steroids is almost never warranted.[38]

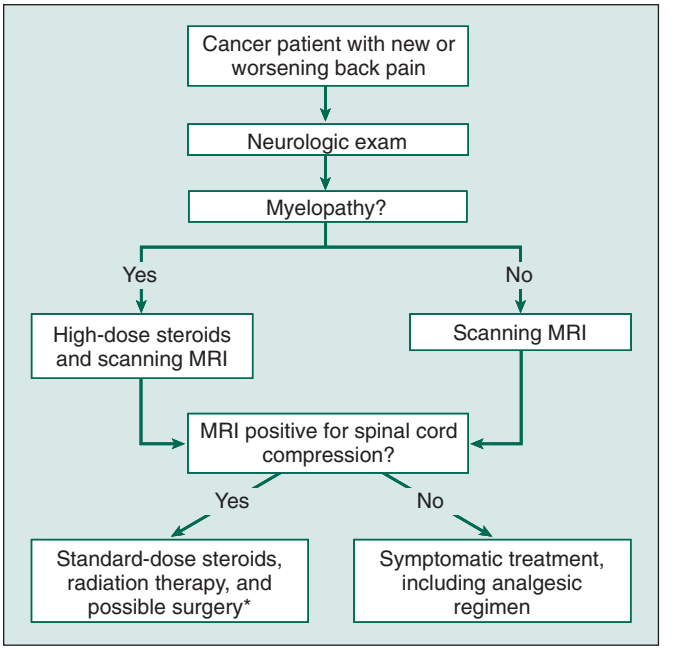

Figure 55-2 • Flowchart for initial workup of patient with suspected spinal metastatic disease. *See Figure 55-3.

In the absence of an abnormal neurologic examination, imaging for spine tumors may include any combination of plain radiographs (with or without myelogram), computed tomography (CT) (with or without myelogram), MRI, nuclear scintigraphy, and positron emission tomography. Although MRI is currently the gold standard for imaging spine tumors and epidural disease, patients may often provide other images that were requested by primary or emergency physicians.

Plain Films

Plain radiographs have long been the first course of imaging obtained for patients with spine pain, mainly owing to ease of use and relatively low cost. They serve mainly as a screening test by revealing lytic or sclerotic areas of bone, pathologic compression fractures, deformity, and/or paraspinal masses. The major proportion of spinal metastatic lesions are osteolytic, but up to 50% of the bone must be eroded before there is a noticeable change on plain radiographs.[39] Notably, osteoblastic/sclerotic lesions most often result from carcinoma of the breast or prostate.[40]

Bone Scan

Bone scanning or nuclear scintigraphy is sensitive for identifying increased metabolic activity throughout the entire skeletal system. Thus, whereas plain films might not detect tumor-induced radiographic changes until 30% to 50% or more of the vertebral medullary space has been replaced,[41] bone scans may reveal the lesion at an earlier stage.[42] However, such scans may detect increased metabolic activity associated with spinal inflammation and infection, leading to overall decreased specificity. In addition, nuclear scintigraphy currently has poor imaging resolution, necessitating correlation with CT or MRI to exclude benign processes and to plan possible operative intervention.[43] Positron emission tomography scanning with

^{18}F-fluorodeoxyglucose is now more commonly used for whole-body metastatic surveys and as a staging technique in patients with known systemic cancer.[44] However, as with nuclear scintigraphy, poor spatial resolution in positron emission tomography necessitates concomitant use of CT or MRI.

Computerized Tomography

CT imaging provides precise representation of the normal osseous anatomy and the extent of tumor involvement within the bone. In combination with myelography, it also provides the most accurate view of compressed neural elements. In this way, it may be extremely useful in determining whether cord compression is secondary to tumor expansion into the canal or whether osseous fragments from a pathologic fracture are the cause of compression. Furthermore, CT imaging is ideal for surgical planning, for which understanding of the regional osseous anatomy may direct the type and extent of spinal instrumentation.

Magnetic Resonance Imaging

MRI is considered the gold standard imaging modality for assessing spinal metastatic disease.[45–47] MRI is more sensitive than standard radiographs, CT, and bone scans in detecting primary malignant bone tumors and metastatic lesions in the spine.[48,49] Such sensitivity is due to the fact that MRI allows for superior resolution of soft-tissue structures such as intervertebral discs, spinal cord and nerve roots, meninges, and paraspinal musculature. Moreover, MRI provides clarity at the osseous–soft-tissue interface, yielding accurate anatomic detail of bony compression or invasion of neural and paraspinal structures.

When a patient has either local or radicular back pain with no evidence of myelopathy, a scanning MRI should be ordered.[50] This study involves a series of T_1-weighted sagittal images extending from the cervical spine to the sacrum. If metastatic lesions of bone are found, the procedure is converted to a more comprehensive set of images. This method is a faster and more cost-effective approach to early diagnosis of spinal cord compression.[50] The comprehensive MRI protocol should include T1- and T2-weighted images and contrast-enhanced studies that provide axial, sagittal, and coronal reconstructions.[51] Owing to the high signal intensity of fat within bone marrow on T1-weighted images, fat suppression techniques are useful in evaluating osseous lesions that enhance with contrast.[51] Diffusion-weighted imaging may be helpful in distinguishing between benign and pathologic compression fractures.[52]

Angiography

This advanced imaging modality is ordered by the neuroradiologist and/or neurosurgeon once the diagnosis of a spine tumor has been made. In patients with spinal metastases that are suspected to result from highly vascular primary tumors, such as renal cell carcinoma, thyroid carcinoma, angiosarcoma, leiomyosarcoma, hepatocellular carcinoma, and neuroendocrine tumors (pheochromocytoma, paraglanglioma),[53] angiography may provide diagnostic and have therapeutic benefit. If the lesions are considered for surgery, preoperative knowledge of vascular supply may prove invaluable. In addition, angiography might allow preoperative embolization of the spinal lesion, leading to decreased blood loss with operative resection.[54] Such intraoperative blood loss can influence the surgeon's ability to visualize an adequate view of the surgical field, thus affecting achievement of complete resection. In addition, significant blood loss may be associated with life-threatening hemorrhage intraoperatively, longer operating times, intraoperative complications, postoperative hematomas, and wound breakdown. In patients who are not candidates for surgery, embolization may be effective as primary treatment for the lesion.[55]

Percutaneous Spine Biopsy

Although imaging modalites have improved vastly over the last two decades, acquisition of tissue is not uncommonly needed for diagnosis. If surgery is not indicated up front and no other systemic lesions can be found, percutaneous image-guided biopsy may be indicated. Improved CT fluoroscopy and needle biopsy systems provide relatively easy access to most lesions with success rates approaching 90%. The majority of such procedures are now done in the outpatient setting.[56,57]

TREATMENT

Treatment of spinal metastases is primarily palliative. As a result, goals of treatment are centered on pain relief, maintenance or restoration of spinal stability, and preservation of neurologic function. Although in rare circumstances, patients may be cured with radical surgical excision (e.g., solitary renal cell carcinoma spinal metastasis),[58] patient variables, including age, tumor burden, life expectancy, and functional status, overwhelmingly influence the choice of therapeutic options. The three traditional mainstays of therapy have been corticosteroids, radiation therapy, and surgery. In the following paragraphs, we will provide the most current treatment paradigms involving each of these modalities and describe how technologic advances (e.g., bisphosphonates, radiosurgery, percutaneous vertebroplasty, aggressive decompressive surgery) have increased the armamentarium against metastatic spine disease and have consequently improved outcomes (Fig. 55-3).

Hormonal Therapy, Chemotherapy, and Medical Therapy

Chemotherapeutic agents can be classified into antitumor drugs and drugs that minimize the secondary effects of the tumor.[59] Except in cases of chemosensitive tumors, such as Ewing's sarcoma and neuroblastoma, antitumor drugs continue to have a limited role in the treatment of spinal metastases. On the other hand, drugs that are used to prevent or ameliorate the effects of spinal tumors (e.g., corticosteroids, bisphosphonates, analgesics) are widely accepted.

The three most common primary tumors that metastasize to the spine are breast, prostate, and lung cancers.[18,19] Unfortunately, although lung cancer is still the leading cause of cancer mortality in the United States, the median survival of patients with lung cancer metastatic to bone disease is reportedly between 3 and 9 months. As a result, most patients die of progressive disease before skeletal complications become a large problem.[60] In most prostate and breast cancers, on the other hand, lesions may be sensitive to hormonal manipulation.[59] Estrogen agonists/antagonists, such as tamoxifen, and aromatase inhibitors, such as letrozole, have been shown to be effective for breast cancer. For prostate cancer, androgen deprivation is the mainstay of treatment with GnRH agonists and/or flutimide.

Chemotherapy is usually given to patients with prostate and breast cancer when hormonal agents become ineffective. Breast cancer is often chemotherapy sensitive, and the most effective agents include doxorubicin and the taxanes. Although prostate cancer is considered less responsive to chemotherapy, some agents have demonstrated effectiveness, such as mitoxantrone, prednisone, vinblastine, and the taxanes. Multiple myeloma responds to combinations of mephalan and prednisone as well as infusioned vincristine and adriamycin.[59]

Corticosteroids

Corticosteroids are the mainstay of pharmacologic therapy for pain associated with vertebral metastases and for the acute neurologic deterioration that often accompanies MESCC. Corticosteroids decrease tumor-associated inflammation (analgesia effect), decrease spinal cord edema (improving short term neurologic function), and may be

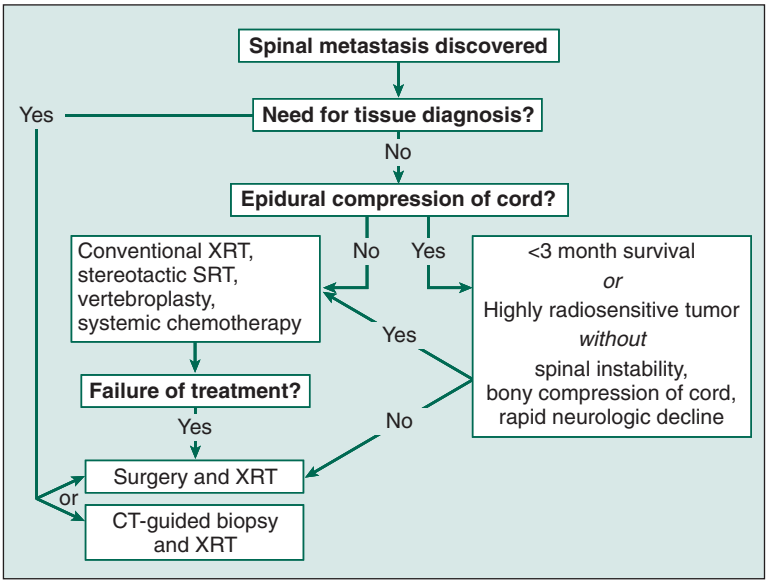

Figure 55-3 • Flowchart for management of spinal metastatic disease.

directly oncolytic, as with lymphoma, multiple myeloma, and breast cancer.[3] Experimental animal models have confirmed the clinical observations that those treated with dexamethasone have improvement in motor function faster than in untreated controls.[61–63] Memorial Sloan-Kettering Cancer Center has popularized a high-dose regimen: a loading dose of 100 mg dexamethasone followed by 6 mg given four times a day (total dose 24 mg),[2,38,64] a regimen that is based on studies demonstrating a dose-response benefit of dexamethasone.[62] However, there is no current optimal dosing regimen for corticosteroids used with MESCC, and no consensus data are available to recommend high-dose steroids (96 mg/day) versus low-dose steroids (16 mg/day). For instance, Vecht and colleagues compared initial doses of 10 mg IV bolus versus 100 mg IV bolus but showed no outcome differences regarding pain, ambulation, or bladder function.[65]

As was stated previously however, if a metastatic spine lesion is suspected, there are minimal drawbacks to starting high-dose dexamethasone in anticipation of an MRI scan. In patients presenting without obvious myelopathy, lower doses of steroids may be started, such as 4 mg every 6 hours or a bolus of 10 mg awaiting MRI.[38] Whatever dose is initiated, however, tapering of the steroid should begin during the course of radiation therapy.[66] By reducing the dose by one third every 3 to 4 days, the steroid course will be almost completely tapered by the end of radiation treatment.[33] Long-term use of corticosteroids, on the other hand, may be fraught with serious clinical side effects. Higher doses of steroids are rarely needed beyond the first 48 to 72 hours or even beyond the initial bolus. Therefore, if neurologic symptoms continue to progress with either the standard or high-dose regimen, prompt surgical intervention may be indicated.[33] In addition, recrudescence of symptoms during the steroid taper may be an indication for increasing the steroid dose or considering surgical decompression.

Bisphosphonates

This class of drugs suppresses bone resorption by inhibiting osteoclastic activity. In this way, bisphosphonates may reduce the risk of pathologic fracture,[67] relieve local pain secondary to lytic lesions,[68] and lower malignancy-associated hypercalcemia. Although most of the clinical trials on bisphosphonates have been conducted in patients with metastatic breast cancer and multiple myeloma, small studies on patients with other metastatic carcinomas have demonstrated benefit.[59]

Analgesia

Poorly managed cancer pain contributes to depression, anxiety, and fatigue.[69] Unfortunately, undertreatment of pain in cancer patients persists despite significant efforts by clinicians to improve delivery of analgesics. The American Pain Society Quality of Care Committee Consensus Statement in 1995 delineated the high prevalences of unrelieved pain across clinical settings with specific regard for cancer pain.[70] The World Health Organization has outlined a three-step system for the treatment of progressively severe pain using nonopioid analgesics, opioid analgesics, and adjuvant medications.[71] First-line agents should be nonopioid analgesics, such as acetominophen, aspirin, and other nonsteroidal anti-inflammatory drugs, which are often efficacious for bone pain. If pain is not controlled, an opioid analgesic should be added. If pain remains uncontrolled, a strong opioid analgesic should then be prescribed. At all levels of this ladder, adjuvant drugs may be added to treat specific types of pain.[72] Specifically, corticosteroids have been shown effective for use in spine tumor pain. In addition, neuropathic pain may respond to anticonvulsant medications (e.g., gabapentin, lamotrigine, carbamazepine), the 5% lidocaine patch, opioid analgesics, and tricyclic antidepressants.[73]

Conventional Radiation Therapy

Conventional radiation therapy (XRT) plays an important role in the palliative treatment of all spinal metastases with the goals of obtaining pain relief, preventing pathologic fractures or vertebral collapse, and avoiding progression or allowing reversal of neurologic dysfunction. Indications for XRT include radiosensitive tumors (lymphoma, multiple myeloma, small cell lung carcinoma, seminoma of testes, neuroblastoma, Ewing's sarcoma); expected survival less than 3 months; inability of patient to tolerate an operation; and multilevel or diffuse spinal involvement.

XRT is typically administered to spinal lesions over a 10- to 14-day course with a total radiation dose of 25 to 50 Gy.[74–76] The standard radiation portal involves the diseased level with a 5-cm margin, which effectively includes two vertebral bodies above and below the target.[77] Local vertebral tumor control is directly proportional to radiation dose delivered to the area, and the primary factor that limits radiation to the spine is the relatively low tolerance of the spinal cord for radiation damage. Unfortunately, conventional XRT

lacks the precision to deliver large single-fraction doses of radiation to the spine near radiosensitive structures such as the spinal cord; therefore, the actual treatment dose that is delivered is often far below the optimal therapeutic dose.[78–80] Allowing greater radiation doses to reach just the specifically targeted treatment volume, as is the potential with stereotactic radiosurgery, may increase tumor control while minimizing the risk of spinal cord injury.

Surgical Approaches and Techniques

As a result of improvements in chemotherapy, radiation therapy, and hormonal therapy with concurrent increases in survival time for many patients with metastatic spine disease, many clinicians have advocated aggressive surgical decompression and stabilization for symptomatic lesions.[81] Effective techniques to achieve dorsal and ventral spinal stabilization have become more widely available in the last two decades, allowing surgeons to achieve adequate decompression and tumor resection with acceptable morbidity. The ability to correctly identify appropriate candidates for surgical intervention requires an understanding of the anatomy of the tumor and its surrounding structures, the biomechanical changes created by vertebral metastases, and the characteristics of the specific histopathology that may affect surgical resection.

Biomechanical Considerations

The vertebral body has been shown with biomechanical studies to support up to 80% of the axial load from above.[82] Since the vertebral body is the most common site of metastatic growth, destructive lesions in this area can have a significant impact on the load-bearing capacity of the spine. Such capacity is directly associated with tumor size, cross-sectional area of the remaining intact body, and bone mineral density. Windhagen and colleagues have shown that pathologic fracture can be accurately predicted (in cadaveric spines) by calculating the product of the remaining intact vertebral cross-sectional area and the bone mineral density.[83] Taneichi and colleagues studied 53 patients with osteolytic metastases and found that impending collapse was predicted by 50% to 60% involvement of the vertebral body in the thoracic spine and 35% to 40% involvement in the thoracolumbar/lumbar spine.[84] As a result, axial loading most commonly creates a compression fracture or a burst fracture with structurally significant lesions. Conversely, invasion and disruption of the posterior spinal elements, such as the facet joints, may predispose patients to dislocation and translational deformity. However, because these dorsal elements are less commonly affected by metastases, such structural pathology is unusual.

Surgical Anatomy and Histopathology Affect Resection

In general, the surgical approach is dictated by the segment of spine that is involved with tumor (cervical, thoracic, lumbar, sacral), the location of the tumor within the spine segment (anterior, posterior, right, left, or circumferential to neural elements), tumor histology, and the type of spinal reconstruction or stabilization required after tumor resection. In addition, patients with hypervascular tumors (e.g., renal cell carcinoma, thyroid carcinoma, hepatocellular carcinoma) may benefit from preoperative embolization to minimize intraoperative blood loss.

Metastatic tumors that cause epidural cord compression typically arise from the vertebral body and extend dorsally; thus, anterior approaches commonly provide the greatest ability to decompress the spinal cord. The cervical spine can be approached easily both anteriorly and posteriorly, and the accompanying reconstructive instrumentation is also familiar to most surgeons. In the thoracic spine, the upper segments (T1 to T4) may be particularly challenging to access, possibly requiring a combination of an anterolateral cervical approach with a sternotomy and/or thoracotomy to decompress the anterior cord.[85] To avoid encountering the great vessels and aortic arch, thoracic levels T5 to T10 are ideally approached via a right-sided thoracotomy unless the bulk of the extravertebral tumor is on the left side.[86] Approaches to the thoracolumbar junction (T11 to L1) may require a combined thoracotomy and retroperitoneal approach, while decompression at the L2 to L4 levels can occur via a retroperitoneal or transperitoneal/transabdominal approach. Disease that is limited to L5 is most commonly treated with posterior decompression and stabilization. Sacral lesions may require posterior alone approaches or transperitoneal entry into the pelvis for anterior-posterior approaches.

Adequate decompression of the spinal cord from a lone posterior approach is challenging but possible. Several authors have advocated bilateral transpedicular or costotransversectomy approaches to decompress the ventral aspect of the spinal cord.[87–92] Reconstruction of the anterior and middle columns of the spine may then be achieved with polymethylmethacrylate (PMMA) secured with Steinman pins[88,89] or a chest tube,[87] titanium mesh cages,[93] or expandable titanium cages.[90–92] One potential criticism of such approaches is that the spine is severely destabilized from such procedures. Specifically, since the normal posterior elements are generously resected to remove the diseased anterior elements, there is potentially increased surgical morbidity and a lower chance of successful biologic osseous fusion owing to the large gap that is created between neighboring bone surfaces.

In general, vertebral body resection for tumor with successive reconstruction/stabilization is now most commonly performed via an anterior approach with subsequent vertebral column reconstruction (distractible of mesh titanium cage) and anterolateral plating. Supplemental posterior stabilization with pedicle screw instrumentation is advocated in those with significant damage to the posterior elements from tumor or from tumor removal surgery, significant kyphosis, or lesions at the thoracolumbar junction and in patients with two or more adjacent vertebrectomies (Fig. 55-4). Lone posterior approaches should likely be reserved for patients with contraindications to anterior approaches (e.g., transthoracic approach in patients with severe lung disease), owing to the severely destabilizing characteristics of such procedures.

Metastatic Epidural Spinal Cord Compression Treatment

Metastatic epidural spinal cord compression (MESCC) is defined as radiographic evidence of an epidural metastatic lesion that is causing displacement of the spinal cord from its normal position in the spinal canal. This condition occurs in roughly 5% to 10% of cancer patients and in up to 40% of patients who have concurrent nonspinal bone metastases.[94–96] The result is approximately 25,000 annual cases of symptomatic MESCC in the United States.[8] Traditionally, treatments for patients with MESCC have included corticosteroids, surgery, and XRT. Historically, surgical options were limited to decompressive laminectomy. Unfortunately, laminectomy procedures frequently did not address the primary site of spinal cord compression, which is the ventral vertebral body. Tumor in this area often causes intrinsic instability of the anterior column of the spine. Laminectomy procedures, which are destructive to the posterior spinal elements, may thus further destabilize the spine and worsen a patient's pain and neurologic status.[87,97] For this reason, combined with improved spinal instrumentation, aggressive surgical decompression with instrumented stabilization has become mainstream.

A review of the literature from 1964 to 2005 by Witham and colleagues regarding articles related to radiation therapy and surgical management for MESCC has shown improved outcomes concurrent with evolution toward more aggressive decompressive surgery and more extensive surgical stabilization (Table 55-1).[98] Review of articles investigating neurologic function following XRT alone in patients with MESCC revealed that a mean of 36% of patients improved and a mean of 17% worsened. Review of articles investigating neurologic function in patients treated with laminectomy with or without XRT

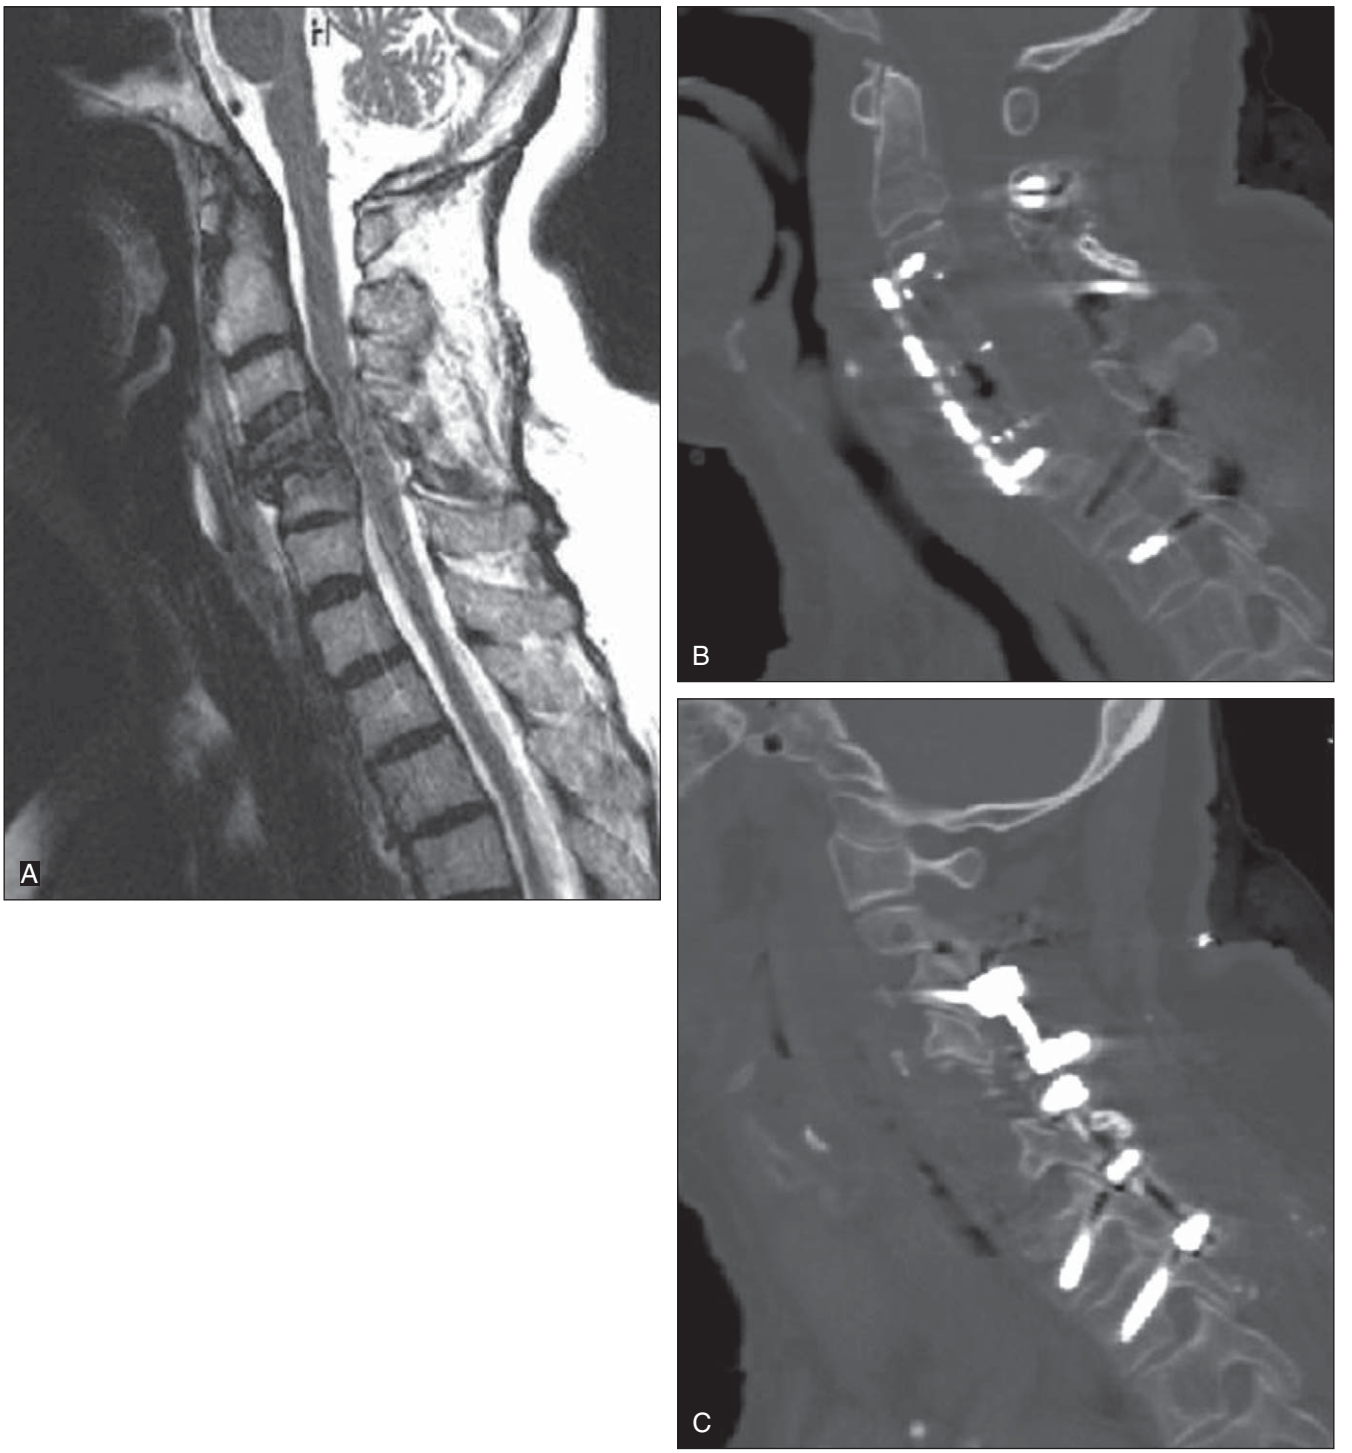

Figure 55-4 • Images from a patient with metastatic breast cancer undergoing surgical decompression and fusion. **A,** T2-weighted sagittal MRI image of the patient showing destructive and compressive lesion in the cervical spine. Postoperative sagittally reconstructed CT images showing anterior cages and plate (**B**) and posterior rods and screws (**C**).

Table 55-1 Review of the Literature for Treatment of Metastatic Epidural Spinal Cord Compression

	Improved Neurologic Function (mean)	Surgical Mortality (mean)
XRT alone	36%	N/A
Laminectomy, +/– XRT	42%	6%
Laminectomy, spinal stabilization, +/– XRT	64%	5%
Anterior decompression, spinal stabilization, +/– XRT	75%	10%

N/A, not applicable; XRT, radiation therapy.

Witham TF, Khavkin YA, Gallia GL, et al: Surgery insight: current management of epidural spinal cord compression from metastatic spine disease. Nat Clin Pract Neurol 2006;2:87–94.

showed results similar to those of the XRT alone series, with improved neurologic function in a mean of 42% of patients and worsened function in a mean of 13% of patients. Notably, surgical morbidity and mortality (mean surgical mortality of 6%) did occur in the laminectomy series compared to the nonsurgical XRT series. Interestingly, in the series of articles involving patients undergoing stabilization procedures performed in conjunction with posterior decompressive procedures, functional outcomes were improved, with a mean motor improvement in 64% of patients. In this series, pain relief was achieved a high percentage of the time (mean: 88%) with a mean mortality rate that was comparable to that of laminectomy alone (5%). Moreover, in the series of articles involving patients undergoing stabilization procedures concurrent with *anterio*r decompression to the spinal cord, functional neurologic improvement was even more remarkable (mean: 75%) with only a slight increase in surgical mortality (mean: 10%).

Recently, a randomized, prospective clinical trial of direct decompressive surgical resection and XRT versus XRT alone for MESCC was conducted by Patchell and colleagues (Table 55-2).[99] Both groups of patients received a total radiation dose of 30 Gy delivered in 10 fractions. The intent of surgery in all cases was spinal cord decompression, removal of as much tumor as possible, and spinal stabilization. Results showed a statistically significant difference in the post-treatment ambulatory rate in the surgery group of 84% (42 of 50) compared to the XRT alone group 57% (29 of 51) ($P = 0.001$). In addition, post-treatment ambulatory patients retained the ability to walk significantly longer in the surgery group than in the XRT group (median of 122 days versus 13 days, $P = 0.003$). Regarding patients who were ambulatory prior to treatment, 94% (32 of 34) in the surgery group continued to be ambulatory compared to 74% (26 of 35) in the XRT group ($P = 0.024$). In addition, 62% (10 of 16) of the patients in the surgery group who were nonambulatory prior to treatment regained the ability to ambulate compared to only 19% (3 of 16) in the XRT group ($P = 0.012$).

Most important, Patchell and colleagues demonstrated that survival time, maintenance of continence, muscle strength (ASIA scores), and functional ability (Frankel scores) were all significantly improved in the surgery group relative to the XRT alone group. Specifically, median survival in the surgery group was 126 days relative to 100 days in the XRT group ($P = 0.033$). Thus, Patchell and colleagues concluded that selected patients with MESCC treated with surgery and XRT possess a modest improvement in survival time, maintain the ability to ambulate longer, and recover the ability to ambulate more frequently than those treated with XRT alone.

On the basis of such results, basic recommendations can be made regarding indications for XRT alone versus surgery and XRT. Indications for lone XRT include MESCC secondary to highly radiosensitive tumors (lymphoma, myeloma, small cell lung carcinoma) *without* spinal instability, significant bony compromise of the spinal canal, or rapidly progressive neurologic decline. Lone XRT could also be indicated in patients with life expectancy less than 3 months. Indications for surgery include MESCC secondary to radio-resistant tumors or those that recur despite XRT, rapid neurologic deterioration during XRT, spinal instability, epidural cord compression from bone, or a need for tissue diagnosis (see Fig. 55-3). Solitary lesions with indolent courses, such as renal cell carcinoma in the absence of additional systemic metastases, may be considered for en bloc tumor resection with total spondylectomy in hope of a cure.[88,100–105]

Spinal Stereotactic Radiosurgery

Although spinal stereotactic radiosurgery (SRS) is a relatively new radiation treatment option for spinal metastases and therefore has not undergone rigorous, long-term investigation, it may have advantages over conventional XRT for the treatment of MESCC. The most common delivery systems are modified linear accelerators (Novalis, BrainLAB Inc., Chicago, IL) and a robotic linear accelerator (CyberKnife, Accuray, Sunnyvale, CA). In these systems, stereotactic

Table 55-2 Results of a Randomized, Prospective Trial Comparing Radiation Therapy Alone to Surgery and Radiation Therapy Combined

	Post-treament Ambulatory Rate	Post-treatment Retention of Ambulation (days)	Ambulatory Prior to Treatment Who Maintained Ambulation	Nonambulatory Prior to Treatment Who Regained Ambulation	Mean Survival (days)
XRT alone	57%	13	74%	19%	100
Surgery and XRT	84%	122	94%	62%	122

XRT, radiation therapy.

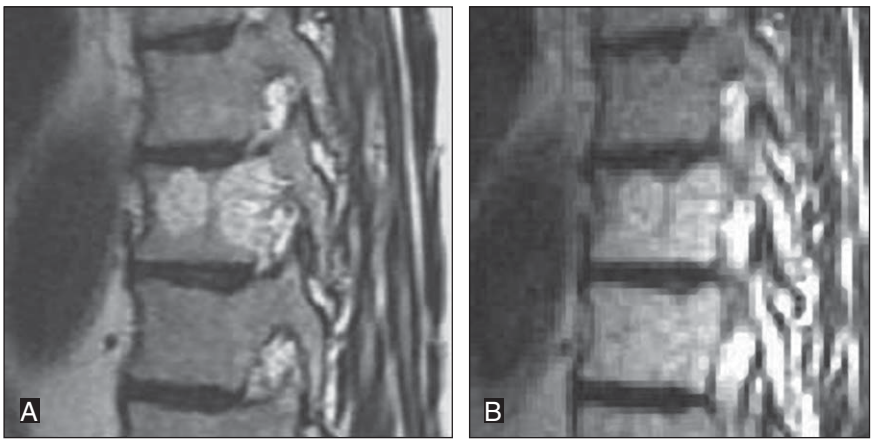

Figure 55-5 • Contrast-enhanced T2-weighted sagittal MRI images showing stable size of metastatic prostate lesions in the T9 vertebra before (**A**) and 5 months following stereotactic spinal radiosurgery (**B**). (Borrowed with permission from Jack Rock, M.D.)

localization provides precise convergence of multiple, "fractionated" radiation beams onto the targeted lesion. Because fractionation allows the normal tissues to optimally tolerate the radiation exposure, spinal SRS and intensity-modulated radiotherapy permit accurate delivery of radiation while minimizing radiation exposure to normal tissues.[74] Total doses typically range from 8 to 18 Gy, and SRS can be administered in one or two sessions in an outpatient setting.

A number of studies involving SRS for MESCC have provided encouraging results. Degen and colleagues presented the outcomes of patients with MESCC who were treated with Cyberknife to treat 58 spinal metastatic lesions that were documented as durable at 1 year follow-up.[106] Of the patients who presented with a neurologic deficit, 31% improved, 47% were unchanged, and 22% worsened. In this same study, a significant improvement in pain was noted, and quality of life was maintained with relatively limited treatment morbidity. Interestingly, there was 100% tumor control for metastatic lesions treated with SRS that had not undergone previous irradiation. In another recent study by Gerszten and colleagues involving CyberKnife radiosurgery for spinal lesions, axial and radicular pain improved in 74 of 79 patients who were symptomatic before treatment.[107] Potential limitations of SRS include the inability to address spinal instability or deformity secondary to metastatic spine disease and the inability to treat large lesions safely, owing to its associated highly concentrated radiation dose. In addition, SRS is still largely viewed as an experimental treatment modality for MESCC. Nonetheless, spinal SRS could prove to be an effective and indispensable weapon in the arsenal against metastatic spine disease (Fig. 55-5).

Percutaneous Vertebroplasty and Kyphoplasty

Traditionally, extensive, multifocal metastatic disease of the spinal column was treated by conventional XRT combined with conservative measures such as bed rest, bracing, corticosteroids, and analgesia. However, successful XRT often does not provide pain relief for up to 2 weeks, and bone strengthening is not seen for up to 4 months if it occurs at all.[108] Although originally developed for the treatment of painful vertebral hemangiomas, percutaneous vertebro/kyphoplasty has now become an effective treatment for the painful, pathologic fractures of metastatic spine disease.

Percutaneous injection of PMMA cement into a pathologically collapsed vertebral body has been shown to be effective for the treatment of pain.[109] Although it is assumed that such techniques minimize mechanical pain via cement-augmented structural support, it is possible that the cement itself possesses analgesic properties within the vertebral body.[110] Vertebroplasty is characterized by direct injection of PMMA into the vertebral body (Fig. 55-6). Kyphoplasty, on the other hand, involves first placing an expandable balloon into the vertebral body. Once inflated, the balloon creates a cavity for the subsequent injection of PMMA. It is postulated that kyphoplasty might actively improve kyphotic deformity of the spine with such balloon expansion.

Exact indications for vertebro/kyphoplasty in relationship to metastatic spinal disease are evolving. The technique is safe and effective for treating intractable pain secondary to vertebral fractures. A relative contraindication to vertebro/kyphoplasty is epidural spinal cord compression; however, when combined with XRT, such procedures can result in dramatic pain relief for poor surgical candidates. For instance, Fourney and colleagues presented 97 procedures in patients with intractable pain secondary to pathologic vertebral body fractures and noted moderate to complete pain relief in 84%.[109] Although rare, complications of such procedures are related to leakage or misdirection of PMMA outside the confines of the vertebral body, leading to spinal cord/root compression or PMMA pulmonary emboli via cement injection into the spinal venous plexus.[111]

CONCLUSIONS

Although management paradigms for patients with metastatic disease of the spine can appear complicated, involving multiple modalities and multiple specialties, technologic advances have allowed many patients to be treated more aggressively, often resulting in improved outcomes. Innovations in spinal fixation devices have permitted surgeons to decompress the spine more adequately, leading to improved functional outcomes. Specifically, a randomized, prospective trial has demonstrated that treatment with the combination of surgery followed by radiation leads to a greater likelihood of regaining and maintaining ambulation after treatment. In addition, improving imaging modalities and focused radiation therapies, such as spinal stereotactic radiosurgery, appear to target lesions of the spine more precisely while minimizing damage to neighboring structures. In this way, spinal metastatic disease, albeit classically managed with palliative care, might eventually be approached with intent to cure for a large proportion of patients.

56 Brain Metastases and Neoplastic Meningitis

Penny K. Sneed, Norbert Kased, Kim Huang, and James L. Rubenstein

SUMMARY OF KEY POINTS

Epidemiology

- Central nervous system metastases are common, affecting up to 25% of cancer patients.
- Most central nervous metastases involve the brain; less often, the dura, leptomeninges, skull base, or cranial nerves may be affected.
- The terms *neoplastic meningitis* and *carcinomatous meningitis* refer to the dissemination of cancer cells within the leptomeningeal space.
- The most frequent primary tumor types that give rise to brain metastases are lung cancer, melanoma, breast cancer, and renal cell carcinoma.

Diagnosis

- Brain metastases are best detected with contrast-enhanced magnetic resonance imaging (MRI) and generally appear as enhancing, well-circumscribed lesions with surrounding vasogenic edema. Biopsy or resection might be indicated to confirm the diagnosis, particularly in a patient with a single lesion and no cancer diagnosis or no known metastatic disease.
- Neoplastic meningitis often eludes early detection because meningeal enhancement is visible on MRI in only about 50% of cases and cerebrospinal fluid cytology may be negative initially in 40% to 50% of cases.

Prognosis

- The most important factors predicting for longer survival of patients with brain metastases include age less than 65 years, good performance status, control of the primary tumor, and lack of extracranial metastases.

Treatment

- The most standard treatment for brain metastases is whole-brain radiotherapy (WBRT), though patients with good prognosis who have a limited number of brain metastases might benefit from more aggressive therapy, such as surgery (especially for a single brain metastasis) or radiosurgery, with or without adjuvant WBRT. After WBRT alone, at least 60% of symptomatic patients improve significantly, and the median survival time is typically 3 to 6 months, with one third to one half of the patients dying of brain metastases and the rest dying of systemic disease. About 24% of brain metastases have a complete response to WBRT, and another 35% of lesions have a partial response, but the 1-year actuarial local control probability may be as low as 15%. Among patients with newly diagnosed brain metastases who are selected for surgery or radiosurgery with or without WBRT, the median survival time is approximately 9 to 11 months. One-year actuarial local control is about 35% for surgery alone, 85% for surgery and adjuvant WBRT, and 75% to 90% for radiosurgery with or without adjuvant WBRT. However, the increased local control that is achievable with surgery plus WBRT or with radiosurgery may only be meaningful in patients likely to live at least 6 or 12 months from the standpoint of their extracranial disease. Chemotherapy is not generally used as a primary treatment for brain metastases, but it has some efficacy on its own, and there is increasing interest in combining drugs with WBRT.
- Intrathecal chemotherapy plays a major role in the management of neoplastic meningitis, alone or in combination with radiotherapy. Because craniospinal radiotherapy causes significant acute toxicity as well as long-lasting myelosuppression, neoplastic meningitis may be managed by using intrathecal chemotherapy combined with more limited radiotherapy, such as a lumbar field for gross disease in the cauda equina, skull base fields for cranial nerve involvement, or WBRT in patients with hydrocephalus stemming from diffuse brain leptomeningeal involvement.

INTRODUCTION

Central nervous system (CNS) metastases result from the intracranial spread of tumor cells that originate outside of the CNS. Most CNS metastases involve the brain parenchyma, dura, or leptomeninges; less commonly, metastases involve the base of skull, cranial nerves, or dural sinuses. This chapter deals with both parenchymal brain metastases and leptomeningeal metastases, also known as neoplastic or carcinomatous meningitis.

BRAIN METASTASES

Epidemiology

Brain metastases appear to be more common than primary malignant brain tumors, though the exact incidence is unknown. In a Memorial Sloan Kettering Cancer Center autopsy series, 24% of cancer patients had CNS metastases, and 15% had brain metastases,[1] and in a Roswell Park Memorial Institute autopsy study of 216 melanoma

patients, 55% had brain metastases.[2] One population-based study in the Netherlands reported by Schouten and colleagues found that 8.5% of 2724 patients with melanoma or lung, breast, colorectal, or renal cell carcinoma developed brain metastases. The 5-year cumulative incidence of brain metastases was 7.4% in patients with melanoma and 16.3%, 9.8%, 5.0%, and 1.2% for patients with lung, renal cell, breast, or colorectal carcinoma, respectively.[3] Barnholtz-Sloan and colleagues calculated the population-based incidence of brain metastasis within the Metropolitan Detroit Cancer Surveillance System. In this cohort, 16,210 patients were found to have brain metastases, representing 9.6% of all lung, melanoma, breast, renal, and colorectal cancer patients diagnosed from 1973 to 2001. Lung and melanoma were the primary sites with the highest rates at 19.9% and 6.9%, respectively, and 5.1% of breast cancer patients, 6.5% of renal cancer patients, and 1.8% of colorectal cancer patients developed brain metastases.[4] It has been theorized that the incidence of brain metastases may be increasing as a result of improvements in cancer management leading to longer survival times and increased sensitivity of lesion detection made possible by contrast-enhanced, high-resolution magnetic resonance imaging (MRI), although Schouten and colleagues found no evidence of an increasing incidence of brain metastases over the period from 1986 through 1995.[3]

The most common primary tumors responsible for brain metastases are lung cancer (making up approximately 40% to 50% of cases), breast cancer (15%), melanoma (10%), and unknown primary (5% to 10%), followed by renal cell carcinoma, colorectal cancer, gynecologic cancers, and other miscellaneous tumors.[5,6] Brain metastases may arise from any primary cancer, but certain tumors such as melanoma and carcinomas of the lung, kidney, and breast have a predilection for spread to the CNS. By contrast, some tumors rarely metastasize to the brain, such as prostate, oropharyngeal, and skin carcinomas. In children, the most common solid malignancies responsible for brain metastases are sarcomas, neuroblastoma, and germ cell tumor.[7]

Cancer can spread to the brain at various points in the course of disease. Synchronous brain metastases, found within 1 month of the primary cancer diagnosis, occur in up to one third of patients,[3] including cases in which brain metastases are responsible for a patient's presenting signs or symptoms. More commonly, however, brain metastases are discovered after the diagnosis of cancer, often after other systemic metastases have developed, at a median of less than 1 year after diagnosis of lung cancer and at a median of 2 to 3 years after diagnosis of melanoma, breast cancer, gynecologic cancer, or renal cell carcinoma.[6] Overall, the median time from primary diagnosis to diagnosis of brain metastases is 12 months.[6]

Pathophysiology

Brain metastases arise primarily from arterial hematogenous spread to the brain, with tumor cells tending to become trapped where blood vessels decrease in caliber at the gray/white matter junction and the distalmost vasculature (the border zones or "watershed" zones between arterial territories).[8] Metastatic cells then adhere to the endothelial cells, penetrate into the brain parenchyma, and proliferate. Larger aggregates of tumor cells that gain access to the venous circulation are filtered out in lung capillaries before entering the systemic arterial circulation, but individual tumor cells may pass through the lung to lodge in the brain. Tumor emboli may also break off from lung metastases or primary lung cancers to travel to the brain via the arterial circulation. It has also been theorized that cells from pelvic or abdominal cancers may gain access to the posterior fossa or leptomeninges through Batson's vertebral venous plexus without passing through the lungs.[5] Intracranial spread may also occur via direct extension from bone or dural metastases or perineural extension along cranial nerves. The distribution of metastases is roughly proportional to the relative blood flow to different regions; approximately 80% of brain metastases are located in the cerebral hemispheres, 10% to 15% in the cerebellum, and 1% to 5% in the brain stem.[5,6] Posterior fossa metastases appear to arise disproportionately from pelvic or abdominal primary tumors.[5]

Most brain metastases are very well circumscribed. Although there may be extensive associated edema, the tumor cells do not tend to infiltrate into surrounding brain tissue, in contrast to primary malignant brain tumors. Most brain metastases are solid, but they can appear cystic because of necrosis, keratin deposits in squamous cell carcinoma, or mucin secretion from adenocarcinoma. Brain metastases may be hemorrhagic, particularly from melanoma, renal cell carcinoma, choriocarcinoma, and, less frequently, bronchogenic carcinoma.[9] The pathologist can easily identify well-differentiated metastases, but immunohistochemistry or electron microscopy might be needed to help make the diagnosis of metastatic versus primary brain neoplasm and to suggest the likely site of origin of poorly differentiated metastases.

Single brain metastases are more common than multiple metastases in patients with renal cell, gastrointestinal, or unknown primary cancers.[6] In the era of computed tomographic (CT) imaging, about 50% of brain metastasis patients had a single brain lesion.[5] By MRI criteria, the actual percentage of brain metastasis patients with a single lesion might be lower than this, because contrast-enhanced MRI is more sensitive than CT is[10] and because triple-dose gadolinium is more sensitive than is single-dose gadolinium-enhanced MRI.[11] Of note, the term *solitary brain metastasis* implies that a single brain metastasis is the only known site of metastatic disease, whereas the term *single brain metastasis* refers to a single cerebral lesion without implying whether or not there are extracranial metastases.

Clinical Presentation

The possibility of brain metastases should be suspected in any cancer patient who develops new neurologic signs or symptoms. Two thirds of cancer patients who are found to have brain metastases at autopsy had experienced neurologic symptoms from the metastases,[12] and only 10% of a series of 729 patients diagnosed by CT or MRI from 1973 through 1993 were asymptomatic.[6] The most common presenting symptoms are headache (24% to 53%), focal weakness (16% to 40%), altered mental status (24% to 31%), seizures (15% to 16%), and ataxia (9% to 20%).[6,13] Symptoms may worsen gradually from a growing tumor and the associated edema. Less often, acute neurologic symptoms may occur from hemorrhage into a brain metastasis. Again, the histologic types with the greatest propensity to produce hemorrhagic brain metastases include melanoma, renal cell carcinoma, and choriocarcinoma.

Diagnosis

It is widely accepted that MRI is the best diagnostic test to detect brain metastases. Standard imaging includes T2-weighted and pre- and post-gadolinium-enhanced T1-weighted sequences; a postcontrast fluid-attenuated inversion-recovery sequence is also helpful in visualizing small metastases near cerebrospinal fluid (CSF) spaces (Fig. 56-1). Gadolinium-enhanced MRI is much more sensitive than either non-enhanced MRI or contrast-enhanced CT imaging.[10,14] In one study, 17 of 55 patients (31%) with a single metastasis based on contrast-enhanced CT imaging were found to have multiple metastases on contrast-enhanced MRI.[15] The sensitivity of MRI is improved by using triple-dose gadolinium (0.3 mmol/kg instead of 0.1 mmol/kg gadoteridol) to increase contrast enhancement[11] and by using contiguous axial 3-mm slices without skips and coronal three-dimensional spoiled gradient echo recovery volume imaging so that small lesions are not missed between slices. Functional imaging techniques such as positron emission tomography, magnetic resonance spectroscopy, and perfusion and diffusion MRI may aid in distinguishing metastatic lesions from necrosis, primary brain tumor, or nonmalignant processes.[16–18]

The differential diagnosis of an enhancing or hemorrhagic intracranial lesion includes brain metastasis, primary brain tumor, CNS

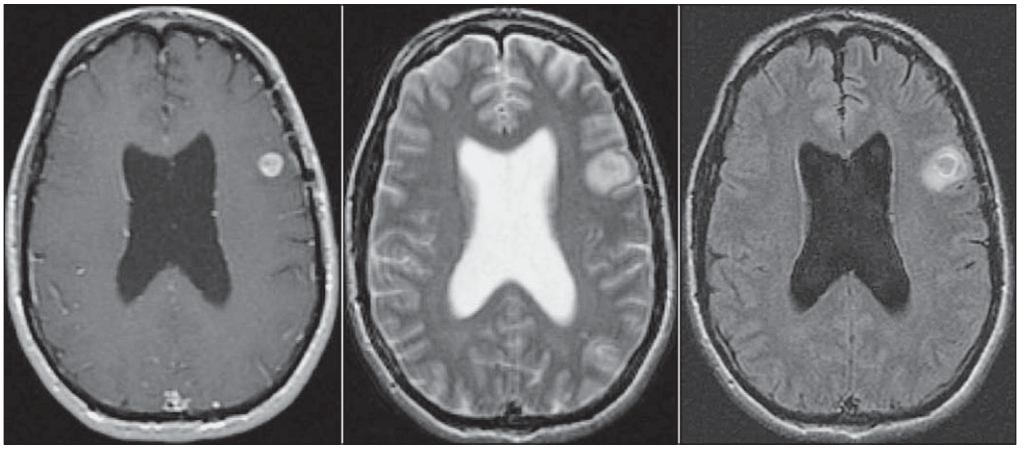

Figure 56-1 • Typical appearance of a brain metastasis on magnetic resonance imaging. The lesion is well circumscribed and brightly enhancing on the postcontrast T1-weighted image (*left*). Both edema and cerebrospinal fluid show up as increased signal on the T2-weighted image (*center*). Both the metastasis and the surrounding edema appear bright on the postcontrast fluid-attenuated inversion-recovery image, while the cerebrospinal fluid signal is suppressed (*right*).

lymphoma, abscess, encephalitis, cerebral infarct or hemorrhage, progressive multifocal leukoencephalopathy, tumefactive demyelinating disease, and radiation necrosis. Factors that aid in making a diagnosis based on imaging include characteristic appearance, a known cancer diagnosis, and multiplicity of lesions. However, a biopsy can be warranted if there is doubt about the diagnosis or if a single brain lesion is seen in a patient with a history of cancer but no other known metastatic disease, because management and prognosis may vary widely depending on the diagnosis. In a study reported by Patchell and colleagues that required biopsy or surgery before WBRT, 11% of 54 patients with a single brain lesion that was thought to be a metastasis turned out to have a glioblastoma, low-grade astrocytoma, abscess, or inflammatory process.[19] A stereotactic biopsy series in 100 patients with multifocal brain lesions and no known primary cancer diagnosed malignant gliomas in 37% of patients, primary CNS lymphoma in 15%, brain metastases in 15%, low-grade gliomas in 12%, infectious processes in 10%, and ischemic lesions in 6%.[20]

Prognostic Factors

In general, brain metastases are associated with a poor prognosis. In the pre-CT era, the median survival time of patients with symptomatic brain metastases was approximately 1 to 2 months without treatment,[21–23] 2 to 2.5 months with corticosteroid therapy,[24] and 3 to 6 months with WBRT.[25–27] Despite some major advances in cancer diagnosis, cancer treatment, and brain imaging, the overall survival time of unselected patients with brain metastases treated with WBRT has remained at 3 to 6 months since the 1950s.[6,28–30] The majority of patients with brain metastases have or will soon develop disseminated systemic disease and overall survival is often determined by the extent and activity of the extracranial disease. In patients with a relatively short life expectancy, the treatment goal is to achieve rapid palliation and a neurologic symptom-free remission interval that is commensurate with the life expectancy. However, long-term survival or cure is possible in a small proportion of patients with brain metastases, and patients with a longer life expectancy from the standpoint of their extracranial disease might benefit from more aggressive therapies that will yield more durable control of their brain metastases.

Two large series of brain metastasis patients evaluated for prognostic factors are summarized here. Lagerwaard and colleagues studied 1292 patients with CT-diagnosed brain metastases who were treated at Daniel den Hoed Cancer Center in Rotterdam from 1981 through 1990.[31] The overall median survival time was 3.4 months, and the most important patient and tumor characteristics that were prognostic for longer survival time included better performance status, limited versus extensive systemic tumor activity, and normal serum lactate dehydrogenase level, followed by lesser factors, including breast cancer versus other primary sites, age less than 70 years, and 1 to 2 versus 3 or more brain metastases.[31] Gaspar and colleagues identified three prognostic groups using a recursive partitioning analysis (RPA) of over 1100 evaluable patients enrolled in three consecutive Radiation Therapy Oncology Group (RTOG) trials conducted from 1979 through 1993.[32] The median survival time was 7.1 months for the subgroup with the best prognosis, RPA class 1, consisting of patients less than 65 years old with a Karnofsky performance status (KPS) of at least 70, controlled primary tumor, and no extracranial metastases (Table 56-1). The subgroup with the poorest prognosis, RPA class 3, including patients with KPS less than 70, had a median survival time of only 2.3 months; and the median survival time was 4.2 months for the remaining patients who made up RPA class 2 (see Table 56-1).[32] The prognostic value of these RPA classes has been validated in 569 patients with single or multiple brain metastases who were treated with radiosurgery with or without adjuvant WBRT, with median survival times of 14.0 to 15.2 months for RPA class 1, 7.0 to 8.2 months for RPA class 2, and 5.3 to 5.5 months for RPA class 3 (see Table 56-1).[33] Similarly, two groups reported median survival times of 13.4 to 25.4 months for RPA class 1, 5.9 to 9.3 months for RPA class 2, and 1.5 to 4.5 months for RPA class 3 patients treated with radiosurgery alone,[34,35] and three surgical series found median survival times ranging from 10.9 to 21.4 months for RPA class 1, 9.0 to 9.9 months for RPA class 2, and 6.0 to 8.9 months for RPA class 3 patients who underwent surgical resection with or without adjuvant WBRT (see Table 56-1).[36–38]

Treatment

The symptoms resulting from brain metastases may be ameliorated with corticosteroids or osmotic therapy for the peritumoral edema or with anticonvulsants for seizure control. Direct antitumor therapies include surgery, radiotherapy (external beam radiotherapy, radiosurgery, and brachytherapy), chemotherapy, and molecular targeted drugs.

Corticosteroids

Corticosteroid therapy is generally instituted in symptomatic patients as soon as brain metastases are diagnosed, to help alleviate symptoms

Table 56-1 Median Survival Time by Radiation Therapy Oncology Group Recursive Partitioning Analysis Class

	RPA Class 1		RPA Class 2		RPA Class 3	
Treatment	**No. of Patients**	**MST (Months)**	**No. of Patients**	**MST (Months)**	**No. of Patients**	**MST (Months)**
WBRT alone[32]	236	7.1	765	4.2	175	2.3
RS alone initially[34]	23	25.4	74	5.9	20	4.2

until the brain metastases and edema improve from specific antitumor treatment. Corticosteroids reduce the permeability of leaky tumor blood vessels and thereby reduce the mass effect and edema caused by brain metastases.[39] The most commonly used steroid is dexamethasone because of its relatively low mineralocorticoid activity, often using a loading dose of 10 mg followed by 4 mg every 6 hours. Lower doses (2 to 4 mg twice daily or 2 to 4 mg three times a day) may be adequate in many situations, and higher doses might rarely be needed. Patients commonly improve within hours after the first dose, attaining maximal benefit after approximately 3 to 7 days. After patients become asymptomatic or reach maximal benefit, the dose should be gradually tapered and either discontinued or maintained at the lowest dose level needed to manage symptoms. If headaches recur or neurologic symptoms worsen during the course of the taper, the dose should be increased as needed, and then the taper should proceed more gradually. Occasional patients develop steroid withdrawal symptoms of depression, fatigue, nausea, or poor appetite, necessitating reinstitution of low-dose dexamethasone and a gradual taper schedule in the low-dose range. Steroids have numerous adverse effects, particularly with long-term use. Common short term side effects include insomnia, increased appetite, fluid retention, mood changes, acne, and exacerbation of diabetes, and some of the serious long-term side effects include significant weight gain, steroid myopathy, immunosuppression, and aseptic necrosis of the femoral heads. Of note, steroid myopathy can cause fairly profound weakness in large proximal muscles, making it difficult for patients to get up and walk; this dysfunction may be mistaken as a sign of progression of CNS metastases and as an indication to continue or increase steroids when it is actually a complication of steroid therapy.

Anticonvulsants

Seizures are very unlikely to occur from infratentorial metastases but may be triggered by supratentorial metastases. About 15% of patients with brain metastases present with seizures and 30% to 40% experience seizures at some point in their disease course.[40] Any patient with brain metastases who experiences a seizure should be started on an anticonvulsant such as phenytoin, carbamazepine, or levetiracetam, but prophylactic anticonvulsants are not generally recommended because prospective and retrospective studies have failed to demonstrate a benefit for prophylactic anticonvulsants in patients with brain metastases.[39–41] Also, anticonvulsants can have adverse side effects or cause serious allergic reactions, such as Stevens-Johnson syndrome. It is important to note that certain anticonvulsants, such as phenytoin, can reduce the efficacy of corticosteroids and can activate the cytochrome P450 enzyme system.[42] This latter property can affect patients who are undergoing chemotherapy by altering the metabolism of some chemotherapeutic agents, thus requiring chemotherapy dose adjustment.

External Beam Radiation Therapy

The most standard treatment for brain metastases consists of WBRT covering the entire intracranial contents with shielding of the eyes (Fig. 56-2). The benefits of WBRT were first described in the 1950s and 1960s. In these early studies, significant symptomatic improvement was noted in about 60% of patients, and the median survival time ranged from about 3 to 6 months with WBRT[25–27] compared with an expected median survival time of 1 to 2 months without treatment.[21–23]

SELECTED RANDOMIZED TRIALS OF WHOLE-BRAIN RADIOTHERAPY ALONE. The RTOG has conducted multiple large phase III randomized trials of WBRT since 1970 (Table 56-2). The first two trials, which compared various WBRT fractionation schemes in over 1800 patients who were treated from 1971 through

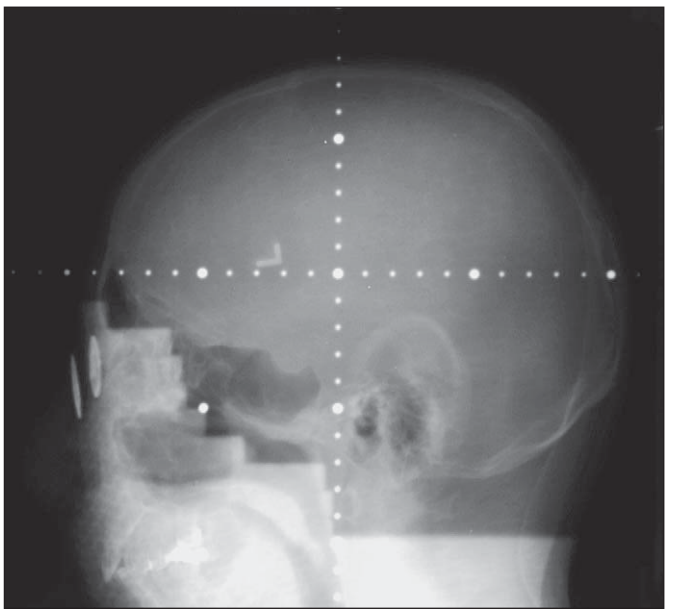

Figure 56-2 • Double-exposed portal image of a typical whole-brain radiotherapy field, showing radiation covering the entire brain with blocking of the eyes and other extracranial structures.

Table 56-2 Selected Randomized Trials of Whole-Brain Radiotherapy Alone for Brain Metastases

Protocol	Years	No. of Patients	Fractionation Scheme	Median Survival Time (Months)
RTOG 6901[28,43]	1971–1973	233	30 Gy/10 fractions/2 weeks	4.8
First study		217	30 Gy/15 fractions/3 weeks	4.1
		233	40 Gy/15 fractions/3 weeks	4.1
		227	40 Gy/20 fractions/4 weeks	3.7
RTOG 7361[28,43]	1973–1976	447	20 Gy/5 fractions/1 week	3.4

Accelerated hyperfractionation		216	54.4 Gy at 1.6 twice daily	4.5

RTOG, Radiation Therapy Oncology Group.

1976, gathered a wealth of data.[28,43] Complete or partial response of specific neurologic symptoms was observed in 60% to 90% of symptomatic patients; 47% to 52% of patients improved to a higher neurologic function class; the median duration of improvement was 10 to 12 weeks; and 75% to 80% of patients' remaining survival time was spent in an improved or stable neurologic state. The overall median survival times were 18 weeks (4.1 months) in the first study and 15 weeks (3.4 months) in the second study, and brain metastases were reported to be the cause of death in 49% or 31% of the patients, respectively. There were no significant differences in symptomatic response rates, duration of response, or survival time according to the treatment regimen: 40 Gy in 20 fractions, 40 Gy in 15 fractions, 30 Gy in 15 fractions, 30 Gy in 10 fractions, or 20 Gy in 5 fractions.[28,43] With the ultrarapid fractionation schemes that were tested by the RTOG (10 Gy in one fraction or 12 Gy in 2 fractions; see Table 56-1), there was some concern that irradiation might have led to herniation and death within 48 hours of treatment in a small number of cases, and time to neurologic progression was shorter than that with more protracted regimens.[44,45] Both of these findings agreed with conclusions of a Memorial Sloan Kettering Cancer Center evaluation of 15 Gy in 2 fractions over 3 days compared with 30 Gy in 15 fractions.[46] Two later RTOG trials failed to show any advantage of 50 Gy in 20 fractions or 54.4 Gy at 1.6 Gy twice daily over 30 Gy in 10 fractions (see Table 56-1),[29,30] further solidifying 30 Gy in 10 fractions over 2 weeks as the most frequently used WBRT treatment regimen. Other common treatment regimens include 35 to 37.5 Gy at 2.5 Gy per fraction, 40 to 50 Gy at 2.0 Gy per fraction, and 45 to 50.4 Gy at 1.8 Gy per fraction. Shorter regimens may be selected for patients with a shorter life expectancy or when WBRT is delaying chemotherapy that is needed to treat systemic disease, and smaller fraction size may be selected in patients with longer life expectancy on the basis of a suspicion that this might give less risk of late neurotoxicity.

RESPONSE AND LOCAL CONTROL. Neider and colleagues studied CT response of brain metastases to WBRT (30 Gy in 10 fractions).[47] By lesion, the complete response rate was 24%, and the partial response rate was 35%. The overall (complete plus partial) response rates were 81% for small cell carcinoma, 65% for breast cancer, 56% for squamous cell carcinoma, 50% for nonbreast adenocarcinoma, 46% for renal cell carcinoma, and 0% for melanoma. Absence of necrosis and smaller volume were associated with improved response rate; complete response rates were 39% for solid metastases, 15% for those with less than 50% necrosis, and 11% for those with at least 50% necrosis, and 52%, 39%, 17%, 20%, 5%, and 0% for lesion volumes up to 0.5 mL, 0.6 to 1.0 mL, 1.1 to 3.0 mL, 3.1 to 6.0 mL, 6.1 to 10.0 mL, and more than 10 mL, respectively.[47] In another study by the same group, there was a suggestion that a higher response rate was obtained with 40 at 2 Gy per fraction with or without a partial brain boost to 50 or 60 Gy compared with 30 Gy at 3 Gy per fraction.[48] For the WBRT-only arm of a recent RTOG trial of WBRT with or without radiosurgery, the complete response rate was 8%, the partial response rate was 54%, the stable disease rate was 22%, and the progression rate was 17% among 78 patients with imaging follow-up.[49] Data on long-term local control of brain metastases after WBRT alone are limited and highly variable. The 1-year actuarial local control probability by patient ranged from 0% to 14% in the WBRT-only arms of randomized trials reported by Kondziolka and colleagues[50] and Patchell and colleagues[19] but as high as 71% in the WBRT-only arm of the RTOG randomized trial of WBRT with or without radiosurgery.[49]

PARTIAL BRAIN RADIOTHERAPY. Partial brain radiotherapy can be considered for a single metastasis in lieu of WBRT, but it is generally not advisable in that it would complicate or preclude later WBRT if needed (unlike radiosurgery, which delivers much more focal radiation dose). Caution is advised when postoperative radiotherapy to the posterior fossa alone is contemplated because cerebellar metastases appear to be associated with an increased risk of leptomeningeal dissemination after resection.[51,52] On the other hand, partial brain radiotherapy might be useful for treating recurrent brain metastases that are not suitable for resection or radiosurgery.

TOXICITY OF WHOLE-BRAIN RADIOTHERAPY. Acute toxicity of WBRT includes hair loss, fatigue, and modest skin reaction in essentially all patients and mild acute ototoxicity in some patients. The skin reaction resolves by several weeks, and fatigue improves gradually over one or several months. Hair generally regrows by 6 months following WBRT, but alopecia may be permanent in a central strip on the top and back of the head from the reduced skin

sparing of tangential radiation beams. In the minority of patients who are long-term survivors after WBRT, there is a risk of late hearing loss, retinopathy if the retina was included in the radiation field, and permanent neurocognitive toxicity. DeAngelis and colleagues reported an 11% risk of severe radiation-induced dementia among 1-year survivors after resection of a single brain metastasis followed by postoperative WBRT to 20 to 40 Gy using high-dose daily fractions.[51] A separate report from the same group described 12 patients cured of brain metastases who developed severe radiation-induced dementia with associated ataxia and urinary incontinence.[53] Imaging with CT showed atrophy, ventricular dilatation, and hypodense white matter. The WBRT fractionation schemes included mostly mixtures of 3- or 4-Gy fractions with 5- or 6-Gy fractions, but two of the affected patients had received the standard regimen of 30 Gy in 10 fractions.[53] Nieder and colleagues reported a 42% 2-year actuarial probability of symptomatic mild, moderate, or severe late radiation toxicity in patients who were treated with resection of a single brain metastasis followed by WBRT to 30 Gy in 10 fractions or 40 Gy in 20 fractions, but no details were provided regarding the nature of the toxicity.[54] Among 112 patients on the WBRT-only arm of a recent RTOG randomized trial, Andrews and colleagues reported four grade 1, one grade 2, one grade 3, and one grade 4 late central neurologic toxicities; two grade 1, two grade 2, and one grade 3 late ototoxicities; and eleven grade 1 and four grade 2 chronic skin toxicities.[49] This RTOG trial did not include formal neurocognitive testing, but it is becoming more common to incorporate baseline and follow-up neurocognitive testing into prospective trials in patients with brain metastases.

Surgery

Surgery has important roles to play in certain subsets of patients: confirming the diagnosis when needed (as discussed in the section on Diagnosis); relieving mass effect from a large, symptomatic lesion (Fig. 56-3); improving the likelihood of durable local control for a single metastasis; and salvaging a failing metastasis after prior therapy. Surgical resection may also be useful for lesions with considerable peritumoral edema despite steroids or for lesions that are causing refractory seizures, even if the lesion is sufficiently small that radiosurgery would be a therapeutic option.[55] Resection of brain metastases has become safer with advances in neuroimaging and neurosurgery, such as image guidance, preoperative and intraoperative functional mapping, and intraoperative ultrasound and MRI.[56]

RANDOMIZED TRIALS OF WHOLE-BRAIN RADIOTHERAPY WITH OR WITHOUT SURGERY. Three prospective, randomized trials have been performed to evaluate the addition of surgery to WBRT (Table 56-3). In the trial reported by Patchell and colleagues, 48 patients with a single brain metastasis were randomized to biopsy and WBRT versus resection and WBRT to 36 Gy in 12 fractions.[19] Patients who underwent resection had significantly improved local control (80% versus 48% for resection and WBRT versus biopsy and WBRT; $P < 0.02$), duration of functional independence (median: 38 weeks versus 8 weeks, $P < 0.005$), and survival (median: 40 weeks versus 15 weeks, $P < 0.01$). Factors that were associated with longer survival included younger age, no extracranial disease, surgical resection, and a longer interval from primary diagnosis to brain metastasis diagnosis.[19]

A trial that was performed in the Netherlands randomized 63 evaluable patients with a single brain metastasis to surgery plus WBRT versus WBRT alone (40 Gy at 2 Gy twice daily; see Table 56-3).[57] Patients on the surgery arm of the trial had longer functionally independent survival (median: 7.5 months for surgery and WBRT versus 3.5 months for WBRT alone, $P = 0.06$) and longer survival time (median: 10 months versus 6 months, $P = 0.04$). The survival benefit was seen only in patients without active extracranial disease, in whom the median survival time was 12 months for surgery and WBRT versus 7 months for WBRT alone ($P = 0.02$); the median survival time was 5 months for patients with active extracranial disease regardless of the treatment arm. Older age (over 60 versus 60 years or younger) was also confirmed as an important unfavorable prognostic factor ($P = 0.003$; hazard ratio = 2.74).[57]

A third trial failed to show a benefit for surgery in addition to WBRT (30 Gy in 10 fractions over 2 weeks; see Table 56-3).[58] The median survival times were 5.6 months among 41 patients randomized to surgery with WBRT versus 6.3 months among 43 patients randomized to WBRT alone (4 of whom had surgery before WBRT and 6 of whom had surgery after WBRT). There was no difference in duration of functional independence between the two treatment arms. The authors concluded that further trials and/or a meta-analysis was indicated,[58] but overall, these studies and previous nonrandomized experience[59–61] support the use of surgery in addition to WBRT in patients with good performance status, controlled extracranial disease, and a single brain metastasis.

RANDOMIZED TRIAL OF SURGERY WITH OR WITHOUT WHOLE-BRAIN RADIOTHERAPY. Postoperative WBRT may help to prevent recurrence at the resection cavity and to prevent the appearance of new brain metastases by treating any microscopic metastases elsewhere in the brain and any dissemination of tumor cells as a result of the surgery. Following up on multiple retrospective studies that suggest a benefit for postoperative WBRT after resection of a brain metastasis, Patchell and colleagues performed a randomized trial (see Table 56-3).[62] Ninety-five adults were randomized to observation versus postoperative WBRT to 50.4 Gy in 28 fractions after complete resection of a single brain

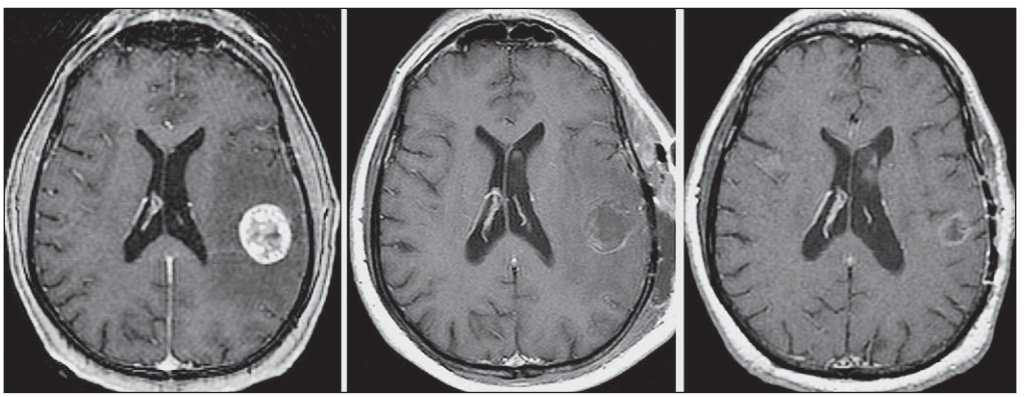

Figure 56-3 • Preoperative (*left*), immediate postoperative (*center*), and 2-month postoperative (*right*) contrast-enhanced T1-weighted magnetic resonance images of a single metastasis treated with surgical resection.

metastasis. The observation arm had a significantly increased risk of local failure (46% for observation versus 10% for WBRT), distant brain failure (37% versus 14%), and any brain failure (70% versus 18%); shorter time to local failure (median: 27 weeks versus more than 52 weeks [6.2 months versus more than 12 months]; $P < 0.001$; hazard ratio: 6.03); and shorter time to any brain failure (median: 26 weeks versus more than 70 weeks [6.0 months versus more than 16.1 months]; $P < 0.001$; hazard ratio: 4.94). Patients who were randomized to observation were more likely to die neurologic deaths (44% versus 14%; $P = 0.003$) but, interestingly, had similar duration of functional independence (median: 35 weeks [8.0 months] for observation versus 37 weeks [8.5 months] for WBRT; $P = 0.61$) and similar survival time (median: 43 weeks versus 48 weeks [9.9 months versus 11.0 months]; $P = 0.39$).[62] Topics that were not addressed in the report included the use or success of salvage therapy and acute and late toxicity of WBRT and salvage therapies.

SURGERY FOR MULTIPLE METASTASES. Surgical resection may also be used successfully to manage selected patients with more than one brain metastasis. Bindal and colleagues reported a median survival time of 14 months among 26 patients with multiple brain metastases who underwent resection of all of their brain lesions in a single operation, identical to the survival time of matched patients who had had resection of a single metastasis.[63] The complication rate was 9% per craniotomy, the 30-day mortality rate was 4%, and only 6% of symptomatic patients worsened, while 83% improved and 11% remained stable.[63] A different group describing results of surgery and WBRT had noted significantly poorer survival among 18 patients with multiple brain metastases compared with 28 patients with a single metastasis, but apparently, only one patient with multiple metastases had undergone gross total resection of all (two) metastases, and this patient survived 46 months.[64] In a recent series, Paek and colleagues reported a median survival time of 8 months after surgery for approximately 103 patients with a newly diagnosed single metastasis versus 11 months after surgery for 46 patients with newly diagnosed multiple brain metastases (only 9 of whom had multiple brain metastases resected). Most patients received postoperative WBRT.[65]

TOXICITY OF SURGERY. The morbidity and mortality associated with surgical resection of brain metastases have decreased over the years as techniques have improved. Lang and colleagues estimated the 30-day mortality rate to be about 4% to 5% after surgery for brain metastasis (essentially identical to the 30-day mortality rate in patients who were managed with WBRT alone).[56] The most common types of postoperative morbidity include wound infection, hemorrhage, meningitis, pneumonia, deep venous thrombosis, and pulmonary embolism, which occur in about 10% to 15% of patients on average.[56,66] Most patients are symptomatic preoperatively; one surgical series reported that 0% to 13% of patients worsened neurologically, 65% to 84% improved, and 11% to 22% remained stable after resection of single or multiple brain metastasis.[63] Paek and colleagues recently reported outcomes in 208 patients who underwent resection of one ($N = 191$) or multiple ($N = 17$) newly diagnosed ($N = 149$) or recurrent ($N = 59$) brain metastases at a single institution using modern neurosurgical techniques.[65] The 30-day mortality rate was 1.9%, with two deaths from hemorrhage in the resection cavity, one from pulmonary embolism secondary to deep venous thrombosis, and one from bowel perforation with sepsis. The median hospital

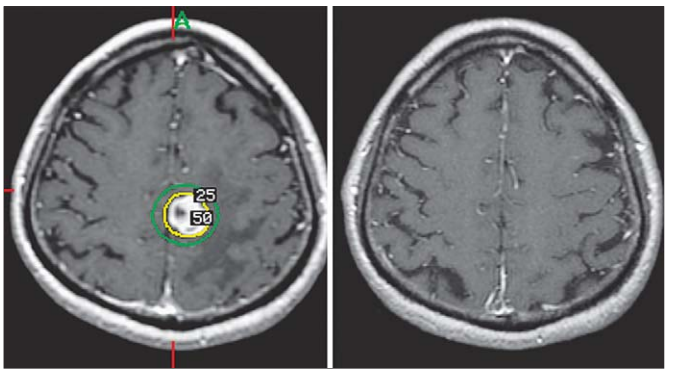

Figure 56-4 • Postcontrast T1-weighted magnetic resonance imaging of a brain metastasis shown on the day of radiosurgery with superimposed 50% and 25% isodose contours (*left*) and follow-up imaging 11 months later, showing near complete response (*right*). A dose of 17.5 Gy was prescribed at the 50% isodose contour.

stay was 3 days after surgery, and KPS improved postoperatively in 33%, remained stable in 61%, and decreased in 6% of patients.[65]

Radiosurgery

Radiosurgery implies the delivery of carefully targeted, very focal radiation to one or more intracranial targets, usually using a specially adapted linear accelerator[67] or a gamma knife.[68] A stereotactic frame may be applied prior to the procedure under local anesthesia to help allow very precise targeting. Multiple beams or arcs provide for very steep falloff of dose outside of the target or targets, minimizing dose to surrounding normal brain tissue, but a thin shell of tissue around the target receives a potentially damaging dose of radiation (Fig. 56-4). Because the risk of radiation injury increases with increasing volume, lower doses are generally prescribed for larger target volumes, and radiosurgery targets tend to be limited to about 2.5 to 3 cm in diameter.

RETROSPECTIVE RESULTS OF RADIOSURGERY. Table 56-4 summarizes results of selected retrospective series of radiosurgery for single or multiple newly diagnosed or recurrent brain metastases treated with or without adjuvant WBRT.[69–83] For median target volumes ranging from 0.9 to 7.5 mL and median prescribed doses ranging from 15.0 to 27.0 Gy in a single fraction, the crude local control rates were 85% to 96% and the 1-year actuarial local control probabilities were 82% to 94% by lesion, with a 0% to 17% risk of symptomatic radiation necrosis (average risk, 4%). In most of the series, the median survival times ranged from 7 to 11 months.

RADIOSURGERY DOSE-RESPONSE RELATIONSHIPS. An RTOG dose escalation trial in patients with recurrent primary or metastatic brain tumors concluded that the maximum tolerated doses of single fraction radiosurgery (without WBRT) were 24 Gy for tumors 2 cm or less in maximum diameter, 18 Gy for tumors 2.1 to 3.0 cm, and 15 Gy for tumors 3.1 to 4.0 cm.[84] A dose-response analysis specifically in newly diagnosed or recurrent brain metastases 2 cm in diameter or smaller found crude local control rates of 91% using a radiosurgery dose less than 20 Gy ($N = 46$), 99% using a dose of 20 Gy ($N = 158$), and 96% using a dose higher than 20 Gy ($N = 24$) when radiosurgery was combined with planned WBRT. Because the risk of complications was 1.9% for radiosurgery doses of 20 Gy or less and 5.9% for doses above 20 Gy, the authors concluded that 20 Gy was the optimal radiosurgery dose for metastases 2 cm or less in diameter. Of note, the crude local control rates were 97% for radiosurgery with WBRT versus 87% for radiosurgery without planned WBRT ($P = 0.0001$).

On the basis of a data set of 518 newly diagnosed or recurrent brain metastases treated with radiosurgery with or without WBRT at

†1-year actuarial.

the University of California, San Francisco,[76] the 1-year actuarial local freedom from progression probabilities were 88%, 75%, and 29% for doses of 18 Gy or more, 15.0 to 17.9 Gy, and less than 15.0 Gy, respectively, and 92%, 83%, 69%, and 37% for maximum target diameters 1.0 cm or less, 1.1 to 2.0 cm, 2.1 to 3.0 cm, and more than 3.0 cm, respectively. A study of 126 lesions in 80 patients who were treated with linac radiosurgery at the University of Chicago found 1-year local control probabilities of 50%, 97%, and 90% for prescribed doses of 10 to 13.99 Gy, 14 to 17.99 Gy, and 18 Gy or more, respectively, and 67%, 94%, and 93% for minimum tumor doses of 12 Gy or less, 12.1 to 18 Gy, and more than 18 Gy, respectively.[85]

RANDOMIZED TRIALS OF WHOLE-BRAIN RADIOTHERAPY WITH OR WITHOUT RADIOSURGERY. The first reported randomized trial of WBRT (30 Gy in 12 fractions) with or without a radiosurgery boost (16 Gy) was performed in patients with a KPS of at least 70 and two to four brain metastases less than or equal to 2.5 cm in diameter, at least 5 mm from the optic chiasm.[50] The study accrued only 27 patients because of early stopping rules based on a significant difference in brain control between the two arms. Compared with WBRT alone, radiosurgery plus WBRT yielded significantly improved time to local failure (median: 36 months versus 6 months; $P = 0.0005$) and time to any brain failure (median: 34 months versus 5 months; $P = 0.002$). However, survival was not significantly different for the two arms (median: 7.5 months for WBRT versus 11 months for WBRT plus radiosurgery; $P = 0.22$; see Table 56-3). Multiple patients who failed WBRT alone underwent salvage radiosurgery.[50]

A recent RTOG trial randomized 331 patients with KPS of at least 70 and one to three newly diagnosed brain metastases to WBRT (37.5 Gy in 15 fractions) with or without a radiosurgery boost within 1 week after WBRT from 1996 through June 2001.[49] Treatment arms were fairly well balanced comparing WBRT alone to WBRT plus radiosurgery, with KPS of 90 to 100 in 63% versus 57%, age less than 65 years in 60% versus 66%, primary disease controlled or absent in 75% versus 77%, extracranial metastases in 69% versus 68%, and a single brain metastasis in 56% versus 56% of patients, respectively. The radiosurgery treatment arm had significantly improved KPS at 6 months ($P = 0.033$), decreased steroid use at 6 months ($P = 0.016$), and improved actuarial local control (with 1-year local control probabilities of 71% for WBRT alone versus 82% for WBRT + radiosurgery; $P = 0.013$). Although survival was not significantly different between the two groups overall (5.7 months for WBRT alone versus. 6.5 months for WBRT + radiosurgery; $P = 0.136$; see Table 56-3), there was a statistically significant difference in survival for patients who had a single metastasis (4.9 months for WBRT alone versus 6.5 months for WBRT + radiosurgery; $P = 0.039$).[49]

RADIOSURGERY WITHOUT WHOLE-BRAIN RADIOTHERAPY FOR NEWLY DIAGNOSED BRAIN METASTASES. Because of concern about potential late toxicity of WBRT, multiple groups have tried managing patients using radiosurgery alone initially, followed by later salvage surgery, radiosurgery, WBRT, or chemotherapy as needed,[33,35,81,86–89] and one prospective, randomized trial of radiosurgery alone versus radiosurgery plus WBRT has been reported to date (see Table 56-3 and the following section).[90] Retrospective comparisons of radiosurgery alone initially to radiosurgery with upfront WBRT are summarized in Table 56-5. Survival was similar for radiosurgery alone initially versus radiosurgery with upfront WBRT for three of five studies (~5 months versus ~6 months;[81] 11.3 months versus 11.1 months;[86] and 8.2 months versus 8.6 months[33]); in one study, median survival time was thought to be shorter in the WBRT group because of worse prognostic factors in this group,[87] and in the fifth study, there was a trend toward longer survival time in patients who were treated with RS + WBRT versus RS alone.[89] Multivariate analyses adjusting for known prognostic factors confirmed that the omission of upfront WBRT had no influence on survival time.[33,81,86,87] Local control was slightly worse for

radiosurgery alone initially, with 1-year actuarial local freedom from progression probabilities of 89% versus 92%,[81] 71% versus 79%,[86] and approximately 62% versus 75%.[87] Because of a much greater risk of developing new brain metastases when upfront WBRT was omitted, brain freedom from progression was significantly shorter for radiosurgery alone initially (median: 8.3 months versus 15.9 months[86] and 9.2 months versus 35.1 months).[87] In one series, the median brain freedom from progression allowing for salvage therapy was 19.8 months for radiosurgery alone initially versus 18.1 months for radiosurgery with upfront WBRT, and only 26% of radiosurgery-alone patients ultimately received WBRT.[86] Among 101 patients with one to three brain metastases who were treated with radiosurgery alone, Lutterbach and colleagues reported 1-year local brain, distant brain, and overall brain freedom from progression rates of 91%, 53%, and 51%, respectively; parameters that were associated with longer overall brain freedom from progression included single brain metastasis and an interval greater than 2 years from primary tumor diagnosis and diagnosis of brain metastases.[35]

RANDOMIZED TRIAL OF RADIOSURGERY WITH OR WITHOUT WHOLE-BRAIN RADIOTHERAPY. Aoyama and colleagues recently reported the first prospective, randomized trial comparing radiosurgery alone ($N = 67$) to WBRT plus radiosurgery ($N = 65$).[90] Patients with KPS of at least 70 and one to four brain metastases less than 3 cm in diameter were accrued at 11 institutions from 1999 through 2003. The WBRT dose was 30 Gy in 10 fractions, and the radiosurgery-alone doses were 22 to 25 Gy for lesions up to 2 cm and 18 to 20 Gy for lesions over 2 cm, with a 30% dose reduction when radiosurgery was combined with WBRT. Age, KPS, and extracranial disease activity were not significantly different between the two groups. Endpoints were measured from the date of randomization. The median survival times were similar for the two groups (8.0 months for radiosurgery alone versus 7.5 months for WBRT + radiosurgery; $P = 0.42$). Intracranial control was significantly lower in the radiosurgery-alone arm, with 1-year local control probabilities of 73% versus 89% ($P = 0.002$), 1-year freedom from new brain metastasis probabilities of 36% versus 58% ($P = 0.003$), and 1-year overall brain freedom from progression probabilities of 24% versus 53% ($P < 0.001$) for radiosurgery alone versus WBRT + radiosurgery, respectively. The majority of new brain metastases were asymptomatic. Salvage therapy for brain metastases was given in 29 patients on the radiosurgery-alone arm versus 10 patients on the WBRT + radiosurgery arm. There was no significant difference in functional independent survival (27% versus 34% at 1 year; $P = 0.53$) or neurologic preservation (70% versus 72% at 1 year; $P = 0.99$) for radiosurgery alone versus WBRT + radiosurgery, respectively. Deterioration of neurologic function occurred in 21 radiosurgery-alone patients and in 22 WBRT + radiosurgery patients; the deterioration was attributed to new or original brain metastases in 18 radiosurgery-alone patients versus 13 WBRT + radiosurgery patients. Leukoencephalopathy occurred in 2 radiosurgery-alone patients versus 7 WBRT + radiosurgery patients, and it was symptomatic in 3 of the 9 patients. The authors concluded that radiosurgery alone "could be a treatment option, provided that frequent monitoring of brain tumor status is conducted."[90]

RADIOSURGERY COMPARED WITH SURGERY. Radiosurgery has potential advantages over surgery in that it is less invasive and can more easily address inaccessible or multiple lesions. In addition, the border zone between the metastasis and normal brain tissue may receive sufficient radiation dose to decrease the risk of local recurrence. The two major disadvantages of radiosurgery are that it is generally applicable only to lesions less than about 2.5 to 3.0 cm in diameter and that it results in slow tumor shrinkage over weeks or months rather than relieving mass effect immediately.

In the absence of data to date from prospective, randomized trials, several authors have compared results cited in the literature for surgical patients with their own results for similar subsets of radiosurgery patients. Auchter and colleagues[69] reported a four-institution experience of radiosurgery and WBRT in 122 adults who met selection criteria similar to those used in randomized trials of WBRT with or without surgical resection: KPS of at least 70 and newly diagnosed, surgically resectable single brain metastases with "nonsensitive" histology (excluding lymphoma, leukemia, multiple myeloma, small cell lung cancer, and germ cell tumors) and no urgent indication for resection. Local control was achieved in 86% of lesions with a 1-year actuarial local control probability of 85%, a median duration of functional independence of 10.1 months, and median survival time of 12.9 months (see Table 56-4), comparable to the results of the surgery + WBRT arms of the randomized trials reported by Patchell and colleagues[19] and Noordijk and colleagues[57] (see Table 56-3).

Three other retrospective comparisons of radiosurgery and surgery are summarized in Table 56-6, with somewhat differing results.[66,91,92] Bindal and colleagues reported 61% versus 87% crude local control rates for radiosurgery (with or without WBRT) versus surgery (with or without WBRT) and median survival times of 7.5 months versus 16.4 months, respectively.[91]

In another retrospective study, Muacevic and colleagues compared outcomes for patients with single metastases less than or equal to 3.5 cm in diameter who were treated with radiosurgery alone (56 patients) or surgery with WBRT (52 patients). One-year local freedom from progression probabilities were 83% for radiosurgery versus 75% for surgery with WBRT ($P = 0.49$); new brain metastases developed in 11 (20%) of the radiosurgery patients versus 6 (12%) of the surgery-plus-whole-brain-radiotherapy patients, but salvage radiosurgery was successful in all 6 radiosurgery patients who were offered salvage therapy. Median survival times were 8.0 months after radiosurgery versus 15.6 months after surgery with WBRT. Death rates from neurologic causes and complication rates were similar for the two treatment approaches, and steroid requirements tended to be less among the radiosurgery patients.[66]

A third retrospective study compared patients with single metastases who were candidates for either surgery or radiosurgery. Most patients received adjuvant WBRT in conjunction with radiosurgery (23 patients) or surgery (74 patients). Pretreatment performance status was worse in the radiosurgery group. Crude local control rates were 100% versus 85% ($P = 0.02$), and 1-year survival probabilities were 56% versus 62% for radiosurgery versus surgery, respectively (univariate $P = 0.15$; multivariate $P = 0.62$ with adjustment for age, performance status, and systemic disease status). Short-term and long-term complications occurred in 0% versus 13.5% and 17.4% versus 17.6% of radiosurgery and surgery patients, respectively.[92]

Because of the difficulties in overcoming selection bias and other confounding factors in retrospective studies, a prospective, randomized trial is underway to better compare radiosurgery versus surgery for single brain metastases.

TOXICITY OF RADIOSURGERY. Acute complications of radiosurgery occur in about 10% of patients, including seizures, headaches, exacerbation of pre-existing neurologic deficits, nausea, and hemorrhage.[66,86,93] Early delayed and late complications may include transient perifocal edema responding to a short course of steroids in 7% to 18% of patients[66,81,93] or symptomatic radiation necrosis in an average of 4% of patients (see Table 56-4), causing headaches, seizures, or neurologic deficits. Symptoms usually respond to steroids, but surgery might be needed if a patient requires a prolonged course of steroids, tolerates steroids poorly, or remains symptomatic on steroids or if there is uncertainty as to whether a lesion represents progressive tumor versus radiation necrosis.

Brachytherapy

Brachytherapy, the insertion of radioactive sources directly inside a tumor or tumor bed, allows delivery of a high dose of radiation to the target volume with a steep falloff of dose outside of the intended

Table 56-6 Nonrandomized Comparisons of Radiosurgery with and Without Whole-Brain Radiotherapy to Surgery with and Without Whole-Brain Radiotherapy for Single Newly Diagnosed Brain Metastases

region owing to the fact that dose intensity decreases with the square of the distance from point sources and also decreases because of attenuation in tissue. Temporary brachytherapy has been applied to brain metastases by using high-activity sources, often within afterloading catheters inserted under stereotactic guidance into gross tumor or a resection cavity or using a balloon within a resection cavity inflated with radioactive liquid. Permanent brachytherapy is generally accomplished by lining a tumor bed with low-activity radiation sources intraoperatively after gross total resection of a metastasis. Results of brachytherapy for brain metastases are summarized in Table 56-7.[94–99] In patients who were treated for recurrent brain metastases, crude local freedom from progression rates ranged from 60% to 95%, and median survival times ranged from 6 to 13.9 months. Among patients who were treated for newly diagnosed brain metastases, local freedom from progression rates ranged from 80% to 95% and median survival times ranged from 9.2 to 17 months (except for an outlier median survival time of 68.2 months in 5 patients). The incidence of symptomatic radiation necrosis ranged from 0% to 30%, with an average of about 9%.

Chemotherapy

Chemotherapy has generally been considered to be relatively ineffective for brain metastases, presumably because the blood-brain barrier prevents adequate access of chemotherapy to these tumors. However, some chemotherapeutic agents partially or even readily cross the blood-brain barrier, and the fact that brain metastases enhance with contrast on CT or MRI is proof that the blood-brain barrier is broken down within metastases. The chemosensitivity of the primary tumor is another critical factor in determining the potential efficacy of chemotherapy for brain metastases.[100] The responsiveness of brain

metastases to chemotherapy is similar to that of the primary tumor and extracranial metastases. Primary small cell lung carcinoma (SCLC), lymphoma, germ cell tumors, and breast cancer are relatively chemosensitive[101] while non-small-cell lung carcinoma (NSCLC) and melanoma are less chemosensitive.

TRIALS ASSESSING CHEMOTHERAPY FOR BRAIN METASTASES FROM A VARIETY OF PRIMARY SITES. Chemotherapy with cisplatin at 100 mg/m^2 on day 1 and etoposide at 100 mg/m^2 on days 4, 6, and 8 every 3 weeks was used as the primary treatment in a phase II study of 22 breast cancer patients with brain metastases, resulting in a 23% complete response rate and a 32% partial response rate.[102] This regimen was then used as first-line therapy in a prospective study conducted from 1986 to 1993 by a nine-institution group; 116 patients with recently diagnosed, previously untreated brain metastases from breast cancer, NSCLC, or melanoma were enrolled, and 107 were evaluable.[103] None of the melanoma patients achieved an objective response, but among the breast and lung cancer patients, the complete response rates were 13% and 7%, respectively, and the partial response rates 25% and 23%, respectively. The median duration of response was 7 to 8 months; the median overall time to progression was 3.9 months for breast and lung cancer patients; and the median survival times were 7.1 months for breast cancer patients, 7.4 months for lung cancer patients, and 3.9 months for melanoma patients.[103] Data were not collected on further therapy given after chemotherapy. Another group examined a similar two-drug regimen using intra-arterial carboplatin plus intravenous etoposide in 27 patients with brain metastases from a variety of primary tumors and were able to achieve a 54% response rate (25% partial response, 25% complete response, and 4% "minor" response).[104]

There has also been interest in temozolomide (TMZ), an oral alkalating agent that crosses the blood-brain barrier. Several studies have assessed the efficacy of TMZ in patients with brain metastases. At Memorial Sloan Kettering Cancer Center, 41 patients with recurrent or progressive brain metastases were treated with TMZ at 150 to 200 mg/m^2 daily for 5 days, repeated monthly. The partial response rate was 5%, 37% of patients had stable disease, and the median survival time was 6.6 months.[105] Another group used a similar regimen in 27 heavily pretreated patients with brain metastases. Of the 24 evaluable patients, the authors reported only one partial response and four cases of disease stabilization, with an overall median survival time of 4.5 months.[106] TMZ has also been used concurrently with other agents. Christodoulou and colleagues administered TMZ at 150 to 200 mg/m^2 daily for 5 days combined with cisplatin at 75 mg/m^2 on day 1 every 28 days in 32 patients with brain metastases. The overall median survival time was 5.5 months. Although nine patients had a partial response (six with breast cancer, two with melanoma, and one with NSCLC), only one patient (with NSCLC) had a complete response, and five patients had disease stabilization.[107] Concurrent TMZ and liposomal doxorubicin has also been investigated; one group reported three complete responses and four partial responses in a cohort of 19 patients given this regimen.[108]

Various studies have examined the use of TMZ in conjunction with radiation therapy. In one phase II randomized trial, 48 evaluable patients were randomized to either WBRT alone or WBRT + TMZ. There were seven complete responses and seven partial responses for the WBRT alone group versus nine complete responses and 14 partial responses in the combined modality group, with median survival times of 7.0 months for WBRT versus 8.6 months for WBRT + TMZ.[109] A later phase II trial randomized 82 patients to receive either WBRT alone ($N = 41$) or WBRT with concurrent TMZ ($N = 41$) and found no significant differences in response rates or survival. The authors did, however, report a significant difference in progression-free survival at 90 days (54% for WBRT alone versus 72% for WBRT and TMZ). They noted that their patients had more aggressive disease and were more heavily pretreated than those in the aforementioned study by Antonadou and colleagues.[110] TMZ is also discussed in the following sections in the context of brain metastases from individual primary sites.

CHEMOTHERAPY FOR BRAIN METASTASES FROM PRIMARY NON-SMALL-CELL LUNG CARCINOMA. Several trials have assessed the response of brain metastases from primary NSCLC after treatment with various systemic agents. Combined carboplatin and etoposide was used in a study of 30 patients with brain metastases from primary lung cancer (18 NSCLC, 12 SCLC); three patients had complete responses (all SCLC), while seven had partial responses (four SCLC, three NSCLC).[111] Concurrent cisplatin and teniposide yielded three complete responses and five partial responses among 23 patients with brain metastases from primary NSCLC.[112] Other regimens that have been studied in patients with brain metastases from NSCLC include vinorelbine, gemcitabine, and carboplatin (with 15% complete response and 30% partial response in 20 patients)[113] and paclitaxel and cisplatin combined with either vinorelbine or gemcitabine (resulting in a 38% objective response rate among 25 patients).[114] Fujita and colleagues used an alternative three-agent regimen of cisplatin, ifosfamide, and irinotecan with rhG-CSF support in 30 patients and were able to achieve a 50% partial response rate, although no patient had a complete response.[115] Two other groups have studied the efficacy of TMZ as a single agent in this context, one group reporting no objective treatment response in 12 patients[116] and another group achieving two complete responses and one partial response among 30 patients.[117]

The use of concomitant systemic chemotherapy and WBRT for brain metastases from NSCLC has also been studied by several groups. In a large phase III trial of 176 patients with brain metastases from NSCLC, Robinet and colleagues examined the use of cisplatin and vinorelbine in conjunction with either early or delayed WBRT. Neither cohort demonstrated significantly different response rates, survival, nor treatment-related toxicities.[118] One recent phase III trial examined outcomes in 42 patients with brain metastases from NSCLC treated either with WBRT alone or with concurrent carboplatin. Neither objective response rates (10% [WBRT alone] versus 29% [WBRT + carboplatin]) nor survival (4.4 months [WBRT alone] versus 3.7 months [WBRT + carboplatin]) were significantly different, and the trial closed early because of poor accrual.[119] The efficacy of TMZ and cisplatin followed by WBRT was studied in 50 patients with brain metastases from primary NSCLC in a recent phase II study; only 2% of patients achieved a complete response, while 10% had partial responses for their cerebral lesions.[120]

CHEMOTHERAPY FOR BRAIN METASTASES FROM SMALL CELL LUNG CARCINOMA. Given the relative chemosensitivity of SCLC, brain metastases from this primary tumor type could theoretically be expected to respond to systemic chemotherapy. Twelves and colleagues examined this concept in an early study of 19 patients with symptomatic brain metastases from SCLC initially treated with cyclophosphamide, vincristine, and etoposide without upfront WBRT. On imaging follow-up, eight patients had a partial response, and one had a complete response.[121] Korfel and colleagues examined the efficacy of topotecan in a phase II study of 30 pretreated, relapsed patients with symptomatic brain metastases from SCLC. Of the 30 patients, 10 achieved an objective response (three complete responses and seven partial responses).[122] In another small study, carboplatin's efficacy as a second-line agent was investigated in 20 patients with recurrent or progressive brain metastases from primary SCLC. Nineteen of the 20 patients were evaluable, with two patients exhibiting a complete response and six showing a partial response.[123]

The use of teniposide, an agent that is known to be active against SCLC, was examined in a phase II study of 80 patients with brain metastases from primary SCLC; 33% of patients had an objective response to chemotherapy (6 had a complete response, and 20 had a

partial response).[124] In a large phase III study also examining the use of teniposide, Postmus and colleagues randomized 120 patients with brain metastases from primary SCLC to receive either teniposide alone ($N = 60$) or concurrently with WBRT ($N = 60$). The teniposide + WBRT cohort had a significantly better response rate (18 complete responses, 16 partial responses) compared to the teniposide-alone arm (5 complete responses, 8 partial responses), although median survival times were not different (3.5 months [WBRT + teniposide] versus 3.2 months [teniposide alone]).[125]

CHEMOTHERAPY FOR BRAIN METASTASES FROM MELANOMA. As was noted earlier, melanoma is relatively insensitive to systemic chemotherapy. The efficacy of various agents in treating patients with brain metastases from primary melanoma have been studied, largely without success. The study by Franciosi and colleagues, as discussed previously, reported no treatment response in melanoma brain metastases treated with cisplatin and etoposide.[103] One group reported only a 12% response rate (with two complete responses and two partial responses) and a median survival time of 4.5 months among 34 melanoma patients with brain metastases treated with sequential dacarbazine and fotemustine.[126] Another group examined fotemustine as a single agent in a subset of patients with brain metastases from primary melanoma within a larger study. Of the 36 patients who had cerebral metastases from primary melanoma, none had a complete response, while 9 patients had a partial response.[127] Mornex and colleagues studied two groups of patients with brain metastases from melanoma; one group was treated with fotemustine alone ($N = 39$), and the other was treated with fotemustine and WBRT ($N = 37$). The authors reported five partial responses—two in the fotemustine-alone group and three in the combined-therapy arm—with no significant differences in median survival time (2.7 months versus 3.4 months, respectively).[128]

TMZ has also been studied in patients with metastatic brain lesions from primary melanoma. One multicenter phase II study examined TMZ alone in 151 patients, none of whom had received any prior radiation therapy. Thirty-four patients, however, had received prior systemic chemotherapy. In the 117 chemotherapy-naive patients, one patient had a complete response and seven had a partial response. In the 34 previously treated patients, there were no complete responses, and only one patient had a partial response. For the entire patient cohort, median survival was only 3.2 months.[129] TMZ was used concurrently with carboplatin in 11 patients with brain metastases from melanoma in a small phase I study; none of these patients achieved an objective response.[130] Another study sought to assess TMZ with concurrent WBRT in 31 patients with no prior radiation therapy. Only one patient had a complete response, and two had partial responses. The median survival time was 6 months.[131]

CHEMOTHERAPY FOR BRAIN METASTASES FROM BREAST CANCER. Aside from the small cohorts of breast cancer patients within the broader studies discussed previously,[102–104,106,107] other groups have focused specifically on patients with brain metastases from breast cancer. Rosner and colleagues examined the efficacy of several multiagent regimens in a group of 100 patients with brain metastases from primary breast cancer. The overall objective response rate was 50% (10 complete responses and 40 partial responses) with the authors reporting a median survival time of 39.5 months, 10.5 months, and 1.5 months for the complete responders, partial responders, and nonresponders, respectively.[132] Another group examined three-agent regimens of either cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) (used in 20 patients) or cyclophosphamide, doxorubicin, and 5-fluorouracil (CAF) (used in two patients). Two patients (one using the CMF regimen and the other using the CAF regimen) had complete responses, while 10 patients had partial responses (nine using the CMF regimen and one using the CAF regimen).[133]

Follow-up and Salvage Therapy

In patients who are doing reasonably well from the standpoint of their systemic disease, we recommend follow-up MRI every 3 months after treatment for brain metastases to detect new, progressive, or recurrent brain metastases that might need to be addressed with salvage therapy. Of note, a contrast-enhancing lesion that is seen after high-dose external beam radiation, radiosurgery, or brachytherapy could represent radiation necrosis rather than recurrent tumor, and additional analyses might be needed before considering retreatment.[134] The same therapeutic options that are available for newly diagnosed brain metastases may be considered for new, progressive, or recurrent metastases, although the type of previous therapy that was given may influence therapeutic options at recurrence. In general, retreatment options include WBRT, radiosurgery (especially for lesions less than about 3 cm in diameter), surgery (especially for a single large or symptomatic progressive lesion), perhaps with permanent brachytherapy to help prevent local recurrence, and chemotherapy. If repeat WBRT is given, lower doses and smaller fraction sizes are generally used, such as 20 to 25 Gy in 10 fractions or 30 Gy at 1.0 Gy twice daily. Results are similar to those reported for a first course of WBRT, with symptomatic improvement in 42% to 75% of patients and median or mean survival time of 3.2 to 5 months after reirradiation.[135–137]

NEOPLASTIC MENINGITIS

Dissemination of cancer cells into the leptomeningeal space is an extremely serious complication that affects approximately 5% of patients with cancer. With incremental improvements in outcomes in systemic cancer, the incidence of metastatic disease to the leptomeninges appears to be on the rise. Neoplastic meningitis presents significant diagnostic and therapeutic challenges; early diagnosis can be elusive, and effective control for leptomeningeal carcinoma is usually difficult to achieve. With current therapies, the median survival time is 3 to 6 months.

Epidemiology

Virtually any type of cancer can disseminate into the leptomeningeal space. Acute leukemias and intermediate- or high-grade lymphomas are common causes of neoplastic meningitis. Among solid tumors, melanoma and small cell carcinoma exhibit the strongest propensity for leptomeningeal dissemination; up to 25% of patients with metastatic disease from these diagnoses develop this complication. Ultimately, between 2% and 5% of breast cancer patients develop carcinomatous meningitis. Leptomeningeal dissemination has also been documented in less common neoplasms, such as sarcomas, squamous cell carcinomas, and germ cell tumors. Primary tumors of the CNS such as medulloblastoma or ependymoma often seed the leptomeningeal space as well.[138–142]

Pathophysiology

The biologic basis for dissemination and multifocal seeding of the leptomeninges by malignant cells is not well understood. Several distinct pathways have been proposed: (1) most obviously as a consequence of drop metastases that may occur during resection of metastatic foci within the brain, especially after resection of posterior fossa tumors; (2) by direct extension from the cerebrum; (3) by infiltration through arachnoid vessels or the choroid plexus following hematogenous dissemination of the tumor; (4) by direct extension along peripheral nerves to the subarachnoid space or perivenous spread from the bone marrow within the skull; (5) by extension along perineural or perivascular lymphatics; and (6) from subependymal or choroid plexus metastases with subsequent escape into the CSF.[143] Spread of tumor cells along the meningeal surface is facilitated by bulk CSF flow. In turn, meningeal deposits may also invade

parenchyma as well as cranial or spinal nerve roots. The most frequently affected regions of the CNS are the basilar cisterns, the posterior fossa, and the cauda equina, where gravity promotes deposition of circulating cells.

Clinical Presentation

Leptomeningeal dissemination of cancer elicits several distinct neurologic presentations. (1) Local tumor infiltration in the brain or spinal cord may cause headache; alterations in mental status; cranial nerve deficits causing diplopia, hearing loss, decreased taste, problems with swallowing, and hoarseness; and incontinence, lower motor neuron weakness, and back or radicular pain. (2) Metabolic dysfunction caused by disturbances in regional blood flow in the affected nervous tissue may cause seizures, isolated neurologic deficits, including strokelike symptoms, and even generalized encephalopathy. (3) Obstruction of normal CSF flow pathways by focal tumor deposits may cause increased intracranial pressure and hydrocephalus.[138–142,144]

Diagnosis

CSF Evaluation

A high index of suspicion is required to make an early diagnosis of neoplastic meningitis; this ultimately requires a detailed examination of CSF. Routine measurements include opening pressure, cell count, differential, protein, glucose and direct cytologic evaluation of the CSF.[138] Patients with carcinomatous meningitis typically have elevated CSF opening pressure, increased CSF protein, and decreased CSF glucose.[145] While the CSF is abnormal in terms of protein or glucose concentration in most patients with neoplastic meningitis, cytologic evaluation of the CSF, the gold standard, is an insensitive test, especially initially; 40% to 50% of patients with neoplastic meningitis have negative CSF cytology on initial lumbar puncture.[138] While repeat CSF cytologic evaluations over time will increase diagnostic sensitivity, the eventual conversion to positive cytology usually occurs in pace with neurologic deterioration secondary to overt tumor progression. Because of the importance of early diagnosis and intervention, there has been significant effort to identify surrogate biomarkers for CNS and leptomeningeal metastases. For example, in the early 1980s, Posner's group demonstrated that the tumor antigen carcinoembryonic antigen as well as the enzymatic activity of β-glucuronidase could be detected in the CSF of patients with brain and leptomeningeal metastases.[146] The presence of these markers was shown to precede clinical detection of neoplastic meningitis and to rise and fall in parallel with the clinical course. Several other biomarkers have been examined in patients with carcinomatous meningitis from a variety of primary tumors, including lactate dehydrogenase, β-human chorionic gonadotropin, alkaline phosphatase, vascular endothelial growth factor, myelin basic protein, creatinine kinase, and others. The utility of these biomarkers is still under investigation.[145] The use of other diagnostic tools such as polymerase chain reactions, fluorescence in situ hybridization, immunohistochemical examinations of the CSF, and cytogenetic analysis may also enhance detection.[147]

Radiologic Features

The most frequent radiographic presentation is hydrocephalus without an identifiable mass lesion. Leptomeningeal contrast enhancement is suggestive of neoplastic meningitis (Fig. 56-5) but may also be seen after lumbar puncture and with infection, inflammatory disease, trauma, subdural hematoma, or changes occurring post craniotomy.[138] The enhancement pattern may be focal (including tumor nodules) or diffuse.[147] While gadolinium-enhanced MRI is more sensitive than CT in identifying leptomeningeal enhancement, only approximately 50% of patients with neoplastic meningitis and spinal symptoms have abnormal imaging studies.[138]

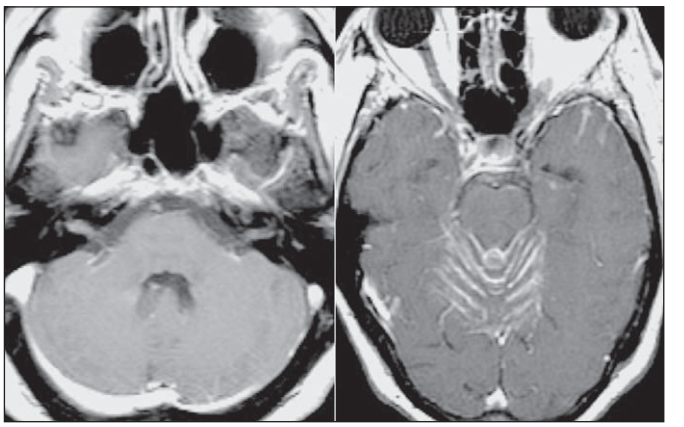

Figure 56-5 • Leptomeningeal enhancement on postcontrast T1-weighted magnetic resonance imaging from carcinomatous meningitis. Note the enhancement of the acoustic nerves (*left*) and cerebellar folia (*right*).

Treatment

Current therapeutic goals for most patients with neoplastic meningitis are to prevent further neurologic deterioration, to cytoreduce leptomeningeal tumor burden, and to prolong survival. Typically, untreated carcinomatous meningitis is associated with an advanced stage of systemic disease, often with concomitant parenchymal brain metastases and with anticipated survival time of 4 to 6 weeks. Because of the inefficient regenerative capacity of the CNS, early aggressive intervention is critical to preserve neurologic function. Therapeutic intervention relies on traditional approaches with radiation and/or chemotherapy with the goal of treating the entire neuroaxis.

Radiation Therapy

Radiation therapy is the most effective means of palliation with the focus on symptomatic sites and regions where imaging studies have demonstrated bulk disease. There is substantial acute toxicity of craniospinal axis irradiation, with nausea, vomiting, marked fatigue, and myelosuppression. There is also a long-duration negative impact on bone marrow function, compromising the safe administration of subsequent myelosuppressive chemotherapy. One strategy is to selectively apply external beam irradiation to symptomatic sites of disease and to rely on intrathecal chemotherapy to suppress the remainder of the disease in the neuroaxis. For example, in patients who present with cranial nerve deficits, one approach is to treat only the base of the skull with radiation. In patients who present with cauda equina syndrome, external beam irradiation may be directed to the lumbosacral spine. Patients who present with seizure or hydrocephalus caused by extensive cranial leptomeningeal disease may best be palliated with whole-brain irradiation.[139–142]

Intrathecal Chemotherapy

The most reliable means of administering intrathecal chemotherapy is to use an implanted subcutaneous reservoir and ventricular catheter (Ommaya device). While subarachnoid injections of chemotherapy result in high local CSF concentrations, studies of administration by lumbar administration suggest that 10% to 15% of lumbar punctures fail to completely deliver all of the drug to the subarachnoid space.[142] In addition, retrospective analysis suggests that intraventricular administration may result in prolonged remission in patients with leptomeningeal leukemia compared with administration by lumbar puncture.[148] Chemotherapeutic agents administered into the ventricle are carried through the neuroaxis by bulk CSF flow. CSF flow abnormalities are common in patients with leptomeningeal metastases, who frequently present with hydrocephalus and increased intracranial pressure as a result of disease that

impedes CSF flow. Radionuclide ventriculography in patients with neoplastic meningitis has demonstrated that as many as 70% have ventricular outlet obstruction, abnormal flow in the spinal canal, or impaired flow over the CSF convexities.[149] These CSF flow abnormalities may be reversed with local irradiation. Because of the potential risk of irreversible neurotoxicity from high sustained concentrations of intrathecal chemotherapy, a CSF flow study is recommended for every patient beginning intrathecal chemotherapy via a ventricular catheter.[139,140]

Methotrexate and cytarabine are the most widely used agents for intrathecal chemotherapy. Intraventricular injection of methotrexate results in therapeutic concentrations (more than 1 μmol) that persist for up to 48 hours; serum levels peak at approximately 0.1 μmol and fall more slowly. Treatment of active neoplastic meningitis typically consists of twice weekly intrathecal therapy until CSF clears followed by weekly and then monthly maintenance therapy unless there is disease progression. The combination of twice weekly methotrexate plus radiation results in an approximate 50% rate of disease stability or clinical improvement. Response should be assessed both in the ventricle and in the lumbar sac, where cytology is more likely to be positive. Intrathecal methotrexate can cause myelosuppression as well as mucositis, toxicities that can be attenuated by leucovorin. Leucovorin does not efficiently cross the blood-brain barrier in amounts that are sufficient to interfere with intra-CNS effects of methotrexate.

Cytosine arabinoside is also commonly used but may have less efficacy in the treatment of neoplastic meningitis. Cytosine arabinoside is inactivated by deamination by the enzyme cytidine deaminase. Low CNS levels of this enzyme result in relatively slow deamination of cytosine arabinoside within the brain and CSF, resulting in an extended half-life in the CNS compartment.[142] Thiotepa, a cell cycle–nonspecific alkylating agent, is another commonly used intrathecal drug.[147] Other intrathecal agents that have been studied in this context include mafosphamide,[150] topotecan,[151] etoposide,[152] interferon-α,[153] and 5-fluoro-2′-deoxyuridine.[154] Further investigation of these agents is warranted.

Treatment-Related Toxicity

Placement of an intraventricular catheter is associated with less than a 1% risk of perioperative hemorrhage. Extended use of the device is associated with at least a 5% risk of infection, usually with *Staphylococcus epidermidis* or *S. aureus*. Impaired CSF flow of chemotherapy secondary to obstruction may result in seizures as well as acute arachnoiditis, characterized by nausea, vomiting, and mental status changes. For this reason, many practitioners will obtain a radionuclide CSF flow study before initiation of intra-Ommaya chemotherapy. Ultimately, the most significant toxicity associated with the treatment of leptomeningeal carcinomatosis is the development of a necrotizing leukoencephalopathy. This is most common in patients who have received intrathecal methotrexate following cranial irradiation. Initial findings are radiographic changes, usually symmetric abnormalities in white matter. Many of these patients subsequently develop progressive dementia that can progress to substantial debility and to death.[142]

Systemic Chemotherapy and New Approaches

A significant fraction of contrast-enhancing tumor that is visualized on neuroimaging studies is theoretically accessible by systemic chemotherapy, which is able to reach this fraction of tumor supplied by an abnormally permeable neovasculature. However, water-soluble chemotherapy drugs are limited by the intact blood-brain barrier, and systemic therapy fails to treat microscopic, nonenhancing disease both in brain parenchyma and in the subarachnoid space. One exception is in the use of high-dose systemic administration of methotrexate, which results in therapeutic levels in the CSF for a longer duration than the intrathecal route; this therapeutic strategy has been shown to be active in neoplastic meningitis both in lymphoma and in solid tumors. Moreover, systemic administration of methotrexate at high doses overcomes the problems associated with CSF flow obstruction, which can compromise subarachnoid administration. However, because high-dose methotrexate administration requires detailed inpatient monitoring of fluid status, urine alkalinization, and renal function, systemic administration of methotrexate at high doses is not appropriate or practical for all patients.[155]

Finally, in the current era of targeted therapeutics, there is increasing interest in the application of biologic therapies in the leptomeningeal compartment, particularly small molecule inhibitors of signal-transducing molecules such as protein kinases or monoclonal antibodies against tumor-associated cell surface molecules. There is increasing evidence that when these agents are administered systemically, they penetrate the leptomeningeal space inefficiently. For example, relatively low CSF levels of monoclonal antibodies that target CD20 in B-cell lymphomas or of small molecules that inhibit the bcr-abl tyrosine kinase have been documented after systemic administration.[156,157] Direct intra-CSF administration of monoclonal antibodies and immunotoxins is an area of current early-phase investigation in the treatment and/or prophylaxis of neoplastic meningitis.[156,158] A recent phase I dose escalation study formally evaluated the safety and efficacy of intrathecal administration of an anti-CD20 antibody in 10 patients with recurrent CNS and intraocular lymphoma.[159] Responses were identified in patients with meningeal, parenchymal, and intraocular disease, and a successor study of intraventricular rituximab plus methotrexate is under way. Another group reported promising results of targeted iodine-131-radiolabeled monoclonal antibodies administered to 52 patients with neoplastic meningitis.[160] Various case reports have also documented responses to trastuzumab, a humanized antibody directed to HER2, in patients with leptomeningeal carcinomatosis from HER2-overexpressing primary breast cancer.[161,162]

57 Bone Metastases

Robert E. Coleman and Ingunn Holen

SUMMARY OF KEY POINTS

Incidence
- A major cause of (often prolonged) morbidity in cancer
- Especially prevalent in breast and prostatic cancer

Causes
- Osteolytic damage is mediated largely by stimulation of osteoclasts via tumor-derived cytokines; intermediary cells, including immune cells and osteoblasts, are involved.
- The vertebral-venous system of vessels is a significant anatomic pathway for metastatic spread to the skeleton.

Diagnosis
- Differential diagnosis includes osteoporosis, degenerative disease, and Paget's disease.
- The isotope bone scan is a sensitive test to detect the presence of skeletal pathology but gives little information about its nature.
- Structural information on skeletal damage from metastatic bone disease is best obtained by skeletal radiography supplemented by computerized tomography or magnetic resonance imaging.

Evaluation of the Patient
- An assessment of patients' symptoms and activity status is essential.
- Skeletal radiography assesses response to treatment, but the information is delayed and the method insensitive.
- Early indications of response of bone metastases to treatment can be obtained by monitoring biochemical markers, including the bone isoenzyme of alkaline phosphatase, osteocalcin, and pyridinium cross-linking amino acids.
- Isotopic bone scanning is not useful in monitoring response to treatment.

Treatment
- Antitumor treatments, such as radiation therapy, endocrine therapy, cytotoxic chemotherapy, targeted biologic agents, and radioisotope therapy have a role in the multidisciplinary palliative treatment of metastatic bone disease.
- The bisphosphonates are inhibitors of osteoclast activity and have become important agents for the treatment of metastatic bone disease, because they relieve symptoms, allow bone healing, and delay complications.

Complications
- Complications include pain, impaired mobility, pathologic fracture, spinal cord compression, cranial nerve palsies, nerve root lesions, hypercalcemia, and suppression of bone marrow function.
- Bisphosphonates in combination with intravenous rehydration constitute the treatment of choice for hypercalcemia.
- Orthopedic surgery has an important role in the treatment and prophylaxis of pathologic fractures and spinal decompression and stabilization in the relief of spinal cord compression.

INCIDENCE

Primary Tumors Leading to Bone Metastases

Primary bone cancer occurs predominantly among children and adolescents and is rare. By contrast, secondary bone cancer—particularly from carcinomas of the breast, lung, prostate, kidney, and thyroid—is common. The incidence of bone metastases from different primary sites recorded in postmortem studies is summarized in Table 57-1. Although the variability in these metastatic patterns is probably related to molecular and cellular biologic characteristics of both the tumor cells and those of the tissues to which they metastasize, other factors, such as vascular pathways and blood flow, are also important.[1]

Given the high prevalence of carcinomas of the breast, bronchus, and prostate, these cancers probably account for more than 80% of cases of metastatic bone disease. The distribution of bone metastases is predominantly to the axial skeleton—particularly the spine, pelvis, and ribs—rather than to the appendicular skeleton, although lesions in the humeri and femora are also common.

Breast cancer, the most common malignancy in women of western Europe and North America and which, in the areas of its highest incidence, accounts for some 10% of all cancers, is the tumor most often associated with metastatic bone disease. Because of the long clinical course this disease potentially can follow even after metastases have developed, morbidity from bone deposits presents a major problem for health care systems. Approximately 70% of patients dying from breast cancer will have radiologic evidence of skeletal metastases before death, and bone is the first metastatic site in over 40% of those with distant relapse. Median survival after first relapse in bone is around 2 years, and significantly longer than is seen after first relapse in visceral sites such as the liver.[1] Although the management of metastatic visceral disease has improved in recent years, the prognosis following visceral relapse remains poor, whereas bone metastases can be a protracted problem over many years. Favorable factors for a longer survival after first relapse in bone are low histologic grade, positive estrogen receptor status, long postoperative disease-free interval, and lack of development of extraosseous disease.[2]

There is increased interest in personalized medicine whereby biologic factors are utilized to predict the probability or distribution of

Table 57-1 Incidence of Skeletal Metastases from Autopsy Studies

Primary Tumor	No. of Studies	Incidence (%) of Bone Metastases	
		Median	Range
Breast	5	73	47–85
Prostate	6	68	33–85
Thyroid	4	42	28–60
Kidney	3	35	33–40
Bronchus	4	36	30–55
Esophagus	3	6	5–7
Gastrointestinal tract	4	5	3–11
Rectum	3	11	8–13

Modified from Coleman RE: Clinical features of metastatic bone disease and risk of skeletal morbidity. Clin Cancer Res 2006;12(Suppl): 6243–6249.

recurrence. The association between estrogen receptor expression and bone metastasis has been appreciated for 20 years.[1] However, more recently, other markers, especially the noncollagenous bone proteins, have been suggested as predictors of bone recurrence. These have included bone sialoprotein (BSP), which in addition to being apparently predictive of bone metastasis in breast cancer,[3] may be relevant in other tumors with a propensity to metastasize to bone.[4] Parathyroid-related peptide (PTHrP) is expressed by a very high proportion of breast cancers in bone,[5] and it was previously suggested that immunohistochemical determination of PTHrP expression by the primary tumor might be a useful predictive test. However, long-term follow-up of a large cohort of patients with PTHrP assessment of the primary tumor has indicated that this is not the case with PTHrP positivity associated with a better prognosis and a lower incidence of metastasis.[6]

Gene expression profiling has identified genetic signatures that are strongly associated with prognosis,[7,8] possibly outperforming conventional panels of clinical and pathologic criteria. However, the risk of metastasis per se does not necessarily predict for metastasis to specific sites. Recently, a 69-gene signature was described that was specifically predictive of metastasis to bone as opposed to metastasis in other sites.[9] The set of genes expressed suggested involvement of the fibroblast growth factor receptor pathway in the process of metastasis to bone. Subsequently, a classifier of 31 genes was constructed that was able to predict all tumors relapsing in bone with a specificity of 50%. Much more work is required to confirm the utility of genetic profiling in clinical management, but this approach holds much promise.

The skeleton is by far the most common site of metastatic disease in prostatic cancer. Unlike breast cancer, in which radiologically the lesions frequently show a mix of osteoblastic and osteolytic appearances, osteosclerotic disease predominates in prostatic cancer. Nevertheless, computed tomography (CT) often identifies lytic areas within these ostensibly sclerotic lesions. Histologic and biochemical studies also have demonstrated increased bone resorption in metastatic prostatic cancer.[10] As in breast cancer, metastatic bone disease in prostatic cancer can follow a relatively long course. For example, patients of good performance status and bone-only disease affecting the axial skeleton have a median survival of about 53 months, compared with 30 months for those with additional visceral disease and only 12 months for poor-performance status patients with both bone and visceral disease.[11]

Several studies have attempted to correlate the extent of skeletal metastatic involvement with survival in patients with advanced prostate cancer. A system based on the number of lesions identified by bone scintigraphy was predictive for survival,[12] and a bone scan index to quantify the extent of skeletal involvement by tumor more accurately has been developed.[13] It is based on the known proportional weights of each of the 158 bones derived from the so-called "reference man," a standardized skeleton in which postmortem-based individual bone weights were reported for the average adult. The bones were considered individually and assigned a numeric score representing the percentage involvement with tumor multiplied by the weight of the bone. In an analysis of outcomes according to the bone scan index in 191 patients with androgen-independent prostate cancer, patients with low, intermediate, or extensive skeletal involvement had median survivals of 18.3, 15.8, and 8.1 months, respectively.[13]

In lung cancer, the incidence of bone metastases identifiable at the time of primary diagnosis is highest in the small cell variety and lowest with squamous cell tumors, but at autopsy the incidence of bone metastases is similar for all four main histologic types of lung cancer (squamous cell, small cell, large cell anaplastic, and adenocarcinoma) at about 30%. Survival from primary diagnosis of lung cancer is poor, and fewer than 10% of patients are alive after 5 years. Once metastatic disease is evident, most patients die within a few months. Bone metastases from lung cancer are usually of the osteolytic type, but because of the poor survival prospects, morbidity from them is much less of a long-term health care problem than for either breast or prostatic cancers.

CAUSES

Mechanisms of Metastases

The predominant distribution of bone metastases in the axial skeleton, in which most of the red bone marrow is situated, suggests that the slow blood flow at these sites could assist in the attachment of metastatic cells. Contrast this, for example, with the circulation in the kidneys, which accounts for a high proportion of cardiac output and in which metastatic disease is extremely rare. Furthermore, the high incidence of bone metastases in prostate and breast cancers, without corresponding lesions in the lungs, is assumed to in part reflect the circulation of tumor cells through the vertebral-venous plexus, which parallels, connects with, and provides bypasses for the portal, pulmonary, and caval system of veins and so provides a pathway for the spread of disease between distant organs.[14] However, these anatomic characteristics do not account adequately for metastatic patterns. It seems likely that molecular properties of both the malignant cells and those of the tissue in which metastases develop are of critical importance.

Pathogenesis

Bone Remodeling

Bone is a highly specialized connective tissue comprising an unmineralized (osteoid) matrix composed predominantly of type I collagen; and a mineralized component of hydroxyapatite crystals, which encloses the marrow space containing a variety of marrow-residing cells (osteoblasts, osteoclasts, bone marrow stromal cells, immune cells, stem cells, adipocytes, fibroblasts, endothelial cells), platelets, fat, and interstitial fluid. During childhood and adolescence, bone is constantly shaped and remodeled, with peak bone mass being reached in early adulthood. Bone turnover continues throughout life, with up to 20% of the skeleton undergoing remodeling at any time so as to replace damaged bone and maintain skeletal integrity. The total duration of a remodeling cycle in young adults is estimated to be around 200 days. This process is essential for providing bone strength and is responsive to mechanical stress.[15]

Bone resorption is mediated by the osteoclast, a multinucleated giant cell derived from granulocyte-macrophage precursors, whereas bone formation is carried out by osteoblasts, derived from mesenchy-

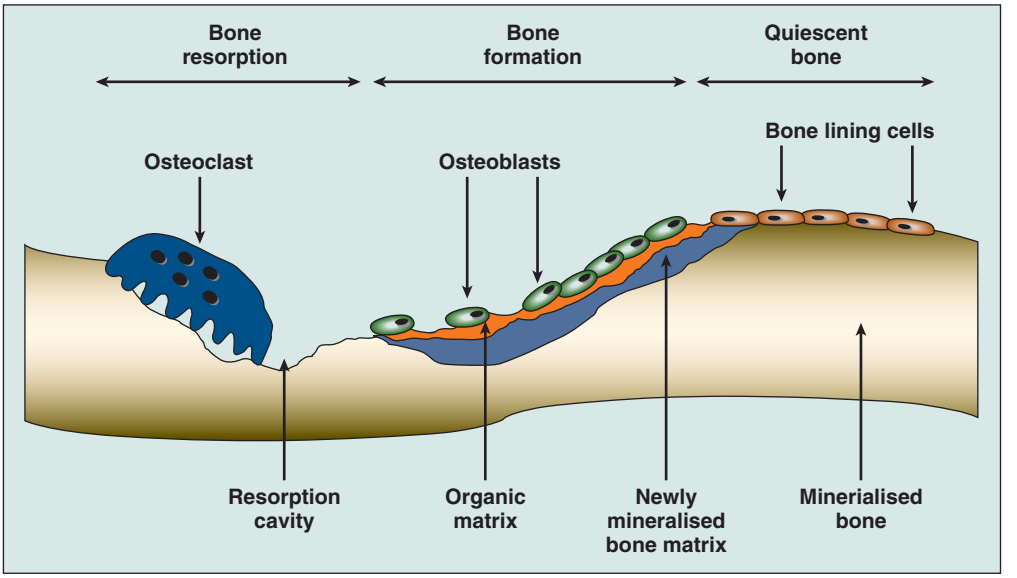

Figure 57-1 • Schematic diagram illustrating the normal bone remodeling cycle. Osteoclasts attracted to a site of fatigued bone create an erosion cavity. Osteoblasts are attracted and synthesize the organic matrix, which will fill the resorption cavity. The new bone is then remineralized to complete the remodeling process.

mal fibroblast-like cells. In a healthy individual, bone resorption and bone formation are coupled and perfectly balanced in location, time, and amount. Bone remodeling is regulated by complex interactions between hormones, paracrine growth factors, and cytokines, and involves interactions between osteoclasts and osteoblasts as well as other cell types present in the bone microenvironment (Fig. 57-1).

The presence of tumor cells in metastatic bone disease leads to disruption of the fine-tuned balance between bone formation and bone resorption, either causing excess bone resorption (as associated with lytic bone lesions) or increased levels of bone formation (as in osteosclerotic bone lesions). In many cases there are mixed lesions, comprising both lytic and sclerotic features (Fig.57-2). In the late stages of cancer, tumor masses may also damage the skeleton by compression of vasculature and consequent ischemia.

Tumor Cell–Bone Cell Interactions

Malignant cells secrete factors that stimulate osteoclastic activity both directly and indirectly, as reviewed by Mundy[16] and recently by Siclari and colleagues,[17] and the importance of interactions between malignant cells and the bone microenvironment in the development of bone metastases has been the focus of intensive research. Factors produced by tumor cells that cause increased bone resorption include prostaglandin-E and a variety of cytokines and growth factors, such as transforming growth factor (TGF) α and β, epidermal growth factor, vascular endothelial growth factor, tumor necrosis factor, and interleukins-1, -6, -8, and -11.

Several proteolytic enzymes are proposed to be involved in the early phases of formation of bone metastases, including matrix metalloproteinase (MMP)-2 and -9 and cathepsin K.[18] Normal bone trabeculae are lined by a thin layer of uncalcified matrix, which protects the calcified bone from osteoclastic activity, and the action of proteolytic enzymes might be a prerequisite for osteoclastic bone resorption. In addition, MMPs are involved in bone metastases formation both through their ability to degrade basement membrane and facilitate tumor cell dissemination, but also by causing release of growth factors and cytokines bound to the bone matrix, thereby supporting further tumor cell proliferation.[19] Malignant cells might also increase bone resorption by stimulating tumor-associated immune cells to

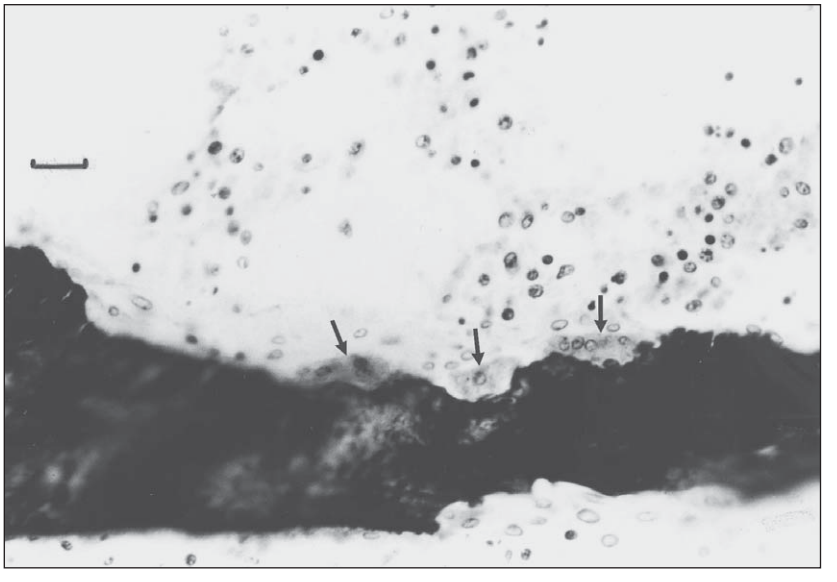

Figure 57-2 • Histologic section showing resorption lacunae on a bone trabeculum. Multinuclate osteoclasts (*arrows*) are resorbing bone in close association with mononuclear hematopoietic cells. The bar represents 20 mm. (From Boyce BF: Normal bone remodeling and its disruption in metastatic bone disease. In: Rubens RD, Fogelman I [eds]: Bone Metastases—Diagnosis and Treatment. London, Springer Verlag, 1991, p 14.)

release osteoclast-activating factors. It has been shown that human melanoma cells produce a factor that stimulates macrophages to release tumor necrosis factor and interleukin-1 in vitro. Furthermore, purification of a cytokine-releasing factor from medium conditioned by melanoma cells has identified it as granulocyte-macrophage colony-stimulating factor, which activates osteoclastic bone resorption.[20] The complex interaction between tumor cells, osteoblasts, osteoclasts, and associated immune cells is summarized in Figure 57-3.

In addition to the local paracrine factors just described, osteoclastic activity can also be stimulated in malignant disease by systemic factors, particularly PTHrP. This peptide is immunologically distinct from PTH, but the two hormones have significant homology at the N terminus of the molecule, which is necessary for osteoclast stimulation. Ectopic production of this hormone, particularly in lung cancer, is a cause of osteoclastic bone resorption and hypercalcemia even in the absence of bone metastases.

The importance of PTHrP in the pathogenesis of osteolysis induced by metastatic breast cancer has been elegantly elucidated.[21] In bone metastases, the secreted PTHrP acts in a paracrine manner to stimulate osteoclastic bone resorption. Not only does this lead to skeletal damage, but it also seems to confer a selective growth advantage on the tumor cells. This results from the release of factors for tumor growth from bone during the osteolytic process. Hence, a vicious circle is established in which the growth of metastatic cells is potentiated, leading to enhanced osteolysis and secretion of additional growth factors to stimulate tumor cell proliferation.[17] This paracrine activity occurs even in the absence of hypercalcemia or increased circulating PTHrP levels. PTHrP stimulates osteoclastic resorption by increasing osteoblast and stromal cell production of receptor activator of nuclear factor-κB (RANK) ligand.[20] RANK ligand binds to its receptor, RANK, on osteoclast lineage cells, resulting in differentiation to mature osteoclasts and stimulation of osteoclast activity. In the normal bone environment, osteoblast secretion of osteoprotegerin (OPG) neutralizes RANK ligand, thus terminating its stimulatory effects on osteoclasts. The MCF-7 estrogen-dependent breast cancer cell line has been found to decrease osteoblastic OPG messenger RNA levels, thus enhancing osteoclast formation.[22] This imbalance is further compounded by release of TGF-β and insulin-like growth factor from resorbing bone, which further promotes tumor production of PTHrP, thus promoting a perpetuating cycle of osteolytic bone destruction.

Tumor cells might also have direct cell-to-cell interaction with bone marrow cells. One study recently found that prostate cancer cells are able to express a soluble form of RANK ligand, a finding that implies a direct ability of prostate cancer cells to affect bone resorption.[23,24]

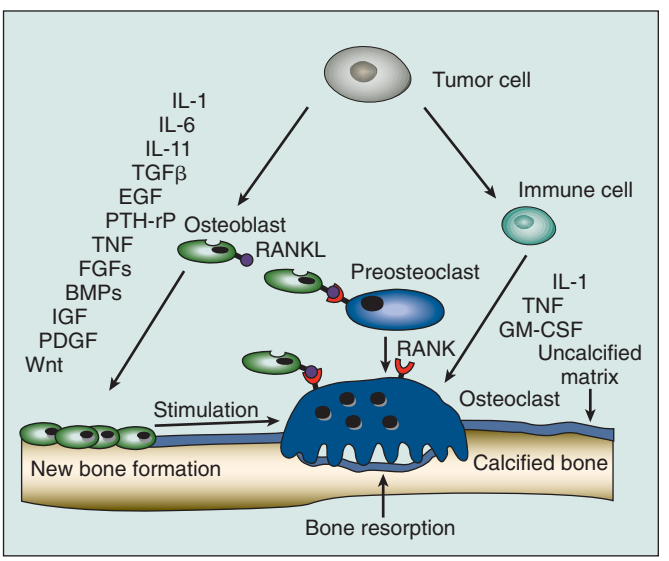

Figure 57-3 • Diagrammatic summary of the cellular and molecular interactions involved in bone resorption and new bone formation in metastatic disease of the skeleton. BMPs, bone morphogenetic proteins; EGF, epidermal growth factor; FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IGF, insulin-like growth factor; IL-1, interleukin 1; IL-6, interleukin 6; PDGF, platelet-derived growth factor; PTH-rP, parathyroid hormone-related protein; TGF, transforming growth factor (α and β); TNF, tumor necrosis factor.

Sclerotic Bone Metastases

Although osteolytic disease is usually most evident at sites of bone metastases, osteosclerosis sometimes can predominate, particularly in prostatic cancer. Prostate cancer, in contrast to breast cancer, tends to cause osteoblastic lesions in bone, leading to dense, sclerotic-looking metastases on plain radiographs, and osteoblast growth factors, such as TGF-β and platelet-derived growth factor, have been purified from prostatic tumor cells. One of the factors that might be involved in prostatic bone lesions is the growth factor endothelin-1 (ET-1), which is produced by prostate cancer cells. Circulating levels have been found to be increased in patients with osteoblastic bone metastases from androgen-refractory prostate cancer, compared with patients whose cancer is confined to the prostate and normal controls.[25] ET-1 has been found to stimulate osteoblast activity in animal models and to inhibit osteoclast activity, whereas antagonists of endothelin have been found to inhibit bone formation in vivo.[26] Furthermore, a recent study found that ET-1 production by prostate cancer cells is reduced by androgens but is stimulated in androgen-insensitive prostate cancer cells by factors (such as TGF-β).[27] This finding is clinically relevant, because metastatic prostate cancer typically develops androgen resistance. It is possible that PTHrP is also involved in the pathogenesis of prostate cancer bone metastases, because coexpression of PTHrP and its receptor has been found in both the primary tumor and in bone metastases of patients with prostate cancer.[28]

Evidence from morphometric studies and measurement of urinary markers of osteolytic bone resorption has led to the hypothesis that initially, osteoclastic bone resorption is important in prostate cancer, followed by intense osteoblastic activity.[29] This might not necessarily always be the case, however. A recent study found that the prostate cancer cell line PC-3 implanted into tibia of SCID mice caused osteolytic lesions, possibly through secretion of RANK ligand.[30] When another prostate cancer cell line (LAPC-9) was used, however, osteoblastic lesions developed even when no osteoclasts were present. Therefore, in this study the authors concluded that osteoclastic activity might not be a prerequisite for the formation of osteoblastic lesions.

There is an increasing interest in the role of the osteoblasts in bone metastases, and it has recently been established that the Wnt signaling system plays a key role in bone development and turnover.[31] Subsequent studies have found that several molecules in this system are implicated in the development of bone metastases.[32] In prostate cancer, tumor-derived Wnt induces osteoblastic activity in bone metastases, which in the early stages of disease may be counteracted by the presence of the Wnt agonist DKK1 (an inhibitor of osteoblast differentiation), thereby favoring lytic lesions. In the later stages of progression of prostate cancer bone metastases, the balance between Wnt and its inhibitors is suggested to be shifted toward Wnt, favoring osteoblastic lesions.

In myeloma bone disease, bone marrow stromal cells are important for the pathogenesis of multiple myeloma. Interleukin-6 seems to be an important growth and survival factor for myeloma cells and for conferring resistance to treatment with dexamethasone, a commonly used treatment for multiple myeloma. Barille and colleagues

also found that matrix metalloproteinases (MMPs), known to be important in normal and malignant remodeling, contribute to the pathogenesis of myeloma. Bone marrow stromal cells secrete interstitial collagenases (MMP-1) and gelatinase A (MMP-2). MMP-1 initiates bone resorption, degrading type I collagen, which becomes a substrate for MMP-2.[33] Malignant plasma cells have been found to upregulate MMP-1 and activate MMP-2.[34]

Dysregulation of the Wnt signaling system has also been implicated in myeloma bone disease, where the production of DKK1 by myeloma cells is reported to be associated with the presence of lytic bone lesions.[35]

DIAGNOSIS

Differential Diagnosis

Metastatic involvement of the skeleton typically affects multiple sites and causes pain, bony tenderness, and increasing disability. The diagnosis is often straightforward but occasionally can be difficult to make, and confusion with benign pathology is particularly a problem for elderly patients, in whom degenerative disease and osteoporosis are common. Particularly difficult clinical situations include elderly women with painful collapsed vertebrae who have a past history of breast cancer and in whom it can be difficult to distinguish osteoporotic collapse from metastatic destruction, and elderly men with prostatic cancer and pelvic pain with sclerotic radiologic changes in the pelvis attributable to either metastases or Paget's disease of bone.

In all cases, appropriate imaging tests are necessary and must be interpreted in conjunction with the clinical picture, information from measurement of biochemical markers of bone metabolism, and—when appropriate—serum tumor markers. Occasionally, bone biopsy under radiologic control or at open operation is necessary. Table 57-2 summarizes the typical clinical, radiologic, bone scan, and biochemical abnormalities of the more common skeletal pathologies.

Diagnostic Methods

Skeletal Radiography

A skeletal radiogram indicates the net result of bone resorption and repair. To be recognized on a plain radiograph, a destructive lesion in trabecular bone must be greater than 1 cm in diameter, with loss of approximately 50% of the bone mineral content. When radiography is used as the primary investigation for bone metastases, such as in multiple myeloma, a skeletal survey is performed. On the basis of the usual distribution of metastases, this normally includes radiograms of the lateral skull and cervical spine, anteroposterior and

Table 57-2 Clinical, Radiologic, and Biochemical Features of Common Skeletal Disorders That May Mimic Bone Metastases

Diagnosis	Clinical Features	Radiologic	Biochemical
Bone metastases	Pain common	Bone scan very rarely completely normal	Alkaline phosphatase usually elevated
	Usually multiple sites	Discrete lytic or sclerotic lesions on radiographs	Increased urinary markers of bone resorption
	Axial skeletal involvement typical	Fracture/vertebral pedicle destruction	Hypercalcemia common
		Soft tissue extension on CT/MRI	
Degenerative disease	Elderly	Spinal involvement results in symmetric increased tracer uptake on scan	Usually normal
	Limb involvement common	Radiograms usually confirmatory	
	Pain and stiffness		
	Long history		
Osteoporosis	Elderly female	Normal scan unless recent fracture or vertebral collapse	Usually normal serum parameters
	Painless unless fracture or vertebral collapse	Diffuse osteopenia on radiograms	Slight elevation of urinary indices
		Normal marrow on MRI	No hypercalcemia
Paget's disease of bone	Elderly	Diffuse involvement of bone on scan	Alkaline phosphatase greatly elevated
	Bone deformity common	Sclerotic expanded appearance on radiograms	Increase in urinary hydroxyproline excretion
	Involved site warm due to increased blood flow		Hypercalcemia very rare
	Skull often involved and enlarged		
Traumatic fractures	History of trauma usual	Intense linear uptake on scan	Usually normal
	Spontaneous rib fractures after chest wall irradiation common	Rib lesions typically aligned, not randomly distributed	
		No evidence of destruction around fracture site on radiographs (unless radiation induced)	

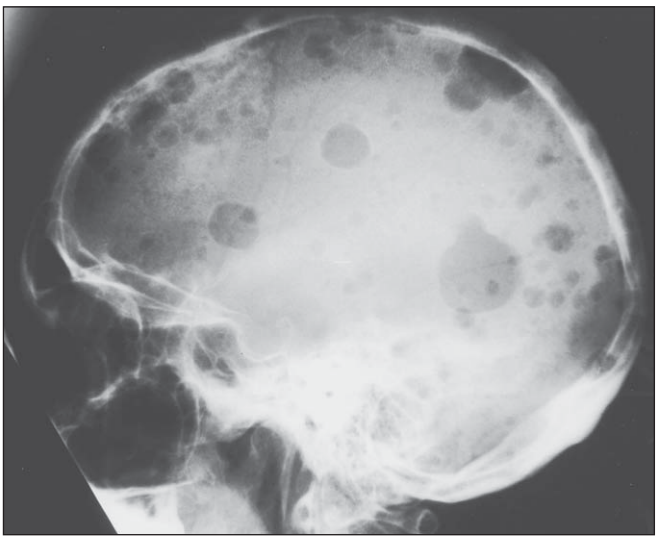

Figure 57-4 • Lytic metastases in the skull.

Figure 57-5 • Sclerotic metastases in the pelvis.

lateral thoracic and lumbar spine, and anteroposterior pelvis and chest radiograms taken at low KVp to visualize the ribs optimally.

It is the predominance of lysis or sclerosis that gives rise to the characteristic radiographic appearances of bone metastases. When bone resorption predominates, focal bone destruction occurs, and bone metastases have a lytic appearance. Conversely, in bone metastases characterized by increased osteoblast activity and associated with a fibrous stroma (e.g., in prostate cancer), the lesions appear sclerotic. Even when one element predominates, both processes are greatly accelerated in the affected bone. Though probably a general phenomenon, this is most apparent in the appropriately termed "mixed" lesions, seen most commonly in breast cancer, in which both lytic and sclerotic components are clearly visible.

Lytic metastases are the most common type arising from breast, lung, thyroid, renal, melanoma, and gastrointestinal malignancies (Fig. 57-4). There is thinning of trabeculae, and the margins are usually ill defined, representing regions of partially destroyed trabeculae between the central destruction and the radiologically normal bone. The width of the margin reflects the aggressiveness of the lesion, with a narrow zone of transition in the less aggressive lesions. If the metastasis is in the medulla, there could be endosteal scalloping, whereas cortical lesions produce subperiosteal scalloping or a focal cortical defect.

Sclerotic metastases are usually from prostate cancer but also arise from breast, lung, and carcinoid tumors (Fig. 57-5). Excessive new bone formation gives rise to thickened, coarse trabeculae, which usually appear on radiograms as nodular, rounded, fairly well-circumscribed sclerotic areas. Sometimes, less well-defined, mottled, irregular areas of increased bone density occur, which can coalesce to produce a diffuse sclerotic appearance to the skeleton.

Radionucleotide Bone Scan

The radionuclide bone scan provides quite different information from the skeletal radiogram. The bone-seeking radiopharmaceutical is absorbed onto the calcium of hydroxyapatite in bone, a reaction that is influenced by osteoblastic activity and skeletal vascularity, with preferential uptake of tracer at sites of active bone formation. The bone scan, therefore, reflects the metabolic reaction of bone to the disease process, whether neoplastic, traumatic, or inflammatory. When bone metastases develop, there is usually sufficient increase in blood flow and reactive new bone formation to produce a focal increase in tracer uptake, often before bone destruction can be seen radiologically, and with the exception of patients with multiple myeloma, the bone scan is a more sensitive technique than plain radiograms for the detection of skeletal pathology. Lesions in the pubis, ischium, and sacrum may on occasion be obscured on the bone scan as a result of bladder activity, and not all established metastases may be visualized.

A bone scan is generally performed by acquiring multiple images of the skeleton 3 to 4 hours after the intravenous injection of ^{99m}technetium-labeled methylene-diphosphonate. If a lesion is identified, particularly when solitary, further investigation is necessary. A suggested protocol for investigation is shown in the accompanying algorithm (Fig. 57-6). Appropriate plain radiographs of a focal lesion should be obtained in the first instance. If these are normal and

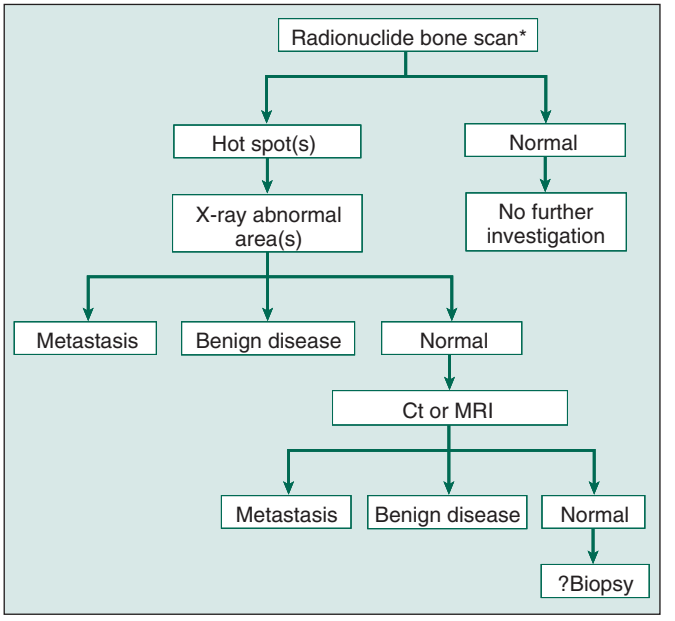

Figure 57-6 • Diagnostic methods for the investigation of a patient with possible bone metastases. *Patients with multiple myeloma are best investigated by performing a skeletal survey.

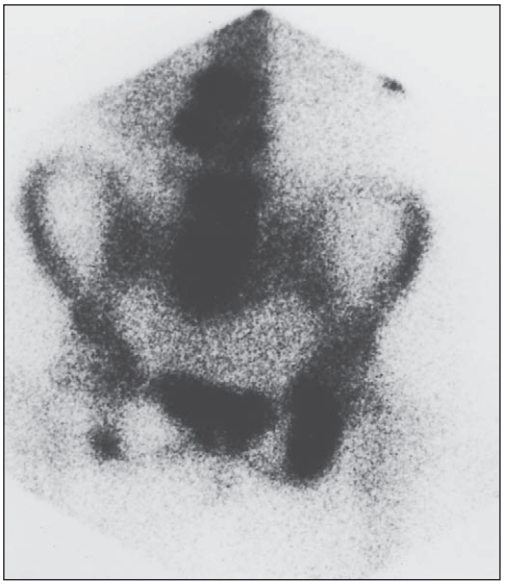

Figure 57-7 • Radionuclide bone scan appearances of metastases in the lumbar spine and pelvis.

clinically a metastasis is likely, then CT or magnetic resonance imaging (MRI) of the area could be diagnostic.

Although bone scan appearances are nonspecific, recognizable patterns of bone scan abnormalities might suggest a specific diagnosis. Metastases are usually multiple, irregularly distributed foci of increased tracer uptake that do not correspond to any single anatomic structure (Fig. 57-7). Generally, they affect the axial skeleton, but metastatic disease can involve the appendicular skeleton, and approximately 7% of patients have involvement of the distal skeleton, the proportion increasing in certain tumor types such as renal cell carcinoma.[36] Although bone metastases are usually multiple when diagnosed, as many as 20% of women with breast cancer present with a solitary hot spot on the bone scan with or without pain.[37]

Because detection of a lesion depends on the presence of a focal increase in osteoblast activity, a false-negative scan will occur when there is pure lytic disease. This is typical of multiple myeloma, which is best investigated radiographically but also can occur in other tumors when there are rapidly growing lytic lesions. In extreme cases, where there has been significant bony destruction, a photon-deficient area (cold spot) can develop (Fig. 57-8). Sclerotic metastases, on the other hand, are generally clearly visualized on the bone scan, the only exception being very slow-growing metastases, in which the alteration in metabolic activity is so subtle that it might not be distinguishable from normal background activity.

When there are extensive skeletal metastases, the focal lesions might coalesce to produce diffusely increased uptake—the so-called "super scan" of malignancy (Fig. 57-9). This occurs most often in prostatic cancer but also is seen in other tumors, such as breast cancer. An increase in the contrast between bone and background soft tissue and faint or absent renal images are the typical appearances.

Computed Tomography

A CT scan produces images with excellent soft-tissue and contrast resolution. Bony destruction and sclerotic deposits are well shown (Fig. 57-10), and any soft-tissue extension of bone metastases is demonstrated clearly. CT is most appropriate for diagnosing spinal metastases, but because the whole spine cannot be scanned readily, CT is normally reserved for assessment of patients with positive bone scans and negative radiograms in an attempt to clarify the pathology.

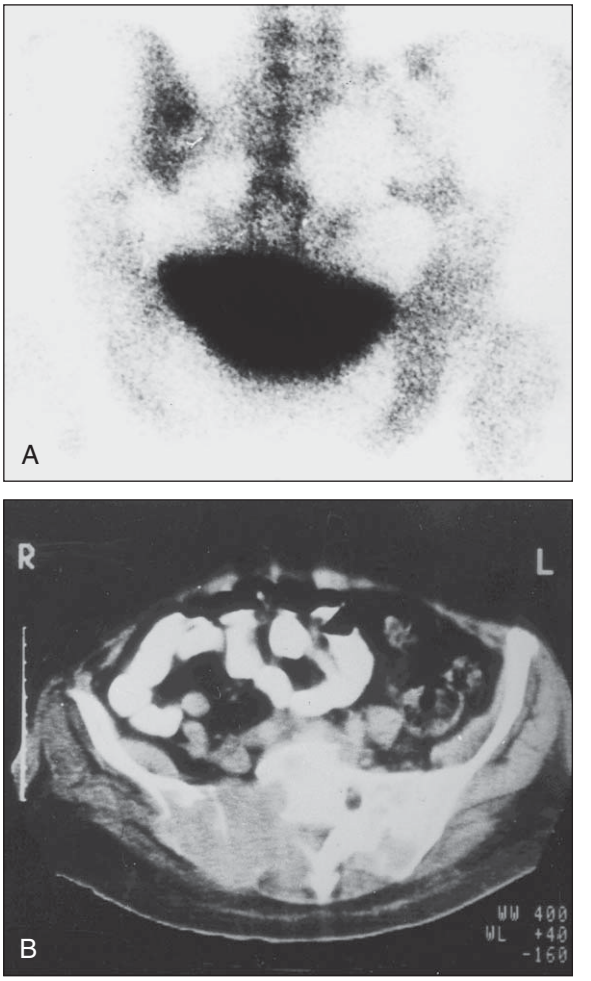

Figure 57-8 • **A,** Photodeficient (cold lesion) in the sacrum resulting from a rapidly progressive destructive bone metastasis as demonstrated by CT scan slice taken through the lesion **(B).**

Magnetic Resonance Imaging

MRI has the advantage over CT of providing multiplanar images that permit (as one example) imaging of the entire spine in the sagittal plane (Fig. 57-11). The solid constituents of cortical bone give no signal on MRI and appear black, whereas the high water content of fat and bone marrow results in strong signals, making these tissues appear white. This signal is variable depending on the pulse sequence used. Detection of bone metastases by MRI depends on differences in MR signal intensity between tumor tissue and normal bone marrow. Metastatic tumor is therefore visualized directly, in contrast to the indirect changes observed by x-ray or radionuclide bone scanning. Like CT, MRI has proved useful for evaluating patients with positive bone scans and normal radiograms and for elucidating the cause of a vertebral compression fracture. MRI is excellent for demonstrating bone marrow infiltration and has also been reported to be more sensitive than the bone scan for the early detection of metastases.[38]

Positron Emisssion Tomography

Scanning with ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}F-FDG-PET) provides the opportunity to visualize function. However, its role in the identification of bone metastases is far from clear. FDG has the advantage of demonstrating all metastatic sites, and in the skeleton it is assumed that its uptake is directly into tumor cells. For bone metastases from breast and lung cancer, FDG-PET has similar sensitivity, though poorer specificity, than the isotope

Figure 57-9 • "Super scan" of malignancy. Note absent renal images and diffuse uptake of tracer throughout the skeleton.

Figure 57-10 • CT scan image through the right shoulder showing mixed lytic and sclerotic disease.

bone scan. However, the evidence is inconsistent, with several studies suggesting that FDG-PET is less sensitive than conventional imaging in breast cancer. There is convincing evidence that FDG-PET is less sensitive than the bone scan for prostate cancer, whereas for multiple myeloma FDG-PET it is clearly better than the bone scan, presumably because FDG is identifying marrow-based disease at an early stage.[39]

Biochemical Markers of Bone Metabolism

The effects of tumor cells on bone cell function can influence serum and urinary levels of biochemical markers of bone metabolism. In recent years, the number of available markers and the clinical relevance has increased rapidly; their value in the diagnosis of bone metastases has been studied in several tumor types.

Bone Formation Markers

BONE ALKALINE PHOSPHATASE. Bone alkaline phosphatase (BALP) hydrolyzes pyrophosphate, thereby removing an inhibitor of osteogenesis while creating the inorganic phosphate that is required for generation and deposition of hydroxyapatite.[40] This enzyme is secreted as a "bud" from the osteoblast cell membrane to the bone matrix vesicles, allowing bone mineralization to proceed.

There are several alkaline phosphatase isoforms secreted by the various organs into the serum. Predominant isoforms originate from bone, liver, intestine, and placenta. Because of these wide sources of activity, limited information may be obtained from a total alkaline phosphatase measurement. However, the bone-specific isoform (BALP) is a relatively specific marker for osteogenesis. Elevated BALP levels occur in Paget's disease, renal rickets, bone cancer, osteomalacia, and celiac disease. In addition, BALP may be increased in patients with liver diseases because it is normally cleared from the serum by the liver.[41]

OSTEOCALCIN. Osteocalcin is the major noncollagen protein in the bone matrix.[42] It is produced by osteoblasts, odontoblasts, and hypertrophic chondrocytes, and is thought to function as a localization site for hydroxyapatite crystals during bone matrix synthesis. Both osteolysis and osteogenesis release osteocalcin into the serum, from which it is eliminated via renal clearance and degradation.[42] Therefore, osteocalcin levels might reflect overall bone metabolism, not just osteogenesis. Detection of serum or plasma osteocalcin may be impaired by high lipid levels because of osteocalcin-lipid binding. Moreover, multiple isoforms exist in the circulation, and current assays have a limited ability to detect them all. Urinary osteocalcin levels may also be assayed, but, because of recovery and degradation, urinary osteocalcin levels typically reflect only basal bone turnover instead of acute changes in bone metabolism.[42]

PROPEPTIDES OF PROCOLLAGEN TYPE I. Collagen type I composes approximately 90% of the organic bone matrix. Extracellular processing occurs before the final collagen fibril assembly wherein the N-terminal (N-terminal propeptide of procollagen type 1 [PINP]) and C-terminal (C-terminal propeptide of procollagen type 1 [PICP]) regions are generated in a 1 : 1 ratio with collagen and released into the serum. Therefore, levels of PINP and PICP may reflect the level of osteogenesis. However, type I collagen is synthesized is some other tissues, which may contribute to the serum PINP and PICP levels. Serum PICP levels have been correlated with bone formation, and decreased levels have been reported after bisphosphonate therapy or hormone replacement therapy. Both PINP and PICP are removed by the liver, but PINP can also be deposited directly into bone and has been found to constitute 5% of the noncollagenous protein in bone.[43] However, recent reports have suggested that PINP has greater diagnostic validity than PICP, and in a multivariate Cox analysis, PINP was shown to be an independent predictive factor for survival in patients with prostate cancer.[44]

Bone Resorption Markers

CALCIUM. Resorption of bone releases calcium, hydroxyproline, and collagen fragments into the circulation. These are cleared by the kidney and excreted largely unchanged into the urine. Serum calcium measurements are performed routinely, but changes within the normal range give little guide to disease activity. Hypocalcemia is seen when osteoblastic metastases predominate; this is more typically associated with prostate cancer but does sometimes occur in advanced breast cancer.

Urinary calcium excretion is a more sensitive indicator of alterations in calcium homeostasis. The molar ratio of calcium to creatinine in an early morning urine sample collected after an overnight fast is a convenient, reproducible method of quantifying calcium excretion. The problem with urinary calcium is that it is not a specific resorption inhibitor but only reflects the net effects of bone formation and resorption and is influenced by diet, the circulating levels of both PTH and PTHrP, and the concomitant administration of drugs such as bisphosphonates (which influence bone resorption independently of any tumor-related effects). Urinary calcium excretion is not increased significantly in the majority of patients with metastatic bone disease, a finding that reflects the effects of bone formation and the renal handling of calcium.

HYDROXYPROLINE. Urinary hydroxyproline excretion is a conventional parameter for measuring bone resorption in benign bone disease; it indicates matrix destruction more specifically but has been generally unreliable in the assessment of metastatic bone disease as a result of contributions from both diet and soft-tissue destruction by metastases.[41]

PYRIDINOLINE AND DEOXYPYRIDINOLINE. Pyridinoline (PYD) and deoxypyridinoline (DPD) are produced from the post-translational modification of lysine and hydroxylysine. They stabilize mature type I collagen in all major connective tissues, cross-linking the telopeptide domain of one collagen fibril to the helical region of an adjacent one. During bone resorption, PYD and DPD are released from bone in approximately a 3 : 1 ratio as free molecules or attached to collagen fragments. They are not recovered by the bone and are excreted via the kidneys with no known metabolic degradation. Urinary excretion is closely related to the rate of bone resorption. Although PYD and DPD are present in other tissues, bone is the major reservoir and has a higher turnover than most connective tissues. In fact, DPD is found almost exclusively in bone. However, the contribution from soft tissues may make these markers less accurate than other markers, especially in the case of PYD.

C-TELOPEPTIDE AND N-TELOPEPTIDE. C-telopeptide (CTX) and N-telopeptide (NTX) are the C-terminal and N-terminal peptides, respectively, of mature type I collagen with the cross-links attached and are released during bone resorption.[6] Degradation products of collagen are of various sizes that may undergo additional breakdown in the liver or kidney to their constituent amino acids and cross-links (PYD and DPD) and are excreted in the urine. However, osteoclast-derived fragments are different from those formed in nonskeletal tissues. The cross-linked peptide is primarily attached as an $\alpha 2$ isoform for NTX from bone and as an $\alpha 1$ isoform from other tissues. The CTX peptide exists as α or β isoforms, with β isoforms found more often in mature bone.[41]Assays for NTX utilize an antibody to the $\alpha 2$ chain and are usually performed on urine samples. However, urinary results must be adjusted for urine dilution, which may add to measurement variability. Urinary CTX measurements have poor precision at concentrations lower than 200 μg/L, so serum or plasma samples are often used. Serum CTX measurements utilize an antibody to the β isoform.

PYRIDINOLINE CROSS-LINKED C-TERMINAL TELOPEPTIDE OF TYPE I COLLAGEN. PYD cross-linked C-terminal telopeptide of type I collagen (ICTP) is another metabolic product of mature type I collagen resorption. Increased levels of serum ICTP correlate well with bone resorption levels in patients with either high or low bone turnover.[44] Serum ICTP level increases of as much as 20% have been reported in patients with osteolytic metastases.[45] Indeed, ICTP levels are elevated in lung cancer patients with bone metastases compared with patients without bone metastases, and in multiple myeloma patients with negative radiograms but positive MRI results.[45,46] Immunochemical characterization of serum ICTP reveal that cathepsin K–mediated bone resorption cleaves the collagen at the antigenic site, and the resulting ICTP fragment is not detected by the assay.[45] However, MMP-mediated release leaves the antigenic site intact, and in this situation the resulting ICTP fragment is detectable. These results explain why the current assay for ICTP is insensitive to physiologic changes in bone turnover such as those induced by estrogen or bisphosphonate treatment but a potentially useful marker in skeletal metastases.

TARTRATE-RESISTANT ACID PHOSPHATASE SERUM TYPE 5b. Tartrate-resistant acid phosphatase serum type 5b (TRAcP-5b) is secreted by osteoclasts after they have attached to the bone surface. The enzyme then enters the circulation where it is inactivated and degraded and active enzyme levels in the circulation

reflect recently released enzyme as a result of bone resorption. TRAcP-5b has been suggested as a useful marker for bone resorption. However, some studies have suggested that TRAcP-5b may reflect osteoclast numbers rather than activity.[47]

BONE SIALOPROTEIN. BSP is a noncollagenous bone matrix protein secreted by osteoclasts and is part of the small integrin-binding ligand N-linked glycoprotein (SIBLING) family. It is secreted by other cells and is present in all mineralized tissues. Elevated serum BSP levels have been reported in patients with prostate cancer, breast cancer, and colon cancer.[48] In fact, BSP levels in patients with bone metastases secondary to prostate cancer were an independent prognostic factor for survival.[49] Elevated serum BSP levels have also been reported in patients with multiple myeloma.[50]

Osteoclastogenesis Markers

RECEPTOR ACTIVATOR OF NUCLEAR FACTOR-KB LIGAND/OSTEOPROTEGERIN. RANK and the RANK ligand (RANKL) are required for osteoclastogenesis. OPG is a soluble decoy receptor that binds RANKL, thereby blocking stimulation of osteogenesis. RANKL exists as two isoforms: a membrane-bound form and a shorter soluble form. In patients with bone metastases secondary to breast cancer, prostate cancer, or lung cancer, both OPG and RANKL were not significantly elevated compared with patients without bone metastases.[51] However, among patients with multiple myeloma, serum levels of soluble RANKL and the RANKL/OPG ratio were elevated and correlated with markers of disease activity.[52]

Bone Markers as Predictive and Prognostic Indicators

Because commonly used radiographic methods do not detect bone metastases in the very early stages of development, the question arises whether serial measurements of bone markers might identify the impending development of bone metastases. Thus far, data relating to this question are sparse. However, once bone metastases have developed, bone markers can provide useful prognostic information. Clinical evidence of correlations between bone marker levels and patient outcomes have been recently reported from retrospective analyses of several large trials in patients with bone metastases.[10,53] Elevated on-study bone marker levels correlated with negative clinical outcomes in patients with metastatic prostate cancer, lung cancer, or other solid tumors.

Specifically, patients with elevated urinary NTX levels either at baseline or at their most recent assessment had an approximate twofold increase in their risk of disease progression and an approximate two- to threefold increase in their relative risk of skeletal-related events (SREs) compared with patients with low NTX levels. Among patients with prostate cancer, elevated NTX levels were associated with a 4.6-fold increased risk of death, and a 2.7-fold increased risk of death was observed in patients with lung cancer or other solid tumors compared with those with low NTX. In contrast, BALP levels were not a consistently strong prognostic indicator.

NTX levels have also been shown to provide valuable prognostic information in a larger analysis of patients receiving bisphosphonate treatment for bone metastases from a wide range of solid tumors and multiple myeloma.[53] Among patients with solid tumors, elevated NTX levels were associated with a significant twofold increased risk of disease progression ($P < 0.001$). Furthermore, elevated NTX levels were associated with a significant four- to sixfold increased risk of dying on study in all patients except those with multiple myeloma ($P < 0.001$ for all).

EVALUATION OF THE PATIENT

A variety of treatments, including radiotherapy, endocrine treatment, chemotherapy, and bisphosphonates, are used for the treatment of metastatic bone disease, and evaluation of their effects is important for both routine clinical practice and research. The current imaging methods used to assess response to these treatments are qualitative and routinely include plain radiographs, radionuclide bone scans, and, in particular situations, CT scans. Assessing the response of bone metastases to therapy is notoriously difficult; the events in the healing process are slow to evolve and quite subtle, with sclerosis of lytic lesions only beginning to appear 3 to 6 months after the start of therapy. Bone is the only site of metastatic disease that has separate criteria for evaluation of response to treatment, based on bone repair and destruction rather than on changes in tumor volume. A complete review of the bone radiographs since the start of treatment is necessary to evaluate response—a slow and tedious process.

Assessing response to treatment in bone is more difficult than evaluation of disease in viscera and soft tissues, where tumor measurements can usually be taken. This difficulty results in reports of lower response frequencies to systemic treatments in the skeleton compared with other sites of disease. Complete response in nonosseous sites affected by breast cancer occurs in 10% to 20% of patients, but a complete response in bone with return of normal trabecular pattern or resolution of sclerotic metastases is very rare. Although a low rate of complete response might represent some biologic phenomenon of site-specific resistance, this is unlikely, and the discrepancy in response frequency is almost certainly a reflection of the insensitivity of the assessment methods. Consequently, patients with metastatic disease confined to the bone are frequently excluded from many therapeutic trials, and patients with widespread metastatic disease (including bone) rely on the changes observed in soft tissue or visceral disease to judge response to treatment.

Although we recognize that the changes seen on serial radiograms remain the "gold standard" for evaluating response to therapy, new methods of assessing response are needed, both to improve patient management and to evaluate specific treatments. Several alternatives or adjuncts to assessment based on plain radiograms have been suggested. None is ideal, each having advantages and disadvantages as outlined in the following sections.

Assessment of Symptoms and Activity Status

The relief of symptoms is the principal aim of palliative therapy and rationally should be the most important marker of response to treatment. The use of pain as a marker of response in clinical trials has not found universal acceptance, however, and there is still no single internationally accepted pain questionnaire in oncology, although the Brief Pain Inventory is frequently used in clinical trials. Subjective response to treatment for bone disease requires information on pain intensity, analgesic consumption, and mobility.[54]

Quality-of-life assessment is now an important aspect of clinical trials methodology and, notwithstanding all the difficulties of analysis and interpretation, well-validated generic tools such as the Functional Living Index in Cancer patients (FLIC) and the EORTC QOL-C30 questionnaire can provide useful information on subjective response to treatment in the routine clinical setting. A specific quality-of-life tool for patients with bone metastases is currently under development by an international consortium.

Imaging of Bone Metastases

Radiologic assessment of response is based on radiographic evidence of bone healing. It is generally accepted that sclerosis of lytic metastases with no radiologic evidence of new lesions constitutes tumor regression (a partial response). Confounding factors include the appearance of sclerosis in an area that was previously normal on the radiogram. This could represent progression of a new metastasis but could also indicate a response, reflecting a radiographic example of the healing flare phenomenon within a lesion that was present at the start but was not destructive enough to be radiographically visible. Interpretation is further complicated by variations in film exposure and by the effects of overlying bowel gas. The evaluation of response

in osteosclerotic lesions is even more difficult, with most patients with sclerotic metastases eventually classified as either "no change" in response to therapy or unassessable. Here, decisions about the efficacy of treatment have to be based on symptomatic response or (when present) on change in extraskeletal disease.

Although the plain radiogram remains the assessment tool for judging response in clinical trials, it is clearly an inadequate technique. This lack of precision for radiographic assessment of response is exemplified by the observation that, in terms of survival, patients with radiographic evidence of sclerosis (partial response) and those with no change in radiographic appearance for at least 3 months have a similar outcome.[55]

The use of bone scanning for assessment of response to therapy has always been contentious; when lytic metastases predominate, it is often unreliable. A reduction in the intensity and number of lesions (hot spots) on the bone scan was previously considered to represent response, and progressive disease was assumed if an increase in intensity or number of hot spots was seen. This interpretation is too simplistic, however. After successful therapy for metastatic disease, the healing processes of new bone formation cause an initial increase in tracer uptake (akin to callus formation), and scans performed during this phase are likely to show increased intensity and number of hot spots. After treatment for 6 months, the bone scan appearances might improve, as the increased production of immature new bone—the cause of the hot spots—eventually ceases and isotope uptake gradually falls. This "deterioration" followed by subsequent "improvement" in the bone scan appearances after successful therapy has been termed the flare response and is now a well-recognized phenomenon in both breast and prostate cancers (Fig. 57-12). Conversely, a reduction in isotope uptake can occasionally be seen in rapidly progressive disease, when overwhelming bone destruction allows little chance for new bone formation, sometimes culminating in a photon-deficient (cold spot) lesion on the bone scan.

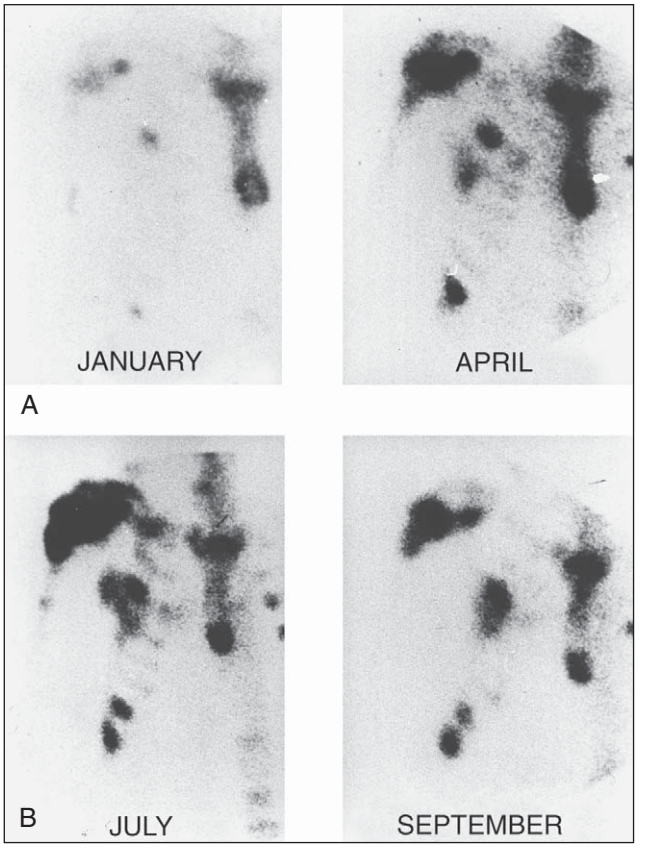

Figure 57-12 • **A,** CT appearances of metastases in a lumbar vertebra. **B,** Evidence of bone healing 2 months after irradiation.

Bone scanning in advanced disease should certainly be interpreted with great caution when performed within 6 months of a change in therapy; it is most useful for restaging at the time of relapse, to identify sites for radiologic assessment, and to bring to the attention of the clinician those sites at risk of pathologic fracture where prophylactic surgery could be indicated.

CT evaluation is effective for diagnosing metastases, particularly in the spine, but it is also occasionally valuable as a parameter of response to metastatic disease. Metastatic lesions that are considered to be representative of the metastatic process (target lesions) and suitable for serial examination with a standard window width and level appropriate for bone are optimum for selection. If required, a region of interest can be defined and the spectrum of Hounsfield values within it calculated by the computer. Changes in the spectrum with time can be determined, with a shift to the right (more positive) indicating replacement of lytic bone (which has a low Hounsfield value) by new sclerotic bone (which has a relatively high Hounsfield number).

CT evaluation is particularly useful for assessing areas that are poorly visualized on plain radiographs (e.g., the sacrum) and might permit assessment of sclerotic bone disease. Within sclerotic metastases, areas of osteolysis are usually present and can be identified by CT. Sclerosis of this lytic component would suggest response to treatment, whereas new areas of lysis appearing within a sclerotic region probably represent progression of disease.

The use of MRI for monitoring response to treatment is not used routinely, and in many parts of the world limited equipment availability makes MRI unlikely to be suitable for routine use. As in primary bone tumors, however, MRI could have a role for detailed evaluation of a specific lesion, for example before surgery.

The role of PET scanning in assessment of response remains uncertain.[56] Uptake of ^{18}F-FDG is related at least in part to function within the tumour and in theory could be useful just as it has been shown to be in the early assessment of soft-tissue tumours.

Tumor Markers

In breast cancer, unlike the germ cell malignancies, there is no highly specific tumor marker for either diagnosis or monitoring of disease. Some breast tumors, however, do produce tumor antigens that can be detected by radioimmunoassay. The most widely studied are carcinoembryonic antigen, which is elevated in 50% to 80% of patients with metastatic breast cancer, and CA 15-3, which is elevated in 60% to 90% of cases with advanced disease. Dynamic changes must be interpreted with caution. Although some patients show the expected increase in markers with progression and decrease in markers with regression, others who respond show an initial surge in tumor marker followed later by the expected decline.

Using an index derived from carcinoembryonic antigen and CA 15-3 in combination with erythrocyte sedimentation rate, a study in patients with metastatic breast cancer found a significant correlation with clinical assessment of response using Union Internationale Contre Cancer (UICC) criteria at 2, 4, and 6 months after systemic endocrine treatment.[57] A multicenter evaluation of the same index confirmed that changes in the markers were in line with and often predated therapeutic outcome criteria for both remission and progression.[58]

Prostate specific antigen (PSA). is a marker of prostatic pathology and can be elevated in any prostate disease: benign prostatic hypertrophy, prostatitis, and cancer. The highest tissue production occurs in prostate cancer, and PSA has proved useful in the early diagnosis, staging, and follow-up of patients.[59] The level of PSA is dependent on the volume of cancer, the volume of benign prostatic hypertrophy in the prostate, and the differentiation of the tumor, with less production of PSA from poorly differentiated tumors. PSA levels usually

decline after androgen deprivation therapy (ADT) and provide a reliable guide to response; elevations of PSA usually antedate other clinical evidence of progression by at least 12 months.[60]

Biochemical Assessment of Response

The stimulation of osteoclast function that results in osteolysis and disruption of the normal coupling between osteoblast and osteoclast function leads to changes in a variety of biochemical parameters. When treatment is prescribed for a patient with bone metastases, the effects of that treatment on the tumor cell population will influence bone cell activity. These changes can be appreciated within the first few weeks of starting effective therapy; for this reason, biochemical markers that reflect the rates of bone formation and resorption, respectively, might provide an early assessment of response to treatment (Table 57-3).

Hypercalcemia is usually indicative of progressive disease, and this is certainly the case if the hypercalcemia has developed more than a few weeks after the start of a new systemic treatment. Rarely, hypercalcemia can be a manifestation of the tumor flare, occurring within a week or so of starting tamoxifen, and in this case it might herald a response to treatment.[61]

More recently, attention has turned to the possible use of collagen cross-link measurements for the assessment of response in bone. Walls and colleagues[62] studied the collagen cross-links PYD and DPD in 36 patients with breast cancer with bone metastases. In women who developed progressive disease, both markers increased and preceded radiologic evidence by a median of 2 months. By contrast, in women who responded to hormone therapy, the markers did not change significantly.

Similarly, Vinholes and associates[63] studied 37 patients with newly diagnosed bone metastases from breast cancer. NTX levels were significantly lower than baseline values ($P = 0.05$) at 1 and 4 months in responding patients, compared with values for patients with progressive disease. Furthermore, a greater than 50% increase in NTX excretion correctly predicted disease progression in 78% of patients. In a larger, more recent study, 97 evaluable patients with metastatic bone disease from a variety of primary sites were followed during systemic therapy to correlate marker changes with response to treatment.[64] Good correlations of urinary NTX, ICTP, and BALP changes with response were observed, with a rise in NTX of greater than or equal to 52% having the highest positive predictive value (71%) for identifying progression of disease.

Although it is now well accepted that bone-targeted systemic therapy—particularly the use of the bisphosphonates—can reduce morbidity of skeletal metastases of breast cancer substantially, the optimization and timing of these therapies remains to be established. Bone markers potentially offer a powerful and relatively simple tool to assist the clinician in developing the most appropriate treatment strategies. Moreover, there is a prospect of using bone markers to tailor treatment to the individual patient.

There is evidence that the individual pretreatment values of a bone marker, particularly NTX, correlate with response to treatment. In patients with metastatic bone pain treated with pamidronate, the baseline values of NTX were significantly higher ($P < 0.02$) in nonresponding patients compared to clinical responders.[65] This study also showed that normalization of bone resorption markers correlated with response to treatment. Clinical benefit, as indicated by an improvement in a pain score, was seen only among those patients achieving a normal bone resorption rate after administration of pamidronate. No response was seen in the patients with persistently elevated levels. This suggested that the aim of bisphosphonate therapy should be to produce a fall in marker levels, preferably into the normal range. A subsequent study has shown that this principle may be extended to the use of bone markers to distinguish between the benefits of different bisphosphonates.[66] In one study, 51 patients were allocated randomly to treatment with either oral clodronate, intravenous clodronate, or intravenous pamidronate. Symptomatic response was more frequent in the pamidronate group than in patients receiving clodronate, and this was reflected by a correspondingly greater decrease in the bone resorption markers CTX and NTX.

The ability of bisphosphonate therapy to reduce the frequency of skeletal complications also seems to be correlated with a reduction in bone resorption markers. Retrospective analyses of large randomized trials with zoledronic acid have shown that among patients with solid tumors, elevated NTX levels despite treatment were associated with a significant two- to threefold increased risk of skeletal complications ($P < 0.001$).[53]

Table 57-3 Biochemical Markers of Bone Resorption and Formation

Resorption	Formation
URINE	**SERUM**
Calcium	Alkaline phosphatase
Hydroxyproline	Osteocalcin
PYD	PICP
DPD	PINP
NTX	
Crosslaps	
Free DPD	
Free PYD	
Galactosyl hydroxylysine	
SERUM	
Calcium	
ICTP	
Galactosyl hydroxylysine	

DPD, deoxypyridinoline; ICTP, type I collagen C telopeptide; NTX, N-telopeptide of type I collagen; PINP, N-terminal propeptide or type I procollagen; PICP, C-terminal propeptide or type I procollagen; PYD, pyridinoline.

TREATMENT

In general, the treatment of bone metastases is aimed at palliating symptoms, with cure only rarely a realistic aim (e.g., in lymphoma); treatment varies depending on the underlying disease. External beam radiotherapy, endocrine treatments, chemotherapy, and radioisotopes are all important. In addition, orthopedic intervention may be necessary for the structural complications of bone destruction, and some patients with bone metastases develop hypercalcemia requiring specific treatment (see Chapter 48). Optimal management requires a multidisciplinary team that includes not only medical and radiation oncologists, orthopedic surgeons, general physicians, radiologists, and nuclear medicine physicians, but also palliative medicine specialists and the symptom control team.

A schema for the management of bone metastases is shown in the accompanying algorithm (Fig. 57-13). Treatment decisions depend on whether the bone disease is localized or widespread, the presence or absence of extraskeletal metastases, and the nature of the underlying malignancy. Radiotherapy is frequently relevant throughout the clinical course of the disease. Resistance to systemic treatments can be expected to develop, necessitating periodic changes of therapy in an effort to regain control of the disease.

External Beam Radiation Therapy

Shortly after the discovery of x-rays by Roentgen in 1895, radiation therapy was tried as an empiric treatment for bone metastases, and

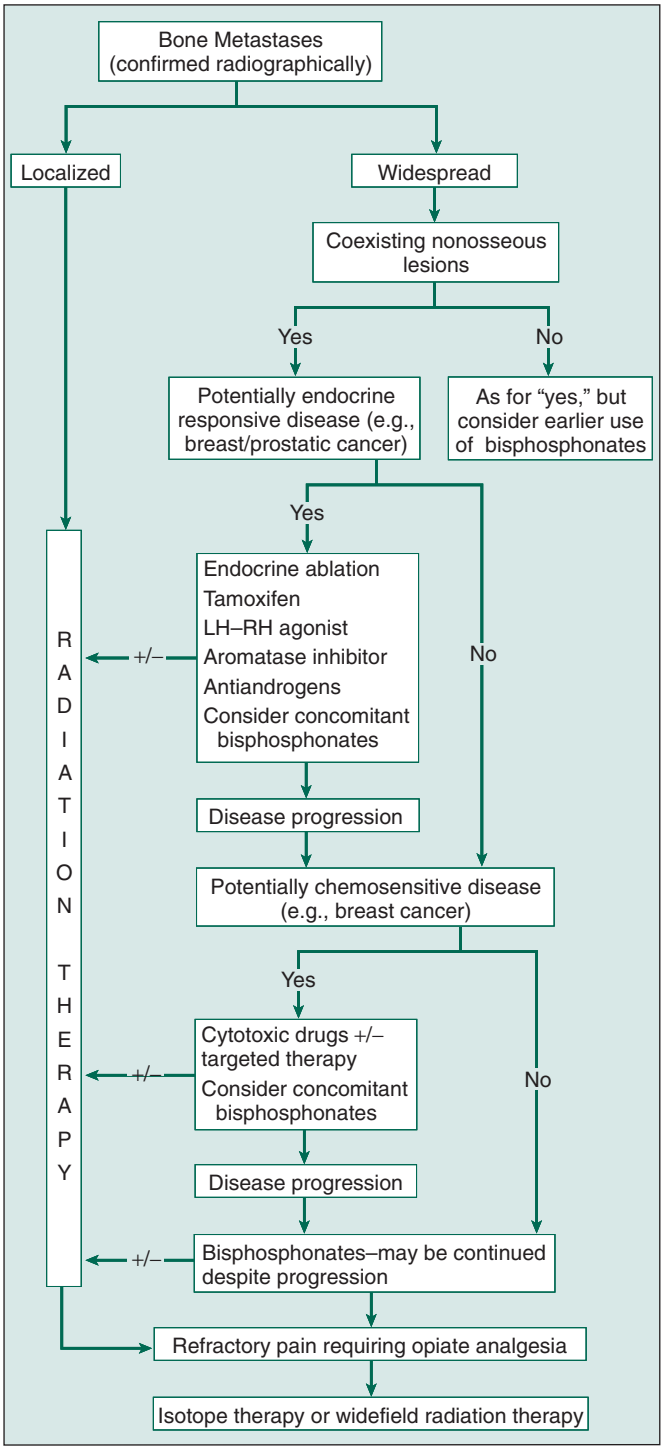

Figure 57-13 • Treatment of bone metastases.

relief of bone pain was observed. Since these early reports, radiotherapy has become established as the treatment of choice for the palliation of painful single sites.

Most treatments for bone pain use an external beam of ionizing radiation, either γ-rays or x-rays. Opposing anterior and posterior fields are used to produce an even dose distribution across the volume to be treated. Although surface anatomy can be used to localize the treatment area, use of a treatment simulator is preferable for accurate localization, particularly if treatment of adjacent areas is likely in the future.

Irradiation of bone can result in a number of pathologic changes that can include atrophy, osteitis, necrosis, and sarcomatous change. Postmortem studies have provided some insight into the structural effects of irradiation on bone-containing metastases. Initially, there is degeneration and necrosis of tumor cells, followed by a proliferation of collagen. Subsequently, a rich vascular fibrous stroma is produced, within which intense osteoblast activity lays down new woven bone. This is then gradually replaced by lamellar bone, and the intratrabecular stroma is repopulated by bone marrow tissue. Radiologically, it can be seen that recalcification of lytic areas begins 3 to 6 weeks after irradiation, with maximum recalcification occurring 2 to 3 months after the time of irradiation.

There is no doubt that local irradiation is effective for bone pain. Overall, response rates of around 85% are reported, with complete relief of pain achieved in one-half of patients.[67] Pain relief usually occurs rapidly, with more than 50% of responders showing benefit within 1 to 2 weeks. If improvement in pain has not occurred by 6 weeks or more after treatment, it is unlikely to be achieved.

Traditionally, treatment techniques and doses have varied considerably between different centers, with prolonged fractionated treatments preferred in North America and single treatments or short fractionation schedules most frequently utilized in Europe. A considerable number of randomized trials have been performed comparing different fractionation schedules. No particular approach seemed to be superior in terms of pain relief. American practice is influenced by the studies by the Radiation Therapy and Oncology Group. A variety of dose fractionation schedules were used ranging from 15 Gy in five fractions to 40.5 Gy in 15 fractions in a prospective randomized study of more than 1000 treatments for metastatic bone pain. An overall response rate of 90% was observed, with approximately half of responders maintaining pain relief until death. Median duration of pain relief in the complete responders was 12 to 15 weeks. The complete response rate was 35% after 40.5 Gy in 15 fractions, compared with a response rate of only 28% after 25 Gy in five fractions ($P = 0.0003$).[68] In Europe several trials have shown no difference in outcome between fractionated treatment and a single treatment, notably a large Dutch trial of 1157 patients with painful bone metastases who were randomized to receive either a single fraction of 8 Gy or a treatment schedule of six fractions of 4 Gy each.[69] No statistically significant differences in pain response, analgesic consumption, treatment side effects, or quality of life were identified. A meta-analysis of eight trials comparing single versus multiple fractions revealed similar response rates; 1011 of 1391 (73%) treated with a single fraction and 958 of 1321 (73%) who received multiple fractionation achieved a symptomatic response.[70] Hence, accumulating evidence strongly favors single-fraction radiotherapy as the treatment of choice for many patients with painful bone metastases.

The option of retreatment of a painful site requires careful review of previous treatment fields, dose, and fractionation to ensure that normal tissue tolerance, particularly of the spinal cord, is not exceeded. When higher radiation doses are administered, retreatment may be precluded; targeted radioisotope therapy is an alternative approach in such patients. After a single 8-Gy fraction, however, retreatment is usually possible, with more than 50% of patients with recurrence of bone pain responding to a second 8-Gy treatment—a finding that further supports the move occurring in many centers toward single-fraction treatments for routine palliation of metastatic bone pain.

When there are multiple scattered sites of painful bone metastases, wide field/hemibody irradiation is an alternative to treating each site individually with local irradiation. Using single fractions of 6 to 7 Gy to the upper hemibody and 6 to 8 Gy to the lower hemibody, pain relief is reported in about 75% of patients, often occurring rapidly and sometimes within 24 to 48 hours of treatment.[67] Hemibody irradiation is inevitably more toxic than localized external beam treatment. Virtually all patients who receive lower hemibody irradiation suffer gastrointestinal toxicity with nausea and diarrhea, requiring premedication with intravenous hydration, steroids, and antiemetics

to reduce these effects. The serious toxicities of hemibody irradiation are bone marrow suppression and radiation pneumonitis. Significant bone marrow suppression is seen in about 10% of patients receiving a single half-body treatment and in most patients who have sequential upper and lower hemibody treatment; these developments often compromise the use of subsequent chemotherapy. Radiation pneumonitis is both dose- and dose-rate-dependent; the occasional cases that do occur are difficult to treat and can be fatal.

Targeted Radioisotope Therapy

The therapeutic use of radioactive-labeled tracer molecules is currently an area of considerable interest and research. The principles of the technique are well established after decades of experience with iodine-131 (^{131}I) for the treatment of follicular thyroid cancer. Targeted radiotherapy has theoretic advantages over external beam radiotherapy in that the radiation dose is delivered specifically to the tumor and normal tissues are spared unnecessary irradiation. Theoretically, it should also be possible to administer high doses of radiation to the tumor on a recurrent basis if necessary. Despite the theoretic attractions of radioisotope therapy, however, technical difficulties have limited the use of therapeutic radiopharmaceuticals thus far.

Therapeutic radionuclides have characteristics different from those used for diagnostic purposes. Ideally, radionuclides for therapy should have a fairly long half-life, allowing adequate accumulation of the radiopharmaceutical within the target tissue. The γ-particle emission should be small to reduce unwanted radiation to nontarget tissues, but present in sufficient amounts to permit localization of the radionuclide by gamma camera imaging. Predominantly α- or β-emitting radionuclides are the most suitable, but, apart from ^{131}I, they have been very expensive to produce. Although many α- and β-emitting radionuclides exist, relatively few have been evaluated clinically.

Because follicular carcinoma of the thyroid commonly metastasizes to bone, the treatment of bone metastases with ^{131}I is now well established, and excellent results can be obtained. In patients with a significant uptake of ^{131}I into the metastases, long-term palliation is usually possible. Treatment is generally well tolerated, although some patients develop a radiation reaction in the salivary glands. More important, however, is the 1% to 2% incidence of radiation-induced leukemias.[71]

Neuroblastomas, and tumors of neuroectodermal origin in general, frequently metastasize to bone. Some 90% of these neoplasms incorporate the radiopharmaceutical ^{131}I-meta-iodo benzyl guanadine (^{131}I-MIBG), and this has now been used to treat many children with metastatic neuroblastoma. Bone marrow suppression is often severe, and ideally, bone marrow harvesting should be performed as a precautionary measure on patients with extensive bone metastases.

^{131}I-MIBG has also been used therapeutically to treat bone metastases from malignant pheochromocytoma, medullary carcinoma of the thyroid, and carcinoid tumors with limited success. Between one-third and one-half of patients achieve symptomatic benefit, but long-term remissions are rare.

Strontium-89 (^{89}Sr) is a β emitter that imitates calcium and is taken up preferentially at sites of new bone formation. It has been shown to localize at the sites of prostatic bone metastases, with greater accumulation occurring in the metastatic lesions than is observed in normal bone.[71,72] The biologic half-life of strontium in metastases is long compared with that of normal bone, with whole-body retention of ^{89}Sr treatments ranging from 11% to 88% depending on the degree of skeletal involvement. The radiation dose to individual vertebral metastases from a single 150-MBq dose of ^{89}Sr has been shown to vary from 9 Gy to 92 Gy depending on the extent of metastatic spread. Of great clinical importance is the low dose of radiation to the bone marrow, which is only about one-tenth of that to the bone metastases.

The selective β-particle irradiation provides pain relief in up to 80% of patients, with 10% to 20% becoming pain free.[72] On average, the response lasts for 6 months, with only mild hematologic toxicity. Several randomized clinical trials have been performed. These have included a double-blind, placebo-controlled trial of ^{89}Sr, with active therapy clearly superior in terms of pain relief ($P < 0.01$).[72] ^{89}Sr has also been compared with conventional radiotherapy (hemibody or local) for the palliation of bone metastases from prostatic cancer. ^{89}Sr was at least as effective as external beam radiotherapy in achieving palliation and seemed also to delay or prevent the development of new sites of pain.

Samarium-153 (^{153}Sm) is both a β- and a γ-ray emitter, making it suitable for combined therapy and imaging. It has a short half-life (46 hours) and, linked to ethylene diamine tetramethylene phosphonate (EDTMP) for use as a radiopharmaceutical, concentrates preferentially in skeletal metastases. Clinical reports indicate that ^{153}Sm-EDTMP can provide excellent palliation of pain in both breast[73] and prostate cancer.[74] The short half-life also makes ^{153}Sm-EDTMP suitable for repeated treatments.

Rhenium-186, an investigational radiopharmaceutical, which is also a β- and a γ-ray emitter, in complex with hydroxyethylidene diphosphonate is used therapeutically. Studies suggest encouraging clinical results with a 70% response rate.[75] Bone marrow toxicity is mild and reversible, making the compound potentially suitable for repeated administration. However, comparative studies of this agent with other therapeutic radionuclides are needed before its clinical role can be defined clearly.

Most recently the bone-seeking, α-particle-emitting radiopharmaceutical Alpharadin $^{223}RaCl_2$ (radium chloride) has been developed. In addition to effective palliation of bone pain, early results suggest an antiumor effect with declines in PSA levels in a population of patients with advanced prostate cancer.[76]

Systemic Therapy

Systemic therapy for bone metastases can be directed against the tumor cell to reduce both cell proliferation and, in consequence, the production of cytokines and growth factors. Alternatively, systemic treatment is directed toward blocking the effect of these substances on host cells. Chemotherapy, biologically targeted agents, endocrine treatments, and bone-seeking isotopes have direct antitumor effects, whereas agents such as the bisphosphonates and denosumab are effective by preventing host cells (primarily osteoclasts) from reacting to tumor products. Systemic therapy, therefore, has either direct or indirect actions.

In general, the systemic treatment for metastatic bone disease is the same as that available for other metastatic manifestations of the malignancy. Treatment must therefore be discussed according to tumor type. Breast and prostate cancers are the most important, first because there are effective (albeit palliative) systemic treatments available, and second because these two tumors represent the majority of patients with bone metastases. For a fuller discussion of systemic cancer management, the relevant site-specific chapters should be consulted.

Breast Cancer

For breast cancer, endocrine therapy is the treatment of choice for the initial treatment of metastatic disease. Exceptions to this are when visceral disease is so extensive and/or aggressive that it is inadvisable to wait 6 to 8 weeks for a possible response—for example, when there are lymphangiitic pulmonary metastases or liver metastases with compromised hepatic function. In these two situations, cytotoxic chemotherapy is the initial treatment of choice.

Hormones act predominantly on cancer cells that express high-affinity binding proteins (receptors) for estrogen and progesterone (PgR). These hormone-receptor complexes, in turn, act on the cell nucleus to mediate the specific cell response of the hormone.

Significant (>50%) tumor shrinkage (a complete or partial objective response) after endocrine treatment occurs in one-third of unselected patients but is more likely among those with either steroid-receptor-positive tumors, a long disease-free interval from diagnosis to relapse, or bone or soft tissue metastases rather than visceral disease.

Selection of specific endocrine treatment for patients is based on menopausal status. Premenopausal patients are now usually treated with a combination of tamoxifen and ovarian ablation, the latter achieved by the use of LHRH agonists, surgical bilateral oophorectomy or in some centres ovarian irradiation. For postmenopausal patients the choice of agents is large with aromatase inhibitors, tamoxifen, fulvestrant, and progestogens the most frequently used. Although in general the median duration of response to endocrine therapy is around 15 months, prolonged responses to first-line hormone treatments lasting several years are not uncommon in patients with bone metastases.

Numerous recent developments in cytotoxic and biological treatments are of relevance to the patient with metastatic bone disease. Patients with disease progressing after endocrine therapy, and those with rapidly progressive life-threatening disease or those who are known to have estrogen receptor- and progestogen receptor-negative tumors, should be considered for cytotoxic chemotherapy. This is usually combined with trastuzumab in patients with tumors overexpressing the HER2neu growth factor receptor. Objectively responding patients usually gain relief of symptoms (including bone pain) and might become able to resume their previous activities.

Responses among women with bone metastases are nearly always only partial, with a median duration of response of 9 to 12 months. The precise choice of drugs and schedule of administration to obtain the best results is not yet certain and vary from one patient or clinical problem to another. The anthracyclines (doxorubicin and epirubicin) and the taxanes (docetaxel and paclitaxel) are particularly active but at full doses are sometimes too toxic for elderly or frail patients. Chemotherapy can be especially hazardous for patients with extensive bone disease because of both poor bone marrow tolerance after replacement of functioning marrow by tumor and the effects of previous irradiation. In view of this, regimens with relatively little myelotoxicity are usually preferable. The use of hematopoietic growth factors may be required to permit chemotherapy to be administered safely.

Prostate Cancer

In prostate cancer, bone is the dominant site for metastatic disease and in many patients is the only symptomatic problem. The appearances on plain radiography are predominantly osteoblastic and because of this, radiologic response is notoriously difficult to evaluate. Nevertheless, at least 80% of prostate tumors show some degree of hormone responsiveness.

Worldwide, the luteinizing hormone-releasing hormone (LHRH) agonists are the most commonly used form of endocrine therapy, although surgical castration remains a first-line treatment in some parts of the world. Stilbestrol is no longer appropriate first-line therapy because of its feminizing effects and cardiovascular risks. The role of combined endocrine therapy causing total androgen blockade (LHRH + antiandrogen) and the timing of endocrine interventions have, and continue to be, areas of intense clinical trial investigation.

Patients with advanced prostate cancer tend to be elderly and often of poor performance status. Because of this and the presence of widespread bone involvement, their tolerance of toxic chemotherapy regimens is often poor, and this has significantly limited the use of this treatment modality. Until recently there was little evidence that cytotoxic drugs prolonged survival for patients with advanced prostate cancer. Mitoxantrone and prednisone has been shown in a randomized trial to provide better palliation of symptoms and improved quality of life compared with that achieved with prednisone alone.[77] More recently, docetaxel has been shown to be an active cytotoxic agent in endocrine-resistant prostate cancer and is able to improve median survival by about 3 months. Cautious use of this agent in appropriate patients is now recommended.[78]

Other Tumors

Skeletal morbidity is a major problem in multiple myeloma, and either widespread lytic metastases or diffuse osteopenia can occur. Around 50% of patients respond to chemotherapy, with a reduction in paraprotein levels and subjective improvement. Alkylating agents, anthracyclines, vinca alkaloids, and the corticosteroids are the most frequently prescribed first-line agents. Despite the subjective improvement that is seen, bone healing is rare, with lytic lesions persisting despite control of the disease for months or years. Survival in multiple myeloma has been shown to be improved by the selective use of high-dose chemotherapy with bone marrow or peripheral blood stem cell support, and this is part of standard first-line treatment in fit patients under the age of 65.[79] Newer agents including thalidomide and related analogs, bortezomib, and arsenic trioxide provide many more options that have transformed the clinical course of multiple myeloma in recent years into that of a chronic disease.

Bone involvement in curable malignancies is uncommon. In patients with germ cell tumors, bone involvement is an adverse prognostic feature, but despite this, cure with chemotherapy is usual. Bone involvement at diagnosis in lymphoma is relatively uncommon. When localized it does not significantly affect the prognosis in Hodgkin's disease but does carry an adverse prognosis in non-Hodgkin's lymphoma. Curative therapy is still possible, however, and there is no evidence that bone represents a "sanctuary site."

Chemotherapy is of only limited and temporary benefit in relatively chemotherapy-resistant solid tumors such as non–small cell lung cancer or melanoma. Patients with skeletal metastases from these tumors derive most benefit from local palliative radiotherapy and bisphosphonates. Alternative (and more effective) systemic treatment approaches are urgently needed for many of these maligancies. Biologic agents, especially the angiogenesis inhibitors sorafinib and sunitinib, are showing great promise in renal cell cancer, and small molecules and antibodies are being developed at a rapid pace across a range of tumors.[80]

Bisphosphonates

In the last two decades the bisphosphonates have become established as a valuable additional approach to the range of current treatments. All bisphosphonates are pyrophosphate analogs, characterized by a P-C-P containing central structure rather than the P-O-P of pyrophosphate, and a variable R′ chain that determines the relative potency, side effects, and the precise mechanism of action.[81] The P-C-P backbone renders bisphosphonates resistant to phosphatase activity and promotes their binding to the mineralized bone matrix. The structures of the commonly used bisphosphonates are illustrated in Figure 57-14.

After administration, bisphosphonates bind avidly to exposed bone mineral around resorbing osteoclasts, leading to very high local concentrations of bisphosphonate in the resorption lacunae (up to 1000 mM). During bone resorption, bisphosphonates are internalized by the osteoclast, where they cause disruption of several biochemical processes involved in osteoclast function, ultimately leading to apoptotic cell death. These include destruction of the cytoskeleton, disruption of the sealing zone at the bone surface, and loss of the ruffled border across which the hydrolytic enzymes and protons necessary for bone dissolution are normally secreted. The molecular mechanism of action of the bisphosphonates are now established, with nitrogen-containing bisphosphonates having been shown to inhibit enzymes of the mevalonate pathway, which are responsible for events that lead to the post-translational modification of a number of proteins including the small guanosine triphosphatases such as Ras and Rho.[81] Non-nitrogen-containing bisphosphonates, such as

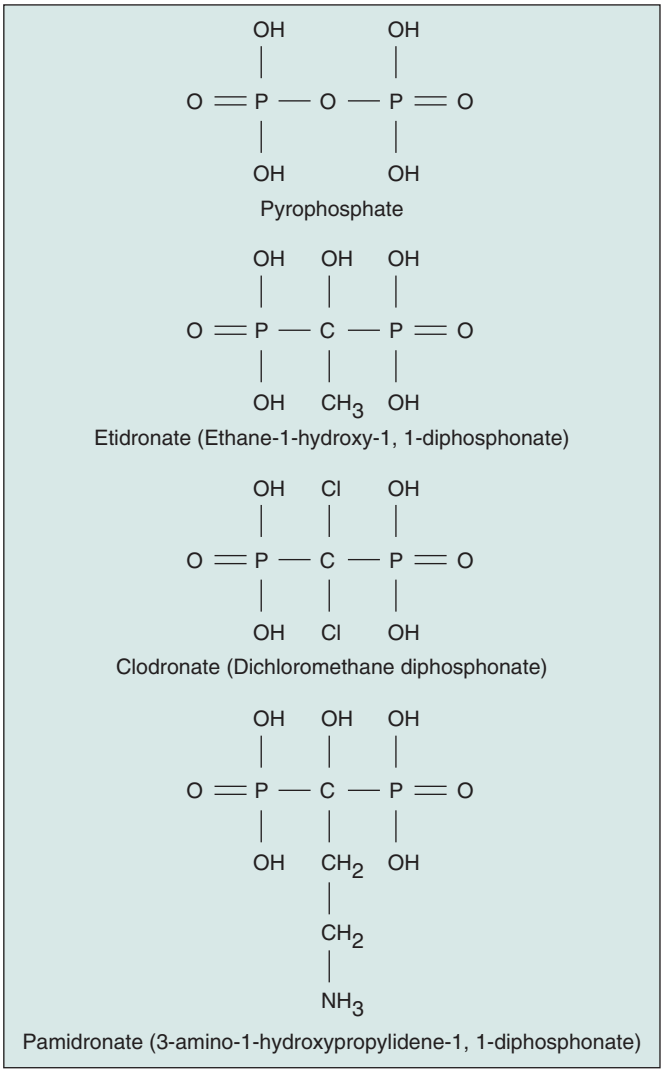

Figure 57-14 • Structural formulas of commonly used bisphosphonates in relation to pyrophosphate.

clodronate, have been found to induce osteoclast apoptosis through the generation of cytotoxic adenosine triphosphate analogs.[82] Recent studies also suggest that bisphosphonates could have direct apoptotic effects on tumor cells, and that this effect may be enhanced by combination with other anticancer agents.[83]

After intravenous administration of a bisphosphonate, approximately 25% to 40% of the injected dose is excreted by the kidney, and the remainder is taken up by bone.[84] All bisphosphonates suffer from poor bioavailability when given by mouth. They must be taken on an empty stomach, because they bind to calcium in the diet and can cause gastrointestinal toxicities such as nausea, vomiting, indigestion, and diarrhea.[85]

Irrespective of the mechanism(s) of action, bisphosphonates have been used successfully in the treatment of conditions characterized by increased osteoclast-mediated bone resorption, such as Paget's disease of bone or osteoporosis. In oncology they have become the standard treatment for tumor-induced hypercalcemia and a valuable, new form of medical therapy for bone metastases.[86]

Rationale for the Wider Use of Bisphosphonates

As indicated previously, it is now generally accepted that osteoclast activation is the key step in the establishment and growth of bone metastases. Biochemical data indicate that bone resorption is of importance not only in classic "lytic" diseases such as myeloma and breast cancer but also in prostate cancer, with values of resorption markers in the latter at least as high as those seen in breast cancer and other solid tumors.[10,53] As a result, the osteoclast is a key therapeutic target for skeletal metastases irrespective of the tissue of origin.

Bisphosphonates to Prevent Skeletal Morbidity and Relief of Bone Pain

Although radiotherapy is the treatment of choice for localized bone pain, many patients have widespread, poorly localized bone pain, whereas others experience recurrence of bone pain in previously irradiated sites. The bisphosphonates provide an additional treatment approach for the relief of bone pain across a range of tumor types, and the effects seems to be independent of the nature of the underlying tumor or radiographic appearance of the metastases, with sclerotic lesions responding similarly to lytic metastases.[87]

Additionally, based on the results of large randomized controlled trials conducted in the late 1990s, the bisphosphonates became the standard of care for the treatment and prevention of skeletal complications associated with bone metastases in patients with breast cancer and multiple myeloma. More recently, they have demonstrated benefits in patients with bone metastases secondary to other cancers including prostate cancer,[88] lung cancer,[88] and other solid tumors (Table 57-4).[89,90]

BREAST CANCER. The greatest experience with bisphosphonates is in the management of bone metastases from breast cancer, and the value of the agents is now undisputed.[91]

Oral Bisphosphonates. The absorption of bisphosphonates from the gut is poor, variable, and dramatically inhibited by food intake. To make matters worse, the absorbed fraction of oral bisphosphonates decreases even further when the absolute ingested amount is lower; thus, the more potent bisphosphonates are even less well absorbed than etidronate and clodronate. Nevertheless, both oral clodronate and ibandronate have been shown in randomized trials to have some clinical efficacy (see Table 57-4).[92,93]

Paterson and coworkers randomized 173 patients with bone metastases from breast cancer to receive either clodronate capsules, 1600 mg daily, or placebo capsules of identical appearance in addition to appropriate anticancer treatment(s).[92] In the patients who received clodronate, there was a significant reduction in skeletal morbidity (219 vs. 305 events per 100 patient years). Most of the benefit was accounted for by a reduction in hypercalcemic episodes and the incidence of vertebral fractures, with no significant effect on nonvertebral fractures, radiotherapy requirements, changes in antitumor therapy, or survival.

Oral ibandronate is the newest and most potent oral agent and is available in Europe and many other countries outside North America. A film-coated formulation of ibandronate has been developed that has been shown to produce a dose-dependent reduction, at doses that are generally well tolerated, in both urinary calcium and collagen cross-link excretion.[93] Phase III placebo-controlled trials of the oral formulation have been completed. The endpoint of a significant reduction in the proportion of patients experiencing a SRE was not met. However the skeletal morbidity rate was significantly less with ibandronate, and the investigators concluded that the activity of oral ibandronate is similar to other bisphosphonates.[94] This new oral agent has obvious attractions to both patients and health care providers, but the place of ibandronate cannot be clearly defined until comparative data with other bisphosphonates are available.

Intravenous Bisphosphonates. In the first randomized study of intravenous pamidronate, Conte and associates[95] randomized 295 patients with breast cancer and bone metastases to chemotherapy

Table 57-4 Effects of Bisphosphonates on Skeletal Morbidity: Results of Randomized Trials

Agent and Route	N	Results	Investigator
BREAST CANCER			
Clodronate 1600 mg PO vs. placebo	173	Reduced SMR 305 vs. 219 events/100 woman years ($P < 0.001$)	Paterson[92]
Pamidronate 45 mg IV vs. control	295	Increased time to bone progression 168 vs. 249 days ($P = 0.02$)	Conte[95]
Pamidronate 90 mg IV vs. placebo	382	Reduced proportion experiencing SRE 65% vs. 46% ($P < 0.001$) Delay in first SRE 7.0 vs. 13.1 months ($P = 0.0005$)	Hortobagyi[97]
Pamidronate 60 mg IV vs. control	401	Median time to skeletal progression 9 vs. 14 months ($P < 0.01$)	Hultborn[96]
Pamidronate 90 mg IV vs. placebo	374	Reduced proportion experiencing SRE 67% vs. 56% ($P = 0.027$) Delay in first SRE 6.9 vs. 10.4 months ($P = 0.049$)	Theriault[98]
Ibandronate 2/6 mg IV vs. placebo	467	Reduced SMR with 6-mg dose, 2 mg ineffective SMR 2.18 vs. 1.61 ($P = 0.03$)	Body[104]
Zoledronic acid 4 mg IV vs. placebo	227	Reduced proportion experiencing SRE 50% vs. 30% ($P = 0.003$) Reduced SMR by 43% ($P = 0.016$)	Kohno[101]
MULTIPLE MYELOMA			
Agent and Route	**N**	**Results**	**Investigator**
Clodronate 1600 mg PO vs. placebo	350	Improved 2-year progression-free survival 24% vs. 12% ($P < 0.05$)	Lahtinen[105]
Pamidronate 90 mg IV vs. placebo	392	Reduced proportion experiencing SRE 24% vs. 41% ($P < 0.001$)	Berenson[107]
Clodronate 1600 mg PO vs. placebo	614	Less skeletal morbidity and pain on progression	McCloskey[106]
MULTIPLE MYELOMA AND BREAST CANCER			
Agent and Route	**N**	**Results**	**Investigator**
Zoledronic acid 4/8 mg IV vs. pamidronate 90 mg IV	1648	Zoledronic acid (4 mg) showed clinical activity equivalent to that of pamidronate (90 mg) In breast cancer patients, 43% had a SRE with 4 mg zoledronic acid, compared with 45% with pamidronate. In myeloma, 47% of patients had a SRE with zoledronic acid and 49% with pamidronate	Rosen[102,103]
PROSTATE CANCER			
Agent and Route	**N**	**Results**	**Investigator**
Clodronate (4 × 520) mg oral vs. placebo	311	Reduction in number of SREs vs. placebo not significant (49% vs. 41%, P = NS)	Dearnaley[110]
Pamidronate 90 mg IV vs. placebo	378	Number of SREs equal in pamidronate and placebo arms, $P = 1.0$	Small[112]
Zoledronic acid 4/8 mg vs. placebo	643	Proportion of patients experiencing at least one SRE during the study was 25% lower in the zoledronate arm than in the placebo arm ($P = 0.021$)	Saad[88,113]
OTHER TUMOR TYPES			
Agent and Route	**N**	**Results (Bisphosphonate vs. Placebo/Control)**	**Investigator**
Zoledronic acid 4/8 mg vs. placebo	773	Significant delay to time of first skeletal event in Zoledronic acid arm compared with placebo ($P = 0.023$) Significant reduction in proportion of patients having an event (47% vs. 38%, $P = 0.039$)	Rosen[89]

SRE, skeletal related event; SMR, skeletal morbidity rate.

with or without intravenous pamidronate, 45 mg every 3 weeks (a dose intensity of pamidronate that is now considered suboptimal). Blinded, extramural review of serial radiographs was performed and identified a 48% increase in the median time to progression in bone in favor of the patient group who received pamidronate (249 vs. 168 days, $P = 0.02$). The other major endpoint of this trial was bone pain. A marked improvement in pain was seen more often in the pamidronate group (44% vs. 30%, $P = 0.025$), indicating that intravenous pamidronate adds to the symptom relief achieved by chemotherapy alone. Similar results were reported in a Scandinavian trial, in which 401 patients receiving chemotherapy for advanced breast cancer were randomly allocated to receive either an intravenous pamidronate infusion (60 mg every 4 weeks) or a placebo infusion of the same dose intensity of pamidronate that was given in the Conte study.[96]

Subsequently, the results of two double-blind, placebo-controlled trials of 90 mg pamidronate infusions every 3 to 4 weeks in addition to cytotoxic or endocrine treatments for patients with breast cancer and lytic bone metastases established bisphosphonate treatment as the standard of care in breast cancer.[97,98] These two studies were of similar design, with the exception of the systemic anticancer treatment at study entry. As in all subsequent bisphosphonate trials the primary endpoint of these studies was the influence of pamidronate on the number of patients experiencing SREs as well as the time to first SRE and the rate of SREs as determined by either a simple annual rate or more complex multiple event analysis techniques. SREs were defined as

- Occurrence of pathologic long bone and vertebral fractures
- Development of spinal cord compression
- Need for radiation for pain relief or to treat or prevent pathologic fractures or spinal cord compression
- Requirement for surgery to bone
- Episodes of hypercalcemia of malignancy

In the chemotherapy study,[97] 382 patients received either pamidronate 90 mg or placebo every month in combination with systemic chemotherapy. The median time to the SRE was significantly longer in the pamidronate group than in the placebo group (13.1 vs. 7.0 months, $P = 0.005$), and the proportion of patients in whom any SRE occurred was significantly lower (43% vs. 56%, $P = 0.008$). Benefits were maintained for at least 2 years. Pain, analgesic use, and Eastern Cooperative Oncology Group (ECOG) performance status were monitored throughout the study period. Because there was inevitably a tendency for the underlying cancer to progress during the study period, there was an overall deterioration in mean performance status, pain, and analgesic consumption. The deterioration, however, was significantly less in the pamidronate group for all of these endpoints. Quality of life was also better maintained in the pamidronate group. Survival was similar in other treatment groups.

In the endocrine study, 374 patients were randomized to receive hormone therapy with pamidronate 90 mg or placebo every month.[97] As in the chemotherapy study, pamidronate reduced the number and rate of SREs. The time to first SRE (excluding hypercalcemia of malignancy) was 6 months for the placebo group and 10 months for those receiving pamidronate ($P < 0.049$). The benefits of pamidronate were slower to appear than in the chemotherapy study, but again the effect was maintained for at least 2 years. The effects on pain and analgesic consumption were even more clearly evident in this study. Again, there was no difference in survival by treatment group.

Zoledronic acid is the most potent bisphosphonate available. A phase I study of 30 patients with hypercalcemia indicated that dose levels as low as 0.02 mg/kg (1–2 mg total dose) were effective in achieving normocalcemia.[99] Following a dose-finding, phase II study of zoledronic acid at doses of 0.5 g, 2 g, and 4 mg zoledronic acid given on a 4-weekly schedule, 4 mg zoledronic acid was selected for phase III evaluation.[100] A placebo-controlled trial of zoledronic acid was performed in Japan.[101] In this study, Kohno and coworkers randomly assigned women with bone metastases from breast cancer to treatment with zoledronic acid ($n = 114$) or placebo ($n = 114$) every 4 weeks. After 1 year, the percentage of patients with at least one SRE (excluding hypercalcemia of malignancy) was significantly reduced by 20% by zoledronic acid (29.8% vs. 49.6% for placebo; $P = 0.003$). Zoledronic acid also significantly delayed the time-to-first SRE ($P = 0.007$) and reduced the risk of SREs by 41% in multiple event analysis ($P = 0.019$) compared with placebo.

Elsewhere in the world zoledronic acid was compared to pamidronate in a randomized, double-blind, phase III trial.[102] The trial was designed as a noninferiority trial, in which the primary efficacy variable was the proportion of patients experiencing at least one SRE. A group of 1130 patients with advanced breast cancer and at least one metastatic bone lesion were randomized to receive either 4 mg zoledronic acid or 8 mg zoledronic acid via a short intravenous infusion, or 90 mg pamidronate via a 2-hour infusion. Treatments were administered every 3 to 4 weeks. Initially, zoledronic acid was administered as a 5-minute infusion in 50 mL of 0.9% saline or 5% dextrose. This was amended to a 15-minute infusion in 100 mL of saline or dextrose because of concerns over renal toxicity. Similarly, the 8-mg dose of zoledronic acid was reduced to 4 mg because of continuing concerns over renal safety.

After 25 months of follow-up, the reduction in the overall proportion of patients with a SRE and the skeletal morbidity rate were similar in patients receiving zoledronic acid and pamidronate. However, zoledronic acid 4 mg reduced the risk of developing skeletal complications (including hypercalcemia of malignancy) as determined by multiple event analysis by an additional 20% compared with pamidronate in the overall population ($P = 0.025$).[103] Thus, the risk of skeletal complications with zoledronic acid is approximately one-half the rate experienced in the prebisphosphonate era (Fig. 57-15). All markers of bone resorption or formation decreased from baseline to the end of the study, but at all time points the urinary marker of bone resorption NTX was significantly less in the zoledronic acid 4-mg group than in the pamidronate group. Median overall survival was similar at approximately 2 years in the study groups. The most common adverse events were bone pain, nausea, fever, and fatigue, and as with the other adverse effects, they occurred generally with a similar frequency in each group. The incidence of renal dysfunction among the patients receiving 4 mg zoledronic acid (given on the 15-minute schedule) was indistinguishable from that for the pamidronate patients.

Ibandronate is another highly potent amino-bisphosphonate that is licensed in Europe for the treatment of hypercalcemia of malignancy, the treatment of metastatic bone disease, and the prevention

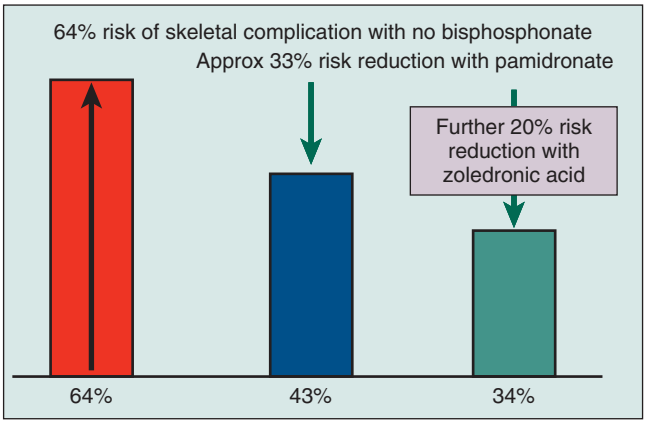

Figure 57-15 • Incremental improvement in the risk of skeletal-related events with use of pamidronate and more recently zoledronic acid in the treatment of bone metastases from breast cancer.

and treatment of osteoporosis. A phase III placebo-controlled trial of monthly infusions in breast cancer has shown a significant reduction in skeletal-related morbidity with ibandronate 6 mg.[104] Additionally, improvements in pain and quality of life were clearly demonstrated at this dose. However, as with the oral formulation, the clinical value of intravenous ibandronate is unclear until comparative trials with established bisphosphonates are completed.

MULTIPLE MYELOMA. Multiple myeloma is typically characterized by a marked increase in osteoclast activity and proliferation. This excessive resorption of bone can be detected histomorphometrically at an early phase in the development of the disease, and this itself could, through the release of interleukin-6 by the osteoclasts, play a contributory role to the growth of myeloma cells in bone. Bisphosphonates could thus be of great benefit in these patients.

ORAL BISPHOSPHONATES. In a randomized, placebo-controlled trial of 350 patients with newly diagnosed myeloma, it was demonstrated that 2.4 g of clodronate daily for 2 years results in a significant reduction in the proportion of patients developing progression of osteolytic bone lesions (24% vs. 12%). There was only a mild, albeit significant, effect on the incidence of bone pain, however, and no effect on the occurrence of fractures or overall survival.[105] Another randomized, placebo-controlled trial of 614 patients evaluated the efficacy of 1600 mg daily of clodronate given from the time of diagnosis. Treatment with clodronate was associated with a 50% decrease in the proportion of patients with severe hypercalcemia (5.1% vs. 10.1%, $P = 0.06$) and a reduction in reported nonvertebral fractures (6.8% vs. 13.2%, $P = 0.04$). Additionally, a 30% reduction in the number of vertebral fractures (80 vs. 146, $P = 0.012$) was observed in a subset of patients with serial spine radiograms available for review.[106]

INTRAVENOUS BISPHOSPHONATES. In the last 10 years, intravenous bisphosphonates have become routine clinical management for most patients with multiple myeloma. This followed the very clear results demonstrated in a 21-month placebo-controlled trial of pamidronate 90 mg conducted in 392 patients.[107] The proportion of patients developing SRE(s) was significantly lower in the group receiving pamidronate than the group receiving placebo (24% vs. 41%, $P < 0.001$). Quality-of-life scores, performance status, pain scores, the incidence of pathologic fractures, and the need for radiotherapy were all favorably influenced by pamidronate therapy.

Zoledronic acid has also been evaluated in multiple myeloma; 450 patients with advanced myeloma were included in a randomized trial comparing zoledronic acid with pamidronate.[102] No significant differences between the two agents were identified. Of the patients treated with zoledronic acid 4 mg, 50% experienced one or more SREs, compared with 54% in the group receiving pamidronate. The risk of an SRE was 7% lower with zoledronic acid, but this difference was not statistically significant.[103]

Intravenous ibandronate has been investigated in a randomized trial; however, the 2-mg dose chosen was unfortunately inactive and not statistically different from placebo.[108] It is now known that a dose of ibandronate 6 mg is required to reduce skeletal morbidity from metastatic bone disease.[104]

PROSTATE CANCER. Bisphosphonates have been shown to reduce biochemical markers of bone resorption in patients with osteoblastic bone lesions that are associated with advanced prostate cancer. Additionally, several phase II studies have assessed bone pain and analgesic use with some benefit in these acute endpoints.[86] However, these trials were statistically underpowered to detect significant effects on skeletal complications, and the results were not sufficiently convincing to lead to either regulatory approval for or widespread use of bisphosphonates for metastatic bone disease in prostate cancer. Furthermore, until recently, randomized, placebo-controlled trials of bisphosphonates had failed to demonstrate a significant reduction in skeletal complications from bone metastases in patients with advanced prostate cancer.

ORAL BISPHOSPHONATES. In a study of 57 patients with hormone-refractory prostate cancer and bone pain at study entry, Smith[109] concluded that etidronate had no significant effects on pain levels or analgesic usage over and above placebo. The Medical Research Council in the United Kingdom performed a phase III trial of oral clodronate (Loron, 1040 mg twice daily) in 311 men with metastatic bone disease from prostate cancer.[110] A slight reduction in the proportion of patients receiving clodronate who experienced a SRE, an improvement in time to progression and increased median survival were observed, but none of these differences was statistically significant.

INTRAVENOUS BISPHOSPHONATES. A more recent clinical trial involving 208 patients investigated both pain and analgesic usage. In this study, intravenous clodronate was added to a background treatment of mitoxantrone and prednisolone. The study also included objectively measurable skeletal complications as clinical endpoints. No significant differences between clodronate and placebo were seen.[111]

Pamidronate has also been studied in 236 patients with prostate cancer and bone metastases treated with intravenous pamidronate (90 mg) or placebo every 3 weeks for 9 months. This trial assessed bone pain as the primary endpoint and included an assessment of SREs as a secondary endpoint. Patients in this trial had very advanced disease (median baseline PSA = 97.8 ng/mL in the pamidronate group), very high levels of bone resorption, and substantial bone pain at study entry. Pamidronate did not reduce the incidence of SREs and had only a slight effect on bone pain.[112]

Despite the failure of all other bisphosphonates, zoledronic acid was investigated in patients with advanced prostate cancer to determine whether the increased potency of this compound would translate into improved clinical benefit. In this study, 643 patients with hormone-refractory prostate cancer and documented bone metastases were randomized to receive either placebo or zoledronic acid at a dose of 4 mg or 8 mg administered every 3 weeks.[88] In the 8-mg arm, the dose was reduced by a protocol amendment to 4 mg because of concerns over renal safety, and conclusions on the efficacy of this cohort are difficult to make. Zoledronic acid was significantly more effective than placebo across all primary and secondary endpoints. The zoledronic acid 4 mg treatment group experienced significantly fewer SRE(s) (33% vs. 44% with placebo; $P = 0.021$). Furthermore, there were consistent reductions in the proportion of patients with each type of skeletal complication, including nonvertebral fractures. Zoledronic acid also prolonged the time to first skeletal complication by more than 4 months ($P = 0.011$). Zoledronic acid 4 mg remained superior to placebo when fractures were excluded, indicating that the beneficial effect was not simply as a result of the prevention of osteoporotic fractures. Using the Andersen-Gill multiple-event analysis, it was calculated that zoledronic acid 4 mg reduced the overall risk of skeletal complications by 36%.[113] Zoledronic acid reduced bone pain at all time points. Despite the favorable effects on skeletal morbidity, however, there were no significant effects on disease-related endpoints such as time to progression and survival. Treatment was generally well tolerated, and in particular the risk of renal function deterioration in patients treated with zoledronic acid 4 mg via a 15-minute intravenous infusion was found to be similar to that of placebo-treated patients. The only adverse events that occurred at increased frequency with zoledronic acid were fatigue, anemia, myalgia, and pyrexia.

OTHER TUMORS. Until recently there had only been anecdotal reports of the use of bisphosphonates in other tumors associated with bone metastases. The pathophysiology of bone metastases is broadly similar in all tumor types, however, and bisphosphonates could thus be expected to be of value in preventing skeletal morbidity, especially

if metastatic bone disease was a patient's dominant site of disease. As part of the development program for zoledronic acid, a phase III randomized, placebo-controlled trial was performed in the management of bone metastases from solid tumors other than breast or prostate cancer.[89] The study found that 4 mg of zoledronic acid significantly reduced the proportion of patients with at least one SRE (39% vs. 48%, $P = 0.039$) and significantly prolonged the time to the first SRE compared with placebo (314 days vs. 168 days, respectively, $P = 0.021$). This is a particularly important result in a population of patients with a very short median survival time (6 months). Overall, zoledronic acid reduced the risk for SRE(s) by about 30% (hazard ratio 0.693 vs. placebo, $P = 0.003$). Of particular note was a 58% reduction in the risk of an SRE in the subgroup of patients with renal cell cancer accompanied by an apparent increase in time to progression and overall survival, albeit in an unplanned subset analysis.[90]

Optimum Use of Bisphosphonates in Metastatic Bone Disease

Criteria need to be determined regarding when in the course of metastatic bone disease bisphosphonates should be started and stopped.[114,115] Because of the logistics and cost of delivering monthly intravenous infusions for all patients with metastatic bone disease, certain empiric recommendations on who should receive treatment are needed.[116] These should take into account the underlying disease type and extent, the life expectancy of the patient, the probability of the patient experiencing a SRE, and the ease with which the patient can attend for treatment (or be treated by a domiciliary service).

Consensus guidance recommendations indicate that all patients with multiple myeloma[116] and radiologically confirmed bone metastases from breast cancer[117] should receive bisphosphonates from the time of diagnosis and continued indefinitely. The development of an SRE is not necessarily a sign of treatment failure or signal to stop treatment; evidence is now available to confirm that bisphosphonates delay second and subsequent complications, not just the first event. However, a recent report suggested that switching to zoledronic acid may be an appropriate option in breast cancer patients in whom pamidronate or clodronate therapy proves unsatisfactory. Clemons and colleagues conducted a phase II clinical trial involving 31 patients with breast cancer who had experienced progressive bone metastasis or SREs while on pamidronate or clodronate therapy. Subjects were switched to monthly administration of zoledronic acid 4 mg. After 8 weeks, 13 of 31 subjects (42%) reported a reduction in pain ($P < 0.001$). The switch to zoledronic acid was also associated with significant reductions in urinary markers of bone turnover ($P = 0.008$).[118]

Bisphosphonate treatment—specifically zoledronic acid—is also appropriate for patients with endocrine-resistant metastatic bone disease from prostate cancer. Patients with other tumors and symptomatic metastasis to bone should be considered for bisphosphonate treatment if bone is the dominant site of metastasis, especially if the prognosis is reasonable (longer than 6 months). Patients with renal cell cancer particularly seem to benefit from treatment.

Despite the obvious clinical benefits of bisphosphonates, it is clear that only a proportion of events is prevented, and some patients do not experience a skeletal event despite the presence of metastatic bone disease. It is currently impossible to predict whether an individual patient needs or will benefit from a bisphosphonate. Overall, bisphosphonates reduce the frequency of skeletal events by 25% to 40%; however, bisphosphonates are a relatively costly additional intervention in cancer care that is now potentially applicable to a very large proportion of patients with advanced malignancy. The cost effectiveness of routine long-term treatment has been questioned, and prioritization of bisphosphonate use is essential.[119,120]

A report on the use of the bone resorption marker NTX suggests that biochemical monitoring could be useful to identify patients at high risk of skeletal complications. In this study of 121 patients with bone metastases, monthly measurements of urinary NTX were made during treatment with a range of bisphosphonates.[121] All SREs, hospital admissions for control of bone pain, and deaths during the period of observation were recorded. NTX was strongly correlated with the number of SREs and/or deaths ($P < 0.001$). Patients with NTX values above 100 nmol/mmol creatinine were many times more likely to experience an SRE or death than those with NTX below this level ($P < 0.01$). Thus, a more cost-effective use of bisphosphonates, particularly in patients with additional extensive visceral metastases or solid tumors associated with a short life expectancy, might be to reserve them until patients have raised NTX levels, and to adjust the dose and schedule to maintain a normal rate of bone resorption. Randomized trials to assess this approach are planned.

Uncertainty remains about the appropriate duration and schedule of treatment. Bone marker–directed therapy is under evaluation in randomized clinical trials, and the value of maintenance therapy after 1 to 2 years of treatment may become clear from the Optimize trial ongoing in the United States. Long-term, full-dose monthly intravenous treatment is associated with the development of osteonecrosis of the jaw (a hitherto rarely encountered problem characterized by painful bone destruction, secondary infection, and delayed healing in the mandible and or maxilla).[122] The risk of osteonecrosis of the jaw is related to duration of treatment at around 1% per year on therapy.[123] Good dental hygiene and pretreatment restorative treatment are recommended to reduce the risk of this unpleasant complication of treatment.[124]

New Targeted Therapies in the Treatment of Metastatic Bone Disease

As our understanding of the signaling mechanisms between bone cells themselves and bone cells and tumor cells increases, several targeted agents have entered clinical development. These include inhibition of RANKL, cathepsin K (an osteoclast-derived enzyme that is essential for the resorption of bone), PTHrP, and Src (a key molecule in osteoclastogenesis). Of all these, inhibition of RANKL seems the most promising.

Denosumab is a fully human monoclonal antibody that binds and neutralizes RANKL with high affinity and specificity, thereby inhibiting osteoclast function and bone resorption. Denosumab could potentially be used to treat bone loss caused by bone metastases, multiple myeloma, or osteoporosis. Following a single subcutaneous dose, denosumab caused rapid and sustained suppression of bone turnover in postmenopausal women with low bone mass,[125] as well as in multiple myeloma and breast cancer patients.[126] A subsequent dose-finding phase II study has defined a dose and schedule for phase III development of 120 mg four times weekly. Currently a broad program in metastatic disease, treatment-induced bone loss, and bone metastasis prevention studies are underway.

Protecting the Skeleton

Prevention of Bone Metastases

Bone is the most frequent site of distant relapse, accounting for around 40% of all first recurrences.[1] In addition to the well-recognized release of bone cell-activating factors from the tumor, it is now appreciated that release of bone-derived growth factors and cytokines from resorbing bone can both attract cancer cells to the bone surface and facilitate their growth and proliferation.[127] Inhibition of bone resorption could therefore have an effect on the development and progression of metastatic bone disease and is an adjuvant therapeutic strategy of potential importance.

Encouraging animal studies with a variety of animal tumor models and a range of bisphosphonates have shown inhibition of bone metastasis development and a reduction in tumor burden within bone.[128] More recently, several clinical trials have been reported using the relatively low-potency oral bisphosphonate, clodronate. In the largest study, 1079 women with primary operable breast cancer were randomized to receive either clodronate 1600 mg daily or placebo for 2

years in addition to standard adjuvant systemic treatment. With a median follow-up time of 5 years, a modest reduction in the frequency of bone metastases in the patients treated with clodronate (63 [12%] vs. 80 [15%] patients) was seen.[129] There was no significant effect on non-bone recurrence (112 [21%] vs. 128 [24%] patients), but patients randomized to the clodronate arm had a higher probability of survival (82% vs. 77%, $P = 0.047$).

In a second study, Diel and colleagues[130] studied 302 patients with breast cancer selected on the basis of immunocytochemical detection of tumor cells in the bone marrow, a known risk factor for the subsequent development of distant metastases. Patients received appropriate adjuvant chemotherapy and endocrine treatment. The incidence of osseous metastases was significantly lower in the clodronate group, and there was also a large, somewhat unexpected, reduction in the incidence of visceral metastases in the clodronate group. Survival was significantly extended. These results have subsequently been updated and show similar results, although the striking effect on extraskeletal visceral relapse is no longer statistically significant.[131] A third study produced conflicting results; the overall 5-year survival was significantly lower in the clodronate group (70% vs. 83%, $P = 0.009$). although there were some prognostic imbalances favoring the control group that may explain this unexpected result.[132]

A definite adjuvant role for bisphosphonates will require the results from much larger randomized studies. The National Surgical Adjuvant Breast Project has completed accrual ($n = 3300$) to a placebo-controlled trial of oral clodronate in stage I to III breast cancer in an attempt to resolve the value or otherwise of adjuvant clodronate. Similarly a large trial of adjuvant zoledronic acid ($n = 3360$) in stage II/III breast cancer has completed accrual. First efficacy results from these studies are not expected before 2008. It is hoped that the added potency of zoledronic acid might have beneficial effects, not only through the inhibition of bone resorption, but also through direct effects on tumor cells in the bone marrow. There is increasing evidence, from a range of cell line and animal model experiments, that zoledronic acid can inhibit tumor cell adhesion and invasion.[133] Additionally, zoledronic acid promotes apoptosis both directly and, more importantly, a schedule-dependent synergy with chemotherapy.[134] These effects are mediated through the mevalonate pathway, using the same molecular pathway that aminobisphosphonates exploit to inhibit osteoclast function. Finally, there are experimental data from animal models indicating that zoledronic acid can suppress angiogenesis.[135]

Effects of Cancer Treatments on Skeletal Health

There are now increasing numbers of long-term survivors from cancer who have received combination chemotherapy, radiotherapy, and hormonal cancer treatment. Many of these individuals are at increased risk of osteoporosis, largely because of the endocrine changes induced by treatment. There might also be clinically relevant, direct effects of cytotoxic drugs on bone. Cancer treatment-induced bone loss is a particularly important long-term problem for women with breast cancer and men receiving ADT.[136] Peak bone mass minus the bone loss associated with age and estrogen deficiency are the main determinants of osteoporotic fracture risk. However, other factors, including genetics, lifestyle, concomitant medication, and nutrition, influence the risk for bone loss.

Bone Loss in Breast Cancer

Cancer treatment-induced bone loss is an increasingly recognized complication in women receiving long-term estrogen-reducing therapies. Estrogen is known to be critical in the maintenance of normal bone mass in women. After menopause a reduction in bone mineral density (BMD) occurs, with the loss most pronounced during the first 3 years, when the rate can be as high as 5% annually, before reducing to a rate of about 0.5% annually thereafter. In the adjuvant setting, all third-generation aromatase inhibitors have demonstrated increased loss of BMD, which may lead to osteoporosis and skeletal complications.[136] In fact, spinal function is negatively affected by bone loss regardless of detectable fractures. Compared with naturally occurring bone loss, aromatase inhibitor-associated bone loss may result in greatly increased BMD loss at 1 year, with rates averaging 5% to 6% in the immediate postmenopausal period.[136]

Several clinical trials have demonstrated increased fracture rates in postmenopausal women with breast cancer receiving aromatase inhibitors.[137] However, a significant proportion of this excess rate of fractures may be due to the absence of the bone-protective effects of tamoxifen. Tamoxifen is known to have a modest estrogenic effect on bone, at least in postmenopausal women, and placebo-controlled trials, for instance in the breast cancer prevention setting, have shown a modest reduction in fracture incidence compared with placebo. Furthermore, in a study of breast cancer patients who received either letrozole or placebo as extended adjuvant therapy, although more patients in the letrozole group had fractures after 5 years, the difference did not reach significance.[138]

A few studies have evaluated women with breast cancer and a treatment-induced premature menopause. Saarto and colleagues[139] studied the effect of clodronate 1600 mg in 148 premenopausal women receiving adjuvant chemotherapy for breast cancer. They observed that rapid bone loss occurred in the women who became amenorrheic after chemotherapy (6% and 2% losses at 2 years in the spine and hip, respectively). Among those receiving clodronate, however, the bone effects of chemotherapy-induced premature menopause were attenuated (2% loss and 1% gain at 2 years in the spine and hip, respectively). In a comparison of risedronate with placebo in a postmenopausal group of patients receiving tamoxifen, Delmas and associates[140] observed an approximate 2.5% increase in BMD at the lumbar spine and femoral neck in the risedronate group compared with the group receiving placebo.

Intravenous bisphosphonate administration is used widely in oncology in the treatment of metastatic disease and could be an attractive option for preventing bone loss in a cancer population. Among patients with breast cancer, 6-monthly zoledronic acid has also been shown to reverse the bone loss induced by a combination of the LHRH analog goserelin plus further estrogen suppression with anastrozole. In this study, the mean loss of bone in the lumbar spine over 3 years in the absence of a bisphosphonate was 17%. However, the bone loss was abrogated by administration of 6-monthly zoledronic acid.[141]

In older postmenopausal women the strategy of immediate 6-monthly zoledronic acid alongside aromatase inhibitor therapy has been compared with initiation of bone protection treatment if osteoporosis or significant bone loss occurs on treatment. The difference in lumbar spine BMD at 1 year was approximately 5%.[142]

Bone Loss in Prostate Cancer

Many men with prostate cancer are at risk of developing osteoporosis, largely because of the ADT they receive for their cancer. ADT may be achieved either by bilateral orchiectomy or, increasingly, by use of a gonadotropin-releasing hormone agonist. These treatments are being introduced earlier and earlier in the course of the disease with the result that men may experience many years of androgen suppression. ADT results in substantially reduced serum concentrations of testosterone (to less than 5% of normal level) and estrogen (to less than 20% of normal level).

It might be expected that androgen deprivation would lead to increased bone loss and increased fracture rate. As yet there seem to have been no large prospective studies of the relationship between fracture rate and ADT, but retrospective studies indicate a significantly increased fracture rate with an estimated 10-year probability of fracture at around 40%.[143] As the potential scale of the problem is being realized, attention is not only focusing on measuring bone density in such patients to assess those at risk, but also on therapeutic options such as bisphosphonates to prevent or treat

therapy-related bone loss in prostate cancer. Pamidronate given on a 3-monthly schedule has been shown to prevent loss in BMD in patients with locally advanced prostate cancer.[144] A multicenter prospective study has evaluated the potent bisphosphonate, zoledronate, in locally advanced or recurrent prostate cancer.[145] At 1 year, in the zoledronic acid arm, BMD increased by 5.3% at the lumbar spine and 1.1% in the total hip. In the placebo arm the BMD decreased by 2% in the lumbar spine and 2.8% in the total hip.

COMPLICATIONS OF BONE METASTASES

Bone metastases cause considerable morbidity: pain, impaired mobility, hypercalcemia, pathologic fracture, spinal cord or nerve root compression, and bone marrow infiltration. In two large randomized trials that included patients with breast cancer and multiple myeloma receiving chemotherapy, the mean skeletal morbidity rates (number of skeletal events per year) in the absence of bisphosphonates were 3.5 and 2.0, respectively, indicating that a skeletal event occurs in metastatic bone disease from breast cancer on the average of every 3 to 4 months and in multiple myeloma every 6 months.[97,107] Despite the clinical importance of metastatic bone disease and the huge expenditure on medical care for skeletal complications, however, there has until recently been relatively little thought given as to how best to coordinate clinical management and deliver optimum care for patients with bone metastases.

Extensive infiltration of the bone marrow by metastatic disease causes leukoerythroblastic anemia and pancytopenia predisposing to infection and hemorrhage. Radiotherapy, often needed for the treatment of bone metastases, can exacerbate this problem, which in turn can compromise the ability to give chemotherapy effectively. Animal experiments have shown that cytotoxic drugs can interfere with osteoblastic function and new bone formation, but the clinical significance of these findings is unknown. Other iatrogenic factors might also aggravate morbidity from bone metastases including corticosteroids and endocrine ablation.

Bone Pain

Bone pain is the most common type of pain from cancer and a significant problem in both hospital and community practice. Pain is usually the presenting symptom and is caused by a variety of factors, including periosteal stretching, compression or infiltration of nerve roots, reflex muscle spasm, and the local effects of cytokines. Features of bone pain are that it is often poorly localized, has a deep, boring quality that aches or burns, and is accompanied by episodes of stabbing discomfort. It is often worse at night, being little helped by sleep and not necessarily relieved by lying down. There is often disturbance of the highly innervated periosteum—possibly giving this pain its neurogenic-like qualities and adding to its intractability.

Spinal instability is the cause of back pain in 10% of patients with cancer.[146] This instability can cause excruciating pain that is mechanical in origin. The patient is comfortable only when lying still, and any movement reproduces severe pain. Consequently, the patient might not be able to sit, stand, or walk. Because the pain is mechanical in origin, radiation therapy or systemic treatment cannot help; the only solution is stabilization of the spine. Stabilization requires major surgery, with risks of significant morbidity and mortality, but with careful selection of patients, excellent results can be obtained.

Hypercalcemia of Malignancy

Hypercalcemia (see also Chapter 48) is another emergency associated with metastatic bone disease. Its clinical features include nausea, vomiting, dehydration, and confusion. Although malignant hypercalcemia is usually associated with demonstrable bone metastases, this is not always the case. Hypercalcemia causes a number of signs and symptoms, which vary considerably from patient to patient. These are often nonspecific, affecting many systems in the body, and can be mistaken for symptoms of the underlying cancer or associated treatment if there is not an astute awareness of the possibility of hypercalcemia. If untreated, a progressive rise in serum calcium leads to deterioration in renal function and level of consciousness. Death ultimately ensues as a result of cardiac arrhythmias and renal failure.

It is now clear that various mechanisms are involved in the pathogenesis of malignant hypercalcemia. These include increased bone resorption (osteolysis) and systemic release of humoral hypercalcemic factors. Bone metastases are common but not invariably present. In some tumors, such as squamous cell cancers, humoral mechanisms are dominant, increasing both renal tubular calcium reabsorption and phosphate excretion. In others—multiple myeloma and lymphoma, for example—osteolysis predominates, whereas in breast cancer both osteolysis and humoral mechanisms seem to be important.

Doubt about the etiology of hypercalcemia in patients with cancer is unusual, but nonmalignant causes must be considered, particularly in the absence of metastases. In the community, hyperparathyroidism is the most common cause of hypercalcemia and may be encountered also in patients with cancer. Measurement of PTH using a modern, specific radioimmunoassay is worthwhile if there is any doubt about the diagnosis; levels of PTH tend to be low or undetectable in malignancy and inappropriately high in hyperparathyroidism.

Intravenous bisphosphonates, in conjunction with rehydration, are now established as the treatment of choice for hypercalcemia. Approximately 70% to 90% of patients will achieve normocalcemia, resulting in relief of symptoms and improved quality of life. Zoledronic acid is the most effective bisphosphonate for the acute treatment of this metabolic emergency.[147]

Pathologic Fractures

Metastatic destruction of bone reduces its load-bearing capabilities, resulting initially in trabecular disruption and microfractures and, subsequently, in total loss of bony integrity. Rib fractures and vertebral collapse are the most common occurrences, resulting in loss of height, kyphoscoliosis, and a degree of restrictive lung disease. The most severe disability, however, is caused by fracture of a long bone or epidural extension of tumor into the spine.

The incidence of pathologic fracture in patients with bone metastases is somewhat uncertain and is dependent on whether rib and vertebral fractures are included and the method of evaluation. In recent series in which regular skeletal surveys were performed the annual risk of a pathologic fracture (in the absence of bisphosphonates) was between 20% in prostate cancer[85] and 40% in breast cancer.[97] Not all of these fractures are symptomatic, and undoubtedly some are due to treatment-induced osteoporosis rather than metastatic infiltration, but nevertheless structural damage to bone is clearly extremely common in metastatic bone disease. Paterson and colleagues,[92] who systematically reviewed serial radiographs in patients participating in a clinical trial of oral clodronate, showed that a woman with bone metastases from breast cancer can expect to experience an average of 1.3 vertebral and 0.4 nonvertebral fractures a year.

The probability of developing a pathologic fracture increases with the duration of metastatic involvement and is therefore, somewhat paradoxically, more common in those patients with bone-only disease who have a relatively good prognosis. A retrospective analysis of 859 patients with bone metastases from breast cancer showed that those with bone-only disease had almost a fourfold increase in the incidence of subsequent pathologic long-bone fractures compared with patients who also had concomitant liver metastases. This finding was attributed to the different survival outcomes between the two groups; the median survival from diagnosis of bone metastases for patients with bone-only disease was 2.2 years, compared with 5.5 months for those with concomitant liver disease.[148] The study also showed that scintigraphic evidence of metastases in the femora and humeri at the

time of diagnosis significantly predicted an increased risk of future fractures.

Because the development of a fracture is so devastating to a patient with cancer, increased emphasis is now being placed on attempts to predict metastatic sites at risk of fracture and the use of prophylactic surgery and long-term administration of bisphosphonates to reduce fracture risk. Assessment of patients with symptomatic bone metastases by a specialist orthopedic and/or spinal surgeon should be a much more frequent component of multidisciplinary management than has been the case until now.

Fractures are common through lytic metastases and weight-bearing bones, the proximal femora being the most commonly affected sites. Damage to both trabecular and cortical bone are structurally important, but it is the relevance of cortical destruction that is most clearly appreciated. Several radiologic features that could predict imminent fracture have been identified. Risk factors that have been taken into account include pain, the anatomic site of a lesion, its radiologic characteristics, and its size. Although intensity of pain, which is difficult to quantify, is not clearly associated with fracture risk, pain that is exacerbated by movement seems to be an important factor in predicting impending fracture. Presumably, such functional pain indicates diminution in the mechanical strength of a bone and in one series was followed invariably by fracture.

As far as radiologic appearances are concerned, there is a general consensus that lytic lesions carry a much higher risk of fracture than either mixed or osteosclerotic lesions. Accordingly, a particularly high fracture rate is found in association with metastases from lung cancer. Given the poor prognosis of this tumor, however, such fractures rarely lead to prolonged disability. By contrast, in breast cancer, which follows a much more protracted course, pathologic fracture is a major cause of prolonged disability.

Radiologic assessment also yields information about the size of a lesion and the extent to which the bone is destroyed. When less than two thirds of the diameter of a long bone is affected, pathologic fracture is relatively unusual but above this limit the fracture rate increases markedly, with an incidence of approximately 80% for such lesions. A practical scoring system incorporating anatomic, radiographic, and symptom-related factors has been described to give valuable guidance in the selection of patients for prophylactic fixation.[149]

Prophylactic internal fixation is usually the treatment of choice for such lesions, followed by radiotherapy to inhibit further tumor growth and avoid further bone destruction. It is easier to stabilize a bone while it is still intact, and the rehabilitation and convalescence are shorter and easier. Providing the lesion is irradiated, there is no evidence to suggest that surgery increases the risk of disseminating tumor cells either locally or into the circulation. Indeed, there is some experimental evidence that pathologic fractures are associated with an increased incidence of pulmonary metastases and that prophylactic stabilization decreases this incidence. If a given patient is not fit for surgery, radiotherapy and avoidance of weight-bearing activity are indicated.

Before surgery, a radionuclide bone scan and radiographs of the entire length of the affected bone should be obtained. These measures ensure that any other metastases that might subsequently develop into a pathologic fracture are also stabilized and included in the radiotherapy field. A pathologic fracture at the edge of a plate or of an intramedullary nail, particularly when fixed with methylmethacrylate, is more difficult to treat than if there were no implant in the bone.

Pathologic fractures are not necessarily a manifestation of terminal disease, and primary internal stabilization followed by radiotherapy are usually the treatments of choice, and certainly the only modalities likely to both restore mobility and relieve pain. Untreated pathlogic fractures rarely heal, and although radiotherapy might achieve local tumor control, bony union remains unlikely. Radiotherapy inhibits chondrogenesis (a prerequisite for fracture healing), and with large areas of bone destruction there could be insufficient matrix remaining for adequate repair.

The type of internal stabilization chosen depends on the site of the lesion, and the range of stabilization devices and custom-made prostheses increases year on year. When feasible, closed intramedullary nailing is preferred; however, at the end of the long bones, intramedullary nailing alone is inadequate, and alternative techniques are necessary. It is essential that the internal stabilization provide sufficient strength to allow unsupported use of the limb and for the legs to bear weight. Fulfilling this demand could require supplementation with methylmethacrylate (which is inserted into the tumor cavity with the implant fixed across the methylmethacrylate while still soft) and bridging normal bone above and below the lesion.

Pathologic femoral neck fractures do not unite despite internal fixation, and this situation requires replacement arthroplasty. Careful preoperative assessment of the pelvis and femur is necessary, and for this, CT scanning or MRI is often helpful. If there is no metastatic involvement of the acetabulum, a hemiarthroplasty could be all that is required. If the acetabulum is involved, however, total-replacement arthroplasty is indicated, and sometimes pelvic reconstruction is necessary. Many patients have metastases in the distal femur together with proximal involvement, and for these patients, a long-stemmed femoral prosthesis is recommended.

For humeral fractures, internal fixation is also useful, providing more rapid and greater pain relief compared with conservative treatment. Although patients with a very short life expectancy can be managed adequately with conservative treatment, those patients expected to survive longer than 3 months are best managed by internal fixation to ensure pain relief and restoration of function. Replacement arthroplasty could be necessary if the proximal humerus is involved, but most pathologic fractures of the humerus can be treated by intramedullary nailing.

Occasionally, patients present with an isolated metastasis in the distal skeleton. If on careful evaluation there is no other evidence of dissemination of the tumor, resection of the lesion should be considered. Local resection and prosthetic replacement are usually possible, but occasionally, amputation is indicated.

Spinal Instability

Spinal instability can cause excruciating pain that is mechanical in origin and not relieved by radiotherapy or systemic treatment. As with pathologic fractures of long bones, stabilization is required for pain relief and involves major surgery, which is associated with significant morbidity and mortality. There are several methods for spinal stabilization, but in general, the posterior approach is technically easier and allows stabilization of a larger area of the spine. With careful selection of patients, excellent results can be obtained. An associated neurologic deficit is not a contraindication to these procedures.

Percutaneous vertebroplasty and kyphoplasty, a new approach to treating spinal pain and instability, involves injecting an acrylic polymer into a diseased vertebral body. The technique was developed initially for the treatment of painful vertebral hemangiomas, and considerable experience with it has been obtained in the treatment of osteoporotic compression fractures. Its use has now been extended to the treatment of malignant spinal disease.[150,151] The technique provides effective pain relief, which is achieved more rapidly than with radiotherapy, and it confers the added benefit of providing structural support to the spinal column, thus reducing the risk of vertebral collapse and instability. Although generally a safe procedure, vertebroplasty can be complicated by leakage of the polymer, which predisposes to spinal cord or nerve root compression. The risk of this is less with kyphoplasty.[151] The technique seems to have the potential for wider use, particularly among patients with limited vertebral disease and those for whom major surgical spinal stabilization procedures are unsuitable.

Compression of the Spinal Cord or Cauda Equina

Compression of the spinal cord or cauda equina in patients with metastatic disease of the spine is a medical emergency necessitating prompt diagnosis and treatment (see also Chapter 55). Its causes include pressure from an enlarging extradural mass, spinal angulation after vertebral collapse, vertebral dislocation after pathologic fracture, or, rarely, pressure from intradural metastases. The most common primary tumors producing this complication, in decreasing order of frequency, are carcinoma of the breast, lung cancer, prostatic cancer, lymphoma, and renal carcinoma.

Back pain is the most common initial symptom of spinal cord compression; two types of pain can occur—local spinal or radicular. Radicular pain varies with the location of the tumor, being common in the cervical (79%) and lumbosacral (90%) regions and less common with thoracic lesions (55%). Both local spinal and radicular pain are experienced close to the site of the lesion identified at myelography. Motor weakness, sensory loss, and autonomic dysfunction are all common at presentation of spinal cord or cauda equina compression.

The development of back pain in a patient with cancer, coincident with an abnormality on a plain spinal radiogram, should serve as a warning for the possible development of spinal cord compression. Compression of the spinal cord or cauda equina can occur in association with spinal stability or in isolation. When there is a greater than 50% vertebral collapse, compression of the spinal cord becomes more likely. The keys to successful rehabilitation are early diagnosis, high-dose corticosteroids, rapid assessment, and urgent referral for either decompression and spinal stabilization or radiotherapy. Neurologic recovery is unlikely if the spinal compression is not relieved within 24 to 48 hours.

In a retrospective analysis of 70 patients with spinal cord compression secondary to breast cancer, the most frequent symptom was motor weakness (96%), followed by pain (94%), sensory disturbance (79%), and sphincter disturbance (61%).[152] Of these 70 patients, 91% had at least one symptom for more than 1 week. The ability to walk was maintained by 96% of those ambulant before therapy. In those unable to walk, 45% regained ambulation, with radiotherapy and surgery equally effective. Median survival was 4 months. The most important predictor of survival was the ability to walk after treatment. These findings stress the importance of prompt presentation, diagnosis, and treatment and suggest that earlier diagnosis and intervention should improve outcome.

The choice between surgical decompression and radiotherapy depends on a variety of clinical features. Surgical decompression is indicated for patients with recent onset of symptoms and with progressive paraplegia and urinary retention of less than 30 hours' duration. The site of compression should be localized to no more than two or three vertebral segments, and the patient should have a life expectancy of at least several weeks. For patients in whom the paraplegia has been established for several days or urinary retention has been present for more than 30 hours, surgical decompression rarely results in the recovery of bladder or motor function. Radiotherapy is indicated for those who are either unfit for surgery or do not meet the criteria for surgical decompression.

Several studies in the past suggested that surgical decompression had no advantage over radiotherapy.[153] It should be appreciated, however, that these studies compared dorsal laminectomy—an outdated and now inappropriate procedure—with irradiation. However, surgical decompression should be followed by spinal stabilization. More recently a randomized trial was performed that compared modern surgical techniques with radiotherapy. Patchell and associates randomized 101 patients to surgery plus radiotherapy or radiotherapy alone. Significantly more patients in the surgery group (42/50, 84%) than in the radiotherapy group (29/51, 57%) were able to walk after treatment (odds ratio 6.2 [95% confidence interval 2.0–19.8] $P = 0.001$). Patients treated with surgery also retained the ability to walk significantly longer than did those with radiotherapy alone (median 122 days vs. 13 days, $P = 0.003$). Thirty-two patients entered the study unable to walk; significantly more patients in the surgery group regained the ability to walk than patients in the radiation group (10/16 [62%] vs. 3/16 [19%], $P = 0.01$). The need for corticosteroids and opioid analgesics was also significantly reduced in the surgical group.[154] Therefore, the choice of management should be decided on an individual basis, and there are undoubtedly patients who will benefit greatly from appropriate and prompt surgical management.

SUMMARY

The management of bone metastases requires an experienced multidisciplinary team to ensure timely diagnosis and the appropriate integration of local and systemic treatments. The effects of tumor cells on bone cell function (especially on osteoclast activity) underpin the rationale for the use of bisphosphonate treatment to reduce skeletal morbidity. These bone-specific treatments are now an accepted part of routine clinical management. Additionally, the disruption of bone remodeling results in release of collagen fragments, which seems to have value in predicting skeletal events, prognosis, and monitoring of response.

Further developments in our understanding of the pathophysiology of bone metastases can be expected to provide new therapeutic strategies. Already, improved knowledge of the signaling molecules involved in regulating osteoclast function—notably OPG and RANK ligand—has led to the development of highly active targeted therapies for bone diseases, including cancer and other novel therapeutic approaches in clinical development. Over the next 5 years several of these compounds can be expected to gain regulatory approval, and ultimately combinations of bone-targeted therapies may be recommended to further reduce the clinical burden of metastatic bone disease.

58 Lung Metastases

Valerie W. Rusch

SUMMARY OF KEY POINTS

Incidence
- Lungs are the second most common site of metastases.
- Lungs are the sole site of metastasis in 80% of patients with sarcoma and in 2% to 10% of patients with carcinoma.

Etiology
- Hematogenous spread
- Lymphangitic spread in carcinomas can occur early or late in the natural progression of all cancers.
- It is not well understood why lung metastases take several years to develop.

Evaluation
- Few lung metastases are symptomatic; only 15% to 20% of patients complain of cough or pain. All patients with isolated pulmonary metastasis from extrathoracic malignancy should be evaluated for the possibility of resection.
- Initial imaging studies should consist of a plain chest radiograph followed by computed tomographic (CT) examination to predict resectability. Newer imaging modalities, such as ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) and magnetic resonance imaging (MRI), have not been shown to be as accurate or cost effective as CT.
- CT is unable to distinguish reliably between malignant and benign lesions.
- CT differs from the final pathology report in 42% of cases.
- CT underestimates the number of malignant lesions in 25% of cases.
- The accuracy of radiologic imaging is only 37%, underestimating the number of lesions by 39% and overestimating them by 25%, for patients undergoing bilateral exploration.

Prognostic Factors
- Number of metastases
- Disease-free interval (<36 months or >36 months).
- Histology/organ site of primary tumor

Surgical Treatment
- First described case of pulmonary metastasectomy was by Weinlechner in 1882.
- Alexander and Haight described the first series of patients; 12 patients remained disease-free for 1 to 12 years.
- General guidelines that should be met before undertaking a resection include the following:
  - Control of the primary tumor, or ability to resect the primary tumor
  - Ability to resect metastatic disease completely
  - Ability of the patient to withstand the extent of pulmonary resection required to remove all gross tumor
  - Absence of extrathoracic metastasis
  - Absence of better alternative treatment
- The location of metastases determines the extent and type of resection:
  - Peripheral metastasis—parenchymal sparing
  - Central metastasis—lobectomy or pneumonectomy
  - Solitary endobronchial metastasis—lobectomy, sleeve lobectomy, or pneumonectomy
- Ensure that all grossly palpable tumors are resected with clear margins.
- More radical resection (lobectomy, pneumonectomy) does not increase survival.
- Bilateral metastases and recurrence of pulmonary metastases are not contraindications to resection and should not deter resection in lesion(s) that can be removed completely.

INTRODUCTION

The first described case of pulmonary metastasectomy was reported in 1882 by a German surgeon named Weinlechner, who removed two incidental pulmonary nodules during a chest wall resection for sarcoma.[1] In 1939 Barry and Churchill[2] reported the first long-term survivor from pulmonary metastasectomy, a patient with metastatic renal cell cancer. Their patient survived 23 years after surgery. Subsequently, Alexander and Haight described the first series of patients undergoing pulmonary metastasectomy and its correlation to survival.[3] Twelve patients in their study remained free of disease for 1 to 12 years. Most important, from this early study came the first generally accepted criteria for pulmonary metastasectomy:

- The primary tumor should be completely removed.
- There should be no evidence of extrapulmonary disease.
- The patient should be able to tolerate the planned operation from the standpoint of overall medical condition.

Subsequently these criteria were modified by other authors to reflect our improved understanding of the management of pulmonary metastases. Current additional criteria include the following:[4]

- Control of the primary tumor, or ability to resect the primary tumor completely simultaneous with resection of metastasis
- Ability to resect metastatic disease completely
- Ability of the patient to tolerate the extent of pulmonary resection required to remove all gross tumor

Table 58-1 Prognostic Factors after Pulmonary Metastasectomy

Disease-free interval
Mediastinal lymph node metastases
Number of pulmonary nodules
Tumor doubling time
Size of pulmonary nodules
Bilateral disease
Surgical margins
Histologic subtype

- Absence of extrathoracic metastasis
- Absence of better alternative treatment

Although these criteria are widely used, there are continued attempts to refine the selection of patients for pulmonary metastasectomy.

Several prognostic factors that are not universal across all tumor histologies have been reported to affect outcome after pulmonary metastasectomy (Table 58-1). The largest series of pulmonary metastectomies reported to date is from the International Registry of Lung Metastasis, which analyzed 5206 cases.[5] The overall 5-year survival after pulmonary metastasectomy without stratifying for tumor type was 36%. Factors associated with better prognosis included a long disease-free interval, complete resection, and a small number of lung nodules. A staging system based on these prognostic factors was proposed (Fig. 58-1).

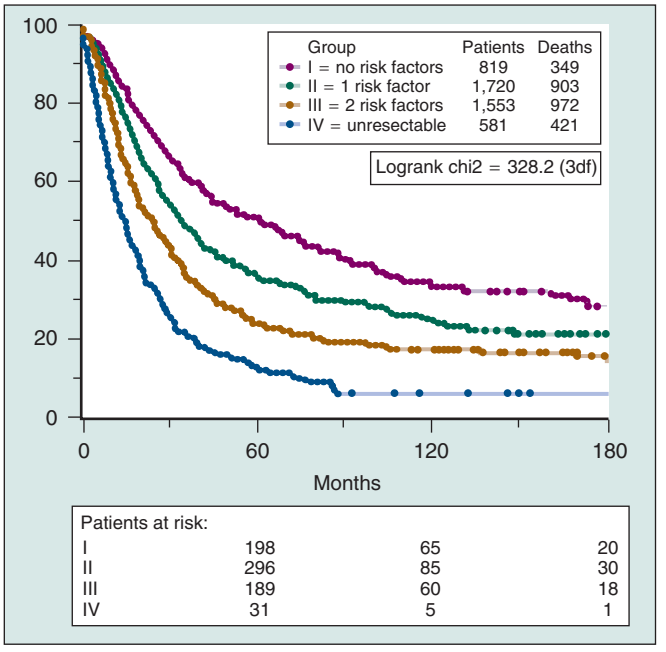

Figure 58-1 • Survival of the four prognostic groups based on the analysis of 5206 patients entered into the International Registry of Lung Metastases. Group I includes patients who had completely resectable disease with a single metastasis and a disease-free interval after resection of the primary tumor (DFI) of 36 months or more; group II, patients who had completely resectable disease with multiple metastases *or* a DFI of less than 36 months; group III patients who had completely resectable disease with multiple metastases *and* a DFI of less than 36 months; and group IV patients with unresectable disease. (From Pastorino U, Buyse M, Friedel G, et al: Long-term results of lung metastasectomy: prognostic analyses based on 5206 cases. J Thorac Cardiovasc Surg 1997;113:37.)

The role of surgery in the treatment of pulmonary metastases will continue to evolve as better systemic therapies become available. Currently, only a minority of patients with metastatic disease from any source are candidates for pulmonary metastasectomy; however, improved imaging studies and the widespread use of computed tomography (CT) might detect more patients who have small-volume pulmonary metastases and are therefore candidates for metastasectomy. A current perspective of the evaluation and treatment of patients with isolated lung metastases is presented in this chapter.

DIAGNOSIS

Few patients with pulmonary metastasis are symptomatic. It is estimated that only 15% to 20% of patients present with cough or nonspecific chest pain and even fewer still with hemoptysis. Traditionally, chest radiography has been the most commonly used and cost-effective modality for screening patients for metastasis from extrathoracic malignancy. The most frequent radiographic appearance of a pulmonary metastasis is a peripherally located, well-circumscribed nodule (Fig. 58-2).[6,7] Several less common radiographic characteristics have also been described. Cavitating lesions are associated with a differential diagnosis that includes benign, infectious, and malignant causes (Fig. 58-3). When malignant, cavitary lesions are usually squamous cell carcinomas. The frequency of cavitation in metastatic nodules is approximately 4%; however, squamous cell malignancy is responsible for 69% of these lesions. Spontaneous pneumothorax also can occur with metastatic lung lesions and is thought to be caused by cavitation and erosion into a bronchiole wall. Spontaneous pneumothorax is most frequently seen in patients with sarcoma. It is said that a spontaneous pneumothorax in a patient with history of a sarcoma should prompt an evaluation for possible occult metastatic lung lesions. Calcification of pulmonary nodules is usually related to a benign process such as a hamartoma; however, metastatic lesions of many types (especially osteogenic sarcoma) are known to produce calcification (Fig. 58-4).[6,7] Calcification in metastatic lesions are thought to be produced by several processes in different tumor types, including bone formation in osteogenic sarcoma, mucinous calcification of adenocarcinomas, or dystrophic calcification of lesions such as synovial sarcoma or giant cell tumors of the bone.[6] Hemorrhage around lung nodules is also seen more frequently in benign lung lesions (e.g., fungal or mycobacterial infections) and is visualized as a halo around the lung nodule. This can also be seen in metastatic lesions and should raise the suspicion for metastasis in patients with a history of malignancy.

Computed Tomography

The use of CT as an adjunct to plain film radiography for the diagnosis of pulmonary metastases has increased dramatically during the last decade. This has been facilitated by the development of high-speed helical scanners. It is clear that CT is able to visualize more lesions than chest radiography.[5,8–17] Chang and coworkers[11] reported that when compared with conventional radiography, CT was able to visualize nearly twice as many nodules.[18] CT is not able to distinguish reliably between malignant and benign lesions, however. McCormack and colleagues[8] retrospectively studied 144 patients who had both a chest x-ray and a CT to identify metastatic lesions. The CT results differed from the final pathology reports in 42% of cases, with CT scan underestimating the number of malignant nodules in 25% of patients. Pastorino and associates[5] reported results of imaging on 2988 patients undergoing pulmonary metastasectomy. The overall accuracy of radiologic assessment of the number of metastatic nodules was 61%, underestimating metastasis in 25% of patients. Interestingly, in those patients (1134) who had bilateral exploration, the accuracy of imaging was only 37%, underestimating the number of lesions in 39%, overestimating in 25%. The accuracy and sensitivity of CT also depends on the size of the lesions (Table 58-2): the larger

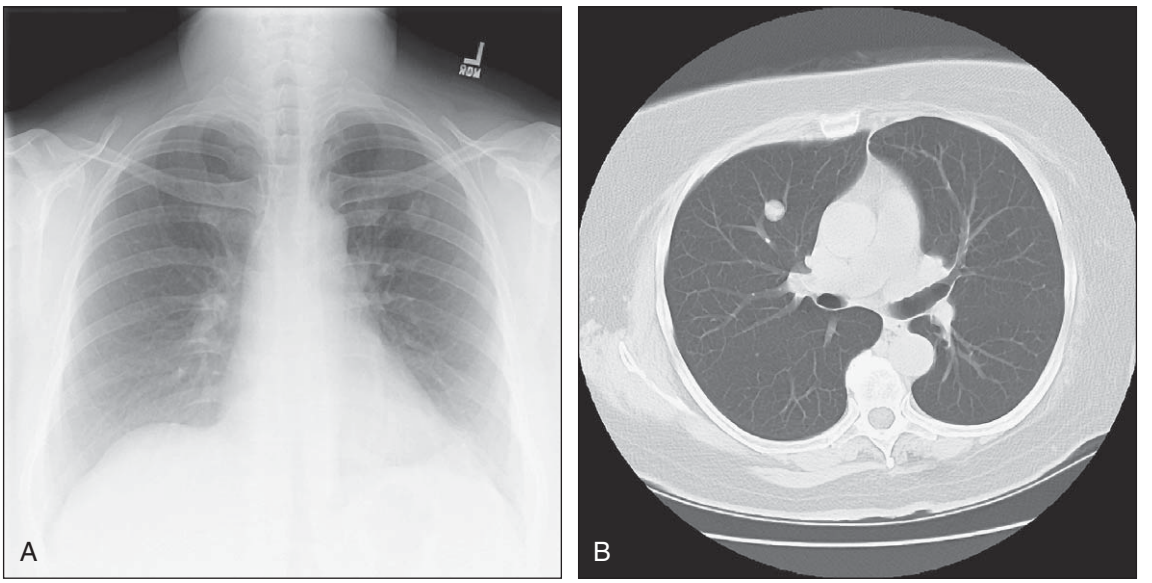

Figure 58-2 • Two patients with metastatic sarcoma demonstrating typical findings of well-circumscribed peripheral lesions. **A,** Plain chest radiograph. **B,** Computed tomographic image.

the lesion, the greater the sensitivity and accuracy. Munden and colleagues[14] reported on the clinical significance of pulmonary lesions less than 1 cm in diameter, finding malignant pulmonary lesions in 81% of patients with a history of malignancy. Multiple authors have described the ability of CT to detect a greater number of pulmonary nodules, while acknowledging a decreasing specificity of identifying malignant nodules with this diagnostic tool.[11,15] Therefore, not all small pulmonary nodules in patients with a history of cancer can be assumed to represent metastatic disease. Currently, there are no established guidelines for the routine screening for pulmonary metastases. Many institutions still use periodic chest radiography as the only imaging modality to rule out pulmonary metastasis. Other authors suggest that the use of CT for routine screening is indicated in groups of patients whose primary tumors have an unusually high propensity to spread to the lungs.[13,16] As the quality and speed of CT scanning progresses, it will probably become the sole screening tool for identifying pulmonary metastases.[11,15]

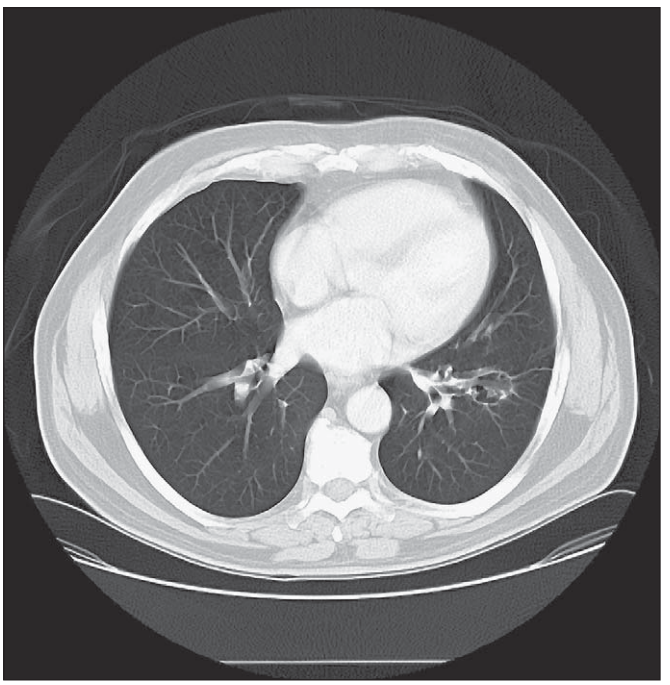

Figure 58-3 • Chest CT scan demonstrating cavitary lesion in a patient with metastatic colorectal cancer.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides the benefits of reduced radiation exposure (of particular interest for cases involving younger patients) and the ability to detect lesions at lung-mediastinal interfaces. MRI has not gained wide acceptance as a screening tool, however, mainly because of its increased time constraints and cost. Further technical considerations that are unfavorable include motion-related artifacts and an inability to detect calcified lesions. Kersjes and colleagues[19] performed a study comparing MRI and helical CT in the detection of pulmonary metastasis and showed MRI to have an overall accuracy of 84%. For lesions smaller than 5 mm, however, the sensitivity of MRI was only 36%. The routine use of MRI is currently not advocated as a screening tool for patients with pulmonary metastasis.

Nuclear Imaging

Imaging with ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) is being used more frequently to assist in the staging of primary tumors. Most often, this is used at the time of diagnosis to rule out distant metastasis but is occasionally used to assess response to therapy. Currently FDG-PET is not used as a screening tool to identify pulmonary metastasis, but multiple authors support the eventual use of this modality as a screening tool.[20,21] Dose and associates[21] studied 50 patients with breast cancer who had FDG-PET evaluation to determine presence of metastatic disease. FDG-PET had a sensitivity of 78.6% in identifying pulmonary metastasis as compared with conventional chest radiography, which had a sensitivity of 41.6%.[21] Other authors report that FDG-PET may not be superior to conventional imaging techniques in identifying pulmonary metastasis from bone and soft-tissue sarcomas.[22,23] Lucas and coworkers[22] studied 62 patients with soft-tissue sarcoma who had FDG-PET during initial evaluation. The sensitivity of FDG-PET in detecting lung metastasis was 86.7% as compared with 100% for CT, leading the authors to conclude that CT is a superior imaging tool

Table 58-3 Surgical Approaches to Resection of Pulmonary Metastases

Surgical Approach	Advantages	Disadvantages
Unilateral Disease		
Posterolateral thoracotomy	Superior exposure and palpation of lung	Painful, large incision
Videothoracoscopy (VATS)	Less painful	Inability to palpate, poor ability to detect deep lesions
Bilateral Disease		
Clamshell thoracotomy	Excellent bilateral exposure	Painful; sacrifice of both internal mammary arteries
Simultaneous bilateral thoracotomies	One hospital stay/procedure	Painful
Staged (sequential) bilateral thoracotomy	Allows technically complex procedures	Two hospitalizations and procedures
Median sternotomy	Bilateral exposure, less painful	Poor exposure to posterior lung fields

for identifying these lesions. Further study is warranted to determine the true benefit, if any, of using FDG-PET as a routine screening tool for identifying patients with pulmonary metastasis. Because PET is currently unable to detect sub-centimeter lung lesions reliably, it is likely that CT will remain the most sensitive imaging modality.

SURGICAL APPROACHES TO LUNG METASTASIS

The goal of pulmonary metastasectomy is to achieve complete resection of all visible and palpable tumors in the lung. The surgical approach is dictated by the extent and location of disease and by the patient's performance status. There are several approaches available depending on the size, number, and location of the lesions. The advantages and disadvantages of these approaches are outlined in Table 58-3.

The standard approach to the patient with disease localized to one hemithorax is a unilateral posterolateral thoracotomy. The thorax is usually entered through the fifth intercostal space. Several variations of this include muscle-sparing incisions, axillary incisions, or an anterior thoracotomy. All of these approaches allow full visual inspection and manual palpation of the entire lung.

During the past decade, the use of video-assisted thoracoscopy (VATS) has been described for pulmonary metastasectomy. This

approach is controversial, however.[24–28] McCormack and colleagues[25] performed a prospective study evaluating the role of VATS to treat pulmonary metastasis. Eighteen patients had preoperative CT followed by VATS resection of all visible and CT-detected lesions. All patients then immediately underwent thoracotomy with resection of any additional lung nodules. Additional malignant lesions were found in 56% of patients after attempted VATS resection of the nodules found on preoperative imaging. The authors concluded that this high failure rate of CT and VATS warranted closure of the study before the intended 50 patients could be enrolled. Recently, other authors have advocated the use of VATS for patients with a solitary pulmonary metastasis. Mutsaerts and associates[24,28] described their experience with 20 patients undergoing either VATS or thoracotomy for resection for single pulmonary metastasis. The 5-year survival and recurrence rates seemed to be similar to those seen with thoracotomy.[28] Other authors have described localization methods using radiotracer injection to help identify small or deeply located lesions during VATS resections.[26] Currently, the practice in our institution is to use VATS primarily for the diagnosis of metastatic disease, or as a therapeutic procedure in highly selected patients for whom thoracotomy may be a higher risk procedure. Thoracotomy or other open procedures remain our preferred approach to pulmonary metastasectomy because of the prognostic importance of complete resection and the potential for missing small metastases by VATS. However, a VATS approach may be appropriate for patients with one or two metastases clearly defined on high-quality imaging studies.

The approach to bilateral disease is more variable, but the principles remain the same. Median sternotomy, "clamshell" thoracotomy (bilateral anterior thoracotomy with transverse sternotomy), sequential bilateral thoracotomies, and simultaneous bilateral posterolateral thoracotomies are used as standard surgical approaches to the resection of bilateral metastases.[29–31] In general, resection of bilateral metastases is preferably done as a single operation. Sequential thoracotomies are performed only when the anatomic location of a lesion requires a complex or extensive operation, or when the patient's comorbidities dictate a more conservative approach to management.

In contrast to primary lung cancers, pulmonary metastases require only a local excision with a surrounding rim (1–2 cm) of benign lung tissue. This is accomplished most frequently by wedge resection performed by precision electrocautery or with a stapling instrument (Fig. 58-5). Segmentectomy, lobectomy, or pneumonectomy are used less commonly. It is important to note that survival after metastasectomy is not increased by a more radical resection such as lobectomy or pneumonectomy. These procedures might be required technically to remove the lesion, however, and should be applied to do so if needed. The most important principle of these techniques is a clear margin of resection.

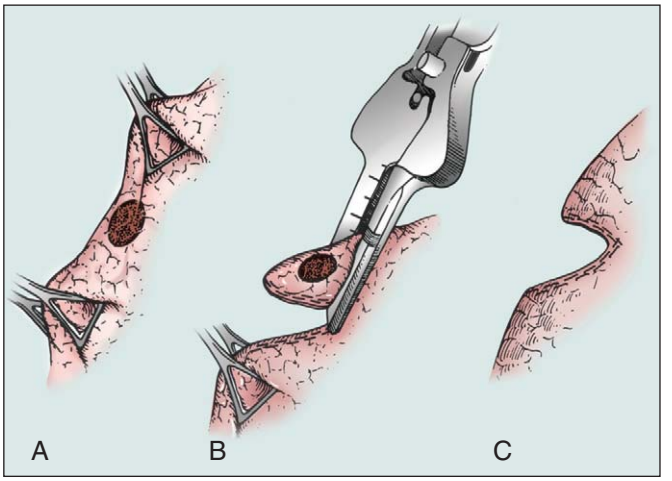

Figure 58-5 • **A–C,** Method of wedge resection by using a stapling device. This technique is most suitable for peripherally located metastases adjacent to the fissures or edges of the lung. (From Rusch VW: Surgical techniques for pulmonary metastasectomy. Sem Thorac Cardiovasc Surg 2002;14:4.)

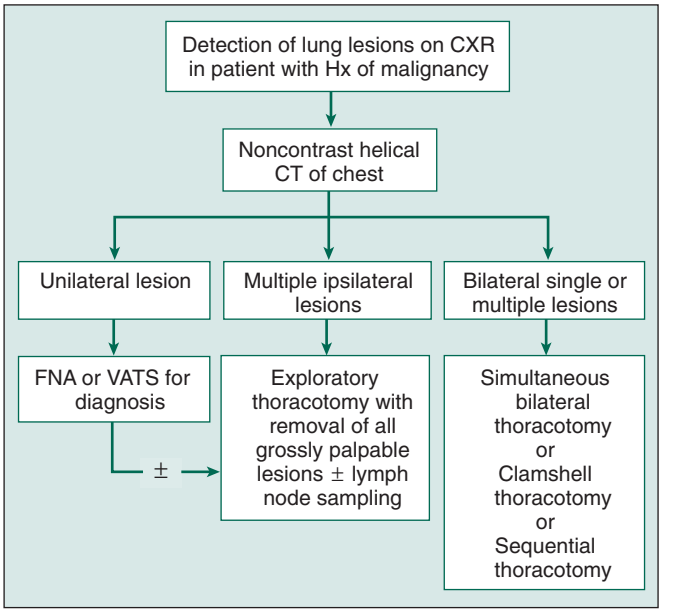

Figure 58-6 • Management algorithm for patients with isolated pulmonary metastasis from extrathoracic malignancy. CXR, chest radiography; FNA, fine-needle aspiration; Hx, history; VATS, video-assisted thoracoscopy.

The risk of resection of pulmonary metastasis using standard wedge resection is very low, with mortality generally 1% or less. Complications include bleeding, infection in the wound, or pneumonia and prolonged air leak. More extensive resections such as lobectomy or pneumonectomy carry only slightly higher morbidity rates, and these operations are very well tolerated by most patients.

The preoperative evaluation for these patients is similar to those undergoing lung resection for any other cause (Fig. 58-6). Pulmonary function testing should be obtained for all patients to assure that the volume of lung resection will not compromise overall respiratory function. Thorough evaluation of underlying cardiovascular disease should also be undertaken, with preoperative stress testing as clinically indicated.

PULMONARY METASTASECTOMY FOR SPECIFIC TUMOR TYPES

Colorectal Cancer

It is estimated that 10% to 25% of patients with primary colorectal tumors will have detectable metastases at the time of diagnosis.[32] Despite advances in adjuvant therapy and surgery, 50% of all patients with colorectal cancer will develop some form of metastasis during their lifetimes.[33] Approximately 15% of patients having curative resection of their primary colorectal tumor will develop distant metastasis, including metastasis to the lung.[34] Pulmonary metastasis can occur even with favorable primary tumor characteristics. Okumura and coworkers[35] reported that 26% of pulmonary metastectomies were performed in patients with Duke's A or B primary colorectal cancer. Since Blalock[36] reported the first pulmonary metastasectomy for colorectal cancer in 1944, several authors have reported their experience regarding overall survival and prognostic factors. The 5- and 10-year survival rates range from 30% to 40% and 27% to

Table 58-4 Survival of Patients Undergoing Pulmonary Metastasectomy for Colorectal Cancer*

Year	Author	Number	5-Year Survival (%)	10-Year Survival (%)
1992	McAfee et al[37]	139	30.5	N/A
1996	Okumura et al[35]	159	40.5	27.7
1998	McCormack and Ginsberg[38]	287	40.0	32.0
2001	Zink et al[39]	110	32.6	N/A
2002	Saito et al[40]	165	39.6	37.2

*Studies represent analysis of 100 patients or more.

37%, respectively (Table 58-4).[37–40] It is clear from the literature that pulmonary metastasectomy for colorectal cancer is associated with long-term survival, especially when a complete resection is performed. McCormack and associates[41] reviewed 144 patients who underwent pulmonary metastasectomy for colorectal cancer and showed that survival for patients who underwent complete resection was approximately 40% at 5 years, whereas incomplete resection was associated with a poor prognosis.

As for other primary tumors, studies evaluating the disease-free interval, the number of lesions (multiple vs. single), and the presence of lymph node involvement have shown these to be significant prognostic factors after pulmonary metastasectomy for colorectal cancer.[35,37–46] Colorectal cancer is also unique in the fact that the serum tumor marker carcinoembryonic antigen (CEA), used as a marker for follow-up, has been shown to be a prognostic indicator for patients with pulmonary metastases.[37–46]

There is some disagreement as to whether single, ipsilateral metastases are associated with a better prognosis than either multiple ipsilateral or bilateral metastases. The presence of bilateral metastases was previously thought to be a contraindication to metastasectomy. Recently, though, several authors have reported that the survival for patients with bilateral lesions is not significantly reduced as compared with patients who have multiple ipsilateral lesions.[38,43] Although a solitary metastasis might be associated with a better prognosis than multiple metastases (either unilateral or bilateral), the main criteria used to select patients with multiple lesions is whether removal of these lesions is technically feasible and removal of the volume of lung parenchyma does not seem to compromise the patient's lung function to a significant extent.

CEA levels are elevated in 40% to 70% of patients before pulmonary metastasectomy. Most authors report elevated CEA levels to be an adverse prognostic factor.[39,40,44,45,47] The reason for this is unclear, although it has been postulated that the presence of CEA may promote adhesion or attachment of tumors cells or could be due to undetected extrathoracic metastasis.[48] Although an elevated CEA is not used currently to exclude patients from resection, it could be useful to consider this in the context of other known prognostic factors. For instance, a patient who rapidly develops pulmonary metastases after resection of the primary tumor, and who has multiple lung nodules and an elevated CEA level, might be treated initially with chemotherapy instead of going directly to pulmonary metastasectomy.

Hilar or mediastinal lymph node metastases occur in 1% to 28% of patients with colorectal pulmonary metastasis.[35,40–43,45] Saito and colleagues[40] reported that 20 of 138 (14.5%) patients who underwent lymph node sampling had positive nodes. The 5-year survival was 48.5% for the patients without hilar or mediastinal lymph node metastasis, vs. 6.2% at 4 years for the patients with lymph node metastasis. More recently, Welter and associates[49] reported that 28 of 169 patients undergoing resection of colorectal pulmonary metastases had hilar or mediastinal nodal metastases. Nodal metastases had a highly significant adverse impact on survival. Okumura and coworkers[35] performed systematic lymph node dissection on 100 patients with colorectal pulmonary metastasis. Fifteen of these patients had positive lymph nodes with a 5-year survival of 6.7% as compared with a 50% survival for those with negative lymph nodes, indicating that complete lymph node dissection does not increase survival. The routine use of mediastinal lymph node dissection in patients with pulmonary metastases seems to be the exception rather than the norm. The presence of malignant lymph nodes could indicate a group of patients otherwise thought to be disease-free who might benefit from additional adjuvant therapy. We favor doing mediastinal lymph node sampling or dissection in these patients. Although these procedures might not have a therapeutic effect, they certainly provide important prognostic information.

Previously, the presence of both liver and lung metastases from colorectal cancer was thought to be a contraindication to metastasectomy. Synchronous or metachronous lung and liver metastasis occurs in approximately 5% of patients with colorectal cancer. Headrick and colleagues[50] reported 5- and 10-year survivals of 30% and 16%, respectively, for 58 patients who underwent resection of both liver and lung metastases from colorectal cancer. Decreasing morbidity and mortality rates for liver resection now make resection of both lung and liver metastases a viable option in carefully selected patients.

Bone and Soft-Tissue Sarcoma

Bone and soft-tissue sarcomas compose a histologically diverse group of tumors accounting for 1% of all adult malignancies, with approximately 6600 cases occurring in the United States annually.[51,52] Metastasis will occur in 25% to 70% of patients with localized disease, and 10% will present with metastasis upon diagnosis.[52] Isolated pulmonary metastases occur in up to 20% of sarcoma patients during the course of their disease, with the lung being the site of failure after treatment in up to 90% of cases.[53,54] Factors associated with an increased risk of pulmonary metastasis include high tumor grade, primary tumor size greater than 5 cm, lower extremity site, and histologic subtype.[53] The lack of effective systemic therapy for most soft-tissue sarcomas makes surgical resection the best treatment for pulmonary metastases. Several studies have shown that the complete resection of pulmonary metastases is associated with long-term survival.[5,51,53,55] Billingsley and coworkers[51] reported that the 3-year actuarial survival was 46% in patients who had complete resection as compared with 17% ($P < 0.001$) for those with incomplete resection of pulmonary metastasis. The cumulative 5-year survival for patients with bone and soft-tissue sarcomas after pulmonary metastasectomy ranges from 31% to 40% (Table 58-5).[5,51,55–57]

The histologic subtype of sarcoma influences both the development of pulmonary metastasis and overall survival. High-grade, undifferentiated, and alveolar soft-part sarcomas produce pulmonary metastasis in approximately 60% of patients.[51] Tumors that are high grade and histologic variants, such as liposarcoma, malignant fibrous histiocytoma, and malignant peripheral nerve tumor, have all been reported to be unfavorable prognostic factors.[51,53,58] Longer disease-free interval, fewer lesions, and unilaterality have also been reported to be favorable prognostic factors.

The incidence of hilar or mediastinal lymph node metastasis in patients with lung metastasis from sarcoma is 2%.[5] This low propensity for lymph node involvement is also a feature of primary sarcomas. Therefore, it seems that routine mediastinal lymph node sampling or dissection is unlikely to offer significant prognostic information or therapeutic benefit.

The rate of recurrence after pulmonary metastasectomy for sarcoma ranges from 45% to 83%; however, the role of repeat resection of pulmonary metastases has been studied by few authors.[53,57–60] Weiser and associates[61] reported experience from Memorial Sloan-Kettering Cancer Center in 86 patients who underwent repeat resection of pulmonary metastases for soft-tissue sarcoma. The 5-year survival after undergoing at least two operations for pulmonary metastasectomy was 36%. Patients who had a complete repeat resection had a median survival of 51 months, as compared with 6 months in those who could not be completely repeat resected. Poor prognostic indicators for repeat resection included three or more nodules, lesions greater than 2 cm in size, and high-grade primary tumors. This study strongly suggested a benefit for repeat or multiple procedures for clearance of pulmonary disease in carefully selected patients.

Pulmonary metastases from osteosarcoma occur most frequently in pediatric patients and respond better to chemotherapy than do soft-tissue sarcomas. Pulmonary metastasectomy within the context of a multimodality therapy program is a well-accepted approach to treatment and is associated with a 5-year survival of approximately 30%. Response to chemotherapy, the disease-free interval from resection of the primary tumor, and the number of metastases and complete resection are reported to influence overall survival.[62–64]

Melanoma

Patients with metastatic melanoma have an especially poor prognosis. The most common sites of metastasis from melanoma are the lungs, distant subcutaneous tissue, and distant lymph nodes, with isolated lung metastasis occurring in 1.9% to 11% of patients.[65,66]

Table 58-6 Survival of Patients Undergoing Pulmonary Metastasectomy for Malignant Melanoma

1998	Ollila et al[72]	45	15.6
2002	Dalrymple-Hay et al[20]	121	22.1

Tafra and coworkers[67] reported their experience with 106 patients with metastatic melanoma who underwent pulmonary metastasectomy. Sixty-five of these patients underwent a complete resection. Although the benefit of a complete (vs. an incomplete) resection on survival could not be demonstrated in a univariate analysis, a multivariate analysis found that surgical resection (vs. no operation) was associated with a significantly better survival ($P = 0.0001$). Other authors have reported that complete resection is associated with prolonged survival.[68,69] Overall, the 5-year survival rates after resection of pulmonary metastasis from malignant melanoma vary from 4.5% to 27% (Table 58-6).[20,66–68,70–72] This wide range of values probably reflects the relatively small numbers of patients included in some studies. Prognostic factors that have been reported include operation, number of nodules, prior immune therapy, histologic type, disease-free interval, and tumor-doubling time.[20,65–72] Harpole and colleagues[69] reported on a large series of patients who had pulmonary metastases from melanoma. Of the total of 945 patients, 112 (11.8%) underwent pulmonary metastasectomy. Histologic type (nodular and acral lentiginous lesions), high Clark level, and thicker primary tumors were significantly associated with pulmonary metastasis. The overall 5-year survival in this group was 4%. Patients who had a complete resection had a significantly higher median survival rate as compared with those who had only partial resection, although all patients who underwent operations survived longer than those who had no operation. An analysis of the subset of patients who had a solitary metastasis found that patients who underwent resection had a significantly better median survival than patients managed nonsurgically. Important prognostic factors after surgery included complete resection, a long disease-free interval from treatment of the primary tumor to the diagnosis of the pulmonary metastasis, treatment with chemotherapy, and the total number of nodules. These data suggest that appropriately selected patients with metastatic melanoma confined to the lungs can benefit from pulmonary metastasectomy.

Renal Cell Carcinoma

Barry and Churchill[2] performed the first pulmonary metastasectomy from renal adenocarcinoma in 1938. Approximately 30% of patients with renal cell carcinoma will present with metastasis, and approximately 30% to 50% of patients with initially localized tumors will develop distant metastases.[73] One-half of patients who have a radical nephroureterectomy will develop pulmonary metastases later and only 16% of these patients will have disease confined to the lung.[74,75] The 5-year survival of patients with unresected metastasis is approximately 2.7%.[76] The 5-year survival after resection of isolated pulmonary metastasis is reported to range from 36% to 44% (Table 58-7).[75–79] Several prognostic factors for survival have been identified, including complete resection, the disease-free interval between primary tumor treatment and metastasis, the number of metastases, and the presence or absence of lymph node metastases.[75,76,78]

Pfannschmidt and associates[76] reported one of the largest series of pulmonary metastasectomy for renal cell cancer; they found that complete resection was possible in 78% of patients and that these patients had a 5-year survival of 41.5% vs. 22.1% for those with incomplete resection. This survival rate of 22.1% in incompletely resected patients was better than that for patients who had no resection at all.

Hilar and mediastinal lymph node metastases are seen in 22% to 30% of patients with metastatic renal cell cancer.[75,76] Fourquier and colleagues[75] and Pfannschnidt and associates[76] performed systematic mediastinal lymph node dissection on 50 and 191 patients, respectively. Both studies found that the presence of lymph node involvement was associated with a poorer survival. Although it is unknown whether lymph node dissection is therapeutic, it offers important prognostic information and should probably be performed in these patients.

*Studies represent analysis of 50 patients or more.

Synchronous metastases are traditionally thought to be a relative contraindication to resection. The true incidence of synchronous versus metachronous metastases is in renal cell cancer is unclear, although in reported series of resected patients, synchronous lesions are less frequent and are thought to indicate a worse prognosis.[75,76] On the other hand, Fourquier and colleagues[75] examined survival in completely resected patients with synchronous lung metastases. Although the overall survival rate was lower in patients with synchronous lesions (48% vs. 20%), this was not statistically significant and again appeared to offer a survival benefit relative to no resection at all.

The recent development of more effective systemic therapy for renal cell cancers through the use of antiangiogenesis agents may alter the need or indications for pulmonary metastasectomy. This is an evolving area of cancer management, and the impact of these drugs on pulmonary metastasectomy warrants study.

Head and Neck Cancer

Approximately 60,000 new cases of head and neck cancer occur each year in the United States.[80] The potential for metastatic spread is dependent on the stage of the primary tumor, with the rate of lung metastasis ranging from 4.3% to 25.1%.[81] Head and neck tumors and especially squamous cell cancers have a predilection for metastasizing to the lung, which is often the only site of metastasis.[82] The diagnosis of lung nodules in these patients becomes even more challenging when one realizes that 10% to 40% of lung nodules in these patients are actually second primary lung tumors.[83] There are few effective systemic therapy options for the treatment of lung metastasis from head and neck tumors, leaving surgical resection as the most viable option. The estimated 5-year survival after pulmonary metastasectomy in these patients ranges from 29% to 59% (Table 58-8).[80,81,83,84] The wide range of survival rates may be related to the heterogeneous histologic groups reported in most series. Squamous cell tumors of head and neck origin have a worse prognosis than their glandular counterparts such as thyroid, adenoid cystic, and mucoepidermoid tumors.[80,81,84] Liu and coworkers[80] reported on 83 patients undergoing pulmonary metastasectomy from head and neck tumors. In their series the 5-year overall survival for squamous cell tumors was 34% as compared with 64% for tumors of glandular origin ($P = 0.14$). Bilateral metastasis and recurrence of metastasis are not contraindications to resection and have not been shown to be adverse prognostic factors at this time.

Germ Cell Tumors

Germ cell tumors compose only 1% of cancers but are the most common neoplasm in men aged 15 to 35 years. The vast majority of these tumors arise in the testis, with an annual incidence of 5 cases per 100,000.[85] The survival of patients with germ cell tumors has increased dramatically during the past 30 years because of cisplatin-based chemotherapy.[85] Monitoring of treatment and recurrence has been made possible by the use of sensitive tumor markers, including α-fetoprotein and human chorionic gonadotropin.

1999	Liu et al[80]	83	50

*Included only patients with squamous cell carcinoma metastasis.

Pulmonary metastasis at the time of presentation in these patients is common, approaching 50% in patients with retroperitoneal disease.[86] Residual masses after chemotherapy are present in approximately 50% of patients and could contain viable malignancy, mature teratoma, or only fibrosis and/or necrosis.[86] Surgical resection of these lesions is crucial to identifying which of the preceding components is present, to predicting outcome, and to determining if any further therapy is warranted. The estimated 5-year survival rate after pulmonary metastasectomy ranges from 59% to 77% (Table 58-9).[85–87] The most significant prognostic factor is the presence of viable tumor cells in the resected specimen. Liu and coworkers[85] reviewed the experience at Memorial Sloan-Kettering Cancer Center over a 28-year period of 157 patients undergoing pulmonary metastasectomy for germ cell tumors. After resection, viable tumor was found in 70 patients (44.5%), necrosis in 47 patients (29.9%), and mature teratoma in 40 patients (25.4%). Survival was significantly poorer in those patients with viable tumor cells (43% over 10 years) as compared with those patients with necrosis/fibrosis (86% 10-year survival) or mature teratoma (84% 10-year survival).[85] The presence of mature teratoma in a specimen did not significantly worsen prognosis. The inability to make an accurate determination of the presence or absence of viable tumor cells in all residual lesions after treatment for germ cell tumors mandates that all of these lesions be resected to determine overall prognosis and potential for further therapy.

More recently, Kesler and colleagues[88] reported the results of resection in 134 patients with either lung or mediastinal metastases. The overall survival at 5 years was 42.3%. Older patient age, lung rather than mediastinal metastases, and the number of metastases (four or more) adversely influence survival.

Breast Cancer

Breast cancer is the most prevalent cancer among women in the United States, with approximately 100,000 cases occurring annually.[89] Approximately 15% to 25% of patients with metastatic disease will have their disease confined to the thorax. The data regarding

Table 58-9 Survival of Patients Undergoing Pulmonary Metastasectomy for Germ Cell Tumors

pulmonary metastasectomy are controversial, with most studies analyzing the outcome of encompassing small groups of patients treated over several decades. The largest series reported to date is by Friedel and colleagues[90] from the International Registry of Lung Metastases. They reported on 467 patients undergoing pulmonary metastasectomy for breast cancer. Complete resection of all metastasis was possible in 84% of patients. The 5-year overall survival was 38% in patients with complete resection, as compared with 18% of patients with incomplete resection ($P = 0.0009$). A long disease-free interval and fewer lesions were associated with a longer survival in this group.[90] McDonald and associates[91] reported on 60 patients undergoing pulmonary metastasectomy for breast cancer and failed to show a survival benefit for surgical management. Because breast cancer also frequently progresses to extrathoracic disease and is sensitive to current systemic therapies, pulmonary metastasectomy is rarely an appropriate treatment option. Indeed breast cancer is an example of the evolution of the role of pulmonary metastasectomy. Before the advent of effective hormonal and chemotherapy, pulmonary metastasectomy was commonly performed for breast cancer with metastases confined to the lungs. Surgery is now infrequently considered for treatment.

Nonsurgical Approaches to Lung Metastasis

Two therapeutic options are emerging as potentially effective alternatives to resection in selected patients with lung metastases: stereotactic body radiation therapy (SBRT) and radiofrequency ablation (RFA). SBRT is a method for delivering focused radiation to a tumor while excluding tissues not grossly involved with the tumor. It is usually delivered as high-dose hypofractionated treatment over just a few days and is therefore an attractive option for patients who have advanced disease or who may also require chemotherapy within a short interval of local therapy. Several small series now report excellent local tumor control rates with low toxicity (Table 58-10). Small, solitary peripheral tumors have been considered the ideal target for SBRT, although some series include patients with larger tumors, multiple lesions, or tumors that include the midline and the hilum.[92] The length of follow-up after SBRT is relatively short in most series,

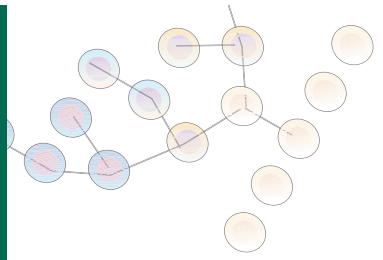
and there are no randomized trials comparing SBRT to surgical pulmonary metastasectomy. The optimal total radiation dose and dose per fraction, and the need for respiratory gating during treatment, are not yet fully defined.[93]

RFA is a thermal energy system delivered via percutaneous needle placed under imaging guidance into a tumor. RFA causes tumor destruction by coagulation necrosis. There is even less experience with RFA than with SBRT for the treatment of pulmonary metastases. Currently most institutions limit the use of RFA to peripheral tumors less than 5 cm in size. However, local recurrence rates of up to 50% are reported, and serious complications including hemorrhage, pneumothorax, severe pleuritic pain, and effusions occur with RFA. Long-term follow-up data in large numbers of patients are lacking.[94–97]

Both SBRT and RFA are potentially promising alternatives to surgical pulmonary metastasectomy in selected patients. However, well-designed prospective clinical trials are needed to define the indications for these nonsurgical approaches along with the associated risks and long-term outcome. Certainly, either of these modalities may be appropriate options for patients who are not surgical candidates.

Other Investigational Approaches to Lung Metastases

Two additional approaches have been investigated for the treatment of unresectable pulmonary metastases: isolated lung perfusion (ILP), and transpulmonary chemoembolization.[98,99] ILP is an extension of the technique of isolated organ perfusion originally developed for limb perfusion of patients with malignant melanoma or sarcoma. First developed by Johnston and coworkers[100] in 1983, ILP requires surgical exploration via thoracotomy or median sternotomy, isolation and cannulation of the pulmonary artery and veins, and chemotherapy perfusion of the isolated lung. However, clinical trials in humans have shown that ILP can be associated with significant pulmonary toxicity. The technical complexity and potential morbidity of this approach to treatment have prevented widespread acceptance of ILP. It remains an investigational treatment modality that should only be used within the context of clinical trials.[98]



Transpulmonary chemoembolization is a method of delivering chemotherapy to the lung without surgery. Selective percutaneous image-guided catheterization of segmental pulmonary arteries is performed with a balloon catheter that occludes blood inflow. Chemotherapy is injected into the segmental pulmonary artery, which is then occluded by a second injection of microspheres. In a small trial involving 23 patients, Vogl and colleagues[99] performed transpulmonary embolization of 26 lung metastases. Tumor regression was observed in 8 patients and tumor stabilization in 6 patients. Treatment was well tolerated with only minor complications. Though clearly an investigational approach to treatment, transpulmonary chemoembolization seems to warrant further study for patients with unresectable pulmonary metastases.

59 Liver Metastases

Nancy Kemeny, Margaret Kemeny, and Laura Dawson

SUMMARY OF KEY POINTS

Incidence

- Liver metastases are most frequently seen in patients with colorectal cancer (CRC; nearly 15% of patients presenting and an additional 60% developing subsequent spread); they are less common in patients with breast cancer (4% of initial failures), lung cancer (15%), and melanoma (24%).

Etiology

- The liver has a rich blood supply from both the hepatic artery and the portal vein; metastases can reach the liver from any organ, but the direct passage of blood from the gastrointestinal tract to the liver via the portal circulation plays a critical role in explaining the high rate of liver metastases from these sites.

Detection

- Contrast computed tomography (CT) and magnetic resonance imaging (MRI) can detect approximately two-thirds of liver metastases.
- CT angiography, CT portography, and intraoperative ultrasound seem to have increased sensitivity as compared with standard techniques.
- Positron emission tomography (PET) is more useful to detect extrahepatic disease.
- Of laboratory tests, carcinoembryonic antigen (CEA) can be useful for patients with metastatic CRC to the liver.

Treatment

Hepatic Resection

- There is general agreement that surgical resection is the treatment of choice for patients with one to three metastases from CRC, producing a 5-year survival of about 30%.
- Significant advances in surgical technique include the ability to perform metastasectomies (rather than formal lobectomies) and total vascular exclusion.
- The liver is the chief site of relapse after hepatic resection (50% of all patients).
- Prognostic variables that influence survival after hepatic resection include the presence of extrahepatic disease, the stage of the primary colon cancer, the time interval between primary and the development of hepatic metastases, and the number of metastases and positive margins.
- The use of adjuvant hepatic artery infusion (HAI) after liver resection has produced positive results in two American trials. There is a clear decrease in hepatic recurrence with adjuvant HAI.

Systemic Chemotherapy

- The objective response rate with intravenous chemotherapy is improving, with response rates of 40% to 50% among patients with breast cancer, gastric cancer, and now even colon cancer.

Hepatic Artery Infusion

- Eight randomized trials demonstrate a higher response rate for HAI than for systemic infusion (42% to 64% vs. 0 to 38%, respectively). Survival advantage is difficult to interpret: two large U.S. studies allowed a crossover from systemic therapy to HAI after tumor failure. New CALGB study without crossover showed a survival advantage. The chief toxicity of HAI is biliary enzyme elevations in 40% and biliary sclerosis in 5% to 35% of patients.

Hepatic Artery Embolization

- Embolization could play a role in highly vascular tumors (neuroendocrine tumors and hepatocellular carcinoma, HCC).
- Embolization agents include Gelfoam, lipiodol, and degradable starch microspheres.
- Embolization is rarely useful for patients with metastatic CRC.
- Chemoembolization involves the local entrapment of drug in the embolization agent in an attempt to provide a prolonged exposure of the tumor to drug locally, with less systemic exposure.

Ablative Techniques

- Cryosurgery involves destruction of tissue using a freezing probe.
- Limitations include the difficulty of controlling freezing and the typical requirement for laparotomy.
- Radiofrequency ablation involves destruction by frictional heat and can be used percutaneously but is rarely good for lesions larger than 3 cm.

Absolute Ethanol Injection

- Ethanol is injected into the tumor under ultrasound guidance and could be of use for small HCCs.

Radiation

- Whole-liver external-beam irradiation therapy alone is limited by the occurrence of radiation hepatitis to about 30 Gy in 15 fractions.
- Parts of the liver can be treated to far higher doses using yttrium-90 (^{90}Y) microspheres, interstitial brachytherapy, and external-beam irradiation therapy guided by three-dimensional treatment planning.

INTRODUCTION

Not so long ago an oncology textbook would not have devoted an entire chapter to liver metastases. Oncologists were so pessimistic about the appearance of such metastases that "no treatment" was often the recommendation. Enormous changes have occurred, so that now, diagnosing liver metastases early can lead to effective treatment and even cure for a growing percentage of patients.

The liver is the primary site of metastases for many malignant neoplasms. Gastrointestinal malignancies are especially prone to spread to the liver because of its portal venous drainage. Extra-abdominal tumors such as bronchogenic carcinoma, breast cancer, and malignant melanoma often spread hematogenously to the liver.

For gastrointestinal tumors, differences are seen in the natural history of the hepatic metastases. In some circumstances, hepatic metastases are a sign of disseminated disease. When gastric and pancreatic cancers metastasize to the liver, the mean survival is short, and widespread metastases often exist, so that radical measures such as hepatic resection or hepatic artery infusion (HAI) are rarely appropriate. In contrast, for colorectal cancer (CRC) the liver might be the sole site of metastatic disease, and a sizeable number of these patients might have isolated liver metastasis. In this setting, progress has been significant in the areas of hepatic resection, regional chemotherapy, and radiation therapy as discussed in this chapter.

For nongastrointestinal tumors, metastases to the liver are less common as the initial site of relapse. Although breast, lung, and melanoma are the main extragastrointestinal cancers to metastasize to the liver, initial isolated metastases in the liver occur in 4%, 15%, and 24% of these patients, respectively.

Treatment of these types of metastases varies according to the sensitivity of the tumor type to chemotherapy. Those that are more sensitive to antineoplastic agents might benefit from systemic therapy or aggressive regional approaches (breast), whereas those that have limited response to chemotherapy (such as melanoma) may be approached regionally in the setting of a clinical trial. Special care must be exercised in choosing patients for regional therapy who do not have CRC, because diseases such as breast cancer and melanoma are rarely confined to the liver.

The last 20 years have witnessed new and more accurate methods of detecting and quantifying liver metastases, more advanced surgical techniques facilitating hepatic resection, and biologic advances that have increased the spectrum of available regional therapies. This chapter discusses advances in detection and treatment of liver metastases.

DETECTION

The need for early and accurate detection of liver metastases has become more critical as the guidelines for resectability of liver metastases have become more liberal. Furthermore, ablative therapies and conformal radiation therapy are more likely to control unresectable liver metastases detected at an earlier stage, with a lower burden of disease. The most common imaging modalities for liver metastases imaging and their usefulness are described in the sections that follow.

Imaging Techniques

Computed Tomography

Computed tomography (CT) has been used for more than 20 years to image hepatic metastases. Modern CT scanners are capable of rapid scanning and high-resolution three-dimensional images of the liver that can be acquired during one breath hold.[1] Projection and reformatted views can be useful when assessing the proximity of liver metastases to the vessels. CT images are routinely evaluated by two window levels to maximize detection of lesions. A soft-tissue window (width of 300–500 Hounsfield units) is used for the initial examination of the liver and adjacent abdominal architecture. A second setting with a narrow window and a lower width (100–150 Hounsfield units) is then used to evaluate the liver, because this setting increases contrast differences between the normal liver parenchyma and abnormalities.

Noncontrast Computed Tomography

Contrast CT is sometimes not possible because of contrast allergic reactions or renal impairment. Although the sensitivity and specificity of noncontrast CT is far reduced as compared to contrast CT, it may help in identifying hypervascular metastases (especially carcinoid tumors, islet cell tumors, and renal cell carcinomas) or visualizing calcifications or hemorrhage. Noncontrast CT often fails to distinguish hypovascular tumors from the liver parenchyma. Nonenhanced blood vessels may also appear as low-attenuation masses and be confused with metastases.[2]

Contrast Computed Tomography

Intravenous contrast is infused over approximately 2 min, with repeat imaging acquired during the infusion to capture the different enhancing phases of tumors. The two most useful phases for hepatic metastases are the arterial phase (25-sec delay) and portal venous phase (60-sec delay). During portal venous imaging, the liver parenchyma enhances and hypovascular metastases, such as those from CRC, appear as filling defects.[2] Most metastases are seen best in the portal venous phase, but some are best seen in delayed venous and occasionally arterial phases. Hypervascular liver metastases may be missed with CT, because very vascular metastases may enhance to the same degree as normal liver parenchyma. Delayed contrast CT, referring to scanning 4 to 6 hr after contrast injection, is most useful as an adjunct to increase the sensitivity and accuracy of contrast CT, because malignant lesions usually do not retain contrast and appear as hypodense areas within the enhanced normal liver parenchyma.[2]

Computed Tomography Angiography and Portography

The rapidity with which multidetector CT scanners can acquire images makes possible imaging of the entire liver during the peak of the bolus of intravenous contrast, supporting CT angiography and portography.[3] This noninvasive imaging can provide images of hepatic vasculature of superb quality, avoiding catheter angiography. This technique is useful to detect vascular anomalies that may help in planning of hepatic resection or hepatic arterial chemotherapy. Most often, imaging is acquired during an arterial phase and a portal venous phase.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) exploits differences in magnetic properties of atomic nuclei to produce images. When placed in a magnet, protons have a nuclear spin that aligns with the magnetic field and give off radiowaves (MR signal) on returning to equilibrium. As the chemical environment changes, there is a change in the frequency of the signal, and the image. Differences in the time to return to equilibrium (relaxation times) are exploited in MRI, using T_1- and T_2-weighted pulse sequences. Most commonly, axial imaging is used for liver metastases imaging; however, coronal or sagittal views can define better a tumor's proximity to adjacent vessels. The most common pulse sequences used for liver metastases imaging are a T_1- or T_2-weighted spin echo. The T_1 images generally show metastases as low-intensity lesions, whereas in T_2-weighted images, metastases are of high signal intensity (Fig. 59-1). T_2-weighted sequences are generally superior for detection and characterization of liver masses. Benign cysts and hemangiomas usually appear homogeneous and bright, whereas metastatic lesions are less bright and more heterogeneous.[2,4] Although MRI inherently provides for soft-tissue contrast, contrast agents, such as gadolinium (Gd) chelates, can improve diagnostic accuracy. Similar to CT, MR angiography can be used as a

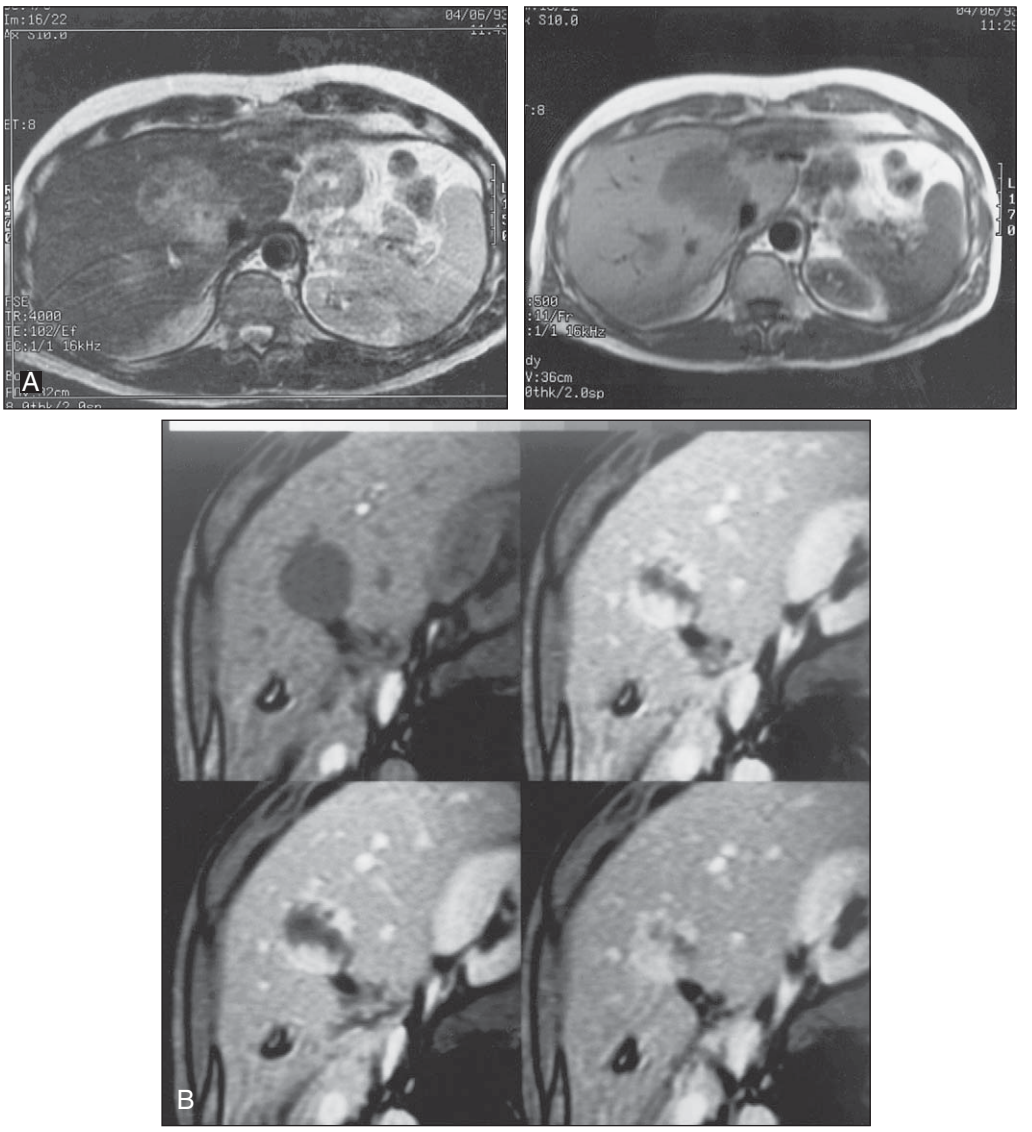

Figure 59-1 • **A,** T_2-weighted spin-echo image (*left*); T_1-weighted spin echo image (*right*). In T_2-weighted images the metastases are areas of high signal intensity. In T_1-wieghted images metastases have a low intensity. **B,** Dynamic gadolinium-enhanced MRI demonstrating peripheral nodular enhancement in a hepatic hemangioma. Enhancement increases as the study advances over time from upper left to lower left and then to upper and lower right.

noninvasive method to evaluate hepatic vasculature. Novel MR contrast agents have the potential for improving detection of liver metastases.[5] Advantages of MRI include the lack of radiation exposure to the patient and the low frequency of reactions to contrast agents. MRI is particularly useful for patients with contraindications to iodinated contrast, and MRI can detect hypervascular lesions that are not well visualized on CT. Limitations of MRI include inherent warping and the time required for imaging, which may lead to artifacts in patients who cannot hold their breath. Parallel imaging allows for high-resolution imaging of the entire liver within one breath hold, with the potential for more sophisticated sequences (such as diffusion-weighted imaging and MR spectroscopy) to improve liver metastases detection in the future.

Ultrasonography

Ultrasonography (US) relies on sound waves to generate an image. US is most commonly used for screening for metastases because of its wide availability and lack of the need for radiation exposure. It is most useful in detecting superficial liver metastases in small patients. Contrast-enhanced US, using intravascular microbubble contrast agents, has shown similar accuracy for liver metastases detection compared to CT and MR.[6] An advantage of contrast-enhanced US is the potential for characterization of liver lesions based on morphologic evaluation as well as temporal vascular enhancement pattern.[7] During the portal venous phase, benign lesions typically enhance more than the liver, whereas malignant lesions enhance less.[8] Expertise in contrast-enhanced US is not yet widespread.

Intraoperative US can also be useful at detecting small, deep hepatic metastases not palpable. In a study of 84 patients undergoing colon resection, intraoperative US detected 14 hepatic metastases that were missed on surgical palpation.[9] In a similar study, intraoperative US detected seven nonpalpable lesions in 70 patients.[10]

Positron Emission Tomography

Positron emission tomography (PET), in which a radioactively labeled tracer is administered to the patient and the scanner collects

the emitted positron radioactivity to generate an image, allows imaging of cellular processes (such as cellular proliferation (^{18}F-labeled thymidine), hypoxia (^{18}F-labeled Miso), and blood flow ([^{15}O]water) to be visualized. The majority of clinical experience has been with fluorodeoxyglucose ([^{18}F]FDG), which images cellular glucose metabolism. A limitation of PET scans of the liver is that they are acquired over many breathing cycles, leading to blurring due to respiratory motion and lower spatial resolution as compared with CT. This has driven the development of dual-modality scanners capable of CT and PET scanning. Scanners capable of respiratory sorting are also being developed.

FDG PET scans have been done to stage patients before resection of liver metastases[11–13] and to evaluate response to treatment.[14] In one study, 6 of 34 liver metastases treated with chemoembolization demonstrated persistent FDG PET activity, which led to further treatment.[15] FDG PET has also been found to be useful in diagnosing peritoneal recurrences in patients with elevated serum carcinoembryonic antigen (CEA), with a sensitivity and accuracy for peritoneal disease detection of 88% and 78%, respectively (as compared with 38% and 44% for CT).[16] In patients with colorectal liver metastases staged planned for resection, Ruers and colleagues found that 10 of 51 patients (20%) had a change in treatment plan due to unresectable metastases or extrahepatic metastases detected on FDG PET.[12] Other studies have also demonstrated a change in treatment resulting from FDG PET scans obtained before planned liver resection in 20% to 58% of patients.[13,17–19] In contrast, 15 out of 52 pathologically proven liver metastases were missed with FDG PET in another study, emphasizing that FDG PET cannot be the sole method used to evaluate liver metastases. Five-year survival of a series of 100 patients with liver metastases, imaged with FDG PET and treated with hepatic resection, was 58% (46% to 72%), demonstrating excellent outcomes in well-selected patients.[20] A continuing Canadian randomized trial of PET versus no additional imaging in resectable liver metastases, funded by the Ontario Clinical Oncology Group (OCOG), has the potential to more clearly define which patients with liver metastases planned for resection are most likely to have a change in treatment and benefit from PET scans obtained before resection (personal communication, Steven Gallinger, Toronto, March 2007).

Comparison of Modalities

Many studies have compared imaging modalities for the detection of liver metastases. A German study[21] prospectively compared dynamic CT with MRI and US in 75 patients with known gastrointestinal tumors before exploratory laparotomy. Ninety-five liver metastases were detected in 32 patients.[22] Of the 95 lesions, 68% were detected by CT, 63% by MRI, and 53% by US. Another prospective study involving 69 patients came to the same conclusion, and also demonstrated the superiority of MRI T_2-weighted images over T_1.[23] Other studies have shown improved detection of liver tumors with MRI,[24,25] and differences in the shape and size of hepatic metastases depending on which CT or MR sequence is used for imaging.[26] Overall, CT scans and MRI seem to have similar sensitivity and specificity for detection of liver metastases using state-of-the-art techniques at experienced centers.

Noncontrast external US has a lower rate of accuracy for liver metastases detection as compared with contrast CT or MRI. A unique study of US before liver transplantation allowed the accuracy to be determined pathologically.[27] Only 36 of 80 tumors in 34 patients were detected, indicating a sensitivity of 45%. The majority of lesions not detected were smaller than 1 cm. Contrast-enhanced US has demonstrated similar accuracy for liver metastases detection compared to CT and MRI.[6]

FDG PET can detect disease not seen on CT or MRI in patients with liver metastases.[12,13,28] In a comprehensive review of the literature,[11] the sensitivity and specificity of FDG PET for hepatic disease detection were 88% and 96% and for extrahepatic disease detection were 92% and 85%, respectively, as compared to 83% and 84% for hepatic disease and 61% and 91% for extrahepatic disease in CT. The management was changed based on FDG PET scans in 32% of cases on average. Overall, most studies have confirmed increased sensitivity of FDG PET as compared with MRI and CT, with increased sensitivity on a per-patient analysis as compared with a per-lesion analysis.[5] FDG PET is less sensitive for detection of small liver metastases (less than 1–2 cm) than state-of-the-art MRI or CT.[5,29,30]

At present, the standard of care for imaging of hepatic metastases is helical multiphasic intravenous contrast CT scan, with MRI or contrast-enhanced US alternatives for patients with contraindications to CT contrast. For patients whose treatment plan includes resection, extra imaging should be considered to help best select patients with liver-confined metastases.

Differential Diagnosis for Liver Metastases

The majority of liver metastases enhance on the portal venous phase of imaging. Arterial and portal venous phase imaging, using CT, MRI, or US, can help in distinguishing malignant from benign lesions and hepatic metastases from primary cancers. However, several benign lesions cannot always be reliably distinguished from metastases. Hemangiomas may be confused with highly vascular tumors and cysts. Dynamic Gd-enhanced MRI can help distinguish hemangiomas from tumors. Hemangiomas can also be mistaken for metastases in noncontrast CT scans and on portal phase contrast CT (see Fig. 59-1). Although portal phase contrast CT is sensitive in detecting small hepatic lesions, it has a high false-positive rate because benign lesions such as hemangiomas, cysts, adenomas, or flow artifacts may be confused with metastases. Technetium-99 (^{99m}Tc) red blood cell scintigraphy is the most specific noninvasive test to diagnose hepatic hemangioma (Fig. 59-2).[31] Table 59-1 lists some lesions that may be confused with liver metastases and suggests the tests to differentiate among those entities. A rare entity that can on occasion be confused with metastases is focal fatty infiltration of the liver (Fig. 59-3). This may be seen in patients receiving hyperalimentation. MRI is helpful for distinguishing these lesions.

Biochemical Laboratory Tests

Unlike imaging techniques, the laboratory tests that are available for liver function assessment are not very sensitive. The basic liver function tests include the alkaline phosphatase, bilirubin, albumin, prothrombin time, lactate dehydrogenase (LDH), and serum transaminases. For patients who have metastatic colon cancer, CEA is also extremely useful (see Fig. 59-3). Several studies have looked at the usefulness of these tests to detect liver metastases, especially metastases from CRC.[32–34] CEA remains the most sensitive test for CRC, but even this test can be normal in the presence of liver metastases, especially with minimal hepatic disease. In a prospective study at the City of Hope Hospital (Durante, CA, USA) in patients with metastatic liver disease deemed resectable by CT, the average alkaline phosphatase and LDH levels were within normal limits, whereas CEA was elevated in 73% of the patients.[35] Serum LDH is useful as a prognostic indicator, with high serum LDH denoting a poorer survival.[36]

HEPATIC RESECTION

Because of recent advances in techniques for liver surgery, hepatic resection for metastatic disease has become increasingly safe and used more frequently in treatment over the last two decades. Hepatic resection of metastases was first attempted just before World War II. Experience gained from trauma centers during the war led to the emergence of techniques applicable to resection of metastatic hepatic lesions. In recent years many new devices have helped in the technical aspects of the surgery and in the overall safety of the procedures.

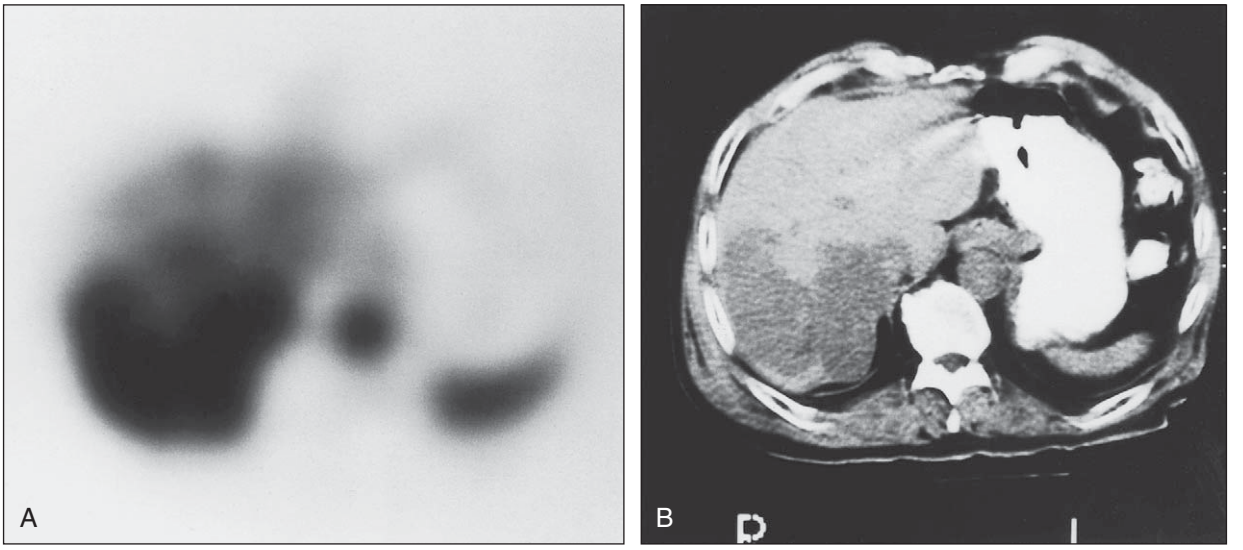

Figure 59-2 • Hepatic hemangiomas. **A,** Transaxial single-photon-emission computed tomography (SPECT) image obtained 2 hours after injection of ^{99m}Tc-labeled red blood cells. Normal blood activity is seen in the liver, and increased blood pooling activity is seen in the aorta and spleen (which is normal). There is a large area of increased blood pooling activity in the posterior section of the right lobe of the liver that corresponds to an area of reduced attenuation on the CT scan. **B,** The CT scan is obtained from the same plane as the SPECT scan. An increase in blood pooling activity with an increase in intensity from earlier images is specific for hemangioma.

In the last few decades hepatic resections have gone from formal lobectomies to resections along nonanatomic lines. Metastasectomies, or removal of the tumor plus a rim of normal hepatic tissue, can be done rather than a formal lobectomy. With the greater familiarity of the hepatic anatomic segments of Couinaud (Fig. 59-4),[37] current resections are more frequently being performed along these lines especially with the use of intraoperative US. These segment divisions cannot be seen by the naked eye on the surface of the liver but can be mapped out with the help of intraoperative US. In the modern operating room the use of intraoperative US is a necessary skill for the operating surgeon. This technique allows for both a reduction in the amount of normal liver removed and resection of disease from both lobes.

Table 59-1 Benign Liver Lesions That May Be Confused with Malignancy

Technique	Benign Lesions	Malignancy
MRI (T_2-weighted)	Vessels	Small metastatic lesions
	Hemangiomas	Highly vascular tumor (islet cell, renal, carcinoid)
	Cysts	Cystic tumors
	Cysts	Highly vascular tumors (islet cell, renal, carcinoid)
CT	Fatty infiltration	Metastases
	Fatty infiltration	Hepatocellular cancer
	Nonenhanced vessels	Metastases
	Adenoma	Abscess
CTP	Hemangioma	Metastases
	Cysts	
	Adenoma	
	Flow artifacts	
Angiography	Focal nodular hyperplasia Hemangioma	Metastases

CT, computed tomography; CTP, CT portography; MRI, magnetic resonance imaging.

Several new devices have been introduced to help with the resection itself. Probably the most commonly used device is the cavitron ultrasonic aspirator, which allows dissection of the liver parenchyma without entering the bile ducts. A new technique for dividing the parenchyma is the multiprobe bipolar radiofrequency device, which was introduced in 2004. This device uses radiofrequency waves to coagulate vessels and bile ducts in the liver parenchyma before dividing the tissue.[38] Other devices are available, but in the end it depends on the operating surgeons and their own techniques, which vary from center to center. No clear advantage has been established for one product over the other.

The operative technique of total vascular exclusion for hepatic resections involving tumors near to the vena cava was introduced in the 1980s by surgeons from the liver transplant community. With this technique the vena cava is cross-clamped in two areas (suprahepatic and subhepatic), and the porta hepatis is also occluded.[39,40] In Bismuth and associates'[41] report on 54 patients using total vascular exclusion, the average duration of cross-clamping was 46 min, and the average operating time was 6 hr. The transfusion requirements were low, and no intraoperative deaths occurred. The application of vascular occlusion seemed to be useful for tumors close to the vena cava or for large central tumors. Again, it is a technique to be used in special circumstances by surgeons who are familiar with the procedure.

The use of the autotransfuser, a technique pioneered in trauma patients, had been avoided initially for patients with malignancies because of fear that tumor cells might be disseminated into the bloodstream with this instrument. Prospective studies on patients undergoing hepatic resection for tumors have not shown this to be true.[42,43] Animal studies also support the concept that metastatic cells are organ specific and would not disseminate if introduced into the bloodstream. Because of these studies, many centers are using the autotransfusers during hepatic resection and reducing the need for multiple blood transfusions.

Another technical advance for hepatic surgery has been the use of fibrin glue, which can aid in sealing the large, raw surfaces of the liver left after major resections.[44]

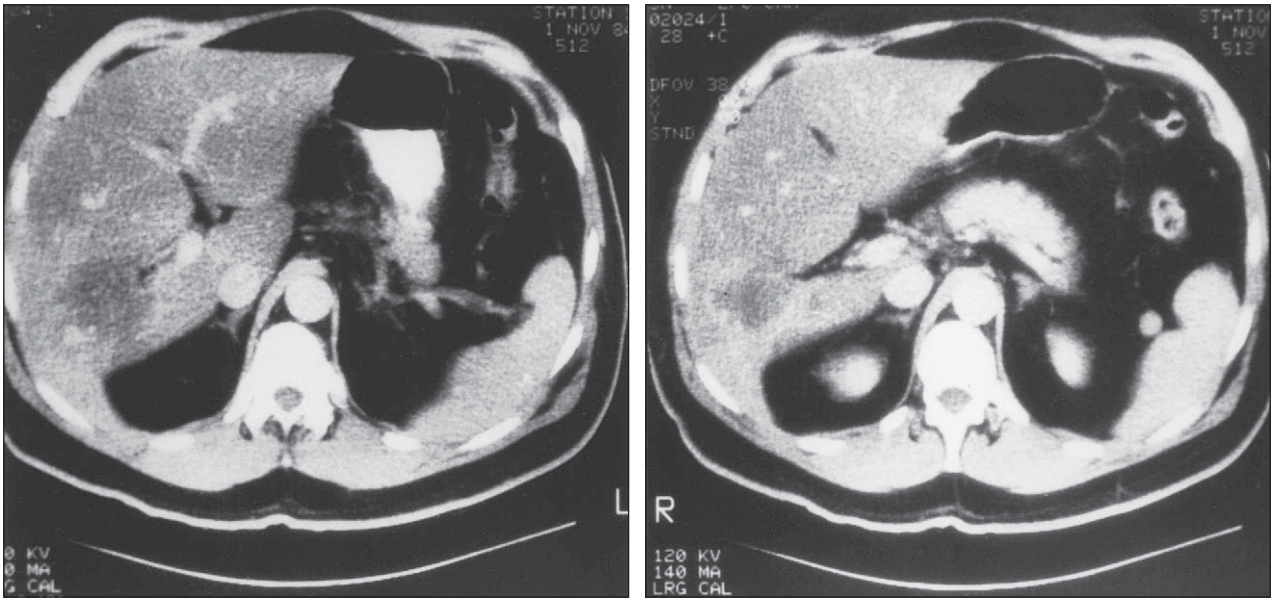

Figure 59-3 • Fatty infiltration. This lesion was thought to represent metastatic disease; surgery revealed it was only fatty replacement.

The question of drainage after hepatic resection has been addressed prospectively in a study that showed no difference in complications in the drained group versus the undrained group. When the data are analyzed more carefully, however, it becomes clear that patients with lobectomies or greater did benefit from drains, whereas those patients with smaller resections did not need drains placed.[45,46] However, this study was done before the advent of fibrin glue, which may reduce the need for drains.

In general, a major surgery such as a liver resection has been reserved for a situation in which the operation can be curative. Experience has shown that the resection of colorectal metastases to the liver can be curative in at least one-quarter of patients with certain requirements. The curability by resection of liver metastases from other primary cancers is not quite as clear. The resection of metastases from other gastrointestinal malignancies, such as stomach and pancreas, has been disappointing because of the aggressive nature of these tumors by the time they become metastatic.[47,48]

The performance of liver resections for metastatic disease from a breast cancer is controversial. Liver metastases from gastrointestinal tumors can be considered regional spread, but for the metastases to go from the breast to the liver requires release of the tumor cells into the systemic circulation. Thus, the concept that the liver could be the only site of spread is harder to prove, and as a result, curative intent is more difficult to achieve. Most of the literature about hepatic resections for breast cancer metastases has come from France. In a recent publication one hospital retrospectively reviewed their experience in 108 patients from the time of 1984 to 2004. Twenty-three (21%) of the patients were found to be unresectable at laparotomy because of intra-abdominal metastases or hepatic lesions that were technically not resectable. Of the 85 patients who had a liver resection, 38% had a solitary metastasis, 32% had two or three lesions, and 31% had more than three lesions. The metastases were small with an average size of 2.8 cm. The median follow-up of the patients was 38 months, with a median survival of 32 months. Only 18 patients were alive after 5 years. A multivariate analysis of factors showed only response to chemotherapy, the absence of extrahepatic metastases, and a clear margin at resection correlated with survival.[49]

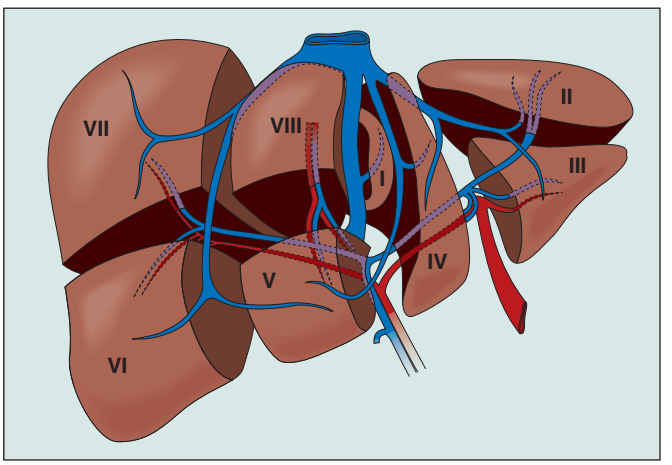

Figure 59-4 • Couinaud's eight hepatic segments. (From Iwalsuki S, Sheahan DG, Starzl TE: The changing face of hepatic resection. Curr Probl Surg 1989;25:281.)

Another Parisian team reported their experience from 1988 to 1997 with 49 liver resections for metastatic breast cancer. They reported no mortality and a morbidity of 11.5%. The 1-, 2-, and 3-year survival rates were 86%, 79%, and 65%, respectively. Recurrence in the remaining liver was seen in 49% of the patients at 3 years after resection. Recurrent disease anywhere in the body was seen in 63.8% of patients at 3 years after the resection. The only factor that correlated with survival was the disease-free interval between diagnosis of the primary breast cancer and the appearance of the liver metastases, with a 3-year survival of 45% if the liver metastases appear in less than 4 years after the primary breast cancer versus a 3-year survival of 82% if the breast cancer was more than 4 years from the appearance of the liver metastases.[50]

Another study from Paris reported on a smaller number of resections of solitary hepatic metastases from breast cancer.[51] Of the 32 patients with isolated liver metastases, 27 were found to have actual metastatic disease, whereas 5 had benign disease. Six of the 27 had diffuse disease that was not amenable to resection, whereas of the 21 who underwent hepatic resection, the average survival time was 26 months. For both of these studies there is no way of judging the usefulness of hepatic resection versus chemotherapy for these patients. It is interesting to note that the more recent study has a superior

survival time. This could signify several factors, including better drugs and improved selection. That the disease-free survival (DFS) is still quite low, however, emphasizes that even with strict patient selection, the chance of cure with a liver resection is quite limited, but real. Thus patients who have metastatic disease to the liver due to breast cancer need to be screened carefully before they are offered resection as a therapeutic option. Issues such as other sites of metastatic disease, response to chemotherapy, and disease-free interval between breast cancer and liver metastases all must be considered before hepatic resection.

Gastrointestinal neuroendocrine tumors frequently metastasize to the liver but their growth is often slow, and patient survival can be prolonged even without surgical intervention. Both the rarity of these tumors and their prolonged course make them poor candidates for prospective trials. Thus, the role of hepatic resection for metastatic neuroendocrine tumors can only be evaluated in a retrospective manner. At the Mayo Clinic, over a 20-year period from 1970 to 1990, only 37 patients with hepatic metastases from a neuroendocrine tumor had a resection (17 curative resections and 20 palliative resections).[52] Eleven of the 17 patients with curative resections were alive 1 to 92 months after surgery (median 19 months) without evidence of disease. Of the 20 patients who underwent palliative resection, 1 died in the postoperative period, 8 died of disease 9 to 76 months after resection, and 19 patients had some relief of symptoms. The authors concluded that resection is reasonable in cases in which the bulk of tumor can be removed and the patients are symptomatic. A second report from the Mayo Clinic reviewed their hepatic resections for neuroendocrine tumors from 1984 to 1992, with a total of 74 cases.[53] Because this is a report from the same institution and there is some overlap of the time period, clearly many more resections were done in the later years (1990–1992) than in the two decades before. The study included patients whose primary tumors were either completely resected or potentially completely resectable. Patients with carcinoid syndrome were injected with subcutaneous somatostatin preoperatively. Most patients[54] had nonanatomic resections, although 36 had a lobectomy or greater. The mortality rate was 2.7%, and the morbidity was 24.3%. Overall survival at 4 years was 73%, with a mean follow-up of 2.2 years. All of the 12 patients who died had tumor progression. There was no significant survival difference among those patients who had curative resections (that is, removal of all gross disease) versus those who had palliative resections. Symptom relief was seen in 90% of patients. The authors concluded that resection should precede hepatic arterial occlusion and systemic chemotherapy, because it provides an excellent response rate and good survival. Other studies with considerably fewer patients also support this conclusion.[55–57]

A review of the literature in 2002 reported on 227 patients with hepatic surgery for metastatic malignancies. The operative mortality for the 212 patients with carcinoid tumors was 2.3% and morbidity was 71%. The overall 5-year survival was 71%, and when looking at only the metastatic islet cell tumors, the survival was even higher at 82%. Symptomatic relief from carcinoid syndrome was 86% with a duration of 4 to 120 months. Some discussion of ablative techniques was offered, but only with very preliminary results. The analysis of these sorts of data suggest that for selected patients liver resection is safe, appropriate, and can result in long-term survival and relief from endocrinopathy symptoms. Guidelines for resection include the preoperative assessment that the primary and metastatic disease is completely resectable (Box 59-1).[59]

The other noncolorectal tumors metastatic to the liver that have been resected enough to have reported studies are the sarcomas. The largest retrospective review comes from M.D. Anderson Cancer Center with 66 patients having liver surgery for metastatic sarcoma. The mean size of the lesions was 3.9 cm and mean number of lesions was 3. The majority of patients had a gastrointestinal stromal tumor (GIST) (36 patients), 18 had a leiomyosarcoma, and the rest had various other sarcomas. Thirty-five patients had resection, 13 patients had radiofrequency ablation (RFA), and 18 patients had the combination of resection and RFA. The operative mortality and morbidity were 4.5% and 15.2% respectively. The recurrence rates were high with 85% of patients, with RFA recurring, 89% with the combination of resection and RFA recurring, and 57% of patients with resection only recurring (statistically better for this group). The 5-year DFS and overall survival were 16% and 27%, respectively. The article discussed the issue of the GIST tumors and the targeted therapy with Gleevec (imatinib mesylate). The authors felt that resection was still recommended for the GIST tumors, because the rate of complete response with imatinib mesylate was only around 5%, and the bulk of the patients progressed after 2 years on treatment. The conclusions of the report were that although recurrence is high, hepatic resection in selected patients is indicated and will lead to longer survival.[60]

The group at Memorial Sloan-Kettering (MSKCC) reviewed their experience with hepatic resections for sarcomas in the period from 1982 to 2000. There were 331 patients with liver metastases from a variety of primary sarcomas, 56 of whom had a hepatic resection. Thirty-four of the 56 patients had a GIST. Ten of the 56 patients have actually survived for 5 years, but only 2 are disease free. The disease-specific survival rate for 3 and 5 years was 50% and 30%, respectively. The patients with GIST had the same survival as those with other types of sarcoma. The time interval (less than or greater than 2 years) between the appearance of the primary sarcoma and that of the liver metastases had a significant influence on survival and was the only independent prognostic variable in a multivariate analysis.[61]

An analysis of hepatic resection for leiomyosarcomas from Germany reported a 40-month median survival in patients who had all tumor removed with negative margins. The conclusions from this study, similar to the other reports, were that hepatic resection for leiomyosarcomas could be done safely and in selected cases could prolong survival. Most of the other reports in the literature about resection of hepatic metastases from sarcomas are anecdotal, with far fewer patients in each study.[62,63]

The use of hepatic resection for metastases from melanoma is moderately rare as seen in a report from two major melanoma centers, where 1750 patients with hepatic metastases from melanoma were identified and only 34 of them had a surgical exploration with the intent to resect the tumor from the liver. Of the 34 patients explored, 24 went on to hepatic resection and 18 of them actually had a resection with curative intent. The median DFS and overall survival in the 24 patients with resection were 12 months and 28 months, respectively. When this was compared with the 6-month overall median survival in the 899 patients with hepatic metastases treated

Box 59-1. SURGICAL GUIDELINES FOR HEPATIC RESECTION

The existence of extrahepatic intra-abdominal metastases should be excluded before attempting a hepatic resection. Because the periportal lymph nodes are the most common site for intra-abdominal extrahepatic metastases, biopsy samples from them should be taken and sent for frozen section. If extrahepatic disease is present the hepatic resection should not be carried out.

The extent of a hepatic resection can span from one small nodule to a trisegmentectomy by which 75% of the liver is removed. The assessment of patients for trisegmentectomy is very difficult, because no tests are currently available to delineate accurately which patients can survive with a 75% loss of liver mass. In general, however, if a patient has cirrhosis, an extensive resection is discouraged. Debilitated (poor performance status) patients are not good candidates for major hepatic resection. Age alone should not preclude a patient's eligibility for hepatic resection.

nonoperatively, it was significantly better. The two major contributors to improved survival seemed to be longer disease-free interval between the primary melanoma and the development of hepatic metastases, and limited hepatic disease that could be completely removed. For the select patients who would fit these criteria—and obviously there are not many—they seemed to benefit from hepatic resection.[64]

Unlike these other primary tumors, the data on the resection of colorectal metastases to the liver has been advancing exponentially over the last 30 years. In the United States, there are more than 50,000 patients each year with liver metastases from CRC. The rate of resection of these metastases has been increasing because of the expanding patient eligibility criteria. In the last decade there have been several retrospective reviews of resection of hepatic metastases from colorectal primaries—some with more than 1000 patients—that have added to the knowledge of which patients will benefit from resection.[54,65–69] In the two largest series, the 5-year survival for patients with one to three metastases who had a resection was 30% or greater.[65,66] Because of the strong feeling over the last three decades that resection was the optimal treatment for patients with one to three metastases, no randomized study of resection versus any other treatment has been performed. Two early studies compared the survival of matched historical control patients who underwent resection with those who had solitary hepatic lesions but did not undergo surgery.[70,71] In both studies, not 1 of the 120 patients without resection survived for more than 3 years, whereas 30% of the resected patients survived for 5 years, underscoring the rationale for resection of solitary lesions.

The retrospective series from MSKCC reviewed their experience with 1001 liver resections in patients with colorectal metastases from the years 1985 to 1998.[65] Because the study was reported in early 1999, there were many patients who did not have a 5-year follow-up; in fact; the median follow-up of survivors was 32 months, which might not be long enough to tell us which patients would survive to 5 years. The median number of liver tumors was two, with 517 patients having solitary lesions and 330 having two or three lesions (Table 59-2). The operative mortality was 2.8%. The 3-, 4-, and 5-year survival rates were 89%, 57%, and 37%, respectively; however, only 24.6% of patients resected before 1994 are 5-year survivors. The number of tumors removed (one or greater than one), the size of the tumors removed (greater or less than 5 cm), the preoperative CEA level (greater or less than 200 ng/mL), the extent of resection (less than or greater than a lobectomy), the resection margin in the hepatic specimen (negative or positive), and the presence of extrahepatic disease all were highly significant univariate and multivariate predictors of postsurgical survival. From these data, a clinical risk score was devised using five clinical criteria: the nodal status of the primary CRC, the disease-free interval from the primary CRC to the development of liver metastases, the number of hepatic tumors, the prehepatic resection CEA level, and the size of the hepatic tumors. Each criterion was given 1 point if the inferior condition existed, and then the points were added to give the score. The 5-year actuarial survival for a clinical risk score of zero was 60% as compared with a 14% survival for a score of 5. This gives surgeons a good insight into the prognostic expectations, but the score was not really intended for exclusion of patients from resection.

Another large series was a multi-institutional report from France reviewing 1568 patients who underwent resection of liver metastases from CRC (Table 59-3).[66,72] Like the previous report, this study also looked at the effect of numerous prognostic indicators on overall survival after liver resection and then combined seven indicators into a prognostic scoring system. In this study, the 5-year survival among patients who had a resection of four or more lesions was 14% as compared with 30% for three or fewer nodules ($P = 0.001$). Both large studies, together with others, emphasize that the resection of more than four hepatic lesions results in significantly fewer cures, whereas for patients with one to three metastases, agreement exists that resection is worthwhile and can offer at least a 30% 5-year survival.[65–70,72–76]

The French series found that one of the most significant prognostic variables was the stage of the primary lesion. For patients with CRC and negative lymph nodes (stage II), the 5-year survival after hepatic resection was 35% as compared with 26% for patients with mesenteric lymph node involvement ($P < 0.001$). Other studies addressing the issue of stage are listed in Table 59-4.[73,76–80] In the French study, preoperative serum carcinoembryonic antigen (CEA) was also significant; patients with a CEA value of less than 5 had a 2-year survival of 70%, as compared with a 56% 2-year survival for patients whose CEA was above 30. For patients with tumor nodules smaller than 5 cm, survival was 30% as opposed to 26% for larger nodules ($P = 0.002$). The age of the patient was not found to be significant in this study or others.[81] The time between the primary tumor and the development of liver metastases in this and other studies was significant for prognosis if the time periods were divided to include at least the first year with the synchronous lesions (Table 59-5).[76–80]

Data from Nordlinger B, Guigiet M, Vallant JC, et al: Surgical resection of colorectal carcinoma metastases to the liver. Cancer 1996;77:1254–1262.

There have been conflicting reports about the importance of the margin of resection when removing hepatic metastases. Although the cutoff used in the French study was different from that used in the Memorial study, the margin of normal hepatic tissue around the resected metastases was significant. For those patients with a margin greater than 1 cm, 32% of patients survived for 5 years, as opposed to a 16% survival for those with a margin less than 1 cm ($P = 0.006$). A report from Germany in 1991, however, showed no significant difference in survival among over 170 patients relative to their margins of resection.[80] This study assigned the margins to three groups: 1–4 mm, 5–9 mm, and greater than 10 mm. More recent studies support this study by showing that if there is no margin of clearance between the tumor and normal liver parenchyma, patients do worse, but whenever there is a margin, the difference between 1 mm, 10 mm, or greater is not significant (Table 59-6).[40,41] These data are understandable from a pathologic standpoint, because these tumors tend to be firm nodules with pushing borders and even a small margin would remove all of the tumor, whereas a positive margin would leave cells behind. This would not be true for primary hepatocellular carcinomas (HCCs), as they can have more diffuse, infiltrative borders.

The French authors created a scoring system by using these seven variables, giving one point for each bad variable and two points for a CEA value over 30.[66] A 2-year survival of 79% was calculated for patients with a score of 0 to 2 points, 60% if they had scores of 3 to 4 points, and 43% if they scored 5 to 7 points.[66] These prognostic scoring systems from the French study and the Memorial study are valuable tools to estimate patients' survival after a resection. For patients with poorer prognoses, other therapies might be added to surgery to try to improve their chances.[66,72]

Although recent studies have suggested that resection of four or more lesions can result in 5-year survivals equivalent to those after resection of one to three lesions, these reports must be examined with caution. A report of 98 patients with hepatic resection of four or more colorectal metastases reported an actuarial survival of 33%. Yet the median follow-up was only 33 months, which is too short for patients with liver resections. The DFS for these patients was 12 months, and 83% of the patients had recurrence. Of this whole group there were only seven actual 5-year survivors, and all of them have recurrent disease. One important point from this article is that the worst survival was seen in patients whose disease was progressing while receiving neoadjuvant therapy before the liver resection.[82]

The Liver Met Survey is an international Internet-based registry that has entered 2122 patients. The 5- and 10-year survivals are 42% and 26%. The 5-year survivals for three or fewer nodules and more than three nodules were 48% and 24% ($P = 0.0001$). Another variable that affected survival concerned whether the tumor was unilateral or bilateral. In this review, preoperative chemotherapy did not benefit patients with solitary metastases (5-year survival of 45% vs. 58%), whereas for patients with more than five metastases, 5-year survivals were 22% and 12% for patients with and without previous chemotherapy.[83]

A group from Paris reporting on surgery for patients who had been downstaged by chemotherapy also found that if the tumors' pathologic response to chemotherapy was less than complete necrosis, the survival after resection was significantly decreased ($P = 0.002$).[84] This group of patients with more than four lesions and progressing disease should probably not be candidates for surgical resection. The use of the PET scan may help increase the survival of patients with liver resections from colorectal primaries because of improved selection of patients. A study of 100 patients who were shown to have disease confined to their liver by PET scan reported a 5-year survival of 58%. PET scan is believed to detect unsuspected tumors in 25% of patients who would have otherwise been considered to have only resectable hepatic metastases. This was not a randomized study, so it is difficult to determine if the PET scan alone was responsible for this improved survival over the usual 30% 5-year survival. However, it may be prudent at this time to perform a PET scan before taking patients to liver resection, so that those who have incurable disease will be spared major surgery.[85]

The issue of trying to downstage patients with unresectable liver metastases and then proceed to liver resection is becoming more relevant as newer and more effective chemotherapy agents are being introduced. A report from Paris followed 1104 patients with liver metastases from colorectal primaries considered to be unresectable. Of these patients, 138 (13%) were downstaged sufficiently to go on to surgery. Eighty percent of these patient developed tumor recurrence, 72% of which involved the liver. DFS was 17% at 5 years. These numbers reflect that the overwhelming majority of patients will not be downstaged by chemotherapy sufficiently for resection, and even those that are do not fare particularly well.[84]

Several studies have addressed the issue of extrahepatic intra-abdominal metastases at the time of hepatic resection. In most instances, surgeons do not proceed with liver resection in the presence

of extrahepatic metastases. In the series from New York, 88 patients with extrahepatic disease were included.[19] More than half of these patients had direct extension into other organs such as the diaphragm. Only 10 patients had positive portal nodal disease. Looking at all 88 patients with extrahepatic disease, the 5-year actuarial survival was 18%. The breakdown between those with discontinuous disease or direct extension was not made. In the Mayo Clinic report on hepatic resections in patients with extrahepatic disease, none of the 22 patients survived for 5 years, and only 1 survived for 3 years.[86] In the Hepatic Registry, of the 61 patients with extrahepatic involvement undergoing hepatic resection, none had a 5-year DFS.[74] These data support the view that hepatic resection in the presence of noncontiguous extrahepatic intra-abdominal disease, with the exception of a local recurrence, is rarely curative and, in general, is inadvisable.

For extrahepatic disease not in the abdomen, the usefulness of resection could be different for disease in the lungs, especially solitary lesions in the lung. A recent study from the Mayo Clinic reviewed their experience with resection of both hepatic and pulmonary metastases from colorectal primaries. There were 58 patients, with no operative mortalities and a 5-year survival rate of 30%. These authors believed that the resection of both lung and liver of selected cases was justified.[87]

Relapse rates after liver resections are described in Table 59-7. In the larger studies it seems that approximately 40% of patients who have hepatic resections will have recurrent disease in the liver as the first sign of the relapse. Of the 69 patients who had relapse in the Milan study, 28 (41%) had relapse in the liver only, 19 (28%) had only extra-abdominal relapse, 9 (13%) had intra-abdominal extrahepatic relapse, and 13 (19%) had relapse in both the liver and at an extrahepatic site.[49] Although extrahepatic failure is of concern, the liver remains the main site of relapse, appearing in more than 60% of patients.

Because of the increased use of hepatic resection for metastatic liver disease, the incidence of repeat hepatic resection has also increased. Approximately 10% of patients who have had a hepatic resection can have a repeat resection (Table 59-8). A study from Paris of 116 patients who underwent repeat hepatic resection reported a low operative mortality of 0.9% and a 3-year survival of 33%.[54] Of the patients who underwent repeat hepatic resection, 55% had recurrence in their liver after this operation. There were 170 patients in a registry report who had repeat hepatic resections with a 5-year survival of 26%, which was comparable to the 5-year survival for the original hepatic resection.[88] A recent study from MSKCC reviewed 126 second liver resections for recurrent colorectal metastases; the 5-year actuarial survival was 34%, with 19 actual 5-year survivors. The operative mortality was 1.6%, and morbidity was 28%.[89] A study of recurrence among these patients revealed a liver recurrence in 67% of the patients. Repeat hepatic resection, when feasible, can be done safely, and the outcome is comparable to that for the original hepatic resection.[90] Thus, if patients have isolated liver metastases (preferably solitary lesions) after hepatic resection, they should be candidates for repeat resection.

The place for ablation of liver metastases whether by radiofrequency (RF) heating or cryotherapy freezing has not yet been delineated adequately. Because extensive reporting on resection has indicated an expected 30% 5-year survival for patients with one to three hepatic metastases from colorectal primaries, the use of ablation in this setting cannot be warranted until a randomized study has shown that the two therapies are equivalent. A retrospective study from M.D. Anderson Cancer Center analyzed a series of 418 patients with liver-only metastases from colorectal primaries, of whom 57 had RF only. The overall recurrence rate and the liver recurrence rate were both significantly higher for the RF group over the resection-only group, with a liver recurrence of four times greater in the RF group. The overall survival and DFS was also significantly better in the resection group. A multivariate analysis continued to show RF as a significant factor in poor prognoses. Interestingly, 31 patients with solitary tumors were treated with RF (we are not told why this happened), and these patients had significantly worse survival than the patients with resection of solitary lesions ($P = 0.025$). The group of patients who had RF alone when compared with those 70 patients with chemotherapy alone had a significantly improved survival.[91] A subsequent report from the same group of investigators compared RF to resection for patients with solitary colorectal metastases. The hepatic recurrence rate was much higher in the RF group than in the

Table 59-8 Survival after Repeat Hepatic Resections for Colorectal Metastases

resection group, 37% as compared with 5%, respectively. The 5-year recurrence-free survival and overall survival were 40% and 50% as compared with 0% and 0% for resection versus RF, respectively. The conclusions are obvious: resection is the preferred method for treatment of solitary metastases whenever possible.[92]

Synchronous Liver Metastases

The question of whether liver metastases can safely be resected at the time of resection of the primary colorectal carcinoma is still uncertain. Small metastases seen at the time of laparotomy for the primary lesion can easily be resected. When patients are evaluated for their primary and are found to have a large burden of metastatic disease, a question may be whether a simultaneous resection of the primary tumor and the metastases should be done, or whether preoperative chemotherapy should be offered. Bolton and Fuhrman reported a 12% operative mortality with simultaneous surgeries that increased to 24% if the surgery included a major liver resection.[93] Nordlinger reported a 7% mortality for simultaneous resections compared with 2% for staged resections ($P = 0.01$).[94] Tanaka and coworkers, Martin and colleagues, and Weber and associates, on the other hand, reported that operative mortality and morbidity were comparable whether staged or simultaneous procedures were done.[95–97] It is the practice in many institutions to do a simultaneous resection with right colon primaries or when single synchronous metastases are found in the liver, and staged resections for rectal primaries or for patients with multiple liver metastases.[98] Some advocate systemic chemotherapy first, followed by resection of liver first, and then resection of the colon[99] or simultaneous resection.[100]

Adjuvant Therapy after Liver Resection

Despite the high curative resection rate of hepatic resections, the recurrence of metastases is around 70%, with 50% recurring in the liver. The use of hepatic artery infusion (HAI) of chemotherapy after liver resection was studied in a small prospective randomized fashion at the City of Hope Medical Center.[101,102] The patients with solitary metastases all had resection of their tumors, and half received postoperative continuous HAI of fluorodeoxyuridine (FUDR). For the six patients who had resection only, their median time to failure was 8.7 months, and three of the six metastases recurred in the liver. For the five patients with resection plus pump, none had recurrence in the liver, and their median time to failure was 30.7 months. There was no difference in median survival between the two groups.

At MSKCC, 156 patients were randomized after liver resection to either HAI with systemic chemotherapy (HAI + SYS) or systemic chemotherapy alone (SYS). Chemotherapy was administered for 6 months. The endpoint of this study was 2-year survival. HAI therapy used was FUDR and dexamethasone (Dex), and the systemic therapy was 5-fluorouracil (5-FU) and leucovorin (LV) or continuous infusion of 5-FU. Patients were stratified by type of previous chemotherapy or no chemotherapy and the number of liver metastases (one, two to four, more than four). Two-year survival was increased in the group receiving HAI + SYS (86%) versus 72% for SYS ($P = 0.03$).[103A] Median survival is presently 68.4 months for the HAI + SYS group and 58.8 months for the group receiving SYS alone. With a median 10-year follow-up, the 10-year survivals are 41% and 27%, respectively (Fig. 59-5).[104] Hepatic DFS is clearly better for the HAI + SYS group, with a median survival not reached, as compared with 32.5 months with SYS alone ($P = 0.003$; Fig. 59-6). Overall, DFS is also increased significantly (31.3 and 17.2 months for the HAI + SYS vs. SYS alone [$P = 0.02$]; Fig. 59-7). Toxicity was increased in the combined group, with increased diarrhea and increased liver function test abnormalities. A total bilirubin greater than 3 mg/dL occurred in 18% of patients receiving HAI and in 2% of the SYS group.[103]

The Eastern Cooperative Group (ECOG) and the Southwestern Oncology Group (SWOG) conducted a randomized study of hepatic resection alone versus resection followed by 4 cycles of HAI-FUDR

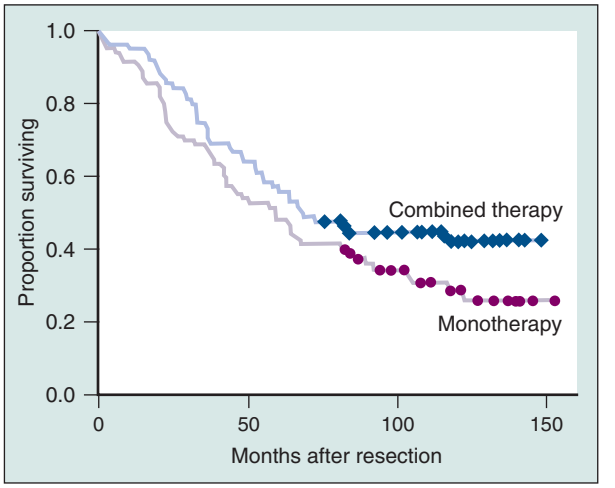

Figure 59-5 • Survival curve. Combined modality treatment: HAI FUDR + systemic 5-FU/LV. Monotherapy: systemic 5-FU/LV.[104]

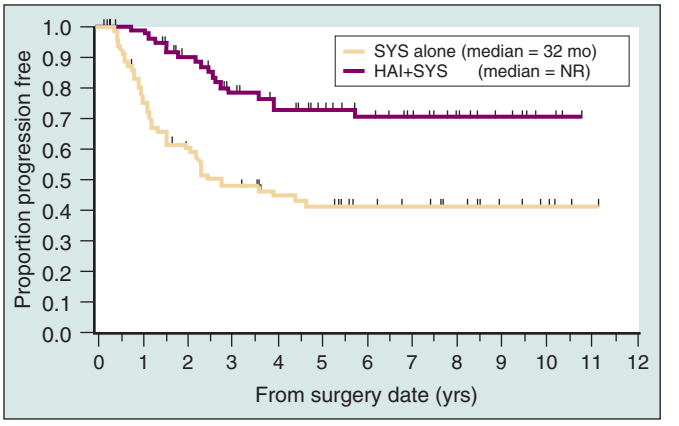

Figure 59-6 • Hepatic progression-free survival. HAI (FUDR/dex) + SYS (5-FU/LV) versus SYS (5-FU/LV) alone. $P < 0.0001$.[104]

and 12 cycles of systemic infusion of 5-FU. Only patients with three or fewer metastases were enrolled in the study. The study was powered to answer the question of whether HAI would increase DFS. Of the 109 patients randomized, only 75 are actually in the study, because several patients were excluded because of extrahepatic disease, unresectable disease, or no tumor. Four-year liver recurrence-free survival was 67% in the chemotherapy group and 43% in the control group ($P = 0.03$). Median survival was 63.7 months for the chemotherapy group and 49% for the control group.[105] The endpoint was obtained with a 4-year DFS of 46% with HAI + SYS and 25% for the control group ($P = 0.035$).

A German cooperative group enrolled patients from 26 different centers and entered 226 patients into a study of resection followed by adjuvant hepatic arterial therapy with 5-FU and LV via a port as compared with a control group receiving no chemotherapy after resection. Although 113 were entered into the hepatic arterial group, only 87 were treated. Only 64% had chemotherapy data available, and only 30% completed treatment. At an 18-month interim analysis, the relapse rate was 33% in the group receiving adjuvant therapy and 36% in the group treated with resection alone. If one looks only at those who were treated, the median survival was 44.8 months from the treated group versus 39.7 months in the control group.[106]

A randomized study from Greece used intraoperative randomization to regional mitomycin C, 5-FU/LV with interleukin-2 via a hepatic arterial catheter with the same drugs via a systemic route versus systemic therapy alone. The 2-year survivals in 122 patients were 80% and 71%, and 5-year survivals were 73% and 60%, in the regional-plus-systemic versus systemic-alone groups, respectively ($P = 0.004$).[107] Five-year hepatic-free recurrence was also significantly increased in the regional-plus-systemic group at 82% versus 49% in the systemic-alone group ($P < 0.001$). Table 59-9 summarizes survival data of the randomized studies and the disease-free survival from these studies.

Tono and coworkers[108] randomized 19 patients to continuous infusion of 5-FU, 500 mg per day for 4 days via HAI for 6 weeks. Although this is a small study, there was an increase in 3-year DFS, 66.7% for the regional group and 20% for the control group ($P = 0.045$). The 5-year survivals were 77.8% for the regional group versus 50% for the control group.

In a nonrandomized study comparing two groups of patients in Japan,[109] the survival was increased with the use of adjuvant regional therapy after hepatectomy for colon cancer. The 5-year survivals were 23% using surgery alone, and 57% when adjuvant chemotherapy with 5-FU, doxorubicin, and mitomycin C were given after surgery. In another nonrandomized study from Japan,[110] 58 patients who had radical resection of metastatic colorectal carcinoma could select whether they wanted HAI + systemic, or systemic alone after surgery. The 5-year survival was significantly increased for the HAI + systemic group at 59%, as compared with 27% for the systemic-alone group ($P < 0.001$), as was hepatic recurrence at 7% versus 57% ($P < 0.001$). In another small study, 4-year survival was 100% as compared with 47% for the HAI and control groups, respectively ($P = 0.05$).[111]

Studies are now testing the new systemic chemotherapeutic agents with HAI as adjuvant therapy after liver resection. A phase I study at MSKCC with systemic CPT-11 (irinotecan) and HAI FUDR/Dex had a 2-year survival of 89% and a 5-year survival of 58%.[112] Another trial using escalating systemic doses of oxaliplatin (Oxali)/5-FU/LV and HAI therapy,[113] with a minimum follow-up time of 26.9 months, had a 2-year survival of 98%. At the Mayo Clinic, FUDR + Dex has been added to systemic Oxali and capecitabine. Presently, the 2-year survival is 86%.[114]

Ongoing studies to address the usefulness of adjuvant therapy after liver resection include the National Surgical Adjuvant Breast and Bowel Project study of HAI + systemic Oxali + capecitabine versus systemic Oxali + capecitabine alone. A trial at MSKCC is

addressing the question of the safety of bevacizumab (Bev) given with HAI + systemic therapy after liver resection in a randomized study of HAI and systemic therapy with or without bevacizumab. Few studies have evaluated the utility of systemic therapy after liver resection. In the ENG study (EORTC/NCIC CTG/GIVIO), 128 patients were randomized to receive 5-FU and LV chemotherapy for 8 weeks versus no further therapy (control) after liver or lung resection. There were no significant differences in DFS or survival between the two groups. The 4-year survivals were 57% and 47% for the treated and control groups.[115] A European intergroup study (FFCD) randomized 173 patients to systemic 5-FU/LV versus no further treatment. The 5-FU and LV were given by the bolus method on a monthly schedule. Two-year DFS was 50.4% for those receiving chemotherapy and 38.1% for the control group ($P = 0.058$). Negative prognostic factors were synchronous disease, multiple metastases, stage III tumor, preoperative hypertension, postoperative complications, and an elevated preoperative CEA. Two- and five-year survivals were 81% and 51% for the chemotherapy group and 82% and 41% for the control group. A trial combining these two studies to increase power demonstrated a DFS of 27.9 versus 18.8 months ($P = 0.058$) and overall survival of 62.2 versus 47.3 months ($P = 0.095$) for the chemotherapy versus surgery-alone groups, respectively. Patient characteristics in this study included one metastasis in 68% of patients, and more than 1 year disease-free interval in 57% of patients. This clearly can affect results, as seen in their own analysis, where DFS was 27 months for one metastasis and 16.8 months for two or more metastases ($P = 0.036$), and survivals were 64.5 and 40 months for one or more than two metastases, respectively. In the MSKCC adjuvant therapy of HAI + systemic 5-FU/LV after liver resection study, the patients had worse baseline characteristics, with 36% of patients having only one metastasis, whereas 19% had more than four metastases, and only 20% had a disease-free interval longer than 1 year.[103]

The efficacy of systemic CPT-11 in posthepatic resection was addressed in 29 patients of whom 62% had only one metastasis, 79% had a disease-free interval longer than 1 year, and 62% had a surgical margin larger than 1 cm. Their median DFS was 45 months, and 2-year survival was 85%.

Adjuvant therapy following resection has also been attempted in HCC. In patients with HCC, a randomized study compared hepatic arterial injection of epirubicin and oral 1-hexycarbamoyl-5-fluorouracil (HCFU) to no further treatment in 57 patients after liver resection of HCC.[116] There was no significant difference between the two groups, and the authors believed that the chemotherapeutic agents chosen might not have been appropriate. Postoperative adjuvant therapy could compromise survival if the treatment is not effective, because it suppresses host immunity. In a small randomized study of intravenous epirubicin with hepatic arterial iodized oil and cisplatin compared to no further treatment after liver resection for HCC, the DFS was shorter in the treated group. There was an increase in extrahepatic metastases in the treated group.[117]

Factors that inhibit hepatic carcinogenesis might be more useful as adjuvant therapies for HCC. Retinoic acid inhibits chemically induced hepatocarcinogenesis in rats, spontaneous HCC in mice, and the production of α-fetoprotein in human hepatoma cell lines. In a study by the Hepatoma Prevention Study Group, 89 patients were randomized to polyphenolic acid (acyclic retinoid) or placebo for 12 months after liver resection. The polyphenolic group had a significant reduction in recurrent or new hepatomas ($P = 0.04$). The drug also improved overall survival, but not significantly.[118]

SYSTEMIC CHEMOTHERAPY

Responses of liver metastases to systemic chemotherapy are variable but usually reflect the response of the primary tumor. Most studies of systemic therapy do not differentiate patients who have only liver metastases, making it difficult to draw conclusions about the usefulness of systemic chemotherapy to treat liver metastases. In some cases, however, the response rates of liver metastases are well documented.

In breast cancer, liver metastases represent a poor prognostic indicator, with median survival of 10 months in some series.[119] Visceral metastases, including liver metastases, have been reported to have fewer estrogen-positive receptors. Insulin-like growth factors are present in the liver and the lung and could be important to the growth and motility factors for breast cancer and lung cancer.[120] In looking at prognostic factors that predict response, patients with liver metastases were the ones who tended to respond the least.[121] Carter's[122] review of single agents (5-FU or cyclophosphamide) demonstrated a 20% response in liver metastases vs. 32% and 27% in soft-tissue and osseous metastases, respectively. The combination of halotestin, prednisone, and 5-FU produced objective responses in 26 of 52 patients (50%) with liver metastases from breast carcinoma.[84] Although combination chemotherapy has substantially improved the response rates obtained in treating breast cancer, liver metastases still have a lower response rate than soft-tissue or pulmonary disease. In a Southwest Oncology Group study of 262 patients, 41 of 88 patients (47%) with liver metastases responded, as compared with 110 of 154 patients (71%) without liver involvement ($P = 0.001$).[123] There is a suggestion that taxoids might be more effective against liver metastases.[124]

For metastases from gastric carcinoma, one of the more commonly used regimens (5-FU, doxorubicin, and mitomycin C) produces a mean response of 35%, whereas for those with hepatic metastasis, the response rate was 28%.[125] The cumulative response for liver metastases was 34%, while the overall mean response rate was 36% for combination chemotherapy in the treatment of gastric carcinoma.[126]

For patients with CRC, the liver is the most common site of dissemination, with as many as 70% of patients with metastatic disease developing liver metastases.[127] Several new agents are now available, among which are irinotecan (CPT-11) and oxaliplatin (Oxali).[128,129] Randomized trials using CPT-11 with 5-FU/LV versus 5-FU/LV alone[130,131] produced an increase in response rate and survival. When CPT-11/5-FU/LV (IFL) was compared to Oxali + 5-FU/LV (FOLFOX), the response rate was increased from 35% to 45%, and the survival was increased from 15 to 19.5 months for the IFL and FOLFOX groups, respectively.[132] When 5-FU was changed to infusion FOLFIRI (CPT-11/5-FU/LV) it became more effective and produced results that are similar to FOLFOX.[133] In the last few years, targeted agents have become available: Bev, a monoclonal antibody to vascular endothelial growth factor and cetuximab (C225), an antibody to epidermal growth factor receptor. The addition of Bev to IFL[134] increased response rates and survival (35% to 45%, and 15.6 to 19.5 months, for IFL vs. Bev + IFL, respectively). For almost four decades, the 2-year survival for metastatic colorectal patients treated with 5-FU or 5-FU + LV was 25%; with these new agents, 2-year survival has moved up to 30% to 39%, with a marked improvement in overall survival from 12 to 20 months.

When does one start systemic chemotherapy for patients with metastatic disease to the liver from breast, gastric, or colon cancer? For patients with colon or gastric cancer who are asymptomatic and have a small volume of disease (<20% of the liver involved with tumor and not resectable), three studies suggest that earlier treatment increases survival and increases the time with good performance status.[135–137] If the patient has rapidly progressive disease or is symptomatic, chemotherapy should be initiated immediately. One should have a baseline CT scan and laboratory values before starting treatment. To assess response, scans should be repeated at 2- to 3-month intervals to evaluate whether the tumor is responding, and therapy should be continued.

Hepatic Arterial Chemotherapy

The rationale for hepatic arterial chemotherapy has an anatomic and pharmacologic basis (Table 59-10):

1. Liver metastases are perfused almost exclusively by the hepatic artery, whereas normal hepatocytes derive their blood supply both from the portal vein and minimally from the hepatic artery.[138]
2. Certain drugs are mostly extracted by the liver during the first pass through the arterial circulation. This results in high local concentrations of drug with minimal systemic toxicity. Ensminger and coworkers[139,140] demonstrated that 94% to 99% of FUDR is extracted by the liver during the first pass, compared with 19% to 55% of 5-FU. This makes FUDR an optimal drug for hepatic arterial chemotherapy. The pharmacologic advantages of various chemotherapeutic agents for HAI are summarized in Table 59-11. Newer drugs, such as CPT-11 and etoposide, do not show an advantage when given by HAI.[141]
3. Drugs with a steep dose-response curve will be more useful when given by the intrahepatic route, because a large dose can be given regionally.
4. Drugs with a high total-body clearance are more useful for hepatic infusion. If a drug is not cleared rapidly, recirculation through the systemic circulation diminishes the advantage of hepatic arterial delivery.[142]
5. The liver is often the first and only site of metastatic disease. The theory of the stepwise pattern of metastatic progression states that hematogenous spread occurs first via the portal vein to the liver, then from the liver to the lungs, and then to other organs.[143,144] Thus aggressive treatment of metastases confined to the liver (resection and/or hepatic infusion) could yield prolonged survival for some patients.

Table 59-10 Rationale for Hepatic Artery Infusion[152]

- Liver metastases are perfused by the hepatic artery. Normal liver is primarily supplied by the portal vein.
- Certain drugs have high hepatic extraction.
- The liver is often the first site of metastases; eliminating liver metastases would prevent extrahepatic disease.
- Many drugs have a steep dose-response curve.
- Drugs with a high total-body clearance are more effective.

Table 59-11 Drugs for Hepatic Arterial Infusion

Drug	Estimated Half-life (min)	Increase on Exposure by HAI
5-FU	10	5- to 10-fold
FUDR	<10	100- to 400-fold
BCNU	<5	6- to 7-fold
Mit C	<10	6- to 8-fold
Cisplatin	20–30	4- to 7-fold
Adriamycin (doxorubicin hydrochloride)	60	2-fold

BCNU, bischloroethyl nitrosourea or carmustine; 5-FU, fluorouracil; FUDR, 5-fluoro-2-deoxyuridine; HAI, hepatic arterial infusion; Mit C, mitomycin C.

Regional hepatic arterial therapy can be done by using either a hepatic arterial port or a percutaneously placed catheter connected to an external pump or to a totally implantable pump. Early studies with percutaneously placed hepatic artery catheters produced high response rates, but clotting of the catheters and the hepatic artery, as well as bleeding, led physicians to abandon this method (Table 59-12). The development of a totally implantable pump allowed long-term HAI with good patency of the catheter and the hepatic artery and a low incidence of infection. One study compared three groups relative to placement of the hepatic artery catheter:

1. Surgical placement of a hepatic artery catheter
2. Percutaneous placement of the hepatic artery catheter
3. An operative implantable reservoir connected to the hepatic artery catheter

The reported ability of each technique to administer chemotherapy for the three groups of patients was 31, 25, and 115 days, respectively.[145] Several trials using the implantable pump produced high response rates with good survivals (Table 59-13).

Randomized Studies

It is difficult to assess the impact of hepatic infusional therapy on tumor response and patient survival without a prospective

randomized study comparing it with systemic chemotherapy. In such studies, patients would have to be stratified for parameters known to influence tumor response rates and patient survivals, such as performance status, extent of liver involvement, and initial LDH level.

The influence of the extent of liver involvement on survival has been demonstrated by many investigators. The median survival for patients with less than 20% involvement was greater than 20 months, whereas survival was only 6 months for those with more than 60% involvement (Fig. 59-8).[146] The influence of certain laboratory parameters on tumor response and patient survival was evaluated at MSKCC, where the initial LDH level proved to be the most significant factor.[147] Patients whose initial LDH and CEA levels were normal had a median survival of 32 months as compared with only 8 months for those with abnormal values (Fig. 59-9).

In a randomized study at MSKCC, patients were stratified by percentage of liver involvement and baseline LDH. All patients underwent exploratory laparotomy for pump placement; patients with extrahepatic disease were excluded from entry. Both groups received a 14-day continuous infusion of FUDR, but the dose was lower in the systemic group than in the HAI group. In patients randomized to systemic therapy, crossover from systemic therapy to HAI was permitted. Of the 99 evaluable patients, partial responses were seen in 53% and 21% of the HAI and systemic groups, respectively ($P = 0.001$). Of the patients who crossed over from systemic to HAI therapy, 25% had a partial response after the crossover and 60% had a decrease in CEA levels. The median survivals for the HAI and systemic groups were 17 and 12 months, respectively ($P = 0.424$). The interpretation of survival is difficult, because 60% of the systemic

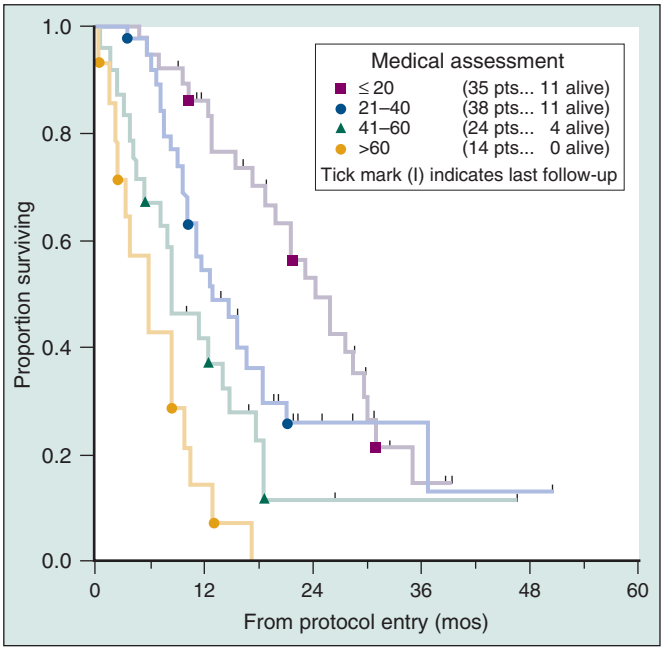

Figure 59-8 • Survival distributions by percentage of liver involvement (medical assessment). The median survival was 25 months for patients with less than 20% involvement vs. 6 months for patients with greater than 60% involvement. (From Kemeny N, Daly J, Oderman P, et al: Prognostic variables in patients with hepatic metastases from colorectal cancer: importance of medical assessment of liver involvement. Cancer 1989;63:742.)

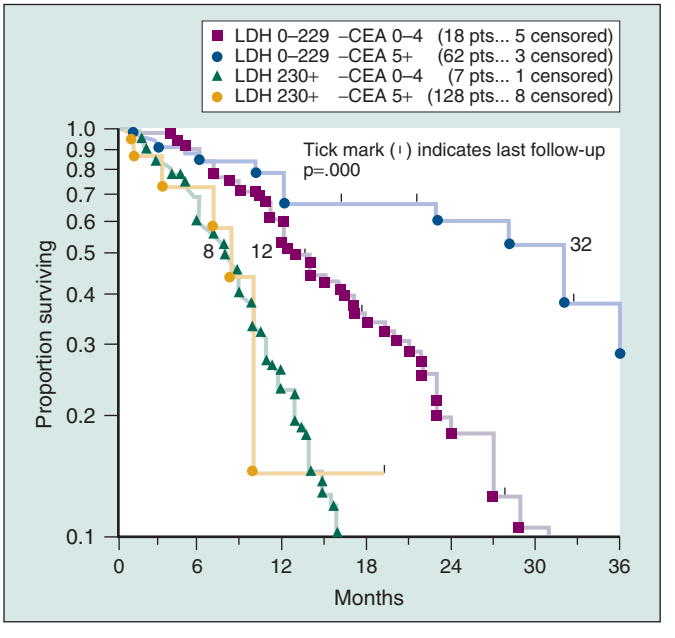

Figure 59-9 • Metastatic colorectal carcinoma (survival). Survival curves based on initial LDH and CEA levels. The median survival of patients with normal LDH and CEA levels at initiation of chemotherapy was 32 months, whereas it was 8 months if both values were abnormal ($P < 0.001$). (From Kemeny N, Braun DW: Prognostic factors in advanced colorectal carcinoma: the importance of lactic dehydrogenase, performance status, and white blood cell count. Am J Med 1983;74:786.)

patients crossed over. Those who did not cross over had a median survival of 8 months, as compared with 18 months for those who crossed over to HAI ($P = 0.04$). Randomized studies are outlined in Table 59-14.

A similar randomized study conducted by the Northern California Oncology Group also used FUDR infusion in both the HAI and systemic groups. A total of 114 patients were stratified by extent of liver involvement, baseline bilirubin values, and performance status. Of the 117 eligible patients, 42% responded to HAI and 10% to systemic therapy ($P < 0.001$). The median times to progression were 401 and 201 days for the HAI and systemic groups, respectively ($P = 0.009$), whereas median survivals were 503 days and 484 days, respectively. Although a crossover design was not built into the study, 43% of the patients on systemic therapy eventually received HAI, which could have obscured survival differences between the two groups.

A National Cancer Institute (NCI) study compared HAI with systemic infusion of FUDR.[148] In 64 patients, the response rates were 62% and 17% for the HAI and systemic groups, respectively ($P < 0.003$). Interpretation of survival data is difficult, because 34% of the HAI group never received chemotherapy, and 38% of the HAI group had positive portal lymph nodes. The 2-year survival was 47% in the HAI group compared with 13% in the systemic group ($P = 0.03$).

Another small study conducted by the Mayo Clinic (69 patients) compared HAI FUDR with systemic bolus 5-FU for 5 days.[123] Objective tumor response was observed in 48% and 21% of patients in the HAI and systemic groups, respectively ($P = 0.02$), and times to hepatic progression were 15.7 and 6 months, respectively ($P = 0.001$). Survival was similar in the two groups (12.6 and 10.5 months, respectively). Forty-eight percent of the HAI groups either were not adequately treated or had extrahepatic disease.

In a French trial of 163 patients randomized to HAI of FUDR versus systemic-bolus 5-FU, the patients were stratified by extent of liver involvement and baseline LDH levels.[118] The response rates were 49% and 14% in the HAI and systemic groups, respectively. Median times to hepatic progression were 15 and 6 months, and median survivals were 14 and 10 months for the HAI and systemic groups, respectively. The 2-year survival was 22% for HAI and 10% for the systemic group ($P < 0.02$).

In a similar study done in England, 100 patients were randomized to HAI FUDR or systemic 5-FU (which was given to symptomatic patients only).[149] Quality of life and survival were improved significantly for the HAI group. Median survival was 405 days versus 198 days for the HAI and systemic groups, respectively ($P = 0.03$).

The German Cooperative Group on Liver Metastases randomized 168 patients in a multicenter trial to one of three treatment groups: HAI of FUDR, HAI of 5-FU/LV, and systemic 5-FU/LV.[150] The median times to progression were 5.9, 9.2, and 6.6 months, and median survivals were 12.7, 18.7, and 17.6 months, respectively. Tumor response rates were 43.2%, 45%, and 19.7%, and development of extrahepatic disease was 40.5%, 12.5%, and 18.3%, respectively. It should be pointed out that only 70% of patients randomized to HAI of 5-FU/LV and 68.5% randomized to HAI of FUDR were actually treated.

The Medical Research Council/European Organization for the Research and Treatment of Cancer (MRC/EORTC) Colorectal Cancer Groups conducted a randomized trial of intravenous versus HAI administration of 5-FU/LV for 290 patients. Median and 2-year survival rates were 13.4 months and 23% in the intravenous arm as compared with 14.7 months and 20% in the HAI arm; however, 37% of patients allocated to the HAI arm did not receive the assigned treatment.[151]

The Cancer and Leukemia Group B (CALGB)[152] trial differs from the 135 other HAI studies in that it included the use of Dex in the HAI arm.[153] In patients, HAI FUDR + Dex + LV was compared to systemic-bolus 5-FU/LV. No crossover was allowed. The HAI group had a significant increase in survival of 24.4 months versus 20 months in the systemic group ($P = 0.0034$; Fig. 59-10). The time to hepatic progression was better in the HAI arm (9.8 months vs. 7.3 months in the systemic group; $P = 0.034$) but the time to extrahepatic progression was better in the systemic arm (14.8 months versus 7.7 months in the HAI group; $P < 0.029$). There was an improved quality of life in the HAI group, especially physical functioning, measured at 3 and 6 months ($P = 0.024$).

There are differences between the CALGB study[152] and the European studies, which could explain differences in outcomes. The CALGB study used pumps instead of ports, and HAI therapy included FUDR with Dex to decrease toxicity.[153] Survival was based on intent to treat in all three studies, and the actual number of patients treated was much lower in the European studies, 66% in the German study and 63% in the English study, whereas it was 86% in the CALGB study. The CALGB study did demonstrate that regional therapy alone can improve survival over systemic 5-FU/LV with a survival similar to that which is seen utilizing the new agents.

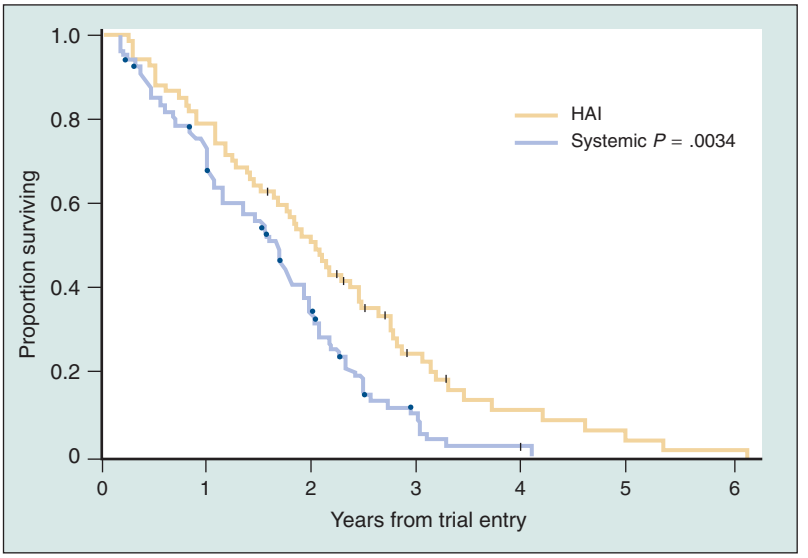

Figure 59-10 • Kaplan-Meier overall survival by treatment arm for all patients entered.

Randomized studies of HAI therapy versus the new therapies have not yet been done.

A meta-analysis combining the results of seven trials supports the use of HAI of FUDR in the treatment of nonresectable liver metastases from CRCs.[154] A significantly better local response rate of 41% was achieved with HAI of FUDR compared with a 14% response rate for systemic 5-FU. In addition, median survival time was increased in patients treated with HAI—16 months versus 13 months for those treated with 5-FU.

New Approaches to Decrease Hepatic Toxicity

The hepatic toxicity induced by HAI of FUDR could be related to portal triad inflammation, which could lead to ischemia of the bile ducts. Therefore, hepatic arterial administration of Dex might decrease biliary toxicity. In patients with established hepatobiliary toxicity from HAI, Dex promotes resolution of liver function abnormalities. In a randomized study of FUDR with Dex as compared to FUDR alone, there was a trend toward decreased bilirubin elevation in patients receiving FUDR + Dex compared with the group receiving FUDR alone (9% vs. 30%, respectively; $P = 0.07$).[153] Although the addition of Dex was not associated with a significant increase in the amount of FUDR that could be administered, the response rate was increased by 71% for the FUDR + Dex group as compared with 40% for the group receiving FUDR alone ($P = 0.03$). Survival was also improved: 23 months for patients receiving FUDR + Dex as compared with 15 months for those receiving FUDR alone ($P = 0.06$)

The use of circadian modification of HAI with FUDR is another method to decrease hepatic toxicity. In a nonrandomized study at the University of Minnesota, a comparison of constant (flat) infusion to circadian-modified hepatic arterial FUDR infusion was conducted.[155] The group with circadian modification received 68% of each daily dose between 3:00 PM and 9:00 PM. The patients with circadian modified infusion tolerated almost twice the daily dose of FUDR, with a decrease in hepatic toxicity compared with patients receiving flat infusions, but the study was not a prospective randomized study.

Another approach to decrease toxicity from HAI is to alternate drugs such as HAI FUDR with hepatic arterial 5-FU. A weekly hepatic arterial bolus of 5-FU does not cause hepatobiliary toxicity; however, it frequently produces treatment-limiting systemic toxicity or arteritis. Stagg and colleagues[156] used alternating HAI of FUDR (for 7 days) followed by a hepatic arterial bolus of 5-FU (weekly for 3 weeks every 35 days). The response rate was 51%, and median survival was 22.4 months. In contrast to the experience with single-agent HAI of FUDR, no patient on the alternating plan has had treatment terminated because of drug toxicity. Davidson and associates,[157] using a similar alternating regimen on 54 patients, produced a 54% response rate, with 3.5% of patients developing biliary sclerosis. Patt and coworkers,[158] using HAI of 5-FU and interferon in 5-FU- and LV-refractory patients, produced a 33% response rate with a median survival of 15 months and no hepatobiliary toxicity.

Warren and colleagues,[159] using weekly HAI 5-FU infusion and systemic LV, produced a 45% response rate in 31 patients without hepatic toxicity and mild systemic toxicity. Metzger and colleagues[160] treated 30 patients with an infusion of 5-FU + mitomycin C; the courses were repeated every 6 weeks. The median survival was 18 months, with a 57% partial response rate. No patients developed sclerosing cholangitis, but mucositis and leukopenia were seen. Catheter complications occurred in 33%, which led to premature termination of treatment in one-third of the patients. Schlag and associates,[161] using HAI of 5-FU via a surgically placed port connected to an external pump, reported a 27% partial response in 33 patients and a median survival of 14 months. Hepatobiliary toxicity was seen in only 5% of the patients. Table 59-15 lists some of the studies using 5-FU and other agents by this technique.

Methods to Increase Response Rate and Decrease Extrahepatic Disease

The potential benefit of multidrug hepatic arterial therapy has been evaluated. A randomized trial of a three-drug regimen (mitomycin C, bischloroethyl nitrosourea, and FUDR) compared to FUDR alone was conducted in 67 patients with disease progression after previous treatment with systemic chemotherapy.[162] The overall response rate and survival were similar. The response rates in both groups were higher than would be expected with a second systemic regimen after failure of first-line treatment. For patients who had been treated previously for metastatic disease, the response rate was 48% for the three drugs as compared with 24% for FUDR alone ($P = 0.03$).

HAI FUDR/Dex + mitomycin C[163] administered through the pump side port produced a 70% response rate in previously treated patients with a median survival of 19 months from the start of HAI therapy after progression on systemic FU/LV.

Sixty-four patients were treated with FUDR and LV by HAI. The overall response rate was 62%, but 15% of patients developed biliary sclerosis. The toxicity of the combination was higher than that of FUDR alone, but the survival was improved: 86% of the patients

Table 59-15 Hepatic Arterial Therapy: 5-FU Plus Other Agents

Investigator	No. of Patients	Dose (mg/m²)	Response (%)	Median Survival
Cortesi et al[346]	109	5-FU 500 × 5 Cisplatin 24 × 5	46	16
Warren et al[159]	31	5-FU 1500 × 24 hr LV 400 weekly × 6	48	17
Sugihara[347]	58	5-FU 360 × 7 then 100 × 7 days	50	11
Kerr et al[348]	43	LV 200 5-FU 400 then 5-FU 1800 × 22 hr	36	—
Howell et al[349]	40	LV 200 5-FU 400 then 5-FU 1600–22 hr every 2 wk	46	19
Patt et al[350]	48	IFN 5 mu 5-FU 1000 × 5 hr every wk	33	15
Borner et al[351]	28	5-FU 750 × 5 days	50	

were alive at 1 year, 62% at 2 years, 33% at 3 years, and 10% at 5 years after treatment.[164]

To further increase response rate without an increase in toxicity, the combination of FUDR, Dex, and LV was tested.[165] The response rate was 78% in previously untreated patients, with only 3% of these developing sclerosing cholangitis. The median survival was 24.8 months, and the 1- and 2-year survivals were 91% and 57%, respectively. In patients who had received previous chemotherapy, the response rate was 52%.

The use of systemic therapy + HAI might produce a decrease in extrahepatic disease. In Safi and coworkers' study[166] comparing FUDR (0.2 mg/kg/day for 14 of 28 days) with a combination of intra-arterial FUDR (0.21 mg/kg/day) and intravenous FUDR (0.09 mg/kg/day) given concurrently for 14 of 28 days, the response rates were 60% for both arms of the study. The incidence of extrahepatic disease, however, was 56% for the group receiving intra-arterial/intravenous treatment compared with 79% for those receiving HAI alone ($P < 0.01$). There was no difference in survival between the two groups ($P = 0.08$).[135] In Lorenz and colleagues,[150] study of 52 patients, combined HAI/intravenous did not increase survival or decrease the development of extrahepatic disease (60% and 62% for HAI/intravenous vs, HAI alone, respectively). Wanebo and colleagues[167] used continuous-infusion 5-FU and LV for 14 days alternating with intrahepatic FUDR, Dex, and LV. Two other studies produced median survivals of 12 and 18 months administering HAI FUDR + systemic 5-FU.[168,169]

A phase I study of HAI FUDR combined with systemic irinotecan[170] in previously treated patients (45% had previous CPT-11) reported a response rate of 74%, a TTP of 8.1 months, and a median survival of 20 months. Thirteen of the sixteen patients with previous CPT-11 exposure responded to this regimen. Systemic Oxali + 5-FU/LV or Oxali + CPT-11 with concurrent HAI FUDR/Dex in 36 previously treated patients (74% had received prior CPT-11) produced response rates of 86% with a median survival of 36 months, and a 1-year survival of 80%.[171]

Toxicity of Hepatic Arterial FUDR Infusion

Most trials of HAI given via an internal implantable pump use FUDR or 5-FU. A summary of the toxicities encountered is listed in Table 59-16. Myelosuppression, nausea, vomiting, and diarrhea do not occur with HAI of FUDR. If diarrhea does occur, shunting to the bowel should be suspected.[172] The most common problems with HAI FUDR are hepatic toxicity and ulcer disease (Box 59-2).[173] Hepatobiliary toxicity is the most problematic toxicity seen with HAI FUDR. Most studies point to a combined ischemic and inflamma-

SGOT, serum glutamic-oxaloacetic transaminase.

Box 59-2. DOSE MODIFICATION FOR HEPATIC TOXICITY

SGOT	Bilirubin	Alkaline Phosphatase	FUDR Dose Reduction (%)
<2 × baseline	—	—	80
3 × baseline	or 1.5×	or 1.5×	50
>3 × baseline	or 2×	or 2×	Hold

Baseline is day 1 or previous FUDR dose. If elevations continue on reduced doses, decrease duration of FUDR to 1 week. If bilirubin is >2 mg/dL, do not repeat treatment for 2 months. If bilirubin levels return to and remain normal, use 25% of the previous FUDR dose for 1 week.

tory effect on the bile ducts as the etiology of this complication. The bile ducts derive their blood supply almost exclusively from the hepatic artery and thus are undoubtedly perfused with high doses of chemotherapy.[174]

Clinically, biliary toxicity manifests as elevations of serum glutamic-oxaloacetic transaminase (SGOT), alkaline phosphatase, and bilirubin. Elevation of SGOT is an early manifestation of toxicity; elevation of alkaline phosphatase or bilirubin is evidence of more severe damage. In the early stages of toxicity, hepatic enzyme elevation returns to normal when the drug is withdrawn and the patient is given a rest period, whereas in more advanced cases it does not resolve.

In patients who develop jaundice, endoscopic retrograde cholangiopancreatography (ERCP) might demonstrate lesions resembling idiopathic sclerosing cholangitis in 5% to 29%.[175] Because the ducts are sclerotic and nondilated, sonograms usually do not show dilation. In some patients, the strictures are more focal and usually worse at the hepatic duct bifurcation; drainage procedures either by ERCP or by transhepatic cholangiogram could be helpful.[176] Duct obstruction from metastases should first be excluded by CT of the liver.

Close monitoring of liver function tests is necessary to avoid the biliary complications. If serum bilirubin rises to 3 mg/dL or higher no further treatment should be given until the bilirubin returns to normal, and then only after a long rest period to prevent the development of sclerosing cholangitis. With proper monitoring, this complication occurs in less than 10% of patients.

Severe ulcer disease results from inadvertent perfusion of the stomach and duodenum with drug via small collateral branches from the hepatic artery and can be prevented via careful dissection of these collaterals at the time of pump placement. Even without radiologically visible perfusion of the stomach, however, mild gastritis and duodenitis still can occur. HAI 5-FU causes less biliary problems and more arteritis (Box 59-3).[156]

Box 59-3. INTRAHEPATIC THERAPY MANAGEMENT OF TOXICITY

Ulcer: Denude vessels that supply stomach and duodenum
Hepatitis: Monitor SGOT, alkaline phosphatase; decrease or hold dose for enzyme elevations.
Biliary sclerosis: Monitor liver enzymes, document by ERCP; if present, do not repeat treatment even if enzymes normalize.
Cholecystitis: Remove gallbladder.
Diarrhea: May be misperfusion or very extensive liver disease (repeat hepatic flow scan).

Complications of Hepatic Artery Infusion Pump Placement and Use

Incomplete or extrahepatic perfusion is usually a surgical problem. It is necessary to mobilize the entire gastroduodenal artery and ligate all branches supplying the stomach, duodenum, bile duct, or pancreas. The postoperative ^{99m}Tc macroaggregated albumin perfusion scan, when compared with the liver scan, can show incomplete perfusion of the liver from either an accessory or replaced hepatic artery not detected preoperatively or an incompletely isolated hepatic artery that is supplying vessels to the pancreas or gastrointestinal tract. These abnormalities can be assessed by performing a side port pump injection (Box 59-4). (Most implantable pumps have a main chamber with a central port in which the drugs, such as FUDR, are placed for constant infusion. These pumps also have a side port that bypasses the main chamber and goes directly into the main catheter.) Often an accessory left hepatic artery arising from the left gastric artery, or an accessory right hepatic artery arising from the superior mesenteric artery, has not been identified. In such instances it might be possible to embolize the accessory vessel, which will allow collateral flow to develop from the main hepatic artery. A common technical error during catheter insertion is placing the catheter too far from the junction of the gastroduodenal artery and hepatic artery. The segment of gastroduodenal artery that is continuously exposed to full-dose chemotherapy will eventually thrombose. There is a learning curve for both the surgeons and the medical oncologists. In one series, technical complications were seen in 37% of patients with inexperienced surgeons and in 6.6% of patients with experienced surgeons.[177]

Hepatic Arterial Infusion: Conclusions

HAI has several advantages. From a pharmacologic standpoint, HAI is more effective than systemic therapy, in that higher drug levels are achieved at the sites of metastatic disease. Utilizing agents with high hepatic extraction virtually eliminates the systemic toxicity observed with "standard" chemotherapy.

Should every patient with unresectable liver metastases and no extrahepatic disease undergo HAI? Hepatic arterial therapy produces higher response rates compared with systemic therapy. Older randomized studies with crossover design did not prove a survival advantage. In ten randomized trials, the response rate was higher using HAI compared with systemic therapy (see Table 59-14). The time to hepatic progression was significantly longer in the HAI groups as

Box 59-4. TECHNICAL ASPECTS OF PUMP INSERTION

1. Rule out extrahepatic disease by colonoscopy, chest radiograph, or CT scan of abdomen and pelvis.
2. Intraoperatively, biopsy samples should be taken from portal lymph nodes to rule out extrahepatic disease.
3. Celiac and superior mesenteric artery arteriography should be done to identify arterial anatomy of liver and vessels to stomach and duodenum and pancreas.
4. Portal vein must be patent.
5. Place catheter into gastroduodenal artery, not directly into hepatic artery, which could lead to thrombosis; secure catheter with nonabsorbable ties.
6. Identify and ligate branches to pancreas and duodenum.
7. Check whole-liver perfusion with 5 mL of fluorescein through side port.
8. Postsurgery macroaggregated albumin scan should be performed through side port of pump to check perfusion of the liver and to ensure no extrahepatic perfusion.

Table 59-17 Randomized Studies of HAI versus SYS: Time to Hepatic Progression

HAI, hepatic arterial infusion; SYS, systemic chemotherapy.

compared with the systemic groups (Table 59-17). The randomized pump studies do not evaluate the issue of survival clearly, for the following reasons: (1) In some studies a crossover was allowed; (2) the number of patients was small; (3) positive portal nodes were included in the HAI-treated groups. Recent HAI trials demonstrate median survivals of 24 to 36 months. Therefore, in a patient with extensive hepatic disease (30% to 60% liver involvement) who can tolerate an operation, hepatic arterial therapy combined with systemic chemotherapy or systemic chemotherapy alone can be used as the first treatment. Patients who start with systemic therapy and whose tumor fails to respond can then still undergo HAI therapy (Fig. 59-11). Table 59-18 lists trials using HAI therapy after progression on systemic therapy. In institutions in which physicians are not familiar with placement of the hepatic arterial catheter and the pump or with the management of patients on regional infusion, systemic chemotherapy is a reasonable option.

Because the liver is often the initial site of metastatic disease in patients with CRC, early intensive therapy with surgical resection or intrahepatic infusion (or both) at a time when the tumor burden is small might prevent the progression of metastases to other sites. Although hepatic arterial therapy is applicable to only a minority of patients with metastatic CRC (those with only hepatic metastases), it might be the best available therapy for these patients.

In the future, molecular markers could help determine the optimal type of treatment. In one small study, patients with low thymidylate synthetase levels had a fourfold greater chance of responding after 5-FU-based infusion.[178] In another study, patients with mutated p53 had a shorter survival.[179]

The use of HAI for other tumor types has not been studied as extensively. Some of the breast studies using HAI are shown in Table 59-19. Most of these studies are on patients whose tumors are failing to respond to systemic therapy, and yet response rates of 50% or greater are seen in five of the eight studies.

Trials have been done using HAI therapy for cholangiocarcinoma and HCC (Tables 59-20 and 59-21). At MSKCC, HAI therapy alone produced a partial response of 47% in cholangiocarcinoma and 28% in HCC.[180] Yoshikawa and associates, using HAI, epirubicin, pararubicin, and carboplatin, had an objective response of 35.4% and 2-year survival of 30% in 319 patients.[181]

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy has been evaluated as a way to decrease hepatic tumor burden for the purpose of proceeding with hepatic resection. Although no randomized prospective trial has been completed testing this as a treatment strategy, the results of a retrospective analysis have been presented, and the results seem promising.

Giacchetti and colleagues[182] conducted a retrospective review of 151 patients with unresectable liver-only metastases from CRC who were treated with 5-FU/LV and Oxali followed by attempted liver resection. The criteria used to define unresectability were as follows: (1) more than four liver metastases (30%), (2) single tumor larger than 5 cm (34%), (3) tumor in both hepatic lobes, (4) invasion of the intrahepatic vascular structures, and (5) high percentage of liver involvement (>25% liver involvement; 48%). Their analyses revealed that of this group, 77 patients (51%) became resectable after neoadjuvant therapy. The 5-year survival rate for the 77 patients who underwent hepatic resection was 50%, progression-free survival was 17 months, and 72% had relapsed within a median of 12 months.[182,183] Adam and coworkers,[84] from the same group, reviewed the records of 1104 patients with unresectable disease who received mainly FOLFOX as neoadjuvant therapy; 12.5% became resectable and the 5-year survival of these patients was 34%, similar to what could be obtained with patients who were initially resectable.

Several trials were designed to address resectability rate after chemotherapy that varied with patient selection. The Mayo Clinic trial considered patients to be unresectable if they had (1) involvement of all three major hepatic veins, portal vein bifurcation, or the hepatic vena cava; (2) involvement of the main right or main left portal vein and the main hepatic vein of the opposite lobe; (3) disease requiring more than a right or left trisegmentectomy; or (4) six or more metastatic lesions distributed diffusely in both lobes of the liver. In patients treated with preoperative Oxali/5-FU/LV, 38% of 44 became suitable for resection, but after resection, 73% recurred in the liver. Median survival was 26 months.[184] A retrospective review of these data demonstrated that 10% of patients were actually resectable before neoadjuvant therapy.

Pozzo and colleagues treated 40 patients with unresectable disease, meaning: (1) six metastases or three per lobe, (2) size larger than 5 cm for one lesion if six metastases were present, (3) contiguity with two hepatic veins, inferior vena cava or liver hilum with neoadjuvant FOLFIRI.[185] Thirty-two percent underwent liver resection with a DFS of 28 months. Other trials evaluating neoadjuvant chemotherapy are in Table 59-22.

Rougier and associates treated 23 patients with cetuximab and FOLFIRI, and seven (30%) became resectable.[186] Oxali/Irinotecan (CPT-11) + HAI in 44 clearly unresectable patients enabled 35% to become resectable (56% even though the majority had received this after second- or third-line therapy). The median survival of the entire group is 36 months, and median survival for the resected group has not been reached. In a Japanese study, 51 patients with unresectable disease were treated with HAI/5-FU and systemic UFT. The 3- and 5-year survivals were 58% and 42% for the resected group. In Italy, 244 patients were randomized to FOLFIRI or FOLFIRI + Oxali (Folfoxiri). In patients with only liver metastases, the resection rate was 12% and 36% for the FOLFIRI and Folfoxiri regimens, respectively.[187]

In making decisions about the timing of liver resection and pre- or postoperative chemotherapy, there are several considerations. The advantages and disadvantages are listed in Table 59-23. For patients

Table 59-23 Pros and Cons of Preoperative Chemotherapy

PROS

- Decrease size
- Control micrometastatic disease
- Assessment of chemotherapy activity
- Better chemotherapy tolerance
- Surrogate marker for success of liver toxicity

CONS

- Liver toxicity
- Steatosis
- Sinusoidal dilatation
- Risk of progression or growth of new sites
- Clinical response may make surgery more difficult
- Secondary splenomegaly
- Selection of resistant clones

with borderline resectability, chemotherapy can be done first but only for short periods of time, and as soon as response is noted, surgery should be performed. Adam reported prolonged chemotherapy (>12 cycles) was related to longer hospital stays after liver resection.[188] For clearly unresectable disease, patients should enter protocols that are addressing the question of how best to decrease liver metastases to allow resection. In patients with synchronous CRC, there are those who advocate for simultaneous resection of both the primary and the metastatic disease, those who recommend chemotherapy first,[189,190] and those who state both surgeries can be done simultaneously.

Supporting the concept of controlling micrometastatic disease, the Liver Met Survey group found patients with more than five metastases survived longer if they were given neoadjuvant chemotherapy, with a 5-year survival of 22% versus 12% ($P = 0.07$) for the preoperatively treated and preoperatively nontreated groups, respectively. In another retrospective review at MSKCC, preoperative chemotherapy did not improve survival. In a review of 230 patients who received HAI + systemic therapy after liver resection,[191] the median survivals for patients who did or did not receive preoperative (neoadjuvant) therapy were 63 and 115 months, respectively($P = 0.26$).

If metastases that disappear on CT remain viable, preoperative chemotherapy may be a disservice. In a review by Benoist and coworkers on 586 treated patients,[192] 38 patients had disappearance

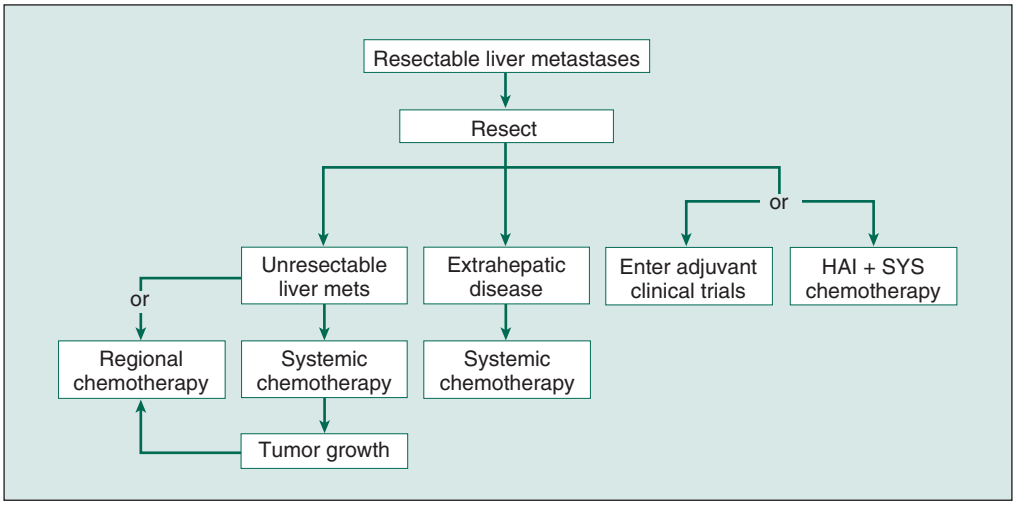

Figure 59-12 • Treatment of liver metastases.

of at least one lesion on CT. Pathologic examinations of sites with a complete response showed that in 11 of 15 (80%) there were viable tumor cells. Areas that could not be found were closely followed, and in 23 of 41 sites (47%), tumor reoccurred.

As use of preoperative chemotherapy increases, reports are emerging about liver toxicity from preoperative chemotherapy. There is an increased incidence of steatosis, sinusoidal abnormalities, venoocclusive disease, and steatohepatitis. In the Rubbia-Brandt and colleagues[193] report on 153 patients undergoing liver resection, 51% of the 87 patients who have received chemotherapy before resection had sinusoidal dilation and 78% who had prior Oxali showed striking sinusoidal alterations, with venoocclusive fibrosis in 48%. Kooby and associates reported on 325 patients with fatty livers undergoing resection at MSKCC and found that those treated with preoperative chemotherapy were more likely to have steatosis (66%), with marked steatosis being an independent predictor of complications following hepatic resection.[194] Vauthey and coworkers reported a 20% incidence of steatohepatitis in patients receiving preoperative CPT-11 versus 4.4% in those who received no preoperative chemotherapy, and an 18.9% incidence of sinusoidal dilation in those receiving preoperative Oxali versus 1.9% in those receiving no preoperative chemotherapy. Patients with steatohepatitis had an increased 90-day mortality, 14.7% versus 1.6% ($P = 0.001$).[195]

Is neoadjuvant chemotherapy useful for resectable liver metastases? The EORTC study is looking at preoperative and postoperative FOLFOX versus observation. They have randomized 364 patients to (1) six cycles of FOLFOX before and after surgery or (2) surgery alone.[196] Presently, in the group receiving preoperative chemotherapy, 7.7% progressed before surgery and 11% were not able to undergo resection. It is too early to look at the DFS and survival. For clearly resectable disease, until we know more from these studies, surgery should be done first, followed by adjuvant therapy. Figure 59-12 provides a treatment algorithm for liver metastases.

HEPATIC ARTERIAL EMBOLIZATION

Because both hepatic metastases and primary liver tumors derive their blood supplies from the hepatic artery, hepatic arterial ligation (HAL) and embolization have been used to reduce the tumor's blood supply.[197] In most hepatic tumors, HAL produces only a transient benefit because of the rapid development of collateral vessels. In vascular neuroendocrine tumors, HAL produces objective tumor reduction, whereas in colon metastases (which are typically less vascular), minimal regression occurs.

The development of a collateral blood supply might be minimized by injecting vasoocclusive particles into the hepatic artery (hepatic artery embolization, HAE), which also provides the opportunity for retreatment, because only the microvasculature is occluded.[103] In one study of 61 individuals with liver metastases from colorectal carcinoma, patients were randomized to HAE, HAL + microspheres (HAE), or no further treatment. The median survivals were 8.7, 13, and 9.6 months, respectively, suggesting that embolization or ligation alone had no effect on survival for patients with CRC.[198] Gerard and colleagues[199] randomized 67 patients to HAL alone versus HAL and portal vein infusion of 5-FU. The median survival in both groups was 12 months; among patients whose median extent of liver involvement was 30%, only one patient responded. Both studies suggest that this technique is not useful for CRC.

HAE has a definite role in highly vascular tumors, such as neuroendocrine tumors of the liver.[200] These tumors usually grow slowly, and a reduction in tumor bulk can result in significant palliation. Ajani and associates[201] treated 22 patients who had islet cell carcinoma with HAE using polyvinyl alcohol particles (Ivalon) and gelatin sponge particles (Gelfoam). The median survival in this study was 33 months from initiation of embolization (range, 1 month to 72 months); 12 patients had a partial response associated with subjective improvement and decrease in hormone levels. Other studies using HAE are listed in Table 59-24; all demonstrate an improvement in symptoms and a decrease in hormone levels. Gelfoam (size 1–2 mm), one of the agents used for embolization, does not lead to peripheral vascular occlusion and has an inconsistent duration of occlusion (due to absorption), whereas Ivalon (size 150–500 μm), a smaller particle, allows for more peripheral occlusion and is not absorbable, allowing for a more persistent arterial occlusion.[201–203] A collagen particle (Angiostat; size 20–250 μm) and a biodegradable albumin microsphere (Spherex; size 15–40 mm) are currently being tested, especially in combination with chemotherapy.

Interference with hepatic blood flow can exacerbate the underlying liver disease and can be dangerous in patients with portal venous thrombosis, which is present more often in patients with primary liver tumors than in those with metastatic disease. In a study by Carr and coworkers,[204] four patients with HCC had reversal of tumor-induced portal vein thrombus. The researchers obtained objective responses in 22 of 35 patients (63%) using Spherex (biodegradable) starch microspheres, doxorubicin, and cisplatin. There is clear evidence that arterial embolization causes antitumor effects, but some randomized studies have not shown increased survival.[205]

Table 59-24 Neuroendocrine Tumors

Investigators	Agent	No. of Patients	Biochemical or Symptomatic Response (%)	Tumor Response (%)
Hepatic artery ligation

Maton et al[385]	Lyodura	13	76	—

Complications of Embolization

The complications of embolization are nausea, vomiting, fever, pain, and changes in liver function tests (Table 59-25). Problems less commonly encountered include the following: injury of the gallbladder by retrograde flow through the cystic artery, ischemic necrosis of the bowel by embolization of one of the vessels to the intestinal tract, pancreatic infarction and pancreatitis by embolization of one of the pancreatic vessels, and dyspnea by embolization of the lungs.[201–203,206–208]

In neuroendocrine tumors responding to HAE, rapid cell death can result in tumor lysis syndrome with symptomatic hyperuricemia, leading to uric acid nephropathy and oliguria. Vigorous hydration and prophylactic allopurinol might prevent this problem. In carcinoid tumors, HAE could cause a life-threatening carcinoid crisis from the rapid release of hormones from tumor cells. Somatostatin analogs may be given, either before the procedure or if a carcinoid crisis should occur.[209] To avoid some of the serious complications of HAE, patients with cirrhosis, portal vein occlusion, and biliary tract obstruction are usually excluded.

Table 59-25 Complications and Management of Hepatic Arterial Embolization

COMPLICATION

Follow WBC, LDH, SGOT, creatinine
Treat by appropriate measures nausea, fever, abscess, infection, ileus

LDH, lactate dehydrogenase; SGOT, serum glutamic-oxaloacetic transaminase; WBC, white blood cell count.

*150–250 mg SC, every 6–8 hrs before procedure.

CHEMOEMBOLIZATION

An extension of the work with embolization is chemoembolization. This process involves a local entrapment of drug in the embolization agent and provides a prolonged exposure of the tumor to the drug locally with less systemic drug circulation. A nonrandomized study by Daniels and colleagues[210] suggested that the addition of chemotherapy to the embolic agent (angiostat) produced an increase in response rate over the embolic agent alone. In a study by Venook and associates,[211] 51 patients with unresectable HCC were treated with Gelfoam and a mixture of three drugs—doxorubicin, mitomycin C, and cisplatin—given via a percutaneous hepatic artery catheter. Twelve (24%) had a partial response, and tumor liquefaction was noted in 70% of patients on CT, with a more than 50% reduction in α-fetoprotein in 68% of patients. Using this technique and the same drugs, these investigators also treated liver metastases from neuroendocrine tumors. In 12 patients with a median liver involvement of 60%, 33% had a partial response with a reduction in hormone levels.[160] Median survival from treatment initiation was 7 months (range 3 months to 3 years). Lipiodol has been found to remain selectively in the primary and secondary liver cancers when injected into the hepatic artery, allowing visualization of tumors as small as 4 mm.[161] Thus, Lipiodol can be used to deliver either chemotherapy or local radiation by combining with an agent such as iodine-131 (^{131}I).[212]

Chemoembolization is rarely used for CRC, because median survivals are usually not increased; average survival is approximately 9 months.[213] Adding systemic therapy to hepatic chemoembolization could improve results. In one trial using regional cisplatin in a polyvinyl alcohol suspension with systemic 5-FU, the partial response rate was 40%, and median survival was 19.3 months.[214]

Another form of chemoembolization is to enclose the chemotherapeutic agents in a microsphere.[215] Degradable starch microspheres injected intra-arterially are trapped in an extracapillary network formed in liver metastases.[215,216] Drug dissolved in the microsphere suspension is retained in the blood vessels of the target organ as long as the blood flow is blocked and then gradually releases the chemotherapeutic agents, resulting in a longer duration of tumor exposure to the drug. The most appropriate agents for microspheres would be those that, like mitomycin C, are preferentially toxic to cells under hypoxic conditions. Another useful drug to use with microspheres is doxorubicin. In a rabbit study, the mean tumor drug

level was significantly higher when this drug was used with the microsphere compared with doxorubicin alone, whereas hepatic uptake of the drug by normal tissue was similar in the two groups.[217] Monoclonal antibodies can also be attached to the microspheres.[218]

Radioembolization attempts have been made using glass microspheres containing ^{90}Y, a β-emitter with tissue penetrance of 2.5 mm. Andrews and coworkers[218] reported 5 of 23 responses with yttrium embolization. A study of ^{131}I- labeled lipiodol administered to 20 patients (15 HCC, 5 metastatic) produced an α-fetoprotein drop in 11 of 12 patients and a response in 9.[219] The response rates for radioembolization of metastatic tumors are far less than those reported for treatment of primary HCC, perhaps because most metastatic tumors except for neuroendocrine primaries are far less vascular than HCC.

Arterial embolization is commonly used for HCC. Responses and increase in time to tumor progression have been documented.[205,220–222] Meta-analysis showed an increase in survival with chemoembolization compared with conservative management.[223]

CRYOSURGERY

Cryosurgery is an in situ destruction of tissue using subzero temperatures. The rapid freeze/thaw of tissues results in cellular damage and death. One advantage of cryosurgery is the ability to use local treatment without sacrificing normal tissue. Among the difficulties with this technique are defining the full extent of the tumor and the inability to monitor the amount of freezing, and thus the possibility of overtreatment of surrounding vulnerable normal tissue. Two technical developments have improved the use of cryosurgery:

1. Cryoprobes cooled by liquid nitrogen allow more precise freezing, even within the liver.
2. Intraoperative ultrasound allow precise placement of the cryoprobe and more accurate monitoring of the freezing process.

Cryosurgery has been used intraoperatively but also can be used percutaneously. In a series of 32 patients with liver tumors (24 with CRC), 28% remained free of disease for 5 to 60 months.[224] In another series using intraoperative cryosurgery on 18 patients who had metastatic CRC with 1 to 12 lesions, Onik and coworkers[225] reported that 4 patients had complete remission with a median survival of 28 months, whereas 14 patients were considered inadequately treated and had a 21-month median survival.

Weaver and colleagues[226] treated 47 patients with cryosurgery with occasional operative resection. The number of metastases ranged from 1 to 12. The 2-year survival was 62%. Morris and Ross,[227] reporting on 67 patients, noted that 75% of patients undergoing cryosurgery had an increase in CEA by 6 months later. Occasionally, the surgeon feels that all disease has been destroyed but, as seen by this study's PET results after cryosurgery, tumor can still be present even though the surgeon feels that no disease has been left behind.

The 2-year survival after cryosurgery varies from 72% to 12%. The Boston series reported the highest survival, which might reflect the type of patient being selected for cryosurgery (i.e, lesser extent of disease and a smaller number of metastases).[228] Adam and associates[229] reported a 2-year survival rate of 50% for patients with colorectal metastases as compared with 67% for patients with HCC. They reported a local recurrence rate of 44% for the colorectal patients. Because local recurrence is high, the use of HAI after cryosurgery could be useful. One small, nonrandomized study doubled survival with the use of HAI after cryosurgery.[230] Other trials are now evaluating the use of HAI with or without systemic therapy. In a series of 185 nonrandomized patients, 71 received adjuvant CPT-11 and/or HAI of FUDR after cryosurgery. Two-year survival was 75% for patients receiving postcryosurgery therapy as compared with 35% if no adjuvant therapy was given.[231] Cryoablation can also be used after hepatic resection with close margins or to remove central lesions. Cryoprobes can be used as a handle to assist in segmental resections. An ice ball is produced with 1-cm margins around the tumor; then the probe is used for traction so that a segmental resection can be performed.[232]

The addition of cryosurgery to conventional surgical procedures was evaluated by Seifert and coworkers[118] in a randomized study. Those receiving surgical procedures plus cryosurgery had similar survival but an increase in liver recurrence for the cryo group.

Cryosurgery does involve some technical issues, including the following:

- Adequate hydration before surgery, because myoglobinuria and tumor lysis can occur.
- Attention to bile ducts, because biliary fistula can occur.
- Two freeze/thaw cycles are preferred.
- The probe should not be pulled or twisted vigorously, because that could cause cracking.[233]

Complications include hepatic cracking secondary to the thermal stresses that occur during rapid freezing; these are usually associated with hemorrhage, which could require packing. Other complications include biliary fistula requiring percutaneous drainage (which occurred in one patient) and myoglobinuria, resulting in acute tubular necrosis.

Published data do not support the use of cryosurgery in patients with resectable disease outside of a clinical trial.[234]

RADIOFREQUENCY ABLATION AND MICROWAVE COAGULATION

Just as tumors can be destroyed by cold, they can also be destroyed by heat. Techniques such as RFA and microwave coagulation (MC) have been used to destroy tumors. RFA involves placing within the tumor a small electrode, which is used to deliver energy to the tissue. The radiofrequency current generates ionic agitation, which is converted into frictional heat and results in breakdown of proteins and cellular membranes. The larger tumors can be destroyed by cryoablation. For RFA, tumors must be less than 4 or 5 cm in size. During the ablation, a hyperechoic area is formed around the tip of the needle, which corresponds to the area treated. It is sometimes difficult to evaluate whether all tumors have been treated. One of the advantages of RFA as opposed to cryoablation is that it can be performed percutaneously, because the probes are 10 mm in length. Solbiati and colleagues[235] treated 109 patients with colorectal metastases. He found a local control of 70%. Recurrence was significantly more frequent among patients with lesions larger than 3 cm. New metastases developed in 50% of patients, and survival rates were 67% and 33% at 2 and 3 years, respectively.[235] Bilchik and associates[236] proposed an algorithm for unresectable hepatic neoplasms, using cryosurgery for larger lesions and radiofrequency for tumors smaller than 3 cm, because local recurrences occurred in 38% of those receiving RFA and only in 17% of patients receiving cryosurgery. Among the most useful situations in which to use RFA is for patients with HCC who also have cirrhosis. Curley and coworkers[237] presented a series of 110 patients with cirrhosis who received RFA for HCC, with no recurrences occurring in 50%.

Cancer cells could be more sensitive than normal cells to heat due to the decreased vasodilation capacity of the neurovascular bed.[238] MC was initially developed for coagulation. When microwaves are applied to living tissue, they act mainly on the watery component. Using a probe to deliver 80-watt output for a 30-sec duration creates a column of coagulated area of 10 mm. In 19 patients with HCC, 28 of 31 nodules underwent complete tumor ablation. Ten of the 19 patients are still free of disease (follow-up, 14–64 months). Advocates of this therapy suggest that MC does not have inhomogeneous distribution within the tumor as seen with percutaneous ethanol injection therapy (PEIT).[239] MC is useful only in very small tumors (<3 cm). Both

modalities (MC and PEIT) might be more useful if combined with embolization. Lesions near hilar structures are not good candidates for MC, but lesions adjacent to hepatic veins can be treated.

A Italian study on 423 patients treated with RFA reported 3- and 5-year survivals of 47% and 24%, respectively,[240] which is similar to surgical series. In a series of 25 patients where resection was not performed because the lesion was close to a major vessel, the 3-year survival with RFA alone was 52%.[241] Elias and colleagues used RFA instead of repeat resections for the treatment of recurrence after liver resection in 47 patients. They found that this increased the percentage of local cures and decreased the need for resection.[242] Livraghi and associates evaluated the role of RFA in 88 patients who were waiting for resection. Fifty-three patients had complete tumor ablation by RFA, and 16 (30%) remained tumor-free. Among these 53 patients with complete ablation, 98% were spared surgical resection—44% because they remained tumor-free and 56% because they developed additional metastases. Lesions in 35 patients (40%) demonstrated local tumor recurrence, and 15 developed unresectable disease.[243]

In the Cleveland Clinic 135 patients received RFA because they were not good candidates for surgical resection, and the median overall survival was 28.9 months. Predictors of survival included size of the lesion and baseline CEA values. There was a median survival of 38, 34, and 21 months for lesions smaller than 3 cm, 3 to 5 cm, and larger than 5 cm, respectively ($P = 0.03$). Median survivals of 34 and 16 months were seen with CEAs of less than 200 ng/mL versus greater than 200 ng/mL, respectively ($P = 0.01$). In the Cox proportional hazards model, only the size of the largest lesion (>5 cm) was found to be a significant predictor of survival.[244] Other studies have reported size as an important predictor of recurrence.[245]

At M.D. Anderson Cancer Center 348 patients with liver metastases from CRC were treated for cure: 190 had resection only, 101 had RFA and resection, and 57 had RFA alone. Recurrences were lowest with resection: 52% versus 64% for RFA and resection, and 84% for the RFA alone. Liver-only recurrence after RFA was 44%. Four-year survival was 65% for resection, 36% for resection and RFA, and 22% for RFA alone.[91] A multivariate analysis of these patients found the type of procedure (i.e., resection, RFA and resection, or RFA alone) influenced survival, with the RFA-alone group having the lowest survival. Of course, RFA was usually a component of therapy when resection was not possible, especially in cases where the anatomic distribution of tumors made complete resection impossible. Therefore, this is not a true comparison of RFA versus resection. However, 3-year survival for patients with one metastasis treated by resection or RFA was 80% versus 40%, respectively, suggesting RFA cannot replace resection.

The combination of RFA and HAI may be useful. In an M.D. Anderson study on 50 patients, 32% remained tumor-free at a 20-month median follow-up. Recurrence at the site of RFA was seen in 10% and new liver metastases in 30%.[246] Kainuma and coworkers treated nine patients with bilobar disease with RFA and regional chemotherapy with 5-FU, doxorubicin, and cisplatin.[247] The local recurrence rate was 55%, and 2-year survival was 39%. Martin and colleagues treated 21 patients with RFA and HAI FUDR. With a median followup time of 24 months, the median survival is 30 months.[248]

RFA has been used in other tumor types. In a Chinese series on 240 patients with HCC and 44 patients with liver metastases treated with RFA, patients with liver metastases had a higher extrahepatic recurrence ($P = 0.019$) and shorter DFS ($P = 0.007$). Patients with multiple liver metastases had a higher local and extrahepatic recurrence[249] in neuroendocrine tumors. RFA can relieve symptoms in 95% of patients.[250,251] Livraghi and associates reported on 24 breast cancer patients whose liver lesions were treated with RFA, and 10 patients are still alive and free of disease with a median follow-up time of 10 months.[252]

Toxicity from RFA is clearly outlined in a series on 312 patients that included liver abscesses (7), portal vein thrombosis (3), pleural effusion (5), colon perforation (1), and renal insufficiency (1).[253]

In conclusion, RFA may have a role during surgical resection when one side of the liver is resected and small disease exists on the other side that cannot be resected. In patients who have undergone a resection and develop a small recurrence, percutaneous or laparoscopic RFA can be used if the lesion can be reached easily and is not close to large vessels. The presence of blood vessels near the tumors causes conduction of thermal energy away from the tumor and spares killing the tumor near the blood vessel.[254] Whether these techniques are more useful than chemotherapy, or should be used in combination with chemotherapy, are not known; the EORTC are exploring the use of RFA and chemotherapy versus chemotherapy alone.

PERCUTANEOUS ETHANOL INJECTION

PEIT was first performed in 1983 in Japan. Ultrasound guidance is used to place up to 30 mL of absolute ethanol into the lesion.[255] In patients with primary hepatoma, this treatment produced 5-year survivals of 43% for small lesions. Suzuki and coworkers[256] assigned 42 patients with HCC less than 3 cm to three groups—(1) chemolipiodolization, (2) chemolipiodolization followed by gelatin sponge transcatheter embolization (TAE) or (3) PEIT—and demonstrated a decrease in local recurrence with PEIT. Local recurrences at 1 year were 61%, 29%, and 20% for groups 1, 2, and 3, respectively. Shiina and colleagues[257] reported a 10-year survival of 66% using PEIT on single hepatocellular lesions smaller than 2 cm. In pooled data on 11,000 patients with HCC from Japan, 3-year survival for surgical resection, PEIT, or embolization was 58%, 53%, and 20%, respectively. Other researchers, however, report a higher recurrence rate after PEIT as compared with surgical resection. The size of the lesion also affects outcome. In an Italian study on 26 patients with metastatic disease, 13 of 15 patients with lesions smaller than 2 cm had responses, whereas among the 6 patients with lesions larger than 4 cm, no response was seen.[257] Yamamoto and associates[258] randomized 100 patients to TAE versus TAE + PEIT. The 3-year survival was 20% for the TAE group and 50% for the TAE + PEIT group, respectively ($P = 0.05$). This technique was also useful for treating small neuroendocrine tumors, possibly because they are highly hypervascular. At present, the technique needs further study to determine where it fits into the therapeutic armamentarium and whether it will increase survival for patients with metastatic liver tumors. Pending further study, it seems that PEIT and cryosurgery could be applicable to patients with small metastatic lesions who cannot undergo surgical resection. Whether these techniques will be more beneficial than regional hepatic arterial therapy is not clear, because they only treat visible disease and do not deal with possible small metastases that are not visible.

ISOLATION PERFUSION

To administer high drug concentrations locally, the liver can be isolated by clamping the hepatic arteries, vena cava, and portal vein and then placing a catheter in the hepatic artery to perfuse the liver. A catheter in the retrohepatic vena cava drains the liver, and extracorporeal filters allow removal of chemotherapeutic agents and simplify the technique of isolated perfusion. With a double-balloon inferior vena cava catheter, doses as high as 5,000 mg/m^2 of 5-FU and 120 mg/m^2 of doxorubicin have been administered. An initial trial using 30 mg/m^2 of mitomycin C produced venoocclusive disease in four of the nine patients.[259] With the use of melphalan (L-PAM), toxicity was decreased, and with doses of 30 mg/kg, complete responses were seen in 2 of 9 patients.[260] Hyperthermic isolation perfusion of tumor necrosis factor and melphalan is being investigated. Melphalan (1.5 mg/kg) and tumor necrosis factor (1 mg) over 60 min of hyperthermic infusion produced a 75% response rate.[261]

GENE THERAPY

Tumors largely restricted to the liver (primary or metastatic) can potentially be treated by gene therapy. The gene transfer agents can be injected locally or via the hepatic artery. One trial involves the use of an adenovirus vector carrying the wild-type *p53* gene. Alteration in p53 function is present in more than half of all malignancies, and reexpression of wild-type p53 can result in apoptosis and in tumor shrinkage in rodents. A phase I study of recombinant adenovirus encoding wild-type p53 administered via the hepatic artery produced no responses in 19 patients.[262] Transgene expression in tumor tissue was seen in patients receiving the highest dose levels. Other gene therapies involve the use of prodrug genes to convert innocuous drugs into active chemotherapeutic agents (cytosine deaminase converts 5-fluorocytosine to 5-FU).[263]

To deliver directed immunotherapy, Rubin and coworkers[264] injected *HLA-B7* gene on a liposomal vector into liver tumors. No responses were seen in 15 patients in the phase I study, but plasmid DNA was detected in 14 of 15 patients. Another concept being evaluated is to have cells express a gene such as thymidine kinase and then kill the cells by use of a ganciclovir, which is converted by thymidine kinase to an active metabolite.[263]

RADIATION THERAPY

In this section, the evolving role of radiation therapy for liver metastases will be reviewed. The first experience in using radiation therapy for liver metastases was with external-beam whole-liver radiotherapy (with and without systemic or regional chemotherapy), in which the doses that could be delivered safely were not high enough to eradicate metastases. More recently, technologic advances in radiation treatment planning allow high-dose radiation therapy to be delivered conformally around liver metastases safely, with the potential for eradication of disease and cure, in appropriately selected patients. Other types of radiation have also been used to treat liver metastases including brachytherapy and hepatic arterial delivery of ^{90}Y-tagged microspheres. Here, the experience following whole-liver irradiation, conformal radiation therapy, brachytherapy, and hepatic arterial ^{90}Y for treatment of liver metastases will be reviewed.

Whole-Liver Irradiation

The approach of using whole-liver irradiation for metastases is limited by the low tolerance of the whole liver to irradiation, with doses required to be less than 30 Gy over 3 weeks to avoid liver toxicity. Several clinical trials of whole-liver irradiation for liver metastases have established the safe whole-liver doses that can be delivered in a variety of fractionations.[265,266] The duration of response and survival rates tend to be short[267–269] (Table 59-26). In contrast, low-dose whole-liver irradiation can produce palliation of painful liver metastases in the majority of cases.[266,269,270]

In an attempt to improve on the poor outcomes following whole-liver irradiation alone, whole-liver irradiation has been combined with systemic or regional chemotherapy. The most widely used drugs in this effort have been the fluoropyrimidines because of their activity against CRC and their radiation-sensitizing properties.[271–273] The results of some of these trials are summarized in Table 59-27. In general, the response rates and survival rates following combined-modality therapy seem to be superior to those obtained following whole-liver irradiation alone. Selection bias may be at least partially responsible for this effect. A recent study demonstrated that whole-liver radiation (20 Gy in 10 fractions) does not improve the efficacy of 5-FU for patients who have diffuse liver metastases.[274]

Conformal Radiation Therapy

Technical advances in liver cancer imaging, radiation planning, methods to account for breathing motion during radiation delivery and image guidance at the time of radiation delivery (Figs. 59-13 and 59-14) have made it possible to deliver high-dose radiation safely to focal liver metastases, while sparing irradiation of the uninvolved liver, using a variety of radiation fractionation schedules.[275] In most studies, higher doses of radiation have been associated with more durable local control rates than lower doses, regardless of the fractionation schedule.[276–278]

Since the late 1980s at the University of Michigan, a series of phase I/II trials for patients with unresectable intrahepatic cancer have investigated dose-escalated conformal radiation therapy delivered concurrently with hepatic arterial chemotherapy (predominantly floxuridine [0.2 mg/kg/day]). In one of the first studies, the objective response rate of 22 patients with unresectable CRC liver metastases, treated with as much as 72.6 Gy at 1.5 Gy twice daily, was 50% (2 complete remission, 9 partial response, 11 stable disease),[279] with a median survival of 20 months. Similar results were obtained in subsequent studies,[280] including the most recent study in which the prescription dose was individualized based on the volume of liver irradiated and risk of toxicity, allowing higher doses (as much as

90 Gy at 1.5 Gy twice daily) to be delivered safely to more patients. The median survival of 47 patients with liver metastases (median diameter ~10 cm) treated on this study was 17.2 months.[277]

Stereotactic body radiation therapy (SBRT), referring to a limited number of high-dose fractions delivered very conformally to targets, using biologic doses of radiation higher than those used in standard fractionation, has also been used to treat liver metastases.[278,281–287] Safety of 1- to 10-fraction SBRT has been described in several retrospective series and more recently confirmed in prospective dose escalation studies (Table 59-28). Blomgren and colleagues from Sweden first reported a response rate of 43% for 14 liver metastases treated with 20 to 45 Gy in one to four fractions,[262] with a prolonged time to maximal response (e.g., maximal response at 16 months for a 13-cm liver metastases). No liver toxicity was seen in patients with metastases, but hemorrhagic gastritis was seen in one patient. In an update in 1998, the local control rate was 95% with a mean survival of 17.8 months for 21 liver metastases.[288] SBRT (20 Gy × 2 or 15 Gy × 3) has also been used safely in patients with recurrent liver metastases following hepatic resection for CRC metastases, with no serious toxicity and local control 13 to 101 months following surgery.[289]

A prospective study of escalated single-fraction SBRT (14 Gy to 26 Gy) did not find a maximal tolerated dose in 60 liver tumors (56 metastases) with a median tumor size of 10 mL (1–132 mL) and found an actuarial local control rate of 81% at 18 months following SBRT.[281,290] SBRT delivered in three fractions (37.5 Gy total) has also been reported to be safe in small liver metastases, with 2-year local control and survival rates of 61% and 41%, respectively.[282,291] A North American prospective study confirmed the safety of three-fraction SBRT in 18 patients with 25 tumors of maximal diameter 6 cm.[278] A Canadian prospective study has shown the feasibility of delivering six-fraction SBRT using an individualized dose allocation approach as first described by the Michigan group, for liver cancers ranging from 3 to 3,000 mL.[292]

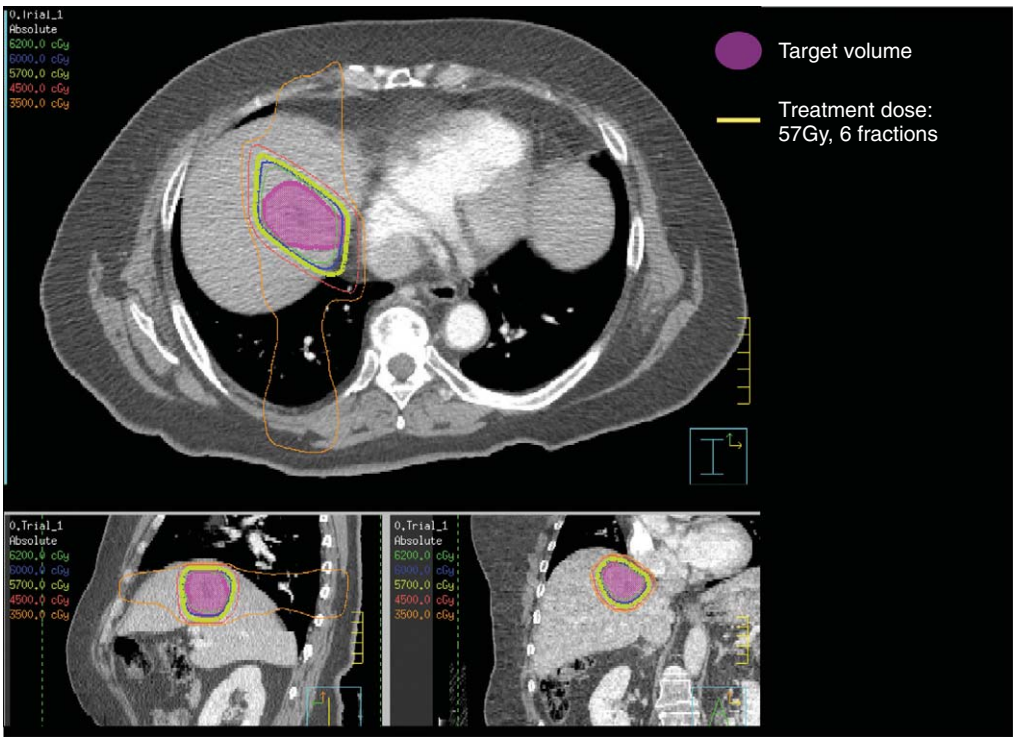

Figure 59-14 • Conformal radiation dose distribution, with the treatment isodose 57 Gy in six fractions, conforming to the target volume (*pink*).

More recently, outcomes following SBRT for 174 liver metastases from colorectal, pancreatic, breast, and lung cancer in 69 patients were reported.[285] The median dose delivered was 48 Gy (range 30–55 Gy) at 2 to 6 Gy per fraction. The local control was 76% and 57% at 10 and 20 months, respectively, with an overall medial survival of 14.5 months. No grade 3 toxicity was reported. Based on this experience, 10-fraction SBRT is being studied in a Radiation Therapy Oncology Group study that is now open.

Brachytherapy

High-dose radiation can also be delivered to focal liver metastases, with maximal sparing of dose to uninvolved liver, using interstitial brachytherapy, in which radiation is delivered from radioactive sources placed within or near the tumor.[293–297] High-dose-rate iridium-192 afterloaded to applicators placed at the time of laparotomy was used to deliver 20 to 30 Gy in 2 to 13 settings, with an actuarial local control rate of 26% at 26 months and two complete responses seen in lesions subsequently biopsied.[296] Iodine-125 seed implants, which deliver low-dose-rate irradiation (less than ~0.15 Gy/hr) over several months also have been used to treat liver metastases, with 10 of 11 tumors controlled at 1 year.[295] More recently, CT-guided placement of iridium-192 for liver metastases has been shown to be feasible in a phase II study[294] of 20 patients with liver cancers (19 metastases, 1 cholangiocarcinoma) unsuitable for thermal ablation. The mean tumor diameter was 7.7 cm (5.5–10.8 cm) for peripheral lesions and 3.6 cm (2.2–4.9 cm) for hilar cancers. The dose delivered ranged from 12 to 25 Gy. Two serious complications were observed. One patient had an intrahepatic hemorrhage on removal of the brachytherapy sources. Another patient developed obstructive jaundice 14 days after brachytherapy and subsequent elevated bilirubin and liver failure 9 months later, perhaps associated

with biliary injury from high-dose radiation. Mild increases in liver enzymes and bilirubin without clinical symptoms were common. The 1-year tumor control rates were 40% and 71% for the large peripheral and small hilar lesions, respectively, with an overall 1-year survival rate of 83%.[294] Interstitial brachytherapy is a highly specialized method of delivering very conformal radiation for liver metastases, only available at a few centers worldwide.

Hepatic Arterial Radioisotopes

Another method of delivering high-dose radiation to liver metastases is by infusing radiolabeled glass or resin microspheres into the hepatic artery (sometimes referred to as selective internal radiation therapy). Although a variety of radioisotopes have been investigated in this setting, the available commercial products for liver cancer use ^{90}Y. ^{90}Y is a pure β-emitter with a half-life of 64.5 hr and an average electron range of approximately 2.5 cm and an effective pathlength of 5.3 mm (meaning that 90% of the energy is deposited within a 5.3-mm radius of the microsphere). ^{90}Y is incorporated into stable glass microspheres (TheraSphere, MDS Nordion Inc., Ottawa, Canada) or resin-based microspheres (SIRTex Medical, Inc., Lane Cove, New South Wales, Australia) which are infused into the hepatic artery as a form of regional therapy for well-vascularized liver tumors.[298–304] A typical prescribed dose is 120 to 150 Gy, where the microspheres are primarily deposited at the periphery of the metastases.[305] A reduction in CEA and radiographic responses are common following hepatic arterial ^{90}Y microspheres for liver metastases. Hepatic arterial ^{90}Y microspheres have been combined safely with regional 5-FU.[300]

A randomized trial comparing the combination of hepatic arterial ^{90}Y microspheres and hepatic arterial floxuridine to hepatic arterial floxuridine alone was conducted in 74 patients with unresectable liver confined colorectal metastases who underwent implantation of an HAI pump and chronic floxuridine in 12-day cycles at 4-week intervals. The patients were randomized to receive a single dose of ^{90}Y microspheres through the hepatic artery within 4 weeks of surgery versus no other therapy. The overall response rate and median time to progression were increased in the group receiving ^{90}Y microspheres (44% vs. 18% [$P < 0.01$] and 16 months vs. 10 months [$P < 0.001$], respectively), with a trend toward an improvement in overall sur-vival (17% vs. 7% 3-year survival).[299] This randomized trial demonstrated that irradiation of metastases improves outcomes over hepatic arterial chemotherapy alone. However, the response rate for hepatic arterial floxuridine in this study was substantially less than typically reported (see earlier in this chapter), and confirmatory studies are warranted.

Challenges associated with hepatic arterial delivery of ^{90}Y include the lack of understanding of dosimetry, the requirement for specialized interventional radiology expertise, and the potential for a radiation hazard associated with lost radioisotopes.

Liver Tolerance to Irradiation

In the early 1960s it was found that doses greater than 30 Gy at 2 Gy per fraction to the whole liver led to an unacceptable risk of liver toxicity. Eight fractions of 2.25 Gy to the whole liver was found to be safe, but a small increase in fraction size to 3.5 Gy was reported in 1973 to be associated with an unacceptable rate of liver toxicity (8 of 25 patients).[306,307] The tolerance of the liver to whole-organ irradiation does not seem to be substantially altered by the concomitant use of fluoropyrimidines. In contrast, whole-liver irradiation in combination with alkylating agents or mitomycin C is associated with an increased risk of liver toxicity.[308–310] Liver toxicity following irradiation has historically been referred to as "radiation hepatitis" and more recently termed "radiation-induced liver disease" (RILD),[308] because there is no evidence of hepatitis on pathologic examination.This complication is a clinical syndrome consisting of anicteric ascites and painful hepatomegaly, occurring in the absence of disease progression, usually within 3 months following a course of radiation therapy. Laboratory evaluation demonstrates a marked elevation of alkaline phosphatase out of proportion to the modest increases in the transaminases. Although the majority of patients recover from RILD, it may progress to liver failure and death.[308] The pathophysiology of RILD is not well understood. Pathologically, venoocclusive disease, similar to that seen following bone marrow translation, is seen.

Partial liver radiation therapy was first reported in 1965 by Ingold and associates, who safely delivered as much as 55 Gy to parts of the liver.[311] Others confirmed that high-dose radiation therapy could be delivered safely, as long as a substantial portion of the normal liver was spared. Conformal radiation planning permits portions of the liver to be treated with doses of radiation far higher than what the entire liver can tolerate so long as a sufficient volume of uninvolved liver can be spared from irradiation, similar to how a surgeon can resect a substantial fraction of the liver if the remaining liver is functional. Conformal radiation treatment planning allows the fraction of uninvolved liver irradiated to be quantified. Theoretical models have been proposed to estimate the volume dependence of normal tissue tolerance—referred to as normal tissue complication probability (NTCP) models.[312–315] Such an NTCP model has been used to describe the partial liver tolerance of 203 patients treated with conformal hyperfractionated radiation therapy and hepatic arterial floxuridine (17 of whom developed RILD). This analysis found that that mean liver dose can provide an estimate of the risk of RILD occurring, with a 5% risk of toxicity following 32 Gy and 37 Gy in 1.5 Gy twice daily for patients with primary liver cancer and metastases, respectively.[316]

The partial volume tolerance of the liver to hypofractionation or SBRT has not been well established, partially in that the majority of clinical SBRT experience has not required large liver volumes to be irradiated. Guidelines used in SBRT planning include sparing of 30% and 50% of the liver from 12 Gy and 7 Gy, respectively, for three- and one-fraction SBRT),[283] and ensuring that at least 700 mL of uninvolved liver receives less than 15 Gy in three fractions.[278] Dawson and coworkers have shown the feasibility of using an NTCP model for allocation of six-fraction SBRT in over 80 patients,[292] with a wide range of liver volumes irradiated.

The safe delivery of high-dose ^{90}Y to small volumes seems consistent with the partial volume estimates from conformal radiation and SBRT series, where the upper limit on the dose of radiation that can be delivered to an effective liver volume irradiated of 20% or less has not been established. The lack of a validated dose distribution in ^{90}Y treatment makes partial liver tolerance analysis challenging for ^{90}Y therapy.

Extrapolation of NTCP models and partial liver tolerances to different centers must be done with caution, because the results may not be valid for different patient populations treated with different treatments. The partial liver tolerance to irradiation, especially in diseased livers and following SBRT and ^{90}Y, should be measured and validated in prospective studies.

FUTURE DIRECTIONS

Although it is becoming established that radiation therapy, delivered using conformal radiotherapy, SBRT, brachytherapy, or ^{90}Y microspheres, can be used safely to treat liver metastases with the potential for sustained local control, recurrences outside the irradiated volume are not infrequent, providing a rationale for combining radiation therapy with other therapies. One possibility would be to combine radiation therapy with repeated cycles of modern hepatic arterial and systemic chemotherapy. More potent radiation tumor sensitizers could also be explored. Studies of targeted therapies combined with radiotherapy should be considered, given the radiation sensitization properties of many targeted agents and survival gains observed following the combination of radiation and targeted agents in other clinical sites.[317] Conversely, normal-tissue radiation protectors, as well as more technologic advances, may allow higher doses to be delivered

to more tumors safely. For instance, the free-radical scavenger amifostine protects the normal liver (but not tumor) from radiation in preclinical studies.[318] It is hoped that these approaches will permit a greater fraction of patients to benefit from high-dose therapy and will increase local control in patients with localized unresectable intrahepatic cancers.

CONCLUSIONS

Liver metastases, especially from colorectal primaries, are treatable and potentially curable. Imaging techniques such as CT, MRI, and sonography have advanced in recent years and have led to increased sensitivity and specificity in the diagnosis of liver metastases. When properly applied, the techniques are nearly as sensitive as surgical exploration in the detection of hepatic lesions and in differentiating benign from malignant processes.

Liver surgery has improved greatly in the past two decades. Dissections along nonanatomic lines have permitted the resection of multiple lesions that might previously have been considered unresectable. The new technique of vascular exclusion might improve the safety of major hepatic resections. Resection of solitary hepatic metastases or up to two to four metastases from CRC should be regarded as the best treatment for this condition.

Noninvasive approaches to liver metastases such as cryosurgery, chemoembolization, radiofrequency ablation, or alcohol injections are available. The usefulness of these techniques compared with surgery or regional therapy is being investigated.

For focal liver metastases unsuitable for or refractory to surgery or other ablative approaches, external-beam conformal radiation therapy, SBRT, or brachytherapy may be used to attempt to locally control disease. Hepatic arterial ^{90}Y-irradiation can be used safely to treat patients with diffuse metastases, with normal bilirubin levels. The optimal timing of radiation and chemotherapy has not been established, and there is rationale for investigating the combination of simultaneous regional or systemic therapies with radiation therapy in future studies.

60 Effusions

Rosalyn A. Juergens, Alex I. Spira, and Julie R. Brahmer

SUMMARY OF KEY POINTS

Malignant Pleural Effusion

Background
- Common complication of cancer
- Frequently seen with breast and lung cancers and lymphoma
- Often asymptomatic

Incidence
- Presenting sign of malignancy in about one-half of patients who develop an effusion
- Approximately 40 cases of malignant pleural effusion diagnosed for every 10,000 hospital admissions

Diagnosis
- Exudative effusions (high protein, lactate dehydrogenase, or cholesterol) are very concerning for malignancy.
- Cytology is the gold standard.
- If an exudative effusion exists but is undiagnosed by other means, video-assisted thorascopic surgery (VATS) should be used for evaluation of the pleura.

Evaluation
- Cytology should be evaluated by an experienced pathologist.
- Low pH (<7.3) is associated with burden of disease, less likelihood of response to pleurodesis, and decreased survival.

Treatment
- Asymptomatic effusions can be monitored.
- Systemic chemotherapy can be effective in stable patients.
- For patients symptomatic from their effusions, effective options include systemic therapy for patients with very responsive disease (e.g., hematologic malignancies, germ cell tumors, breast cancer, small cell lung cancer) or repeated thoracentesis.

For patients requiring frequent thoracentesis or who rapidly redevelop effusions, options include the following:
- Pleurodesis with talc (favored), doxycycline, or bleomycin
- Pleurodesis with placement of a drainage catheter only
- VATS with mechanical abrasion
- Open surgical procedure in highly selected patients

For patients refractory to pleurodesis, options include Denver-type drainage catheter or clinical trial

Malignant Pericardial Effusion

Background
- Less common complication of cancer than pleural effusion or ascites
- Frequently seen with breast and lung cancers and lymphoma
- Size of effusion not correlated with symptoms; rather, acuity of collection and compliance of pericardium most associated with tamponade physiology
- Often a preterminal event

Incidence
- It is found in 2% to 30% of patients with cancer at autopsy.
- Only about 10% to 20% of patients with pericardial metastases develop tamponade.

Diagnosis
- Cytology is the gold standard but not very sensitive.
- Consider malignancy, comorbidities, and side effects of treatment (e.g., mediastinal radiation) in the differential diagnosis of a pericardial effusion in a cancer patient.

Evaluation
- Cytology should be evaluated by an experienced pathologist.
- Pericardial biopsy could be required if cytology is negative.
- Patients should be evaluated for clinical signs of cardiac tamponade (hypotension, signs of low cardiac output, abnormal pulsus paradoxus).
- Electrocardiogram should be evaluated for low voltages and electrical alternans.
- Echocardiogram should be obtained for all patients.

Treatment
- Asymptomatic effusions can be monitored.
- Systemic chemotherapy might be effective for stable patients, even those with solid tumors.
- Those with hypotension/clinical instability should proceed to emergent pericardiocentesis and placement of pericardial drainage catheters.
- Stable patients requiring drainage should undergo subxiphoid pericardiostomy.
- Open procedures or pericardial sclerosis should be saved for refractory patients.

Malignant Ascites

Background
- Common complication of cancer
- Frequently seen with ovarian cancer (most common cause), gastrointestinal malignancies, and carcinoma of unknown primary
- Rarely life-threatening

Incidence
- Accounts for approximately 10% of all patients with ascites
- Often (about 50% of the time) can be a presenting feature of malignancy

Diagnosis
- Ascites with low serum-to-ascites-albumin gradient is concerning for malignancy rather than portal hypertension.
- Cytology is the gold standard.

Evaluation
- Cytology should be evaluated by an experienced pathologist.
- Patient should be assessed for symptoms and probable response to systemic chemotherapy.

Treatment
- Asymptomatic ascites can be monitored.
- For patients symptomatic from their ascites, effective options include:
  Diuresis with spironolactone/furosemide
  Repeated paracentesis as needed
- Patients with moderate long-term survival can be considered for either percutaneous tunneled drainage catheter or peritoneovenous shunt.

MALIGNANT PLEURAL EFFUSIONS

A malignant pleural effusion is a common complication of cancer and is encountered frequently by oncologists and other physicians caring for such patients. Their effects can range from causing no symptoms to being markedly symptomatic. Treatments must be tailored appropriately (Fig. 60-1).

Collections of pleural fluid are likely to be directly related to tumor involvement of the pleura. For the patient with cancer, diagnostic accuracy in the assessment of pleural effusion is of the utmost importance. In many instances, the existence of a malignant pleural effusion drastically alters the treatment modalities that a patient will ultimately undergo; likewise, it drastically alters the likelihood of curing a patient with cancer. Nevertheless, many patients with cancer might have undergone surgery, have had radiation, or have other possible reasons for an effusion; there could therefore be alternative, benign reasons for an accumulation of pleural fluid. With this in mind, it is important to determine the appropriate cause of an effusion to provide optimal care.

Etiology and Pathogenesis

Pleural Space

The pleural space is a real space completely surrounding the lung up to the hilar root; the visceral pleura covers the lung and interlobar fissures, and the parietal pleura covers the chest wall, diaphragm, and mediastinum. The small amount of normal physiologic pleural fluid allows transmission of the breathing effort from the lung to the chest wall, thereby allowing respiration to occur. With the aid of a lavage technique in humans, each normal lung has been found to have approximately 0.13 mL pleural fluid/kg body mass (approximately 7 mL per lung).[1,2]

Under normal conditions the body is highly efficient in controlling the amount of pleural fluid present; a 10-fold increase in the production rate of fluid results in only a 15% increase in pleural fluid volume.[3] Malignant effusions are caused by both increased entry and decreased exit of fluid. Increased fluid entry seems to be the principal abnormality, because there are multiple pathways and channels of fluid resorption. Among patients whose effusion reaccumulates rapidly after drainage, it is likely that the patient has mainly an increased production of fluid. Exit blocks probably account for a small number of patients (5% to 10%) with a malignant effusion and most often appear as a transudate upon analysis.[4] In evaluating the cause of an effusion, it is helpful to classify effusions according to their mechanism (Table 60-1).

The molecular biology of pleural effusions has begun to be understood, with vascular endothelial growth factor (VEGF) emerging as a major role player.[5] Because it induces endothelial vasodilation and enhances the permeability of the mesothelium 50,000 times more potently than histamine, VEGF is thought to be a major, if not the most important, cytokine in the etiology of effusions.[6] It might one day be part of the diagnostic evaluation of effusions. Novel approaches that use anti-VEGF mechanisms will probably be evaluated once this is better understood.[7]

Incidence

More than a million pleural effusions occur each year, with about one-half arising from congestive heart failure (CHF). About one-fifth of effusions are malignant, but malignancy is the most common cause of symptomatic effusions. Under-reporting in most series might also be a significant issue. The causes of malignant pleural effusions are shown in Table 60-2 and reflect the incidence of cancers in general, with lung and breast cancers at the top of the list.[8–14]

Diagnosis and Evaluation of a Pleural Effusion

Pleural effusions are apparent on a chest radiograph when a volume of 200 mL or greater of fluid is present.[15] Oncologists' patients can be generally subdivided into those with clear advanced disease and probable malignant pleural effusion and those who have a history of malignancy but in whom the effusions may or may not be malignant. Among patients with advanced cancer, there is often no question as to whether the effusion is directly related to the malignancy, or the question is unimportant in terms of the patient's overall clinical management. In such a case, one can simply observe asymptomatic patients. For the patient in which an effusion could be malignant, however, accurate diagnosis becomes imperative for patient care and management, and one must consider all alternative causes in the etiology of the effusion. These include the possibility of other coexisting illnesses (e.g., CHF, infection), consequences of treating a prior malignancy (e.g., sequelae of prior surgery, radiation, or chemotherapy), and the possibility that the effusion is indeed malignant. Most locally advanced solid-tumor malignancies are considered incurable if the effusion is malignant, and treatments and goals of treatment will thus become dramatically different. In some cases, however, such as for childhood tumors (e.g., Ewing's sarcoma) or germ cell tumors, patients might remain curable but treatment plans can become radically different. Hematologic malignancies (e.g., lymphomas) might be upstaged, and this step might or might not affect

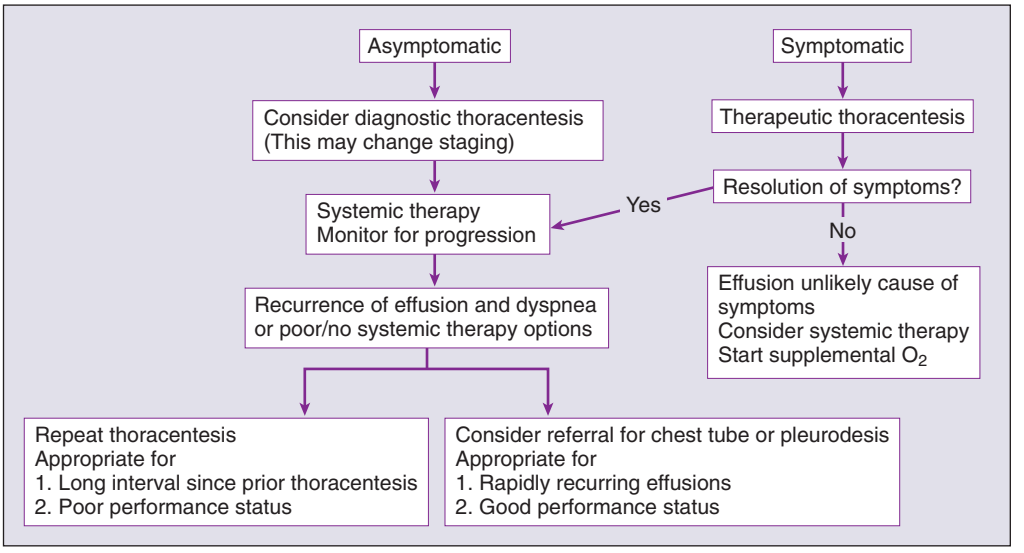

Figure 60-1 • Treatment approach to malignant pleural effusions.

Table 60-1 Differential Diagnosis of Pleural Effusion by Mechanism

INCREASED PERMEABILITY OF CAPILLARIES/LYMPHATICS
Malignancy
Metastatic malignancy
Intrathoracic malignancy (lung cancer)
Malignant mesothelioma
Infection
Bacterial, viral, fungal, mycobacterial, mycoplasmal, parasitic empyema
Pulmonary embolism
Connective tissue disorders
Drug induced (nitrofurantoin, procarbazine, amiodarone)
Esophageal rupture
Pancreatitis
Uremia
Postradiation
Collagen vascular disorders
Rheumatoid arthritis, systemic lupus erythematosus, Wegener's granulomatosis, polyarteritis nodosa, Churg-Strauss syndrome
Dressler's syndrome (postmyocardial infarction syndrome)
Subdiaphragmatic abscess
Systemic capillary leak syndrome/adult respiratory distress syndrome
Vascular trauma
Postsurgical (including thoracic and abdominal surgeries)
Sarcoid
Yellow-nail syndrome
Myxedema
INCREASED VENOUS HYDROSTATIC PRESSURE
Congestive heart failure
Superior vena cava syndrome
Massive pulmonary embolism
INCREASED LYMPHATIC PRESSURE
Malignancy
Metastatic malignancy
Lymphoma
Sarcoidosis
Chylothorax
Post–lymph node irradiation
Meig's syndrome
Peritoneal dialysis
DECREASED ONCOTIC PRESSURE
Hypoalbuminemia (often from cancer cachexia)
Hypoproteinemia
Cirrhosis
Nephrotic syndrome
Glomerulonephritis
ALTERED INTRAPLEURAL DYNAMICS
Trapped lung (infection, malignancy)
Atelectasis

Table 60-2 Malignant Neoplasms Associated with Pleural Effusion

Cause	No.	Percent
Total malignant effusions	1283	100
Lung cancer	450	35
Breast cancer	256	20
Lymphomas and leukemia	256	20
Unknown primary (adenocarcinoma)	154	12
Unknown primary (all types)	95	7
Gastrointestinal tract	90	7
Reproductive tract	70	5
Genitourinary tract	66	5
All other*	39	3

*Includes causes of malignant effusion (each less than 1%): endocrine, head and neck cancer, mesothelioma, soft-tissue sarcoma, bone cancer, and myeloma.

the planned treatments. Lung cancer, the most common etiology of malignant effusions, can cause effusions both via direct involvement of pleura by tumor with increased fluid production and by decreased exit via lymphatic blockage. Patients with non-small-cell lung cancer and transudative effusions on multiple evaluations of their pleural fluid are, in fact, considered early stage and are usually treated with curative intent, as if the effusion were caused by lymphatic blockage and not direct involvement of the pleura. Those with exudative effusions are considered to have advanced disease, even if malignant cells cannot be found, and are treated in a palliative manner. Patients with small cell lung cancer with exudative effusions are considered to be "extensive stage" because the field cannot be covered in a single, tolerable radiation port; these patients are treated in a palliative manner with chemotherapy alone. Patients with other nonmalignant reasons for effusions (e.g., large amount of ascites and cirrhosis or CHF) may be observed, but the physician should have a low threshold for reevaluation should clinical conditions change (e.g., a new fever or new shortness of breath) or if the effusion fails to resolve with appropriate measures.[16]

History and Physical Examination

Patients with pleural effusions usually present with dyspnea, chest pain, cough, or orthopnea. Other symptoms, such as hemoptysis, fever, and dysphagia, might also occur but are less common. Physical examination usually demonstrates dullness to percussion, decreased or absent breath sounds, and absence of fremitus. As a result of atelectasis of the adjacent lung, one can often hear crackles at the superior borders of the effusion. Both sides should be listened to equally to determine whether the effusion is unilateral or bilateral. Bilateral, symmetric effusions might be more associated with volume overload states such as CHF, although this is a nonspecific finding. The examination should also be alert for signs of systemic infection or other clues about the etiology of the effusion.

Radiologic Evaluation

The use of a chest radiograph to evaluate a suspected pleural effusion is the most valuable and easiest tool. Lateral views should be obtained along with posterioanterior views, because the latter miss as much as 500 mL of fluid hidden behind the dome of the diaphragm. At least 75 mL of fluid is needed to obscure the posterior costophrenic angle; up to 175 mL of fluid is required to obscure the lateral costophrenic angle. If the effusion reaches the fourth rib, 1000 mL is present; as little as 10 mL can be seen on a decubitus film. In terms of sampling

for thoracentesis, a general rule of thumb is that an effusion that is thicker than 1 cm on a decubitus film is large enough for sampling by thoracentesis.[17] Computed tomography (CT) scanning is even more accurate in detecting small effusions, including as little as 2 mL of fluid. The volume of the fluid present can best be determined radiographically by using three-dimensional reconstruction.[18] Neither magnetic resonance imaging (MRI) nor CT scan can distinguish transudates from exudates accurately, although both can be helpful in evaluating the pleural contents for masses, nodules, and pleural-based thickening once the fluid is removed.[19] Ultrasound is useful in evaluating for the presence of an effusion and as a guide during thoracentesis. Ultrasound also may aid in distinguishing an exudate (echogenic) from a transudate (anechoic), although this finding is not definitive.[20]

Thoracentesis

Among patients with an effusion that requires evaluation, the radiograph should be evaluated to determine whether the effusion is loculated. If the effusion is not free-flowing on the decubitus film and is therefore loculated or if the volume is insufficient to attempt a safe, unguided thoracentesis, ultrasound guidance should be used.[21,22] When obtaining fluid, samples should be collected into tubes containing heparin to prevent clot formation; cloudy fluids should be centrifuged before the analysis described shortly.[23] Relative contraindications to thoracentesis include a skin infection at the site of needle insertion, an abnormal coagulation profile (prothrombin time or partial thromboplastin time >1.8 times normal, platelets <25,000/mm^3, or creatinine >6 mg/dL), or uneasiness of the operator in performing the procedure.[24] Mechanical ventilation does not seem to increase the risk of pneumothorax, but there could be a higher likelihood of developing a tension physiology if a pneumothorax does occur.[25] Complications of the procedure include pain, bleeding (hemothorax or hematoma), infection, splenic or hepatic laceration, seeding of the needle tract with tumor, or, most commonly, pneumothorax.[26] Studies show that in thoracenteses performed by trained physicians, pneumothoraxes occur approximately 10% of the time, with a much higher rate when performed by trainees.[16,25] Small pneumothoraxes can be observed in nonventilated patients, whereas larger ones might require chest tube decompression. Although chest radiograph is often obtained after thoracentesis, it is not required for patients who are clinically asymptomatic after the procedure (absence of cough, chest pain, shortness of breath, and a normal lung examination), who do not experience aspiration of air, and for whom only one needle pass was used during the procedure.[27] The use of a therapeutic thoracentesis is discussed shortly.

Evaluation of Fluid: Transudates and Exudates

Fluids are classified as either transudates or exudates. Transudates arise from a disturbance in the hydrostatic or colloid forces across a barrier and have low protein and cellular contents. By definition this is a noninflammatory process without pleural disease. A classic example of a transudative effusion is one due to CHF. Transudates may be thought of as volume overload states and are in general benign. Exudates, on the other hand, are formed by active secretion, inflammation, leakage, or permeability of a lymphovascular barrier and have a high cellular or protein content. They have a broader list of potential causes, can be more serious in their effects, and mandate a more thorough evaluation. In reality, most effusions that will be referred to an oncologist will be exudative in nature, because transudative effusions often present with a known systemic disease—for example, heart failure, cirrhosis, or nephrotic syndrome.

Dividing effusions into one of these two categories is conceptually useful in classifying patients with unknown effusions. In 1972 Richard Light published what has become the classic criteria for the biochemical classification of a pleural effusion and now is commonly known as Light's criteria.[28] According to this system, the values of lactate dehydrogenase (LDH) and protein are measured both in the pleural fluid and in serum, and the effusion is classified as an exudate if any one or more of the following three criteria are met:

1. Ratio of pleural protein to serum protein greater than 0.5
2. Pleural LDH greater than two-thirds of the upper limit of normal for the serum reference range
3. Ratio of pleural LDH to serum LDH greater than 0.6

Criterion number 2 reflects a modification from the original published manuscript to account for the wide variation in the normal range of LDH in various reference laboratories.[23,29] A recent reevaluation of Light's criteria comes from Keller, demonstrating that Light's criteria have an overall sensitivity for an exudate of near 100%, but a specificity of only approximately 80%.[30]

Cholesterol

The level of cholesterol is higher in exudative than transudative effusions for unclear reasons. Costa and colleagues were able to demonstrate that a cholesterol concentration greater than 45 mg/dL and an LDH greater than 200 IU/L in the pleural fluid alone identified exudates with a very high sensitivity (99%) and specificity (98%) without the requirement for a serum sample.[29] Using a pleural cholesterol to serum cholesterol ratio threshold of 0.3, Valdes and associates were able to provide fewer misclassifications than when applying Light's criteria.[31] In short, the level of cholesterol in pleural fluid seems useful in distinguishing exudates from transudates.

Optimal Testing

Light's criteria have stood the test of time and are the most widely regarded. A meta-analysis of eight studies including 1448 patients was unable to define an optimal diagnostic technique.[32] Based on these results, a 21st-century version of Light's criteria, modified only slightly from Light's original work by the addition of cholesterol as a marker, could be suggested as the best means of determining an exudate. According to these updated criteria, a patient can be said to have an exudate if any of the following criteria are met[32]:

- Pleural fluid protein greater than 2.9 g/dL
- Pleural fluid cholesterol greater than 45 mg/dL
- Ratio of pleural fluid LDH to serum LDH greater than 0.6

The aforementioned meta-analysis demonstrated no superior combination (paired or triplet) to any one of these single tests. In most cases, particularly in the presence of obvious, known cancer, one should not have to delve beyond these criteria in the initial evaluation of a pleural effusion.

Other Testing

There are other situations in which a specific test might not differentiate between an exudate and a transudate but still might be helpful in differential diagnosis. However, although these tests are useful, they are not 100% specific but merely provide the clinician with some general clues that must be evaluated further.

VISUAL EVALUATION. The first step in the evaluation of pleural fluid is visual observation as it is removed. Strawlike fluid is more likely to be benign and transudative in nature. Fluid containing puslike material is more likely to be infective in nature. Bloody fluid is related to causes such as pulmonary infarction, malignancy, or a postoperative state. In general these clues can be helpful, but no diagnosis can be made definitively.

pH. In a diagnostic thoracentesis, pleural fluid pH should always be measured. For proper analysis, pleural fluid should be collected into a single syringe and a sample then transferred to a smaller, heparinized syringe for analysis.[33]Analysis should be via a blood gas machine, not on litmus paper, because the latter is unreliable and not an acceptable alternative.[34] Normal pleural fluid pH ranges from 7.60 to 7.64.

In one study, 46 patients with a pleural fluid pH less than 7.30 all had an exudate and one of the following six diagnoses: malignancy, empyema, collagen vascular disease, tuberculosis, esophageal rupture, or hemothorax.[35] Furthermore, patients with known malignant effusions and a pH less than 7.30 have a worse prognosis, shorter mean survival, poorer response to tetracycline pleurodesis, and a high rate of finding malignant cells on initial fluid cytology.[36] It should be remembered that patients with a parapneumonic effusion with either a pH less than 7.3 or gross pus should be considered for chest tube placement for drainage. The reader is referred to other texts for the management of empyemas.

CELL COUNT AND CYTOLOGY. Cell counts are often obtained on pleural fluids but are rarely useful or diagnostic. Very high nucleated cell counts (>50,000 per milliliter) are associated with complicated parapneumonic effusions and empyema but rarely are diagnostic.[16] Because most cells are normally neutrophils or monocytes, a predominance of lymphocytes (>50%) should make one more seriously entertain the idea of a carcinomatous pleural effusion, and greater than 85% lymphocytes should make one entertain the diagnosis of lymphoma, sarcoidosis, chylothorax, rheumatoid pleurisy, or yellow nail syndrome.[16,37] An increase in pleural fluid eosinophilia (>10% of nucleated cells) might be associated with benign disease (hemo- or pneumothorax), but also can be associated with all types of malignancy.[38] The presence of mesothelial cells is not helpful in terms of diagnosis.[37,39]

Pleural fluid cytology is the simplest and most definitive method of diagnosing a malignant effusion. The sensitivity depends on the type of malignancy, extent of disease, and experience of the cytopathologist. Fluids should be concentrated first for optimal detection of malignancy.[40] In general, the sensitivity is on the order of 62% to 90% and, as the gold standard, pleural fluid cytology is virtually 100% specific in the hands of an expert cytopathologist.[41] If an effusion demonstrates carcinoma and breast cancer is a diagnostic possibility, the cytologic specimen can be stained for estrogen and progesterone receptors as a means of both diagnosis and selection of potential treatment. In short, the presence of an abnormal cell population should prompt a further workup for the aforementioned causes, including malignancy.

Other tests have been evaluated in numerous studies as a means to refine the diagnosis of pleural effusions. For example, an elevated adenosine deaminase concentration has a high association with tuberculosis.[42] Elevated lipids (triglycerides) can be associated with a chylothorax and obstruction of the thoracic duct by any number of means, including malignancies.[43] In clinical experience, this and other tests (e.g., creatine kinase, LDH isoenzyme analysis, β_2-microglobulin, albumin, ferritin, lysozyme, and others) are rarely used, are rarely associated with malignancy, and are therefore discussed elsewhere.[23] Other tests including tumor markers (carcinoembryonic antigen [CEA], CA 19-9) have also been evaluated for use in determining the etiology of effusions but have not been found to be sensitive or specific.

Evaluation of a Suspected Malignant Effusion

Although most malignant effusions occur among patients with known cancers, they can be the first indication of the presence of malignancy in as many as 30% of patients.[44] In some patients an effusion often can be the only site of a potential malignancy after a thorough evaluation. Once a patient has been diagnosed with an exudative effusion, a malignant cause must be high on the list of differential diagnoses. A thorough history and complete physical examination must be performed, with careful attention to any potential causes or risk factors of malignancy. Once this evaluation takes place, the physician must gather some definitive evidence to institute appropriate evaluation. Frequently, such evidence involves consultation between the patient's primary physician and either a pulmonologist or an oncologist. Many clues about the etiology of the effusion are obtained with the performance of further evaluations, such as chest radiographs, CT scans, or mammograms. Alternatively, cytologic evaluation of an exudative effusion can reveal the presence and type of malignancy directly.

It is important to keep in mind the most common malignancies that cause effusions. Not surprisingly, a majority of these are caused by lung cancer. Breast cancers and lymphomas also cause a significant number of these, with approximately one-third of all malignant pleural effusions being caused by other types of malignancies (see Table 60-2).[45] Appropriate evaluations should be performed as indicated (e.g., careful breast examination and mammogram in women with effusions; particular attention for lung cancer among patients with a history of smoking). It should be noted that there is a recently established entity, primary effusion lymphoma. This is found in patients positive for the human immunodeficiency virus; it is associated with human herpesvirus 8 infection and has a pathogenesis similar to Kaposi's sarcoma.[46] This syndrome also can include pericardial effusions and ascites. Patients with mesothelioma often have a history of asbestos exposure and show evidence of both effusion and pleural thickening on CT scan. These patients can be considered for CT-guided biopsy of the appropriate areas, which is often effective in making a diagnosis.[47] A small percentage will be diagnosed with carcinoma of unknown primary, whose management, usually via chemotherapy, is also discussed in Chapter 98. Even after an extensive evaluation, results can be nondiagnostic, and the patient must undergo further evaluation to determine the etiology of the effusion because no other cause has been identified although malignancy is still suspected. These further evaluations will now be discussed.

Closed Pleural Biopsy

These refer to blind, percutaneous biopsies of the parietal pleura using a special needle, such as a Cope's needle. Unfortunately, among patients with a cytology-negative malignant effusion, the yield of this procedure is only about 7%.[48] Novel approaches to this procedure, such as the use of brushings or a Tru-cut needle, might ultimately prove to be better diagnostically, but the procedure is currently rarely used in such situations because of its poor yield.[49,50]

Thoracoscopy

Video-assisted thoracoscopic surgery (VATS) is the most commonly used procedure for thoracoscopy in the United States and is usually performed by thoracic surgeons. This procedure, using several ports and trochars, requires general anesthesia with single-lung ventilation and many single-use disposable instruments.[51] Although VATS is well tolerated, it does have some risks and carries with it a significant expense, due to general anesthesia and the requirement for expensive instruments. On occasion, it requires conversion to an open procedure if there are significant adhesions or if there are undue risks noted with the insertion of a thoracoscope.[45] Single-lung ventilation is also required and might be difficult for patients with significant lung disease.

With these techniques, fewer than 10% of malignant pleural effusions go undiagnosed, and thus thoracoscopy of some sort has become part of the evaluation algorithm when necessary if other methods fail.[52] Interestingly, a recent technique uses a semi-rigid pleuroscope, which is similar to bronchoscopes currently in use by pulmonologists but easier to use. These can be used to drain and pleurodese effusions and might ultimately decrease the need for VATS in diagnosing potentially malignant effusions if comparison studies demonstrate its effectiveness.[53]

Treatment

For most malignancies, the existence of a malignant effusion places the patient into a noncurable, advanced staging category, but one
