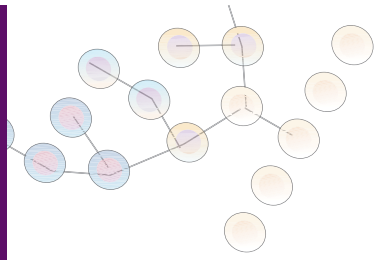
Memorial

Martin D. Abeloff, MD

Martin D. Abeloff, a founding editor of *Clinical Oncology,* died on September 14, 2007 in Baltimore, Maryland after a courageous battle with cancer, a disease he had dedicated his life to fighting. He was a wonderful and caring clinician, an extremely effective leader, and a beloved mentor to many trainees and young faculty. Marty was the kind of friend you hope to have and the kind of clinician and clinical scientist that you would want to be. He will be sorely missed as a colleague, a physician, a father, a husband, and a friend.

Marty was born on April 4, 1942 in Shenandoah, Pennsylvania. He received his BA from The Johns Hopkins University in 1963, and his MD from The Johns Hopkins University School of Medicine in 1966. He spent the next year as an intern at the University of Chicago Hospitals and Clinics. In 1967, he eclipsed his already numerous accomplishments by marrying Diane Kaufman. The two daughters of this union, Alisa and Jennifer, represent Marty's most enduring and important legacy.



His second legacy, in medicine, was established on his return to Baltimore in 1971, as a fellow in clinical oncology. He would spend the rest of his career at The Johns Hopkins Hospital. He achieved the rank of Professor of Medicine in 1990 and, at various times, served as the training program director, chief of medical oncology, clinical director of the cancer center, oncologist in chief at The Johns Hopkins Hospital, and, since 1992, the director of The Johns Hopkins Oncology Center, later renamed the Sidney Kimmel Comprehensive Cancer Center. During that time, Marty brought to life the idea of a comprehensive, user-friendly textbook of oncology that would be as valuable to the practicing oncologist as to the primary care physician and physicians-in-training. The first edition of *Clinical Oncology* was published in 1995 to a gratifying response. It is now established as a cornerstone reference for those caring for patients with cancer.

In the fourth edition, we mourn the loss of our friend and colleague, but we continue Marty's vision for a better, unique, and

user-friendly text. In his honor, this edition has been renamed *Abeloff's Clinical Oncology* so that future generations of oncologists will remember his inspiration and leadership.

The editors, all of whom were recruited by Marty to work with him on this book, dedicate this text, which is already a tangible aspect of his legacy in medicine, as a living memorial to him. *Abeloff's Clinical Oncology* will serve as a reminder to all its users of this extraordinary person and exemplary physician who went before them. It was a privilege to have worked with him.

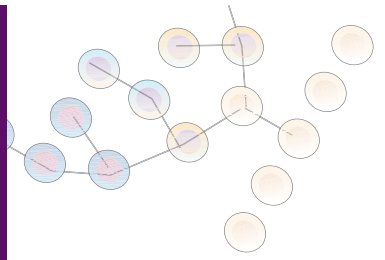
W. Gillies McKenna, MD, PhD

Preface

Few specialties in medicine are experiencing the rapid advancement in both laboratory and clinical science that is occurring in clinical oncology. The genetic mechanisms underlying cancer and their downstream effects are quickly becoming understood. This improved understanding of the molecular pathways in specific cancers is being translated into improved therapy. The development of antibodies and small molecules aimed at specific molecular targets that are key in the neoplastic process provide the promise of less toxic and more effective therapeutic options. Cancer prevention as a clinical science is making advances both in eliminating known carcinogens (e.g., tobacco) and in the development of drugs that inhibit carcinogenesis. The accumulative effect of these advances is, for the first time, sustained reduction in the age-adjusted death rate from cancer in the United States.

The fourth edition of *Abeloff's Clinical Oncology* incorporates these exciting changes. Each chapter begins with a summary highlighting the key points that would, for example, allow one to pass a board exam. In addition to a critical analysis of the literature, authors present their own opinions in specially identified boxes and algorithms. The use of color throughout the text makes the material more easily understood.



Our goal is to provide a textbook that is the most useful, understandable, attractive, and thorough in presenting the principles of clinical oncology. It is meant to be equally useful to students and trainees, experts in the various disciplines of oncology, and as a reference text for physicians from other disciplines who also see patients with cancer. It is our hope that readers will find this scholarly textbook properly balanced between the disciplines of science, clinical medicine, and humanism and that it will serve them well in their efforts to prevent, diagnose, and effectively treat their patients suffering from cancer.

The multidisciplinary nature of cancer care is, and will continue to be, reflected in our editors. Specialists in pediatric oncology, surgical oncology, radiation oncology, medical oncology, and hematologic malignancies direct the development of the book. Reflecting the interdisciplinary care necessary for optimal care of patients, many chapters are the joint product of several of these disciplines. The editors are deeply indebted to our outstanding authors who, in a most diligent and thoughtful way, have brought their knowledge and skills to the fourth edition of *Abeloff's Clinical Oncology*.

ACKNOWLEDGMENTS

This fourth edition represents a highly collaborative and dynamic effort between the editors and Elsevier. We are greatly indebted to Dolores Meloni for her creative input and guidance and for turning the principles behind this text into a reality. Mary Beth Murphy and Nancy Lombardi are acknowledged for their truly exceptional support of this project. The expert support provided by Michele Pass, Elaine Ryan, Simone John, Margaret Hall, and Kim Bennett is also greatly appreciated. Finally, we want to express our gratitude to our outstanding authors for their superb contributions and for their generosity and friendship.

A. BIOLOGY AND CANCER

1 Molecular Tools in Cancer Research

Nadia Rosenthal

SUMMARY OF KEY POINTS

- Our understanding and treatment of cancer have always relied heavily on parallel developments in biological research. Molecular biology provides the basic tools to study genes that are involved in cancer growth patterns and tumor suppression. An advanced understanding of the molecular processes that govern cell growth and differentiation has revolutionized the diagnosis and prognosis of malignant disorders.
- Current cancer research seeks to integrate the complex interaction of the cell's genome with its environment and emphasizes the need for a systematic approach to the analysis of gene function and dysfunction in the context of the intact organism. Discovery of the mechanisms that are responsible for genetic instability may lead to more reliable tests for hereditary susceptibility to cancer and, ultimately, to more effective therapies.
- This introductory chapter relates basic principles of molecular biology to emerging perspectives on the origin and progression of cancer and explains newly developed laboratory techniques, including whole-genome analysis, expression profiling, and refined genetic manipulation in animal models, providing the conceptual and technical background necessary to grasp the central principles and new methods of current cancer research.

INTRODUCTION

Since the previous edition of this book was published, advances in our understanding of the basic mechanisms of cancer have continued to inform and refine clinical approaches to prevention and therapy. New prognostic and predictive markers derived from molecular biology can now pinpoint specific genetic changes in particular tumors or detect occult malignant cells in normal tissues, leading to improved technologies for tumor screening and early detection. Diagnostic approaches have expanded from morphologic criteria and single-gene analysis to whole-genome technologies imported from other biological disciplines. A new systemic vision of cancer is emerging, in which the importance of individual mutation has been superseded by an appreciation for the new parameters set by gene-environment interactions, with profound influences on a tumor cell's transcriptional profile and function. Results from these cross-disciplinary applications underscore the complexity of carcinogenesis and promise to streamline the design of strategies for both cancer prevention and advanced cancer therapy.

This overview will serve as a foundation of conceptual and technical information for understanding the exciting new advances in cancer research that will be described in subsequent chapters. Since the discovery of oncogenes, which provided the first concrete evidence of cancer's genetic basis, applications of advanced molecular techniques and instrumentation have yielded new insights into normal cell biology as well. A basic fluency in molecular biology will soon be a necessary prerequisite for clinical oncologists, since many of the new diagnostic and prognostic tools that are in use today and will be in use tomorrow will rely on these fundamental principles of gene, protein, and cell function.

OUR UNSTABLE HEREDITY

Cancer genetics has classically relied on the candidate gene approach, detecting acquired or inherited changes in specific genetic loci accumulated in a single cell, which then proliferates to produce a tumor composed of its identical clonal progeny. During the early steps of tumor formation, mutations that lead to an intrinsic genetic instability allow additional deleterious genetic alterations to accumulate. These genetic changes confer selective advantages on tumor cell clones by disrupting control of cell proliferation. The identification of specific mutations that characterize a tumor cell has proved invaluable for analyzing the neoplastic progression and remission of the disease.

Methods for mutation detection all rely on the manipulation of DNA, the basic building block of heredity in the cell. DNA consists of two long strands of polynucleotides that twist around each other clockwise in a double helix (Fig. 1-1). Nucleic acid bases attached to the sugar groups of each strand face each other within the helix, perpendicular to its axis. These comprise only four bases: the purines adenine and guanine (A and G) and the pyrimidines cytosine and thymine (C and T). During assembly of the double helix, stable pairings of nucleotides from either strand are made between A and T or between G and C. Each base pair forms one of the billions of rungs in the long, unbroken ladder of DNA that forms a chromosome.

The functional unit of inherited information in DNA—the gene—is most often represented by a discrete section of sequence that is necessary to encode a particular protein structure. Gene expression is initiated by forming a copy of the gene, messenger RNA (mRNA), which is constructed base by base from the DNA template by a polymerase enzyme. Once the sequence is transcribed, an RNA transcript is modified at both ends and then undergoes a highly regulated process called splicing. In higher organisms, most protein-coding gene sequences are interrupted by stretches of noncoding sequences, called introns. The genetic machinery must remove these introns to form a continuous chain of coding sequences, or exons, which subsequently undergo translation into protein. The splicing process requires absolute precision because the deletion or addition of a single nucleotide at the splice junction would throw the three-base coding sequence out of frame.

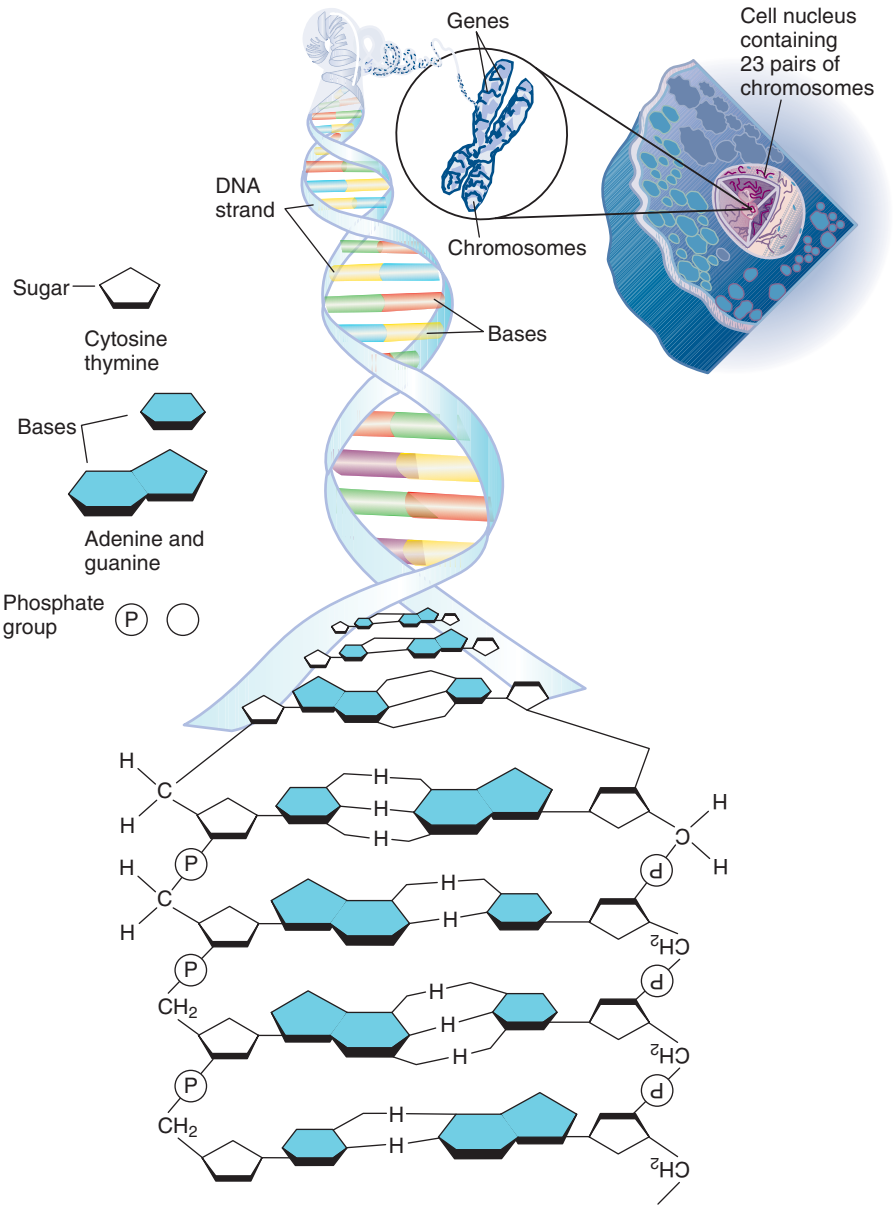

Figure 1-1 • DNA (deoxyribonucleic acid) is the cell's genetic material, contained in single compacted strands comprising chromosomes within the cell nucleus. In the DNA double helix, the two intertwined components of its backbone are composed of sugar (deoxyribose) and phosphate molecules that are connected by pairs of molecules called bases. The sequence of four bases (guanine, adenine, thymine, and cytosine) in the DNA helix determines the specificity of genetic information. The bases face inward from the sugar-phosphate backbone and form pairs with complementary bases on the opposing strand for specific recognition. The arrangement of chemical groups is unique for each base pair, allowing base pairs to be specifically targeted by transcription factors, polymerases, restriction enzymes, and other DNA-binding proteins.

The biologic importance of RNA splicing is not entirely understood, but many medically relevant genes have alternative splice patterns in which different combinations of exons are chosen for the final mRNA transcript, such that one gene can encode many different proteins (Fig. 1-2). The choice of protein isoform to be expressed from a gene with multiple splicing possibilities is a decision that can be perturbed in disease. Since protein synthesis occurs in the cytoplasm, genetic information is transported out of the nucleus by mRNA. In the cytoplasm, proteins are then synthesized, or translated, in macromolecular complexes called ribosomes that read the mRNA sequence and convert the nucleic acid code, based on three-base segments or codons, into a 20-amino-acid code to form the corresponding protein.

The complete set of DNA sequences carried on all the chromosomes is known as the genome. Although the general map of the genome is shared by all members of a species, the recent sequencing of the human genome has given us new tools to reveal the more subtle variations that arise between individuals. These variations are critical, both as a natural engine driving heterogeneity within a species and as a source of predisposition to cancer types. The most common forms of human genetic variations arise as single-nucleotide polymorphisms (SNPs). Because these allelic dissimilarities are abundant, inherited, and dispersed throughout the genome, SNPs can be used to track racial diversity, personal traits, and susceptibility to common forms of cancer (Fig. 1-3).

How do SNPs arise between individuals? One source of variation in DNA sequence derives from deviations in the strict base-pairing rule underlying the structure, storage, retrieval, and transfer of genetic information. The duplicated genetic information in the two strands of DNA not only permits the repair of a damaged coding sequence, but also forms the basis for the replication of DNA. During cell division, polymerase enzymes unwind the DNA strands and copy them, using the base sequences as a template for constructing a new helix so that the dividing cell passes its entire genetic content on to its progeny. Errors in this process are rare, and person-to-person differences make up only about 0.5% of the human genome. SNPs are inherited if they occur in the germline. Most genetic variation is of no obvious functional consequence, occurring in regions that do not

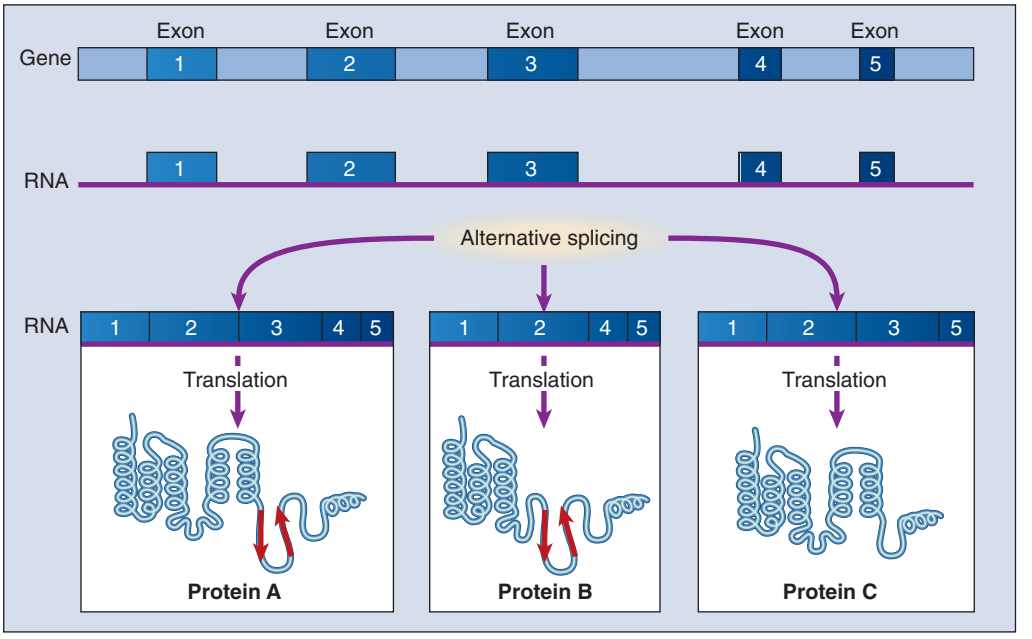

Figure 1-2 • Alternative splicing produces multiple related proteins, or isoforms, from a single gene. (Adapted from Guttmacher AE, Collins F: Genomic medicine: A primer. N Engl J Med 2002;347:1512–1520.)

encode protein or alter the regulation of nearby genes. Given the disruptive effects that even subtle genetic changes can have on cell function, it is important to distinguish SNPs that represent mutations from benign polymorphisms.

Our ability to monitor hundreds of thousands of SNPs simultaneously is one of the most important advances in modern medical genetics. Relatively simple genotyping technologies for SNP detection rely largely on the polymerase chain reaction (PCR). In this procedure, two chemically synthesized single-stranded DNA fragments, or primers, are designed to match chromosomal DNA sequences flanking the segment in which an SNP is positioned. The strands of genomic DNA are separated by heating and, after cooling, the primer

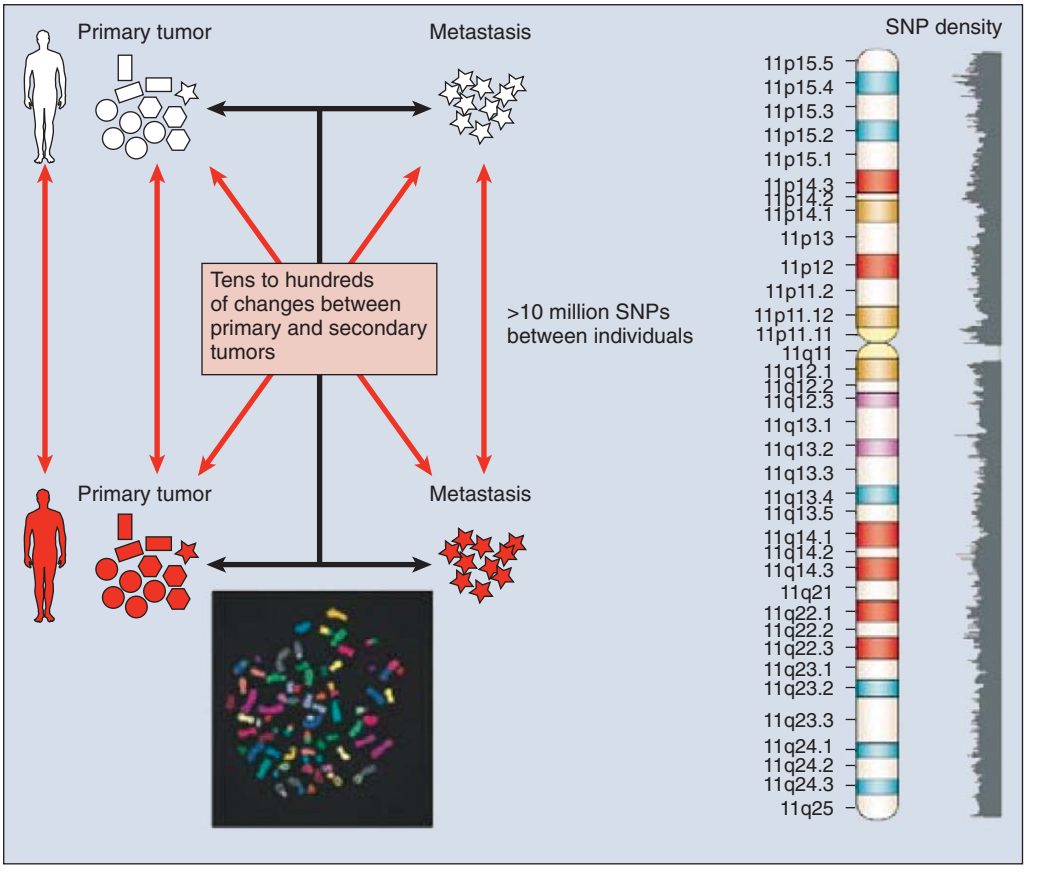

Figure 1-3 • Using SNPs to determine cancer susceptibility. Millions of single-nucleotide polymorphisms (SNPs) exist between individuals, as depicted by the *red arrows* and the SNP density map of human chromosome 11 (*right*). By contrast, point mutations, deletions, insertions, and rearrangements between normal tissues and tumors or between primary and secondary tumors probably number in the tens to hundreds (or potentially thousands), as depicted by the spectral karyotype image at the bottom of the figure. Because the constitutional genetic polymorphisms are present in all of the tissues of the body, it might be possible to distinguish differences in metastatic versus nonmetastatic tumors and in nontumor tissue before they ever happen to develop a solid tumor. (Adapted from Hunter K: Host genetics influence tumour metastasis. Nat Rev Cancer 2006;6:141–146.)

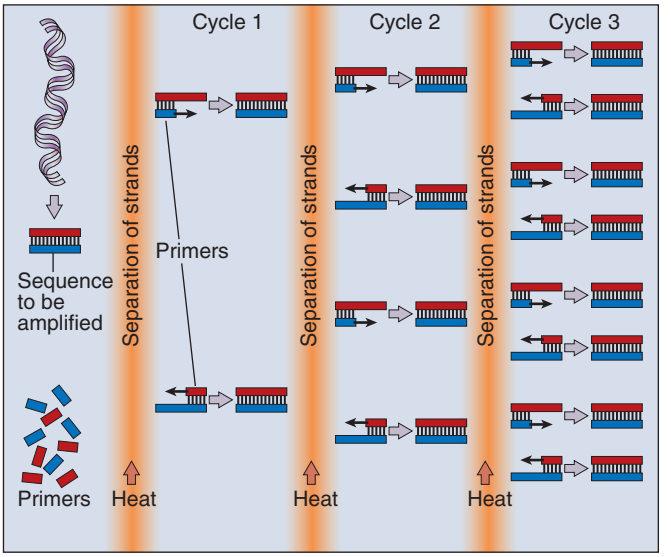

Figure 1-4 • Amplification of DNA by PCR. The DNA sequence to be amplified is selected by primers, which are short, synthetic oligonucleotides that correspond to sequences flanking the DNA to be amplified. After an excess of primers is added to the DNA, together with a heat-stable DNA polymerase, the strands of both the genomic DNA and the primers are separated by heating and allowed to cool. The polymerase elongates the primers on either strand, thus generating two new, identical double-stranded DNA molecules and doubling the number of DNA fragments. Each cycle takes just a few minutes and doubles the number of copies of the original DNA fragment.

binds to its matching sequence in the genomic DNA. With the addition of nucleotide building blocks and a heat-stable DNA polymerase, the primer pairs, or amplicons, initiate synthesis of new DNA strands using the chromosomal material as a template. Each successive copying cycle, initiated by "melting" the resulting double-stranded products with heat, doubles the number of DNA segments in the reaction (Fig. 1-4). The technique is exceptionally sensitive; millions of identical DNA copies can be generated in a matter of hours with PCR using a single DNA molecule as the starting material. Other novel methods for large-scale SNP detection include single nucleotide primer extension, allele-specific hybridization, oligonucleotide ligation assay, and invasive signal amplification, which detect polymorphisms directly from genomic DNA without the requirement of PCR amplification. Regardless of the method that is used to characterize them, the collective SNPs in a selected genomic region characterize a haplotype, or specific combination of alleles at multiple linked genetic loci along a chromosome that are inherited together.

Even when the SNPs within a given haplotype are not directly involved in a disease, they provide markers for clonality and for the loss or rearrangement of specific chromosomal segments in growing tumors. In the human nucleus, each of the 23 tightly compacted chromosomes has a characteristic size and structure and a distinctive base sequence that carries unique protein coding information. Other noncoding DNA sequences are used for directing the transcription of neighboring genes through complex regulatory circuits that involve protein binding and modification of the DNA itself or shifting of its chromosomal packaging. Although genomic instability is generally considered a consequence of tumor formation rather than the initial trigger of cancer, the loss, gain, or rearrangement of chromosomal segments through deletion or translocation is a common form of neoplastic mutation, as protein-coding segments from different genes are combined or regulatory sequences are brought into new proximity to genes that they do not normally control. Gross changes in DNA arrangement can be detected by cytogenetic analysis of chromosomal features on metaphase spreads. Fluorescent in situ hybridization provides greater resolution by localizing specific chromosomal DNA sequences corresponding to fluorescently labeled probes (Fig. 1-5) and can be used to track specific alterations in chromosomal structure where known genes are involved.

Although cytogenetic techniques are useful in detecting consistent, nonrandom structural abnormalities of clonal tumor cells, they

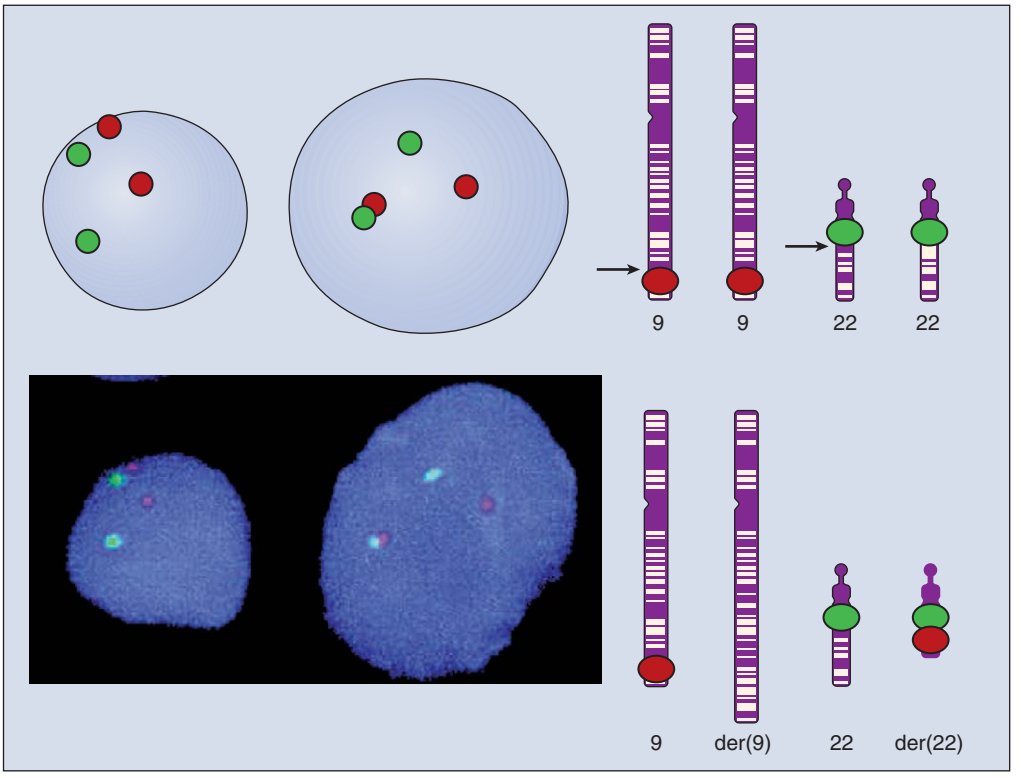

Figure 1-5 • Detection of chromosomal translocations in interphase cells by fluorescent in situ hybridization. This technology uses a labeled DNA segment as a probe to search homologous sequences in interphase chromosomes for the t(9;22)(q34;q11) translocation, associated with chronic myeloid leukemia. On the *left*, patient nuclei were hybridized with probes for chromosome 9 (labeled with SpectrumRed fluorophore) and chromosome 22 (labeled with SpectrumGreen). Molecular cytogenetics in solid tumors: laboratorial tool for diagnosis, prognosis, and therapy. 2003;45–58; permission conveyed through Copyright Clearance Center, Inc.)

require cell culture, which can limit their usefulness, particularly in analyzing solid tumors. Particularly when chromosomal alterations are too small to be detected by cytogenetic analysis, exploitation of the exquisite sequence specificity of certain bacterial DNA endonucleases, called restriction enzymes, allows the systematic cleavage of very large DNA molecules isolated from tumor samples into predictable, manageable subfragments. These can be identified by hybridization of a short, specific DNA or RNA oligonucleotide probe to its complementary base sequence, or target, in the fractionated genomic material. In most applications, the enzyme-digested sample of DNA is size fractionated by gel electrophoresis and transferred or "blotted" onto a nylon membrane to which labeled probe is then applied. In this procedure, DNA fragments containing sequences that hybridize with radioactively labeled probe can be detected by autoradiography or, alternatively, by nonisotopic colorimetric or chemiluminescent systems (Fig. 1-6). When a SNP occurs in the recognition site of a restriction enzyme, lost or rearranged DNA produces a change in the enzyme cleavage pattern, and these restriction-fragment-length polymorphisms can be detected by blotting analysis. PCR-based analysis using flanking DNA sequences as primers is also used to produce fragments, changes in the size of which, due to addition or loss of DNA bases, can be detected by gel electrophoresis. Subtler single base mutations can be identified by automated DNA-sequencing techniques.

The plethora of data that arise from genome-wide association studies using currently available techniques poses particular challenges to cancer researchers. Discerning the causal genetic variants among genotype-phenotype associations requires extensive replication, control for underlying genetic differences in population cohorts, and consistent classification of clinical outcomes. New technologies must be met with equivalently sophisticated and rigorous analytical methodologies for the true genetic cause of cancer to be teased out from our variable and often unstable heredity.

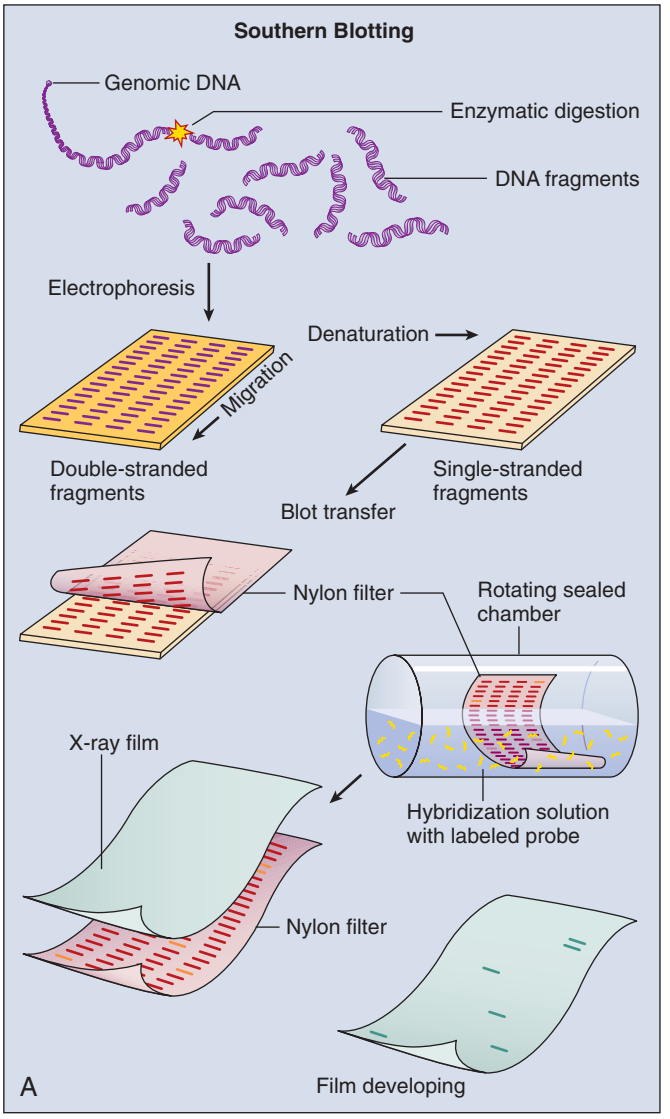
ENGINEERING GENES

The engineering of genes by recombinant DNA technology evolved from methods that were initially devised to provide sequences in amounts sufficient for biochemical analysis. The original protocol involves clipping the desired segment from the surrounding DNA and inserting it into a bacterial or viral vector, which is then amplified millions of times in a host bacterium. Using recombinant DNA technology, genetic engineering can routinely produce industrial quantities of pure, clinically useful products in a cost-effective way. For diagnostic purposes, it is easier and faster to amplify a known genomic DNA sequence directly from a patient sample with PCR, but the classic approach is still applied to the construction of recombinant DNA libraries.

To be useful, a DNA library must be as complete as possible, with recombinant members, or clones, sufficiently numerous to include all the sequences in an individual genome. For certain kinds of gene linkage analysis that require long, uninterrupted stretches of DNA, special vectors, such as bacterial or yeast artificial chromosomes, can carry foreign DNA fragments of enormous lengths. Chromosomal segments represented in genomic DNA libraries can contain the structure of an entire gene, including the information that regulates its expression and formed the starting material for sequencing the human genome.

For some applications, construction of partial libraries, which contain only the DNA sequences transcribed by a particular tissue or type of cell, is sufficient. The starting material in this case is mRNA. For cloning purposes, the enzyme reverse transcriptase can convert mRNA into complementary DNA (cDNA). Advanced techniques for acquiring full-length copies of RNA transcripts include rapid amplification of cDNA ends. The cDNAs are then incorporated into bacterial vectors. The number of clones in a cDNA library is much smaller than that in a genomic library, since a cDNA library represents only the genes that are expressed by the tissue of interest and contains exclusively the coding portion of genes. Screening DNA libraries for a specific gene classically relied on mass growth of bacterial hosts on agar, transfer of replicates to nylon filter and exposure to a specific DNA probe. The probe's unique sequence of nucleotides ensures that it hybridizes only to a nucleic acid molecule with the complementary sequence, which marks the position of the target clone. Cloning vectors can also be modified to drive the expression of their payload, producing "expression" libraries in bacteria that can be screened for protein production using specific antibodies, a technique that becomes increasingly important in large-scale screening of protein products.

LOSING CONTROL OF THE GENOME



Mutations that lead to oncogenic transformation of a cell invariably affect the expression of its genetic information that specifies functional products, either RNA molecules or proteins used for various cellular functions. The primary level of gene control is the transcription of DNA into RNA. Gene regulation, or the control of RNA synthesis, represents a complex process that is frequently a target of neoplastic mutation.

DNA regulatory sequences do not encode a product. Yet without them, a cell could not coordinate the expression of the hundreds of thousands of genes in its nucleus, select only certain genes for expression, and activate or repress them in response to precise internal or external signals. These control centers of the genome contain binding sites for multiple proteins, called transcription factors, which interact to form regulatory networks that control gene transcription. Their function can be altered by signals that induce modifications such as phosphorylation, or by interactions with other regulators such as steroid hormones. Many of the cell's responses to a wide variety of external stimuli, such as neurotransmitters, antigens, cytokines, and growth factors, are mediated through transcription factors binding to DNA regulatory sequences.

Certain regulatory DNA sequences common to many genes are positioned upstream of the transcription start site (Fig. 1-7). Collectively called the promoter of a gene, these proximal sequences comprise binding sites for the RNA polymerase and its numerous cofactors. Whereas the position of the promoter with regard to the transcription start site is relatively inflexible, other DNA regulatory elements, known as enhancers, occur in unpredictable locations, often at a considerable distance from the genes they control. Some transcription factors bind to particular regions of enhancers and drive their associated genes in many types of cells, whereas others, which are active in only a limited variety of cells, maintain a tissue-specific pattern of gene expression. Enhancers are often responsible for the aberrant expression of genes induced by chromosomal translocation-associated specific forms of cancer; a normally quiescent gene promoting cell growth that is dislocated to a position near a strong enhancer may be activated inappropriately, resulting in loss of growth control.

Enhancers and promoters have been assigned specific roles by means of cell culture assays or in transgenic animals in which putative regulatory DNA sequences are linked to test or "reporter" genes and are examined for their ability to activate expression of the reporter gene in response to the appropriate signals. By assessing the effects of deleting, adding, or changing DNA sequences within the regulatory element, the precise nucleotides that are critical for recognition by transcription factors can be determined.

The interaction between protein and DNA is also used to identify transcription factor-binding sites in a regulatory region. Whereas electrophoretic mobility shift assays, or DNA footprinting, were once standard techniques for determining protein-DNA interactions, emerging genome-wide technologies, such as chip sequencing (see Fig. 1-13 later in the chapter), are revolutionizing the way in which we see the simultaneous interaction of a transcription factor complex

Figure 1-6 • A, Analysis of DNA by gel electrophoresis and Southern blotting. Genomic DNA is cut with restriction enzymes into fragments before being separated according to size by gel electrophoresis. The four lanes on the gel represent the digestion of the DNA with four different restriction enzymes. In Northern blotting, total cellular RNA, including messenger RNA, can also be separated according to size. After electrophoresis, the nucleic acids in the gel are transferred directly onto a charged nylon filter, to which they are tightly bound. Thus, the filter contains a precise replica of the nucleic acid distribution in the gel. The filter is then hybridized in a rotating sealed chamber with a DNA or RNA probe specific for the target of interest (in this case, sequences in a microbial pathogen). Probes have traditionally been radioactively labeled with nucleotides containing phosphorus 32; however, the use of nonradiolabeled probes is becoming more common. After the probe has hybridized to its target sequence, the nonhybridized probe is washed away, and the filter is exposed to x-ray film. A DNA sequence complementary to the probe is seen as a dark band on the developed film. The position of the hybridized target sequence in each lane is unique to the restriction enzyme that is used to digest the DNA. This procedure is termed Southern blotting when DNA is analyzed and Northern blotting when RNA is analyzed. **B,** Cytogenetic and molecular analyses of tumor cells. Three methods of detecting the specific genetic alterations shared by all the neoplastic cells in a tumor are shown. (1) If the genetic alteration is large enough, as in the deletion of a region of DNA between loci A and B, cytogenetic analysis can detect grossly visible karyotypic changes. (2) Southern blot analysis can detect small changes in gene structure that routine karyotyping studies cannot find. In this example, a probe to locus A normally detects a large DNA restriction fragment, as shown by the band for the normal DNA sample. Because of the deleted DNA segment in the tumor cells, the probe for the region between loci A and B hybridizes to a smaller, rearranged, tumor-specific restriction fragment. The normal, larger band shown on the blot is from DNA contributed by nonneoplastic stromal and reactive cells. (3) In many applications, the polymerase chain reaction (PCR) can detect alterations in DNA structure with the highest degree of sensitivity. Here, the primers that anneal to loci A and B in normal DNA are too far apart to yield an amplified PCR product. The deletion shown in the tumor DNA brings the two annealing sites close to one another, allowing the generation of a novel amplified PCR product. (**A,** Modified from Naber SP: Molecular pathology-diagnosis of infectious disease. N Engl J Med 1994;331:1212–1215. **B,** From Naber SP: Molecular pathology-detection of neoplasia. with virtually all of its potential genomic targets in a particular cell state.

Our appreciation of oncogenic perturbations, either by mutation of regulatory protein-coding genes or in the target sequences these proteins recognize, has recently extended to include epigenetic lesions, although these mechanisms have been more difficult to define. Multiple levels of control are necessary to ensure correct gene expression, which is so central to the normal function of the cell. Epigenetics refers generally to control information that is inherited during cell division along with the DNA sequence itself.

A key component of epigenetic regulation, chromatin, wraps DNA into coils with scaffolding proteins such as histones as a necessary component of chromosomal compaction but also plays a critical role in gene accessibility (Fig. 1-8). Active genetic loci are associated with loosely configured euchromatin, whereas silent loci are condensed in heterochromatin. The formation of chromatin configurations both controls and is controlled by patterns of methylation on specific DNA sequences, relating the underlying genetic information to its higher-order structure that determines whether a particular gene regulatory element is available to transcription factors. These epigenetic modifications of the nuclear environment that determine the accessibility of a gene can persist during cell division, as inherited patterns of methylation provide permanent marks for altered chromatin configuration in daughter cells.

Recent research has linked rearrangement of chromatin and associated DNA methylation with the inactivation of tumor suppressor genes and neoplastic transformation. Defects that could lead to cancer involve perturbations in the "epigenotype" of a particular locus through the silencing of normally active genes or activation of normally silent genes, which are associated with changes in DNA methylation, histone modification, and chromatin proteins (Fig. 1-9). Changes in the number or density of heterochromatin proteins associated with cancer-related genes such as EZH2 or of euchromatic proteins such as trithorax in leukemia can also be associated with abnormal patterns of methylation in gene promoter regions as well as with higher-order chromosomal structures that are only beginning to be understood. Finally, it is increasingly evident that interactions between the "epigenome," the genome, and the environment are a common target for mutation and can have profound effects on the gene expression readout of a cancer cell.

PROFILING TUMORS

Monitoring global gene expression patterns of cells represents one of the latest breakthroughs in developing a molecular taxonomy of cancer. Genome-wide profiling of gene expression in tumors delivers an unprecedented view into the biological processes underlying tumor progression by following the changes in a tumor cell's transcriptional landscape. Relying on two-color fluorescence-based microarray technology (DNA microarray), simultaneous evaluation of thousands of gene transcripts and their relative expression can provide a snapshot of the "transcriptome," the full complement of RNA transcripts that are produced at a specific time during the progression of malignancy.

Transcriptional profiling using microarrays typically involves screens of mRNA expression from two sources (such as tumor and normal cells), using complementary cDNA or oligonucleotide libraries that are arranged in extremely high density on microchips. These are probed with a mixture of fluorescently tagged cDNAs generated from the tumor and normal samples, which results in differential staining of each gene spot. The relative intensity of the two different colors reflects the RNA expression level of each gene in each sample as analyzed with a laser confocal scanner (Fig. 1-10). By using microarrays, single genes that constitute diagnostic, prognostic, or therapeutically relevant markers can be systematically monitored. Alternatively, the entire set of expressed genes can be collectively analyzed by using powerful statistical methods to classify tumors by their transcriptional profile. Microarray analysis has already dramatically improved our ability to explore the genetic changes that are associated with cancer etiology and development and is providing new tools for disease diagnosis and prognostic assessment. For example, DNA microarray analysis of multiple primary breast tumor transcriptomes has revealed a reproducible 70-gene expression signature that was recently cleared by the U.S. Food and Drug Administration for a PCR-based application in which expression analysis of a relatively small gene group can predict the prognosis of early-stage breast cancers. When applied on a larger scale, these assays can predict response to chemotherapy or optimize pharmaceutical intervention by targeting therapeutic approaches to specific patient populations and, ultimately, to individualized therapy.

Serial analysis of gene expression (SAGE) provides a simultaneous, comprehensive evaluation of multiple mRNA species. Unlike microarray analysis, SAGE does not require prior knowledge of the genes of interest and provides quantitative and qualitative data of potentially every transcribed sequence in a particular tissue or cell type. Furthermore, SAGE can quantify low-abundance transcripts and can reliably detect relatively small differences in transcript concentrations between cell populations. The SAGE method generates a short sequence tag that functions as a unique identifier of a transcript, derived from a defined location within that transcript. Many transcript tags are concatenated into a single molecule and then sequenced, revealing the identity of multiple tags simultaneously. The relative presentation of each member of a SAGE tag library is proportional to the corresponding mRNA abundance in the original transcript

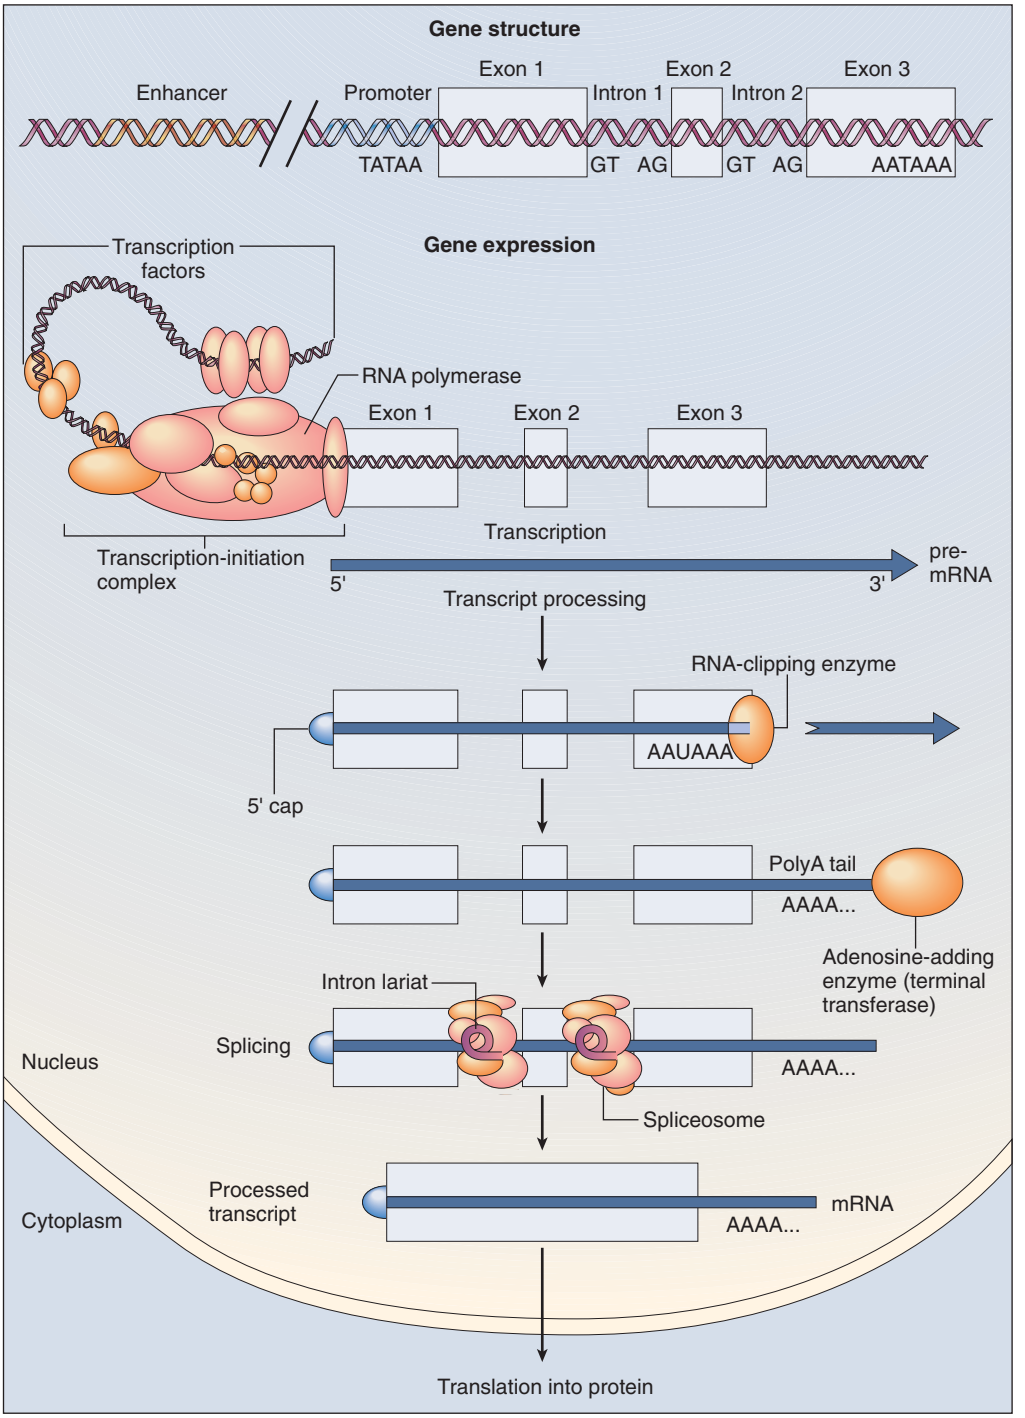

Figure 1-7 • Mammalian gene structure and expression. The DNA sequences that are transcribed as RNA are collectively called the gene and include exons (expressed sequences) and introns (intervening sequences). Introns invariably begin with the nucleotide sequence GT and end with AG. An AT-rich sequence in the last exon forms a signal for processing the end of the RNA transcript. Regulatory sequences that make up the promoter and include the TATA box occur close to the site where transcription starts. Enhancer sequences are located at variable distances from the gene. Gene expression begins with the binding of multiple protein factors to enhancer sequences and promoter sequences. These factors help to form the transcription-initiation complex, which includes the enzyme RNA polymerase and multiple polymerase-associated proteins. The primary transcript (pre-mRNA) includes both exon and intron sequences. Post-transcriptional processing begins with changes at both ends of the RNA transcript. At the 5′ end, enzymes add a special nucleotide cap; at the 3′ end, an enzyme clips the pre-mRNA about 30 base pairs after the AAUAAA sequence in the last exon. Another enzyme adds a polyA tail, which consists of up to 200 adenine nucleotides. Next, spliceosomes remove the introns by cutting the RNA at the boundaries between exons and introns. The process of excision forms lariats of the intron sequences. The spliced mRNA is now mature and can leave the nucleus for protein translation in the cytoplasm. (Adapted from Rosenthal N: Regulation of gene expression. N Engl J Med 1994; 331:931–932.)

population. Comparative expression profiles can then be deduced by comparing the abundance of individual tags within each sample set. This allows changes in global expression profiles of normal or malignant tissues under different therapeutic conditions to be rapidly evaluated.

These technologies can be applied to the analysis of noncoding RNA species as well. Beside the 20,000 protein-coding transcripts that are used to classify a wide variety of human tumors, hundreds if not thousands of small, noncoding interference RNA species have recently been discovered with critical functions in multiple biological processes, many of which are directly or indirectly involved in the control of cell proliferation. Known as microRNAs (miRNAs), these short transcripts arise from primary genome-encoded transcripts of variable sizes that are processed into 70- to 100-nucleotide hairpin-shaped precursors, which are processed into mature miRNAs of 21- to 23-base-pair RNA molecules (Fig. 1-11). miRNAs function by base-pairing with specific mRNAs to inhibit translation or to promote mRNA degradation. In the context of cancer, miRNAs could act in concert with other effectors such as p53 to inhibit inappropriate cell proliferation. A global decrease in miRNA levels is often observed in human cancers, indicating that small RNAs could have an intrinsic function in tumor suppression. The utility of monitoring the expres-

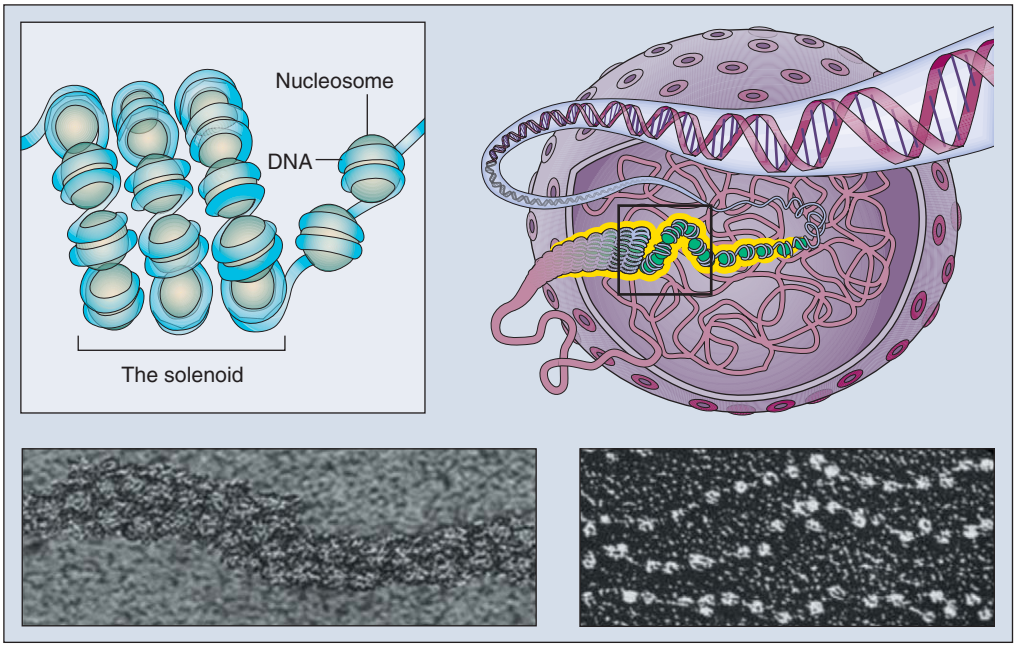

Figure 1-8 • Chromatin packaging of DNA. The 4 meters of DNA in every human cell must be compressed in the nucleus, reaching compaction ratios of 1:400,000. This is achieved by wrapping the DNA (*blue*) around histone protein complexes (*green*), forming nucleosomes that are connected by a thread of free linker DNA. Each nucleosome, together with its linker, packages about 200 base pairs (66 nm) of DNA. The nucleosomes are then coiled into chromatin, a rope of nucleoprotein about 30 nm thick (bottom left electron micrograph). To allow DNA to be accessed by transcription and replication apparatus, chromatin is relaxed (bottom right electron micrograph). (Courtesy of Jakob Waterborg www.umkc.edu/sbs/waterborg/chromat/chromatn.html © 1998 Jakob Waterborg.)

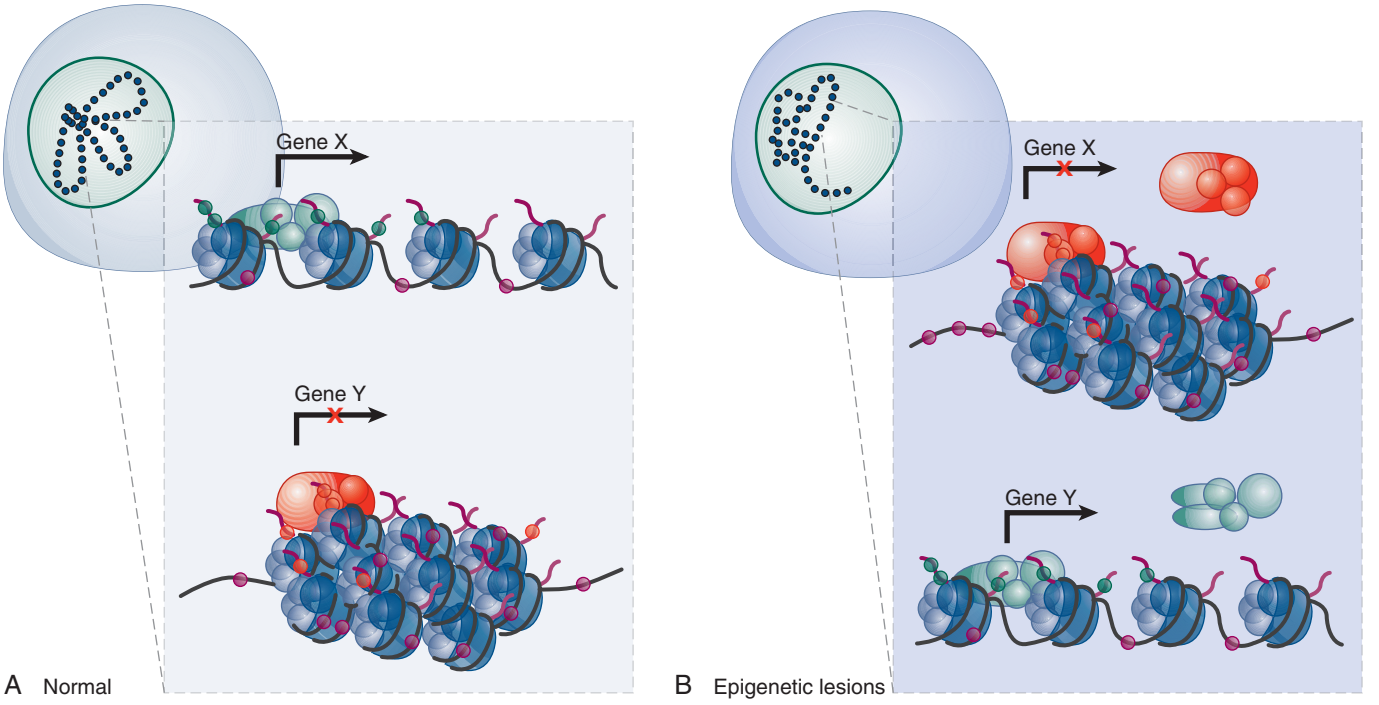

Figure 1-9 • Gene accessibility through epigenetics. The nature of epigenetic lesions. The cartoon depicts known and possible defects in the epigenome that could lead to disease. **A,** X is a transcriptionally active gene with sparse DNA methylation (*brown circles*), an open chromatin structure, interaction with euchromatin proteins (*green protein complex*), and histone modifications such as H3K9 acetylation and H3K4 methylation (*green circles*). Y is a transcriptionally silent gene with dense DNA methylation, a closed chromatin structure, interaction with heterochromatin proteins (*red protein complex*), and histone modifications such as H3K27 methylation (*pink circles*). **B,** The abnormal cell could switch its epigenotype through the silencing of normally active genes or activation of normally silent genes, with the attendant changes in DNA methylation, histone modification, and chromatin proteins. In addition, the epigenetic lesion could include a change in the number or density of heterochromatin proteins in gene X (such as EZH2 in cancer) or euchromatic proteins in gene Y (such as trithorax in leukemia). There may also be an abnormally dense pattern of methylation in gene promoters (shown in gene X) and an overall reduction in DNA methylation (shown in gene Y) in cancer. The insets show that the higher-order loop configuration may be altered, although such structures are currently only beginning to be understood. (Adapted from Feinberg AP: Phenotypic plasticity and the epigenetics of human disease. Nature 2007;447:433–440.)

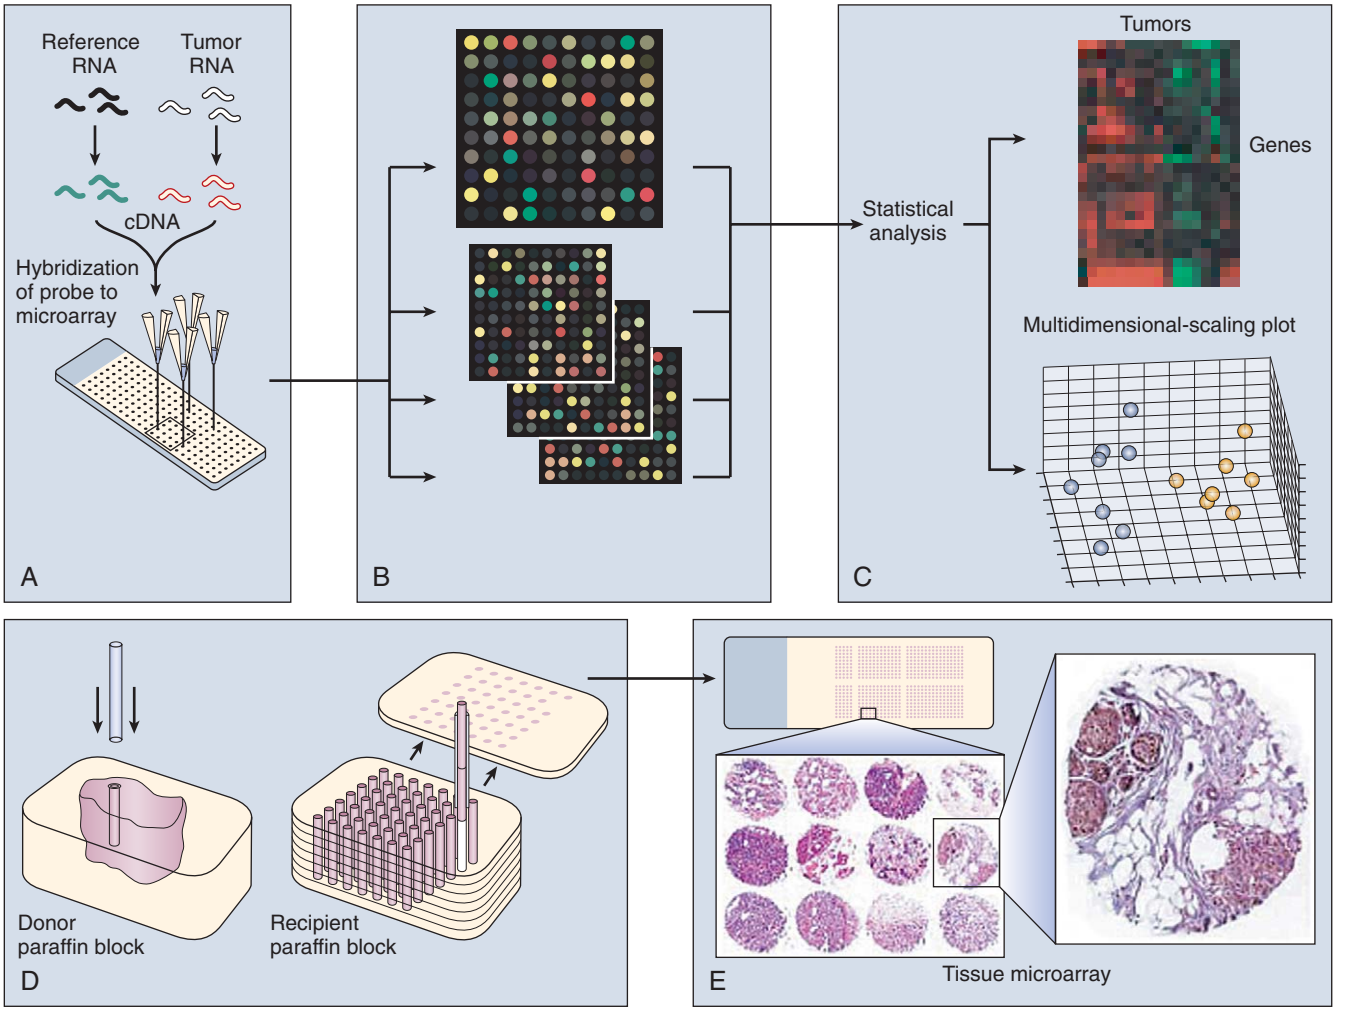

Figure 1-10 • Microarray-based expression profiling of breast tumor tissue. **A,** Reference RNA and tumor RNA are labeled by reverse transcription with different fluorescent dyes (*green* for the reference cells and *red* for the tumor cells) and are hybridized to a cDNA microarray containing robotically printed cDNA clones. **B,** The slides are scanned with a confocal laser scanning microscope, and color images are generated with RNA from the tumor and reference cells for each hybridization. Genes that are upregulated in the tumors appear red; those with decreased expression appear green. Genes with similar levels of expression in the two samples appear yellow. Genes of interest are selected on the basis of the differences in the level of expression by known tumor classes (e.g., BRCA1-mutation-positive and BRCA2-mutation-positive). Statistical analysis determines whether these differences in the gene expression profiles are greater than would be expected by chance. **C,** The differences in the patterns of gene expression between tumor classes can be portrayed in the form of a color-coded plot, and the relationships between tumors can be portrayed in the form of a multidimensional-scaling plot. Tumors with similar gene expression profiles cluster close to one another in the multidimensional-scaling plot. **D,** Particular genes of interest can be further studied through the use of a large number of arrayed, paraffin-embedded tumor specimens, referred to as tissue microarrays. **E,** Immunohistochemical analyses of hundreds or thousands of these arrayed biopsy specimens can be performed to extend the microarray findings. (From Hedenfalk I, Duggan D, Chen Y, et al: Gene expression profiles in hereditary breast cancer. N Engl J Med 2001;344:539–548.)

sion of miRNAs in human cancer is just now being explored, but preliminary findings reveal an extraordinary level of diversity in miRNA expression across cancers and the large amount of diagnostic information that is encoded in a relatively small number of miRNAs. Significant technologic advances facilitating the profiling of the miRNA expression patterns in normal and cancer tissues hint at the unexpected greater reliability of miRNA expression signatures than the respective signatures of protein-coding genes in classifying cancer types. Along with their potential diagnostic value, miRNAs are also being tested for their prognostic use in predicting clinical behaviors of cancer patients.

Although Northern blot analysis is a reliable technique to detect gene expression at the mRNA level, it has some limitations, such as unequal hybridization efficiency of individual probes and difficulty in detecting multiple miRNAs simultaneously. For cancer studies, it is important to be able to compare the expression pattern of all known miRNAs between cancer cells and normal cells. Thus, DNA microarrays are used to detect the full complement of miRNA expression at a single point in time. Since probe specificity in miRNA microarray analysis can be problematic, owing to the small target size, hybridization can first be performed in solution and then quantified by using multicolor flow sorting. Real-time PCR can also be employed to quantify specific miRNA sets or to capture a more detailed picture of their changing expression profiles in tumor progression. Identification of the miRNAs that are involved in tumor pathogenesis and elucidation of their action in a specific cancer will be the next necessary steps for their manipulation in a therapeutic setting.

THE CANCER PROTEOME

The term *proteome* describes the entire complement of proteins that are expressed by the genome of a cell, tissue, or organism. More

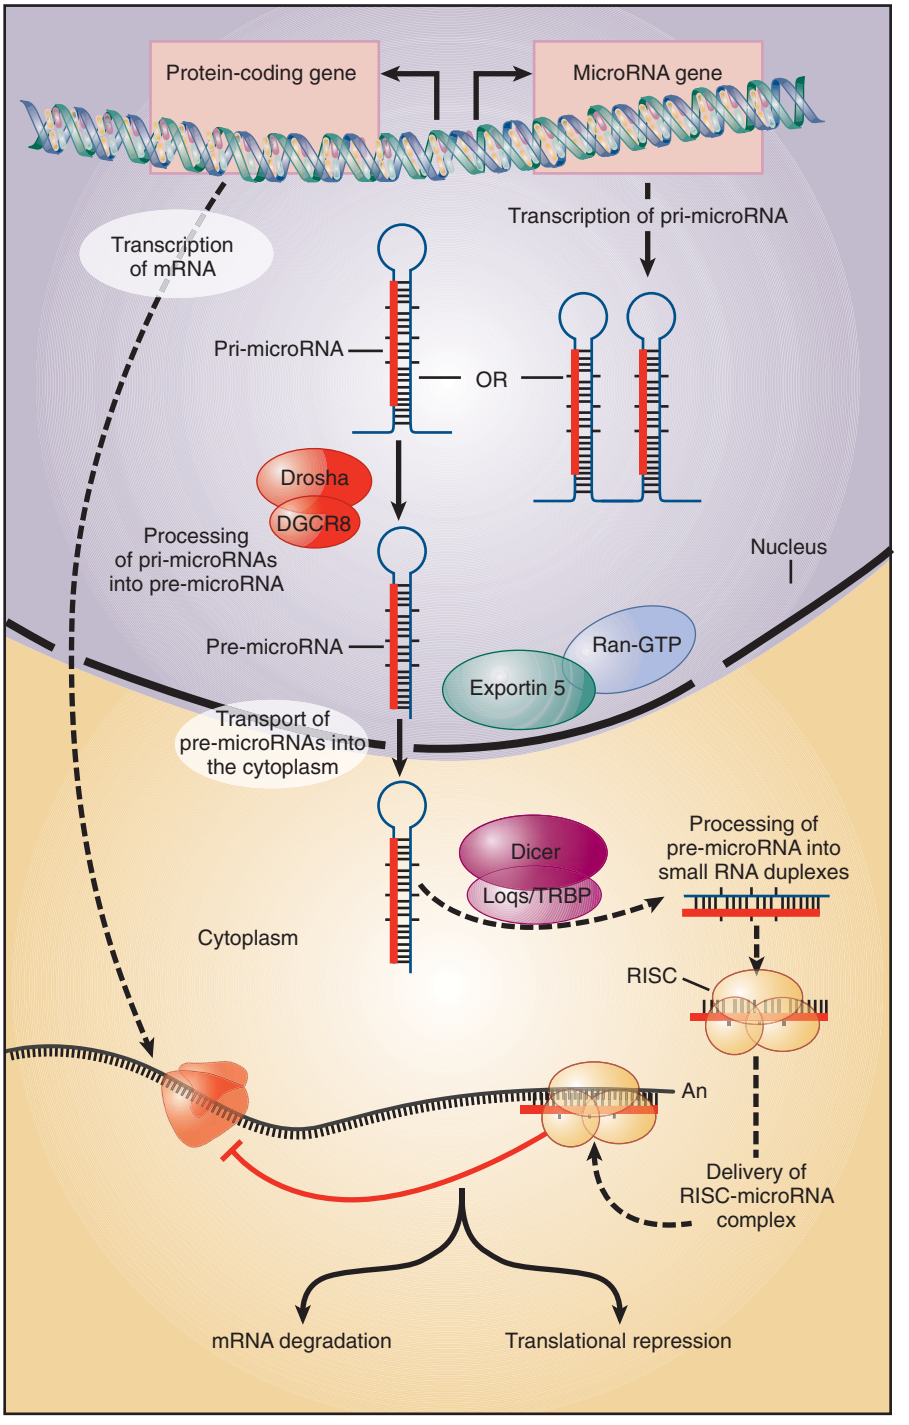

Figure 1-11 • MicroRNA production and gene regulation in animal cells. Mature functional microRNAs of approximately 22 nucleotides are generated from long primary microRNA (pri-microRNA) transcripts. First, the pri-microRNAs, which usually contain a few hundred to a few thousand base pairs, are processed in the nucleus into stem-loop precursors (pre-microRNA) of approximately 70 nucleotides by the RNase III endonuclease Drosha and DiGeorge syndrome critical region gene 8 (DGCR8). The pre-microRNAs are then actively transported into the cytoplasm by exportin 5 and Ran-GTP and further processed into small RNA duplexes of approximately 22 nucleotides by the Dicer RNase III enzyme and its partner Loqacious (Loqs), a homolog of the human immunodeficiency virus transactivating response RNA-binding protein (TRBP). The functional strand of the microRNA duplex is then loaded into the RNA-induced silencing complex (RISC). Finally, the microRNA guides the RISC to the target messenger RNA (mRNA) target for translational repression or degradation of mRNA. (Adapted from Chen C-J: MicroRNAs as oncogenes and tumor suppressors. N Engl J Med 2005;353: 1768–1771.)

specifically, it is used to describe the set of all the expressed proteins at a given time point in a defined setting, such as a tumor. Like RNA transcription, the synthesis of proteins is a highly regulated process that contributes to the specific proteome of a particular cell and can be perturbed in diseases such as cancer.

Advances in protein analytical techniques over the last decade have progressed to the point at which even small numbers of specific proteins expressed in tissues can be used to predict the prognosis of a cancer. The improvement of protein-based assays has made it possible to identify and examine the expression of most proteins and to envision large-scale protein analysis on the level of gene-based screens. Various systematic methodologies contributed to the current explosion of information on the proteome and are being compared for their ability to provide suitable platforms for generating databases on protein structural features, interaction maps, activity profiles, and regulatory modifications.

The yeast two-hybrid system is a popular genetics-based approach for detecting protein-protein interactions inside a cell (Fig. 1-12). One protein that is fused to the DNA binding domain (bait) and a different protein that is fused to the activation domain of a transcriptional activator (prey) are expressed together in yeast cells. If the bait and prey interact, transcription of a reported gene is induced and

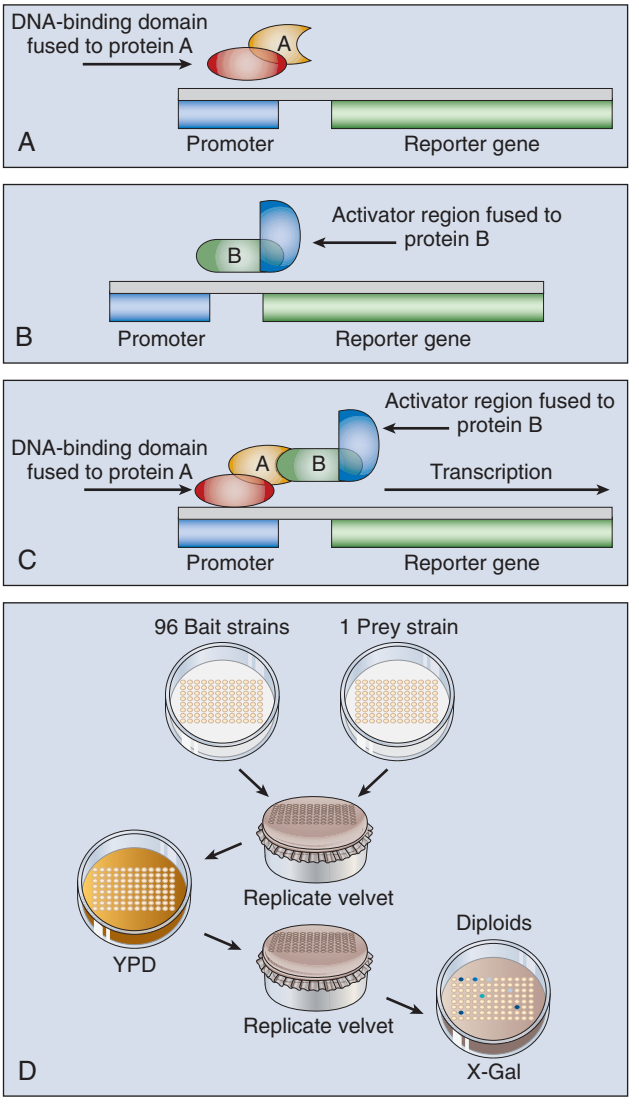

Figure 1-12 • Exploring protein-protein interactions with the yeast two-hybrid system. Two-hybrid technology exploits the fact that transcriptional activators are modular in nature. Two physically distinct functional domains are necessary to get transcription: a DNA-binding domain that binds to the DNA of the promoter and an activation domain that binds to the basal transcription apparatus and activates transcription. **A,** The known gene encoding protein A is cloned into the "bait" vector, fused to the gene encoding a DNA-binding domain from some transcription factor. When placed into a yeast system with a reporter gene, this fusion protein can bind to the reporter gene promoter, but it cannot activate transcription. **B,** Separately, a second gene (or a library of cDNA fragments encoding potential interactors), protein B, is cloned into the "prey" vector, fused to an activation domain of a different transcription factor. When placed into a yeast strain containing the reporter gene, it cannot activate transcription because it has no DNA-binding domain. **C,** When the two vectors are placed into the same yeast, a transcription factor is formed that can activate the reporter gene if protein B, made by the second plasmid, binds to protein A. **D,** Screening a yeast two-hybrid library. The plate on the left holds 96 different yeast strains in patches (or colonies), each of which expresses a different bait protein (*top*). The plate on the right holds 96 patches, each of the same yeast strain (prey strain) that expresses a protein fused to an activation domain (prey). The plate of bait strains and the plate of prey strains are pressed to the same replica velvet, and the impression is lifted with a plate containing YPD medium. After 1 day of growth on the YPD plate, during which time the two strains mate to form diploids, the YPD plate is pressed to a new replica velvet, and the impression is lifted with a plate containing diploid selection medium and an indicator such as X-Gal. Blue patches (*dark spots*) on the X-Gal plate indicate that the lacZ reporter is transcribed, suggesting that the prey interacts with the bait at that location. (**C,** Text after http://www.invitrogen.com/catalog_project/cat_hybrid.html [July, 2000]; figure retrieved from http://www.nature.com/nature/journal/v403/n6770/pdf/403601a0.pdf. **D,** From Bartel PL, Fields S (eds): The Yeast Two-Hybrid System. New York, Oxford University Press, 1997; Finley RL Jr, Brent R: Two-hybrid analysis of genetic regulatory networks. Retrieved from http://www.genetics.wayne.edu/finlab/YTHnetworks.html.)

detected, typically by a color reaction that reflects the transactivation of the reporter gene and, by proxy, the interaction of the two test proteins. The method can also be used for large-scale protein interactions, RNA-protein interactions, and protein-ligand binding.

As a complementary proteomics tool, mass spectrometry is an accurate mass measurement of charged peptides that are isolated by two-dimensional gel electrophoresis, producing a mass-to-charge ratio of charged samples under vacuum that can be used to determine the sequence identity of peptides. Combined with a specific proteolytic cleavage step, mass spectroscopy can be used for peptide mass mapping. Automation of this process has made mass spectroscopy the analytic tool of choice for many proteomics projects.

Monoclonal antibodies (mAbs) have been a cornerstone of protein analysis in cancer research and more recently have risen to prominence as cancer therapeutics based on their exquisite specificity for protein targets and their potent interference with protein function. Laboratory mice have been the animal model of choice for generating a ready source of diverse high-affinity and high-specificity mAbs; however, the use of rodent antibodies as therapeutic agents has been restricted by the inherent immunogenicity of mouse proteins in a human setting. The more recent application of transgenic mouse technology to introduce variable regions encoded by human sequences into the corresponding mouse immunoglobulin genes has enabled the generation of "humanized" therapeutic mAbs with reduced immunogenicity. Numerous of these mAb-based agents are currently in trial or in use as therapeutics for cancer, and the potential for further optimization of mAbs through genetic engineering promises to open new avenues for in vivo therapy.

From an epigenetics perspective, new techniques are enabling the genome-wide characterization of protein-DNA interactions that can uncover novel transcription factor targets, histone modifications, and DNA methylation patterns within a cancer cell. Combining chromatin immunoprecipitation (ChIP) with microarray (ChIP-on-chip) allows genome-wide screening for the binding position of protein factors to their gene targets. In ChIP-on-chip assays, a cross-linking reagent is applied in vivo to proteins associated with DNA in the nucleus, which then can be coimmunoprecipitated with specific antibodies to the protein under analysis. The bound DNA and appropriate controls are then fluorescently labeled and applied to microscopic slides for microarray analysis, rendering a simultaneous profile of all the binding positions of specific proteins in the cancer cell's genome (Fig. 1-13).

After a decade of development, proteomics is still primarily a basic research activity, yet in the near future, this technology is likely to have a profound impact on medicine. By defining the collective protein-protein interactions in a cancer cell (its "interactome"), func-

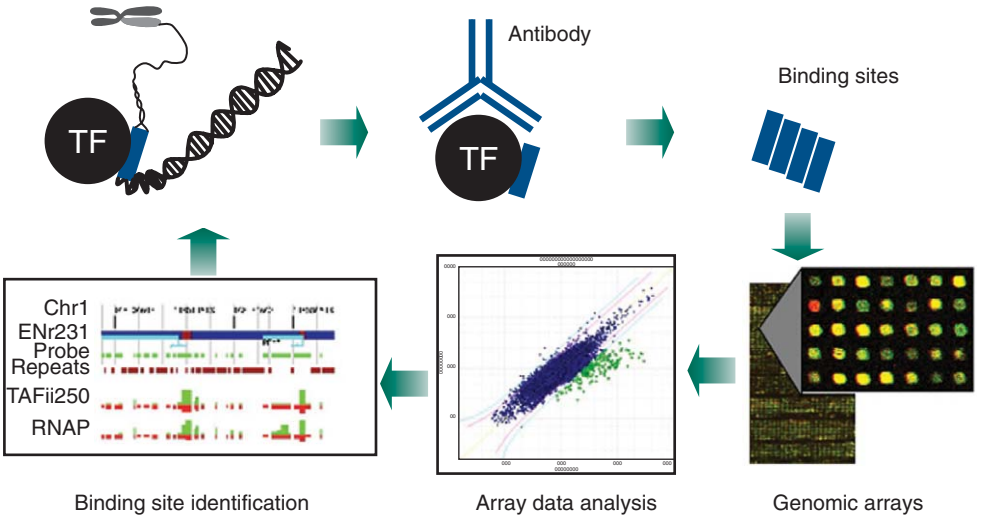

Figure 1-13 • ChIP-on-chip is a technique for location, isolation, and identification of the DNA sequences occupied by specific DNA-binding proteins in cells. These binding sites may indicate functions of various transcriptional regulators and help to identify their target genes during development and disease progression. The types of functional elements that one can identify using ChIP-on-chip include promoters, enhancers, repressor and silencing elements, insulators, boundary elements, and sequences that control DNA replication. (Adapted from Ren lab: www.chiponchip.org/Images/scheme_800x600_crop.jpg.)

tional relationships between disease-promoting genes could be revealed that would provide novel candidates for intervention. Networks of disorder-gene associations are already being built that offer a platform for describing all known phenotype and disease gene associations, often indicating the common genetic origin of many diseases. A precise diagnosis of cancer using proteomics could be envisioned, based on highly discriminating patterns of proteins in easily accessible patient samples. Proteomics information also promises to provide sophisticated mathematical models of the molecular events underlying a process as complex as neoplastic transformation, which will capture the dynamics of the disease with unprecedented power.

MODELING CANCER IN VIVO

Once the mechanistic underpinnings of a particular cancer have been described, creating an animal model to test that mechanism becomes critical to understanding the pathophysiology and to design therapeutic strategies for treatment. Recent advances in manipulating the mouse genome have resulted in more sophisticated models of human cancer. These methodologies can circumvent embryonic death by targeted alteration of gene expression only after a critical period in development and reduce the complexity of gene functional analysis by restricting its pattern of activation. Inducible gene expression or silencing also allows acute, as opposed to chronic, effects to be assessed.

Integrating an oncogene that causes malignancy into the genome of a mouse without altering the mouse's own genes generates a transgenic, cancer-prone mouse that transmits this trait to its offspring with a dominant pattern of inheritance. Although species differences in tumor susceptibility and disease remission exist between mouse and human, the tools for genetic manipulation in mouse are superior to those in other mammals, and useful information about the function of oncogenes can be gained by targeted expression of mutant protein products in mouse tissues.

The technology for producing transgenic mice joins recombinant DNA methodology with standard techniques that are used today by in vitro fertilization clinics, relying on our understanding of mammalian reproduction and the development of protocols to harvest, manipulate, and reimplant eggs and early embryos (Fig. 1-14). The transgene is constructed so that the gene product will be expressed under appropriate spatial and temporal control. In addition to all the standard signals that are necessary for efficient transcription and translation of the gene, transgenes contain a promoter, or regulatory region, that drives transcription in either a ubiquitous or tissue-restricted pattern. This requires an extensive knowledge of genetic regulation in the target cells. A recent advance that circumvents this requirement involves embedding the transgene inside another gene locus that is expressed in the desired pattern. Held in a bacterial artificial chromosome for easier manipulation, this long stretch of DNA surrounding the host gene is likely to carry all the necessary regulatory information to guarantee a predictable expression pattern of the introduced transgene.

The transgene DNA is then injected into the male pronucleus of a fertilized mouse egg, obtained from a female mouse in which hyperovulation has been hormonally induced. The injected eggs are cultured to the two-cell stage and then implanted in the oviduct of another recipient female mouse. Transgenic pups are identified by the presence of the transgene in their genomic DNA (obtained from the tip of the tail and analyzed by PCR). Typically, several copies of the transgene are incorporated in a head-to-tail orientation into a single random site in the mouse genome. About 30% percent of the resulting pups will have integrated the transgene into their germline DNA and constitute the founders of the transgenic lines. RNA analysis of their progeny determines the level of transgene expression and whether the transgene is being expressed in the desired location or at the appropriate time. Given the variability in transgene number and chromosomal location, transgene expression patterns and levels can diverge considerably among different founder lines carrying the same transgene.

In general, transgenesis is optimal for modeling oncogenic mutations that cause a gain of function, producing disease even when they occur in only one of a gene's two alleles. For example, an activating mutation in a growth factor that causes abnormal cell proliferation can be mimicked by introducing a transgenic version of the mutated growth factor gene under the control of an appropriate regulatory sequence for expression in the tissue of interest. The relative susceptibility of such a transgenic mouse to tumorigenesis can help to distinguish between a primary and secondary role of the mutant factor, and established lines of these animals can be used for testing new therapeutic protocols.

The genetic construction of cancer-prone transgenic mice with the capacity to induce oncogene expression in vivo provides a new avenue to modeling the role of oncogenes in tumor generation and maintenance. This technology relies on conditional mutagenesis.

Producing conditional mutations in mice requires a DNA recombinase enzyme that does not recognize any mouse sequence but rather targets short, foreign recognition sequences to catalyze recombination between them. By strategic placement of these recognition sequences in appropriate orientations either beside or within a mouse gene, the

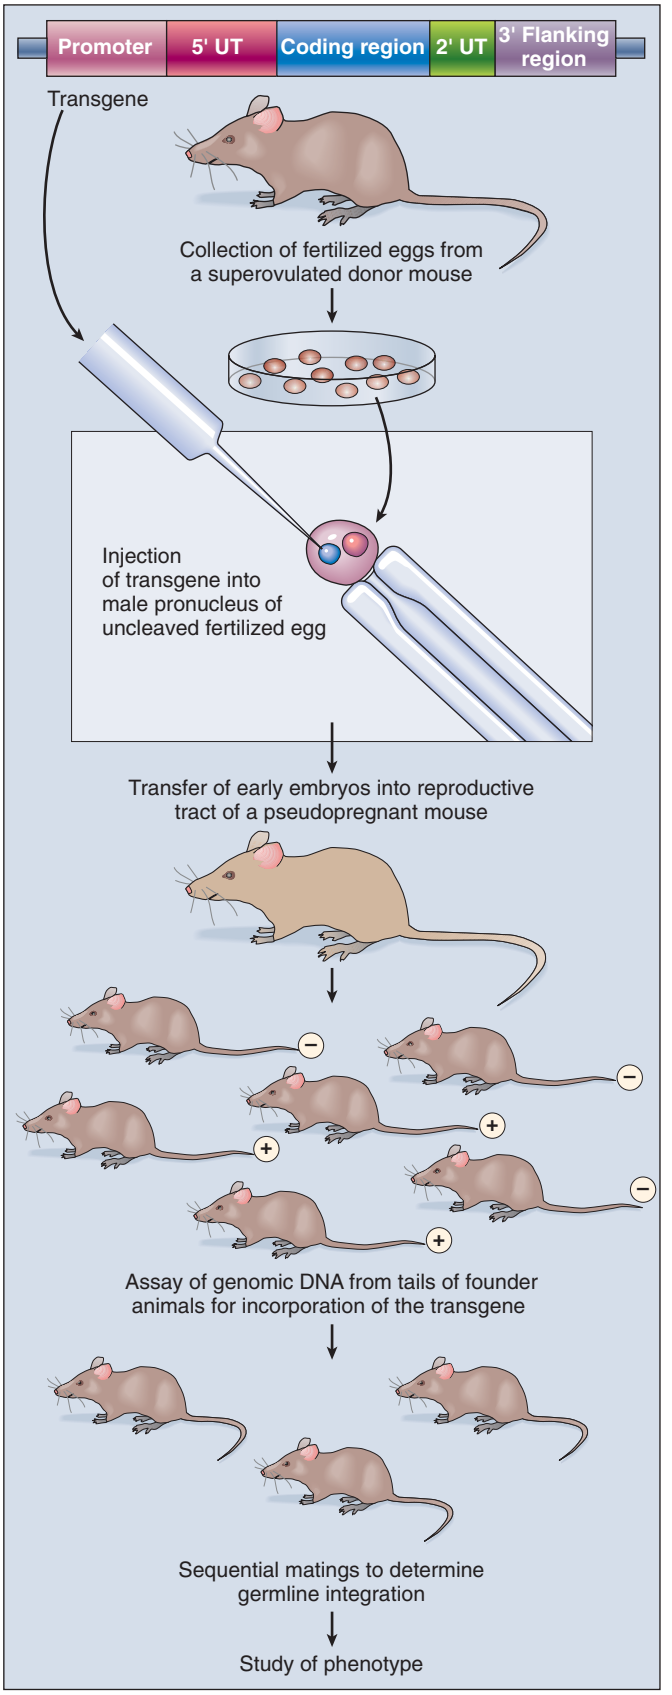

Figure 1-14 • Generation of transgenic mice. The transgene containing the DNA sequences necessary for the expression of a functional protein is injected into the male (larger) pronucleus of uncleaved fertilized eggs through a micropipette. The early embryos are then transferred into the reproductive tract of a female mouse that has been rendered "pseudopregnant" by hormonal therapy. The resulting pups (founders) are tested for incorporation of the transgene by assaying genomic DNA from their tails. Founder animals that have incorporated the transgene (+) are mated with nontransgenic mice, and their offspring are mated with each other to confirm germline integration and to establish a line of homozygous transgenic mice. Several transgenic lines that have incorporated different numbers of transgenes at different integration sites (and thus express various amounts of the protein of interest) are usually studied. UT, untranslated. (Adapted from Shuldiner AR: Transgenic animals. N Engl J Med 1996;334:653–655.)

recombination results in deletion, insertion, inversion, or translocation of associated genomic DNA (Fig. 1-15). Two recombinase systems are currently in use: the Cre-loxP system from bacteriophage P1 and the Flp-FRT system from yeast. The 34–base-pair loxP or FRT recognition sequences do not occur in the mouse genome, and both Cre and Flp recombinases function autonomously, without the need for cofactors. Cre- or Flp-mediated recombination is not distance or cell-type dependent and can occur in proliferating or differentiated tissues.

The general scheme involves two mouse lines, one carrying the recombinase either as a transgene driven by inducible regulatory elements or knocked into one allele of a gene expressed in the desired tissue. The other mouse line harbors a modified gene target, including recognition sequences. Mating the two lines results in progeny carrying both the target gene and the recombinase, which interacts with the target gene only in the desired tissue.

A popular conditional methodology is based on the activation of nuclear hormone receptors to control gene expression. Two current systems involve activation of a mammalian estrogen receptor, an estrogen analog 4-hydroxy-tamoxifen, or an insect hormone receptor with the corresponding ligand ectodysone. Although several variations on these hormone-receptor systems are currently in use, the underlying principle is the same. The Cre recombinase gene or another regulatory protein, such as a transcription factor, is fused with the ligand-binding domain from a nuclear hormone receptor protein. The resulting chimeric transgene is placed under the control of a promoter that directs expression to the tissue of interest, and transgenic animals are generated. In the absence of the hormone or an analog, the fusion protein accumulates in the desired tissue but is rendered inactive through its association with resident heat shock proteins. Administered hormone, either systemically or topically, binds to ligand-binding domain moiety of the fusion protein, dissociates it from the heat shock protein, and allows the transcriptional regulatory component to find its natural DNA targets and promote lox-P mediated recombination or, in the case of an inducible transcription factor, activate expression of the corresponding genes. If the ligand-binding domain is fused to a recombinase, administration of hormone leads to the rearrangement of target sequences. This reaction is not reversible but lends additional temporal control over recombinase-based mutation. If the ligand-binding domain is fused to a transcription factor, removal of hormone leads to inactivation of the fusion protein and gene downregulation.

Another inducible method in use is the tetracycline (tet) regulatory system. In the classic design (tTA or tet-off), a fusion protein combining a bacterial tet repressor and a viral transactivation domain drives expression of the target transgene by binding to upstream tet operator sequences flanking the transgene transcription start site. In the presence of the antibiotic inducer, the fusion protein is dissociated from the operator sequences, inactivating the transgene. In a

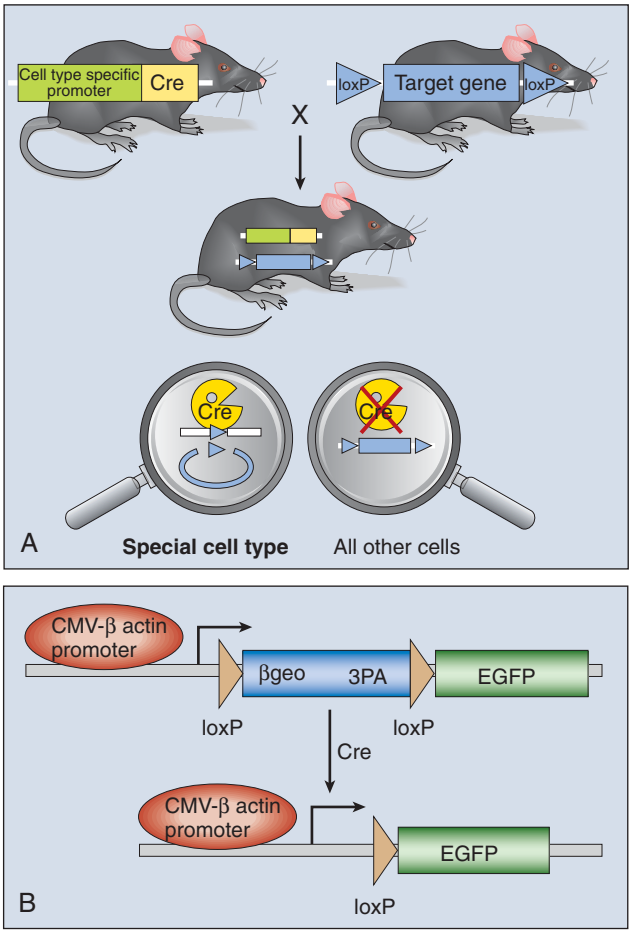

Figure 1-15 • Conditional mutagenesis schemes demonstrated with the Cre-loxP system. **A,** Two mouse lines are required for conditional gene deletion: a conventional transgenic mouse line with Cre targeted to a specific tissue or cell type and a mouse strain that embodies a target gene (endogenous gene or transgene) flanked by two loxP sites in a direct orientation ("floxed gene"). Recombination (excision and consequently inactivation of the target gene) occurs only in cells that express Cre recombinase. Hence, the target gene remains active in all cells and tissues that do not express the Cre recombinase. **B,** The Z/EG double reporter system. These transgenic mice constitutively express lacZ under the control of the cytomegalovirus enhancer/chicken actin promoter. Expression is widespread, notable exceptions being liver and lung tissue. Expression is observed throughout all embryonic and adult stages. When crossed with a Cre recombinase-expressing strain, lacZ expression is replaced with enhanced green fluorescent protein expression in tissues that express Cre. This double reporter system makes it possible to distinguish a lack of reporter expression from a lack of Cre recombinase expression while providing a means to assess Cre excision activity in live animals and cells. (**A,** Courtesy of Kay-Uwe Wagner, National Institutes of Health. **B,** From Novak A, Guo C, Yang W, et al: Z/EG, a double reporter mouse line that expresses enhanced green fluorescent protein upon Cre-mediated excision. Genesis 2000;28:147–155.)

complementary design, called reverse tTA (rtTA or tet-on), structural modification of the tet repressor makes the antibiotic an active requirement for binding of the fusion protein to the operator sequences, such that its administration activates transgene expression at any time during the life span of the mouse, whereas withdrawal results in downregulation of the gene. It is important that the transgene integrate into a genomic locus that permits proper tTA or rtTA regulation so that the system exhibits minimal intrinsic leakiness and good antibiotic responsiveness.

Conditional expression systems have already been developed to generate hematopoietic, leukemogenic, and lymphomagenic mutations in the mouse, as well as solid tumors. These inducible cancer models can be exploited to identify oncogenic signals that influence host-tumor interactions, to establish the role of a given oncogenic lesion in advanced tumors, and to evaluate therapies targeted toward cancer-causing mutations. Potential clinical application of inducible systems include targeting virally delivered transgene expression to malignant tissues by the use of specific inducible regulatory elements, restricting the expression of transgenes exclusively to affected tissues, and increasing the therapeutic index of the vectors, particularly in the context of solid tumors. In all cases, a basic knowledge of the specific mutations that are involved in the molecular genetics of malignancies is required, since it is often unclear that the causal mutation underlying the genesis of neoplasia continues to play a central role in the progression to the fully transformed state. This is particularly important in modeling cancers that are characterized by genetic plasticity, in which drug resistance can arise subsequent to primary tumor formation.

MODELS OF RECESSIVE GENE MUTATIONS IN CANCER

In contrast to dominantly acting oncogenes, recessive genetic disorders, such as loss-of-function mutations in a tumor suppressor gene, require both copies (alleles) of a gene to be inactivated. The methods that are needed to produce animal models of recessive genetic disease differ from those that are used in studying dominant traits. Gene knockout technology has been developed to generate mice in which one allele of an endogenous gene is removed or altered in a heritable pattern (Fig. 1-16). Gene disruption or replacement is first engineered in pluripotent cells, termed *embryonic stem* (ES) *cells*, which are genetically altered by introduction of a replacement gene that is inactive or mutant.

To reduce random integration of the foreign DNA, the replacement gene is embedded into a long stretch of DNA from its native locus in the mouse, which targets the recombination event to the homologous position in the ES cell genome. Inclusion of selectable markers along with the replacement gene allows selection of the cells in which homologous recombination has taken place. Site-specific recombinase systems combined with gene-targeting techniques in ES cells can also be used to inducing recessive single point mutations or site-specific chromosomal rearrangements in a tissue- and time-restricted pattern. In a variation on this theme called knock-in, a foreign gene, such as one encoding a marker, can be placed in the locus of an endogenous gene. The engineered ES cells are then microinjected into the cavity of an intact mouse blastocyst sufficiently early in gestation that these cells can, in principle, populate all the tissues of the developing chimeric embryo. This is rarely the case, so contribution of ES cells to the resulting animal is most often assessed by using ES cells and blastocysts whose genes for coat color differ.

If the ES cells contribute to the germ cells of the founder mouse, their entire haploid genome can be passed on to subsequent generations. By mating subsequent progeny of the founder mouse, both alleles of the mutated gene can be passed to a single animal. Overlapping genetic functions can also be defined by crossbreeding mice with mutations in different genes. In this way, it is possible to study the combinatorial effects of oncogene and tumor suppressor gene mutations.

These experimental systems are of great value in dissecting the pathogenesis of many tumor types. In some knockout studies, the phenotype of the mutated gene is anticipated by prior knowledge of the gene's function. However, unexpected mutant phenotypes may help clarify the mechanism of the underlying neoplasia. Pharmacologic manipulation of transgenic knockout animal models of cancer will prove useful in screening therapeutic agents with

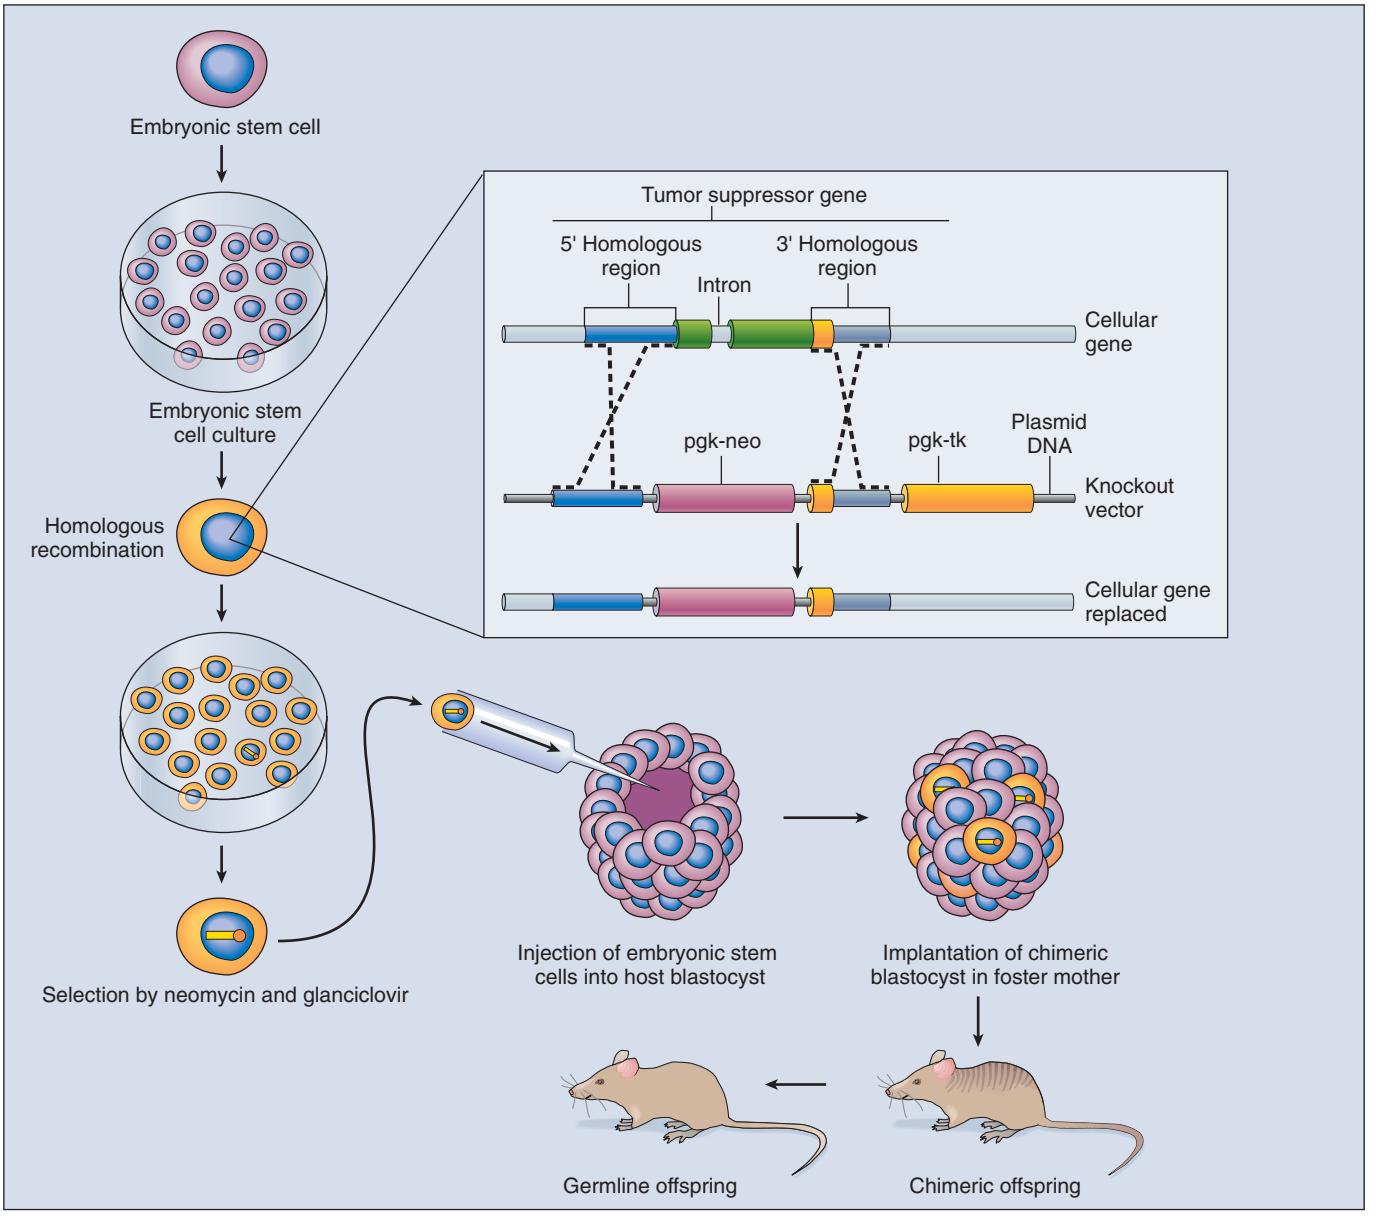

Figure 1-16 • Gene knockout strategy for generating mice that lack a tumor suppressor gene. Embryonic stem cells (*upper left panel*) contain the tumor suppressor cellular gene (*upper right panel*), which consists of exon 1 (*olive green*, a 5′ noncoding region), an intron, and exon 2 (*red*, a protein-coding region, and *yellow*, a 3′ noncoding region). A knockout vector consisting of a collinear assembly of a DNA flanking segment 5′ to the cellular gene (*blue*), the phosphoglycerate kinase-bacterial neomycin gene (pgk-neo, *violet*), a 3′ segment of the cellular gene (*yellow*), a DNA flanking segment 3′ to the cellular gene (*green*), and the phosphoglycerate kinase-viral thymidine kinase gene (pgk-tk, *orange*) is created and introduced into the embryonic stem cell culture. Double recombination occurs between the cellular gene and the knockout vector in the 5′ homologous regions and the 3′ homologous regions (*dashed lines*), resulting in the incorporation of the inactive knockout vector, including pgk-neo but not pgk-tk, into the cellular genomic locus of the embryonic stem cell. The presence of pgk-neo and the absence of pgk-tk in these replaced genes will allow survival of these embryonic stem cells after positive-negative selection with neomycin and ganciclovir. The clone of mutant embryonic stem cells is injected into a host blastocyst, which is implanted into a pseudopregnant foster mother and subsequently develops into a chimeric offspring (*bottom panel*). The contribution of the embryonic stem cells to the germ cells of the chimeric mouse results in germline transmission of the embryonic stem cell genome to offspring that are heterozygous for the mutated tumor suppressor allele. The heterozygotes are mated to produce mutant, cancer-prone mice that are homozygous for tumor suppressor deficiency. (Modified from Mazjoub JA, Muglia LJ: Knockout mice. N Engl J Med 1996;334:904–906.)

potential for study in clinical trials. Therapy involving gene or cell replacement can be also tested in genetically engineered disease models.

Several caveats are important in considering the use of knockout technology. Most knockout mutations are loss-of-function (null) germline mutations. Inactivation of widely expressed genes with multiple functions may have complex phenotypes. Conversely, if the functions of two genes overlap, a mutation in one of the genes might not produce an abnormal phenotype, owing to compensation by the unaltered partner.

Perhaps the greatest drawback of conventional knockout technology derives from the disruption of gene function at the earliest stage of its expression. If the gene has a vital developmental role, the identification of functions later in development can be occluded. There-

fore, although the generation of a null mutation is an excellent starting point for analysis, it is far from being functionally exhaustive. For these reasons, conditional mutagenesis is the method of choice for the elucidation of the gene functions that exert pleiotropic effects in a variety of cell types and tissues throughout the life of the animal, which is particularly relevant for the generation of mouse models of adult-onset diseases such as cancer.

By using recombinase-mediated gene mutation described previously for conditional transgenesis, conditional knockout mutations can be designed to disrupt the function of a target gene in a specific tissue (spatial control) and/or life stage (temporal control). Depending on the design of the experiment, recombinase action can delete an entire gene, remove blocking sequences to induce gene expression, or rearrange chromosomal segments. With the advent of recent internationally coordinated systematic mutagenesis programs that aim to place a conditional inactivating mutation in each of the 20,000 genes in the mouse genome, the possibilities for modeling cancer are limited only by a researcher's choice of the gene loci to test. The constantly evolving techniques for gene manipulation in vivo constitute a major advance in cancer research. They promise to provide integration of underlying molecular biological principles of malignancy with pathophysiologic consequences, generating an invaluable resource for understanding the complex genetics of tumor formation that holds great promise for improved treatment of human cancer.

2 Intracellular Signaling

Sara A. Courtneidge

SUMMARY OF KEY POINTS

- Cell growth, metabolism, death, differentiation, movement, and invasion are all controlled by intracellular signaling pathways. These pathways are initiated by ligands binding to, and activating, their cognate receptors, which are usually plasma membrane proteins.
- Receptor activation initiates cascades of signaling events, including activation of protein and/or lipid kinases, as well as the recruitment of adaptor proteins, the activation of transcription factors, and changes in the cytoskeleton. Together, these signaling cascades ultimately fashion the response of the cell to the ligand. Intracellular signaling thus translates cues from the extracellular environment, such as peptide growth factors, extracellular matrix proteins, hormones, and cytokines, into appropriate cellular and organismal responses.
- As normal cells make the transition to malignancy, alterations in key receptors and signaling pathways occur. Some of these alterations are a result of activating mutations in receptors and signaling pathway components. Other mutations inactivate negative regulators of these pathways. The net result is both enhanced proliferation and inappropriate survival of the cancer cells, as well as unregulated cell movement and invasive capacity. Together, then, alterations in signaling pathways underlie all aspects of the cancer phenotype.
- In recent years, as the genetic alterations in cancer cells have begun to be characterized, new drugs have been developed that target these unregulated signaling pathways. In several cases, these drugs have been shown to be effective against tumors that harbor the appropriate mutations. Current research and development efforts are aimed at uncovering all aberrant intracellular signaling pathways in cancer cells and designing drugs to control them.

INTRODUCTION

Definition

During embryonic development and in the adult organism, the fate of a cell is decided by the cues it receives from its surroundings. For example, growth factors instruct cells to divide, and extracellular matrix proteins provide survival signals. Other stimuli can cause cells to migrate, to differentiate, to undergo programmed cell death (apoptosis), or to enter a survival state that involves autophagy. Each of these outcomes is initiated by binding of diverse protein and non-protein ligands to receptors, most of which are localized on the cell surface. Receptor activation results in the recruitment of adaptor molecules and enzymes, particularly protein and lipid kinases. These recruited proteins then relay signals to the nucleus, the cytoskeleton, and other subcellular compartments to affect the response. Each type of receptor initiates a discrete set of signaling pathways, such that different ligands binding to the same cell can have different effects. Furthermore, the same ligand can have different effects on different cell types because of innate differences in the signaling components present in the cells. Thus, the combinatorial action of several intracellular signaling pathways dynamically controls the responses of cells and organs to external cues from the environment.

Clinical Relevance

The first clues that components of intracellular signaling pathways are important in causing cancer came from research on tumor viruses in model systems such as chickens and mice.[1] Many RNA tumor viruses (retroviruses) contain cancer-causing genes called oncogenes, which derive from host sequences. For example, the first retroviral oncogene to be discovered, *src*, the transforming gene of Rous sarcoma virus, derives from the cellular *src* gene, which encodes a protein tyrosine kinase. During the transduction event, 3′ sequences of the *src* gene were lost, resulting in the production of a protein that lacks the regulatory carboxy-terminus. Thus, while the cellular Src protein is normally tightly regulated in cells, the viral form of the protein is constitutively active and transforming. Other examples of oncogenes that are transduced by retroviruses include *ras*, *myc*, *sis* (encoding the growth factor PDGF), *akt*, *raf*, *fos*, and many more. Equally important lessons were learned from the study of DNA tumor viruses. The oncogenes of these viruses do not derive from the host genome. Rather, in this case, the oncogenes associate with and modify the functions of key signaling proteins. For example, most DNA tumor viruses encode proteins that are able to inactivate negative regulators of signaling, such as p53 and Rb. Many can also activate signaling by binding to proteins such as Src, the platelet-derived growth factor (PDGF) receptor, and cyclins. These oncogene studies therefore provided the early tools necessary to dissect the signaling pathways that control cell growth. Other important information, particularly on the control of cell survival, has come from the study of genetically tractable organisms such as fruit flies and the nematode *Caenorhabditis elegans.* More recently, whole genome sequencing projects have allowed the direct analysis of human clinical specimens for alterations in key signaling pathways.

With the use of the systems and tools described previously, much progress has been made in the last decades in the characterization of intracellular signaling: Several classes of receptor have been defined,

all protein kinases (the kinome) have been described,[2] and some signaling pathways are now known in their entirety.[3] Furthermore, there has been intense study of the perturbations that occur in intracellular signaling during cancer progression. This effort has resulted in the definition of new molecular targets for cancer drug discovery.[4] Indeed, some new drugs that target cellular signaling have recently been approved, and many more are in clinical testing. While not yet fully realized, the promise is that defining and targeting signaling pathways responsible for all aspects of the cancer phenotype will result in more potent and less toxic chemotherapies.

This chapter reviews the basic principles of intracellular signaling. Then some examples of receptors and their mechanisms of activation are given (antigen and other immune receptors are not discussed). This is followed by an overview of some common signal transduction intermediates and some selected examples of signal transduction pathways elicited by certain receptors. Finally there is a brief discussion of how these signaling pathways are dysregulated in cancer and how this might be exploited for targeted therapeutic intervention. This is not intended to be a comprehensive list of all receptors and signals; rather, examples have been chosen that have relevance to the cancer phenotype. The references that are provided are intended to point the reader to more detailed and thorough reviews of the topics covered; primary references are provided only for new discoveries that have not yet been the subject of reviews. Furthermore, many of the examples and themes that are briefly described in this chapter are explored in more detail in later chapters. For example, in Chapter 5, Craig Thompson and Rebecca Elstrom describe in some detail the control of cell death and in Chapter 4, Jacqueline Lees reviews how signaling pathways feed into the cell cycle. Furthermore, each of the chapters on specific malignancies contains descriptions of the dysregulated signaling pathways that are involved in each disease.

FUNDAMENTAL SCIENCE

General Principles of Intracellular Signaling

Intracellular signaling is the mechanism by which cues that are present in the extracellular environment are relayed and interpreted by the cell. These external cues can be growth factors that signal a cell to divide, extracellular matrix proteins that promote survival, hormones that change the metabolism of the cell, cytokines that instruct the cell to differentiate, or other signals that promote motility and invasive ability. Complex multicellular organisms have evolved to have a large array of receptors for these external cues, as well as an even larger number of intracellular signaling molecules. Both embryonic development and adult homeostasis require specificity as well as temporal and spatial control of these signaling pathways. Many disease states, including cancer, diabetes, and immune disorders, can arise if these signaling pathways are inadequately controlled.

Intracellular signaling can at first glance seem overwhelmingly complicated. A given receptor can engage a number of different signaling pathways, each eliciting a distinct phenotype. One signaling pathway can affect the output of another, a phenomenon known as *cross-talk*. The same ligand can have different effects in different cell types. And the activation of a receptor frequently also elicits negative regulatory pathways that are designed to switch the system off after a defined period of signaling.[5–7] But this complexity can be reduced somewhat. Experimental observation has shown that the members of any given family of receptors signal in approximately the same way. Furthermore, many receptors use similar components to signal; for example, cytokine, growth factor, and G protein-coupled receptors all activate the MAP kinase pathway and the PI 3-kinase pathway.[8,9] Finally, most signaling pathways make use of adaptor or scaffolding proteins. These proteins lack catalytic activity and instead are made up of multiple protein-protein and sometimes also protein-lipid interaction domains.[10,11] In this way, adaptor proteins orchestrate the simultaneous activation of a number of pathways following receptor activation. Signaling specificity can be provided by the recruitment of distinct adaptor proteins by different receptors. A schematic of how signal transduction pathways can involve different components is outlined in Figure 2-1.

Receptor Activation by Ligand

Most of the receptors that receive cues from the extracellular environment are found in the plasma membrane of the cell, where they initiate signaling for those peptide and protein ligands that cannot cross the lipid bilayer. In contrast, receptors for lipid soluble ligands are found in the cytoplasm and the nucleus. A broad overview of the molecular makeup and mechanism of activation of several different classes of receptor will be described later.

G Protein-Coupled Receptors

The largest class of plasma membrane receptor is the so-called G protein-coupled receptor (GPCR) family, which has more than 1000 members.[12] Ligands include agents that stimulate neurotransmission, light and taste perception, and cell division and differentiation as well as the chemokines, which are ligands that are involved in cell attraction.[13] All GPCRs share a common architecture, with seven transmembrane α-helical domains, connected by both extracellular and intracellular loops. Because of this architecture, GPCRs are sometimes also referred to as serpentine or heptahelical receptors. The extracellular domain is responsible for ligand binding, which causes a conformational change such that the G protein binding to the intracellular domain becomes activated. G proteins are heterotrimeric proteins that consist of α, β, and γ subunits. Activation causes the dissociation of the α subunit from the $\beta\gamma$ complex; both separated components then go on to mediate signaling events that are very similar to those initiated by receptor tyrosine kinases.[14]

Receptor Tyrosine Kinases

The next largest class of receptors is the receptor tyrosine kinases (RTKs).[2,15,16] This class consists of approximately 90 members, most of which are involved in the control of cell growth, motility, and differentiation as well as metabolic control. Examples include PDGF receptors, epidermal growth factor (EGF) receptors, the ephrin receptors, hepatocyte growth factor receptors, fibroblast growth factor (FGF) receptors, insulin receptors, and many more. While the ligands for most classes of RTK are now known, some remain "orphans," with their ligands yet to be discovered. At least one RTK, Her2 (also known as ErbB2), has no known ligand but instead signals by heterodimerization with other EGFr family members.[17,18] Also, by sequence analysis of the catalytic domains, several RTKs are predicted to lack catalytic activity. In one of these cases, Her3, the receptor is transphosphorylated when heterodimerized with other EGFr family members (particularly Her2) and acts as an adaptor protein. The majority of the RTKs are single polypeptide chains that contain an extracellular ligand-binding domain, a short hydrophobic transmembrane domain, and a cytoplasmic region containing the kinase domain, as well as other sequences that regulate recycling and/or turnover of the receptor and interaction with signaling molecules. One exception to this rule is the insulin receptor family, which is composed of a disulfide-bonded tetramer, with two identical extracellular ligand binding subunits and two transmembrane subunits with catalytic activity. Another exception is the Met/Hepatocyte growth factor receptor family, in which a single polypeptide chain is cleaved to produce a stable dimer with ligand binding invested in one subunit and catalytic activity in the other. While it is generally thought that the single membrane pass RTKs are monomeric in the absence of ligand,[15,19,20] there is some recent evidence that EGF receptors can exist in a dimeric but inactive state in the absence of ligand.[15]

Some RTK ligands are dimers (e.g., the PDGFs), while others are monomeric (the EGFs). The FGF receptors require both FGF ligands and heparin sulfate proteoglycans for full activation.[21,22] Yet other

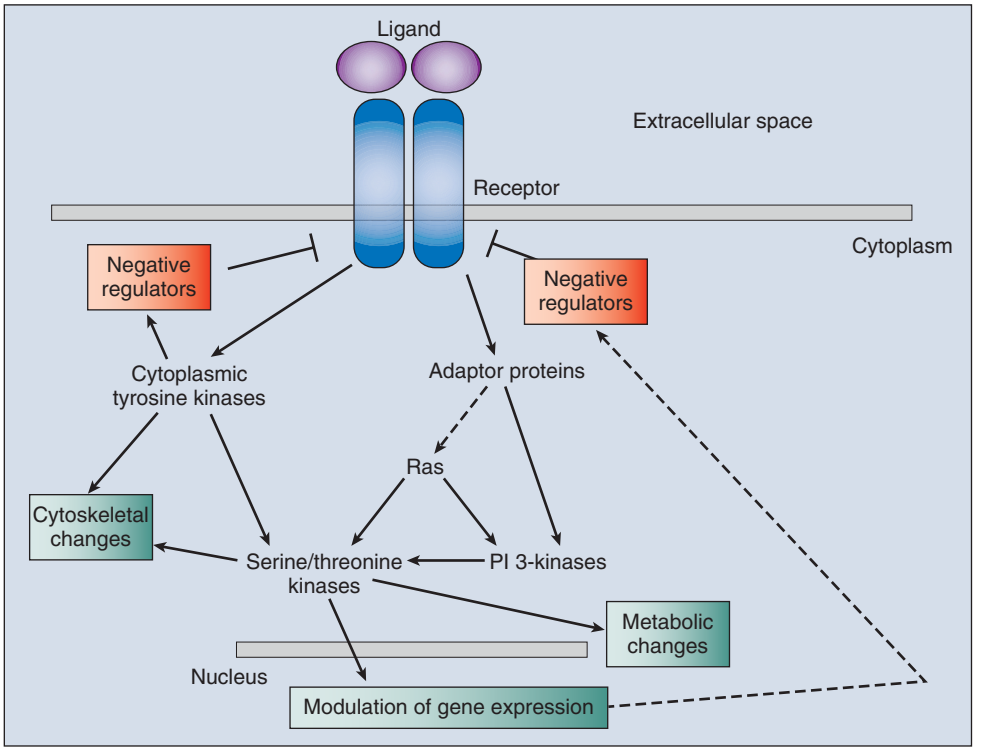

Figure 2-1 • Schematic of intracellular signaling. A prototype receptor is shown. Dimerization of the receptor by ligand elicits multiple signaling pathways, whose outputs result in changes in gene expression, in the cytoskeleton, and in metabolism. These signaling pathways also elicit the production of negative regulators, which ultimately turn the signal off.

RTKs, notably Ret and MuSK, do not bind ligands directly, requiring a coreceptor to present the ligand.[23,24] Despite these differences, RTKs generally share a common mechanism of activation on ligand binding, which involves dimerization and often further oligomerization to form higher-order structures. Recent crystallographic studies have revealed the molecular mechanisms behind ligand-induced activation and how monomer ligands can induce dimerization. In the case of the EGFr, the dimerization occurs at an interface between two receptor monomers, the ligand presumably serving to initiate the domain rearrangements that are necessary to make these contacts.[19,20] In contrast, FGFs, while monomeric, have two receptor-binding sites. Dimerization is thus achieved by interactions between the receptor and the ligand. The heparin sulfate is required to organize and strengthen the interaction of ligand and receptor as well as to provide specificity to the interactions.[21,22] Regardless of how the extracellular domains are brought into close apposition, the result is the juxtapositioning of the two catalytic domains and the subsequent transphosphorylation of tyrosine residues in the activation loop of the kinase domain, as well as elsewhere in the intracellular domain. These phosphorylations serve to initiate further conformational changes that stabilize the active form of the enzyme as well as to provide binding sites for the enzymes and adaptor proteins that are described later.

Serine and Threonine Kinase Receptors

The proteins in this family act as receptors for transforming growth factor (TGF)-β, activins and inhibins, and bone morphogenetic protein.[25] Members of this family of receptors, which together are often known as the TGF-β superfamily, play key roles during development and morphogenesis, as well as in cell cycle progression, motility and wound healing, and immune surveillance.[26] The ligands can be homodimers or heterodimers, and they interact with two single-pass membrane proteins called type I and type II receptors. Both receptor subunits have intrinsic serine/threonine kinase activity in the cytoplasmic domain. Signaling is thought to be initiated by ligand-induced oligomerization of two type I receptors with two type II receptors.[25] The type II receptor, which has constitutive kinase activity, phosphorylates and activates the type I receptor, which then goes on to phosphorylate substrate proteins.

Integrin Receptors

Integrins are heterodimers of an α and a β subunit, each of which is membrane-spanning.[27] Mammals have 18 α subunits and 8 β subunits that can combine to form 24 distinct heterodimers. Integrins derive their name from their ability to bind to ligands outside the cell and cytoskeletal components inside the cell and so integrate the two environments.[28] Their extracellular ligands can be either extracellular matrix proteins or cell surface proteins on neighboring cells. In their low-affinity state, the extracellular domains of the β subunits adopt a "bent" conformation. Ligand binding generates a higher-affinity, straightened structure of the β subunit, corresponding allosteric changes in the extracellular domain of the α subunit, followed by conformational changes in the transmembrane and cytoplasmic domains.[29] Clustering of integrins also occurs because of the multivalent nature of the ligands. The net result is a separation of the cytoplasmic domains of the α and β subunits, which mutational studies have shown is required for this "outside-in" signaling. Integrins do not contain intrinsic kinase activity but instead signal through associated cytoplasmic kinases such as Src and FAK.[30]

Unlike any other class of membrane receptor, integrins can also signal from the cytoplasm to the extracellular space, so-called inside-out signaling.[31] In this form of signaling, cytoplasmic signal transduction pathways, for example, caused by activation of the EGFr or Frizzled receptors, generate a conformational change in the integrin extracellular domain, resulting in increased adhesion to extracellular ligands and subsequent outside-in signaling. Although the exact mechanism by which this conformational change is transmitted was unclear until very recently, it was known that the cytoskeletal protein talin was required. Talin binds to the cytoplasmic tails of most β integrins through its PTB-like domain. Reducing talin expression or preventing its association with the β subunit is sufficient to inhibit inside-out signaling. Talin adopts an autoinhibited structure in

quiescent cells. Intracellular signaling pathways release this inhibition, allowing it to bind to and change the conformation of the integrin, thus promoting high-affinity interactions of the integrins with their ligands.[32]

Cytokine Receptors

The cytokine receptor superfamily consists of the receptors for growth hormone, prolactin, erythropoietin, thrombopoetin, G-CSF, and the interleukins as well as the interferon receptors.[33–35] They are grouped together because of their use of functionally related receptors. Most receptors use a common γ chain, together with variant β chains and sometimes α chains. Structural homologies among these chains include four conserved cysteine residues in the extracellular domain and a WSXWS motif located near the transmembrane domain. The cytoplasmic domains of these subunits lack any catalytic activity but instead have two regions of low homology, called "box 1" and "box 2." Although the exact functions of these boxes are not known, it is clear from mutagenesis studies that they are necessary for receptor function. Activation of cytokine receptors occurs when ligand binding causes dimerization, perhaps by promoting a rotational switch near the WSXWS motif.[36] Kinases of the JAK family, which are constitutively associated with the cytoplasmic domains, then transphosphorylate the receptors to initiate signaling. The most important substrates of the JAKs are the Stat proteins, which have an SH2 domain and a transcriptional activation domain. Signaling by this class of receptors thus involves tyrosine phosphorylation-induced dimerization of the Stats, which renders them transcriptionally competent.[37]

Another class of cytokine receptors is represented by the tumor necrosis factor (TNF) receptor superfamily, also known as death receptors, which control apoptosis in response to exogenous signals.[38] Members of this family include the TNF receptors 1 and 2, Fas, CD40, and TRAIL and are simple single-pass transmembrane proteins, with cysteine-rich ligand-binding domains on the outside and either a death domain (R1 receptor) or a TRAF-binding domain (R2 domain) on the inside.[38] They have no intrinsic catalytic activity. It was originally thought that TNF activated its receptor by inducing trimerization, but it is now known that this class of receptors breaks the ligand-induced oligomerization rule. Instead, the TNF receptors are found as preformed trimers on the cell surface.[39] This is thought to be required for their function. For example, TNF-α signals through TNF-R1 to initiate cell death and through TNF-R2 to activate NFkB. If the ligand were to initiate the formation of trimers, mixed oligomers would form in any cell that expresses both receptors. Since only a trimer of death domain-containing receptors is functional, this would result in the suppression of death signals. Thus, preassembly of receptor complexes might promote the formation of homotypic receptors and confer more specificity in the response. As with other, more conventional receptors, ligand binding is thought to elicit conformational changes that render the cytoplasmic domains competent for signal transduction.

Frizzled Receptors

Frizzled receptors are the binding partners for the Wnt family of ligands.[40] This is a large class of peptides that control a wide array of developmental processes and have also been implicated in cancer. Of particular current interest is the role of Wnts in the control of stem cell fate.[41,42] Frizzled receptors have a cysteine-rich extracellular Wnt-binding domain, followed by seven transmembrane domains and a short cytoplasmic tail. Frizzled alone is unable to transduce Wnt signals. Rather, members of the LRP family, which are single-pass transmembrane proteins, are required as coreceptors. The current model for the way in which Wnts activate their receptors is an interesting and novel one in which it is postulated that Wnts bring LRP and Frizzled into close proximity.[40] In support of this model, coexpression of chimeric fusion proteins that cause the close apposition of Frizzled and LRP is sufficient to induce Wnt-independent signal transduction.

Notch Receptors

There are four mammalian Notch receptors, which play important roles in development and tissue homeostasis, by specifying cell fates and creating boundaries between different cells.[43–47] Each receptor is a single-pass transmembrane protein, with an EGF repeat domain that binds ligand in the extracellular domain, and a cytoplasmic domain that lacks catalytic activity but instead contains several ankyrin repeats and a C-terminal PEST domain. During transport through the Golgi, the receptor is cleaved into ligand-binding and transmembrane domains that remain associated with each other through noncovalent interactions. The ligands for Notch are called DSLs (for delta-serrate-lag2 family), and they are also single-pass transmembrane proteins with EGF-like repeats in their extracellular domains. Signaling between Notch and DSLs therefore takes place when one cell carrying the ligand and one cell expressing the receptor are in close apposition. Unlike the other receptors discussed here, in which ligand binding usually controls oligomerization of the receptor and phosphorylation of the cytoplasmic domains, activation of the Notch receptors is accomplished by regulated and specific proteolysis.[48] The binding of ligand to Notch makes the receptor susceptible to cleavage first by an ADAMs family metalloprotease in the extracellular domain and then by a γ-secretase in the transmembrane domain. This frees the intracellular domain of Notch, which translocates to the nucleus, where, together with a DNA-binding protein called CSL and coactivators, it activates transcription. Uniquely among the plasma membrane receptors, then, the Notch receptor family does not use a series of signal transduction pathways to exert their effects but rather affects gene expression directly.[47]

Nuclear Hormone Receptors

Some receptors, particularly those for estradiol, progesterone, androgen, glucocorticoids, polyunsaturated fatty acids, and the retinoids, predominantly exert their effects by acting as transcriptional activators and/or repressors.[49] These nuclear hormone receptors are regulators of many aspects of homeostasis, as well as sexual development. Many have been implicated in disease, including cancer, lipid disorders, and diabetes.[49,50] In addition, several are the targets of important drugs; for example, PPARγ is the target of the antidiabetes drug rosiglitazone. Most of the nuclear hormone receptors consist of a single polypeptide chain with a DNA-binding domain, a transactivation domain, a ligand-binding domain, and sequences that mediate interaction with coregulators. While some receptors can bind DNA with high affinity as monomers, most require dimerization.[51] This requirement is particularly true of the retinoid receptor family, in which the exact nature of the heterodimers that are formed dictates the transcriptional output. The ligands for the nuclear hormone receptors either diffuse passively into the cell or are produced within the cell during normal metabolism. In some cases, association between receptor and ligand takes place in the nucleus. In other cases, particularly the sex hormone receptors, the receptor is cytoplasmic and bound to chaperone proteins in the absence of ligand. Ligand binding dissociates the chaperones and allows translocation to the nucleus. Once they are nuclear, ligand-dimer complexes interact with DNA and recruit transcriptional regulators to effect their responses. Thus, in this canonical mechanism of action, nuclear hormone receptors as a class do not require intracellular signal transduction pathways. However, there are a growing number of cases, particularly well studied in the case of the estrogen receptor, in which hormone can also bind a plasma membrane receptor.[52,53] Although the identity of the membrane receptor is currently not established (some investigators think that it is the same as the nuclear form, whereas others have suggested it is a GPCR[54]), it is clear that this form of the receptor can elicit canonical signaling involving Src, MAP kinases, and lipid kinases in a similar way to RTKs.[52] The roles of these two forms of receptor signaling, which are often called genomic and nongenomic, particularly in cancer causation, awaits further clarification.

Components of Intracellular Signaling Pathways

With the exception of the nuclear hormone receptors and the Notch receptors, ligand-activated receptors do not have direct mechanisms of action. Rather, their activation results in the initiation of one or more signal transduction cascades that ultimately change the phenotype of the cell. Many general principles and some individual elements of these signal transduction cascades are shared by different classes of receptor. Some of the more commonly used strategies are described in overview here.

Adaptor Proteins

Perhaps one of most common features shared by most receptor signal transduction cascades is the use of adaptor proteins,[10] which are defined as proteins with protein-protein interaction and sometimes also protein-lipid interaction domains. Common protein interaction motifs include SH2 and some PTB domains, which bind to phosphotyrosine-containing peptides[55]; SH3 domains, which bind to proline-rich ligands[56]; WW and WD40 domains, which bind phosphorylated serine and threonine residues, respectively[57,58]; and PDZ domains, which bind carboxy-terminal sequences of proteins.[59,60] In each case, neighboring amino acids provide specificity to the interaction. For example, the SH2 domain of Grb2 preferentially binds a phosphotyrosine followed by the sequence XN, where X is any amino acids and N is asparagine. The SH2 domain of Src, in contrast, prefers the sequence Y(p)EEI. PH, PX, and FYVE domains bind phosphoinositides, particularly those phosphorylated in the 3, 4, and/or 5 positions by phosphatidylinositol (PI) kinases.[61–63]

Since most adaptor proteins have multiple interaction domains, they act as scaffolds that cluster together distinct signaling molecules. Adaptor proteins can serve to give specificity to receptor signaling by clustering distinct sets of signaling proteins in a particular subcellular location. In some instances, the recruited proteins might modify each other's activity, for example, when a kinase phosphorylates a coassociated protein. Some adaptor proteins are selective for certain receptor-signaling systems. For example, death domain-containing adaptors are used exclusively by the superfamily of TNF receptors,[64,65] the insulin receptor substrate family of proteins is dedicated to the insulin receptor and cytokine receptor families,[66,67] and FRS2 is involved in FGF and nerve growth factor signaling.[68] Others, such as Grb2 and Shc and the Gab, Dok, and Vav families, are used by multiple receptor types.

Cytoplasmic Tyrosine Kinases

Some receptors have intrinsic tyrosine kinase activity, while others, such as GPCRs and cytokine receptors, do not. Yet each of these receptor classes uses tyrosine phosphorylation as a signal. They do this by recruiting, or being stably associated with, cytoplasmic tyrosine kinases (CTKs). There are several subfamilies of CTKs,[2] the most important for signal transduction being the Src family, the Abl family, the Tec family, the FAK family, and the JAK family. These kinases become activated by association with the receptor, usually through dimerization and transphosphorylation. In these cases, the CTKs can be considered to be noncovalently associated receptor subunits that provide the required catalytic activity. But it is interesting that even the RTKs recruit CTKs, which is required for their full function.[69,70] An example of this, the recruitment of Src family kinases by the PDGFr, is given later. While these observations led some researchers to speculate that RTKs were able to phosphorylate only associated proteins and therefore required CTKs to phosphorylate all downstream signaling components, it now seems clear that different tyrosine kinase families have broadly different substrate specificities and that some signal transduction pathways are dependent on the substrates phosphorylated by the RTK and some on the CTK substrates. In keeping with this, cytokine receptors and GPCRs also recruit and/or activate more than one class of CTK.

Cytoplasmic Serine and Threonine Kinases

There are 518 protein kinases in the human genome. Of these, 90 are tyrosine kinases, either RTKs or cytoplasmic kinases as described previously. All other members of the kinome phosphorylate serine and threonine residues.[2] While many of these enzymes have housekeeping functions in the control of metabolism, DNA replication, and so on, many more are obligate proximal members of signal transduction cascades from receptors. The best studied of these kinases are the ones that make up what is called the MAP kinase (MAPK) pathway.[8] MAPKs are small single-subunit serine/threonine kinases. They have a number of substrates, but chief among them are transcription factors, whose subcellular localization and activity are regulated by MAPK phosphorylation. MAPKs fall into three classes: the ERKs, the JNKs, and the p38 family. All of these enzymes are normally inactive in quiescent cells, but become activated upon growth and/or stress stimulation of the cells. This activation is accomplished by enzymes that are generally known as MAPK kinases (MKKs). These are dual-specificity enzymes; they phosphorylate MAPKs on both a tyrosine and a threonine in the activation loop phosphorylation, causing a large increase in catalytic activity of the MAPKs. While there is some cross-talk, different MKKs appear to be somewhat selective in activating the different classes of MAPKs (Fig. 2-2). The MKKs in turn need to be phosphorylated to be activated, which is accomplished by a broad range of serine/threonine kinases, generally called MKK kinases (MKKKs), from a number of different families. While the combinatorial complexity of these cascades of kinases could be staggering, recent evidence suggests that scaffold proteins exist that provide specificity and regulation to each cascade.[71]

The best studied of all the MAPK pathways, and one that is central to all mitogenic signaling from receptors, is the one known

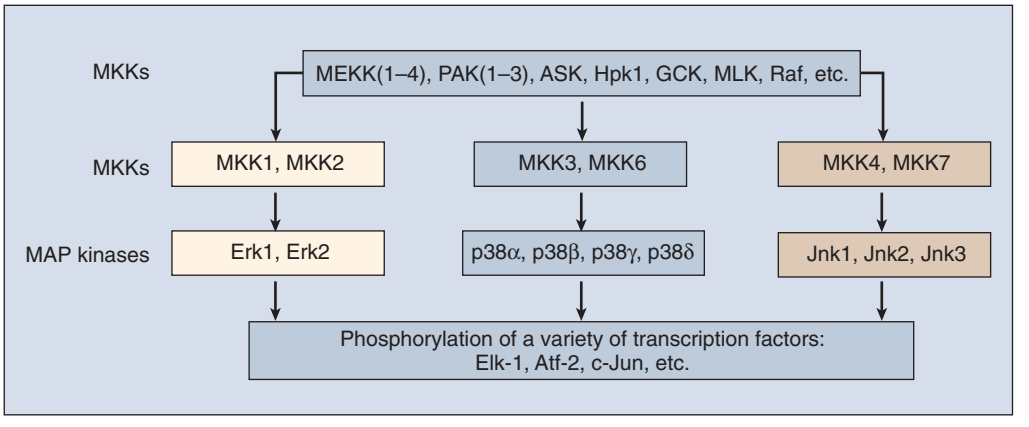

Figure 2-2 • Mitogen-activated protein kinase (MAPK) cascades. Intracellular signaling from various receptors involves activation of members of the mitogen-activated kinases. The MAPKs consist of three families of related kinases (Erks, p38s, and Jnks). Activation of MAPKs is mediated by phosphorylation by a series of related kinases, MKKs (MAPK kinases), which are activated by a broad spectrum of kinases through phosphorylation. Activated MAPKs translocate to the nucleus and phosphorylate a variety of structurally unrelated transcription factors. The transcription factors and gene expression are thus activated.

as the Ras-Raf-MAPK pathway.[72] The Ras family consists of three small GTPases: H-, N-, and K-Ras. Of these, K-Ras has been implicated in many human cancers. For example, more that 90% of pancreatic cancers and approximately 50% of colon cancers have an activating mutation in K-Ras.[73–77] In unstimulated cells, Ras is found in an inactive, GDP-bound form. Many ligands activate Ras, by stimulating the exchange of GDP for GTP, which is accomplished by activating proteins called guanine nucleotide exchange factors and inhibiting proteins called GTPase-activating proteins. In the case of growth factor signaling, the guanine nucleotide exchange factor that is involved is called Sos, which is usually associated in the cytoplasm with an adaptor protein called Grb2. The GTPase-activating protein that is involved is p120Gap. On receptor activation, two different types of adaptor protein, called Shc and Gab, become recruited to receptors in the membrane and phosphorylated on several tyrosine residues. Several of these sites are in YxN motifs, which are canonical binding sites for the Grb2 SH2 domain. Thus, receptor activation results in the following cascade of signaling: Shc (or Gab) > Grb2: Sos > Ras. Once Ras is in the GTP-bound state, it initiates a number of different signaling pathways, including PI 3-kinase activation, and cytoskeletal changes.[78–81] But of particular importance, it recruits the serine/threonine kinase Raf to the plasma membrane, where other signals, including tyrosine phosphorylation, activate its intrinsic kinase activity.[82] Raf then goes on to phosphorylate and activate MEK 1 and 2, which in turn activate ERK1 and 2.

Space does not allow a full description of all serine/threonine kinases that are involved in signal transduction here. But there is one enzyme complex that has attracted much recent attention: mTor (mammalian target of rapamycin).[83–88] mTor is a signal integrator, linking information about nutrients, energy status, and growth factor stimulation to outputs such as protein synthesis, ribosome biogenesis, metabolism, and cell survival and proliferation (Fig. 2-3). There are two structurally distinct mTor complexes, with proteins known as Raptor and Rictor. The mTor/Raptor complex is regulated by a small GTPase known as Rheb, which is normally kept in an inactive state by a GTPase-activating protein consisting of a complex of two tumor suppressors TSC1 and TSC2. A variety of signals, including signals from Akt, ERKs, and other serine/threonine kinases, inactivate the TSC1/2 complex, thus activating Rheb and in turn mTor/Raptor. The signaling outputs from this complex include mRNA translation, ribosome biogenesis, and autophagy through phosphorylation of substrates such as 4E-BP1 and ribosomal S6K. The mTor/Rictor complex is less well understood, but it is activated by RTKs and plays an important role in activating Akt.

Lipid Signaling

As we saw earlier, many adaptor proteins have domains that interact with phosphorylated phosphoinositides, which frequently serves to recruit them to the plasma membrane or subcellular organelles such as endosomes. In other cases, phosphoinositide binding serves to activate the catalytic activity of the enzyme to which it is bound. The most important lipid modifiers in signal transduction pathways are a family of enzymes known as phosphatidylinositol 3-kinases (PI 3-Ks).[9,89] These come in three classes, based on sequence alignment and substrate preference. Class I enzymes have two subunits, one with catalytic activity and one that specifies the association of the enzyme with other signaling molecules. They generally generate PI 3,4,5-P3 (PIP3) from PI 4,5-P2. Class II enzymes have a single subunit, which contains both catalytic activity and regulatory sequences. They predominantly generate PI 3-P and PI 3,4-P2. Class III has just one member, the Vps34 protein, which was originally identified as a gene required for vacuolar sorting in budding yeast and generates PI 3-P. Relatively little is known about the functions of the class II and class III enzymes in mammals, although Vps34 has recently been implicated in mTor regulation and autophagy, suggesting a role in the response of cells to nutrients. Class II enzymes bind clathrin, suggesting a possible role in receptor trafficking and/or endocytosis. But it is the class I family members that have been most intensively studied for their roles in intracellular signaling pathways and cancer.[86,90–93]

Class I enzymes can be further subdivided into Class IA and Class IB. All members have structurally related catalytic subunits. But the regulatory subunits of class IA members all contain 2 SH2 domains, and some also have an SH3 domain, whereas in class IB, the regulatory subunits are structurally distinct. Class IA members are activated by RTKs, whereas class IB members are activated by GPCRs. In all cases, activation occurs when the PI 3-K is recruited to the membrane by regulatory domain sequences, for example, the SH2 domains in the case of class IA. This brings the enzyme into close proximity with its substrate and allows catalysis to take place. PIP3 then acts as a lipid second messenger by binding to PH domains in a variety of proteins, including the serine/threonine kinases PDK1 and Akt (see Fig. 2-3). One important target of Akt is the FOXO family of transcription factors, which are sequestered in the cytoplasm and inactivated by phosphorylation, thus inhibiting gluconeogenesis.[94] Other metabolic targets include the glucose transporter Glut4, glycogen synthase kinase 3, and ATP citrate lyase. Akt also has effects on the cell cycle via its inhibitory effects on FOXO and GSK3 as well as by directly phosphorylating proapoptotic proteins such as BAD. In

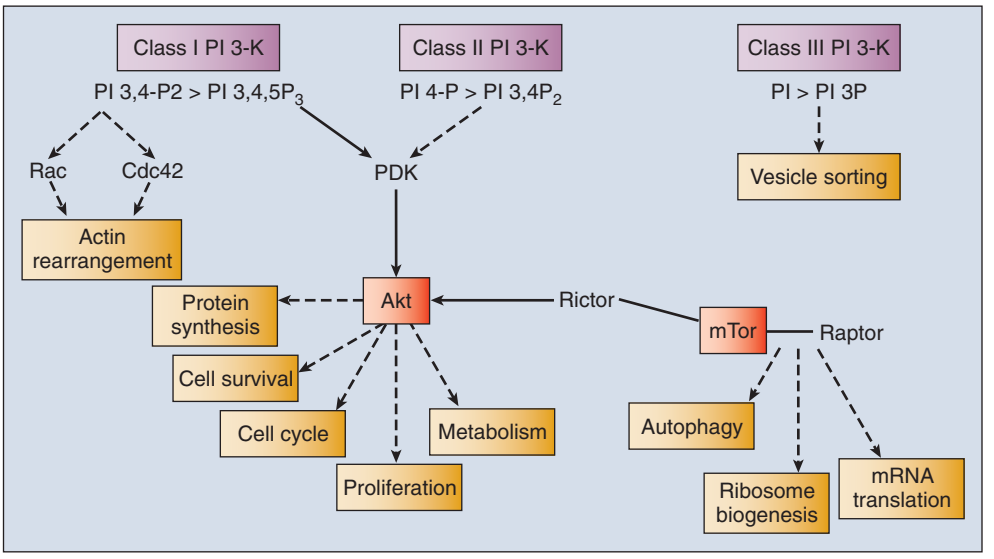

Figure 2-3 • mTor and PI 3-K signaling. The figure illustrates some of the key components of the mTor and PI 3-K signaling pathways and highlights the central role that the serine/threonine kinases Akt and mTor play in the control of several intracellular signaling events. The three classes of PI 3-K are activated by a variety of cell surface receptors and make different lipid products, which bind to lipid-binding domains in a variety of signaling molecules. Lipid binding activates signaling by recruiting the signaling molecules to intracellular or plasma membranes or by causing a conformational change. Once Akt is activated by PDK1 and other serine/threonine kinases, it phosphorylates a number of substrates to cause profound changes in cell homeostasis. mTor responds to changes in nutrients and growth factors and exerts its effects via forming stable complexes with either Rictor or Raptor.

concert with the small GTPases Rac and Cdc42, class I enzymes also control actin dynamics and thus regulate cell polarity and motility.

Negative Regulators of Signaling

Given the power of signal transduction pathways to regulate all aspects of a cell's phenotype, it is vital that these pathways be tightly controlled. Indeed, in the absence of such control, cancer often arises. We have seen that some control is provided in the recruitment and activation of defined signaling modulators. But there are also other layers of control that ensure that the signal is switched off in a timely manner. A number of different mechanisms are used. The first is at the level of the receptor itself. Following ligand binding, most receptors are internalized via mechanisms using clathrin-coated pits and endocytosis.[95–98] In some cases, this results in degradation of both receptor and ligand in lysosomes; in other cases, the unoccupied receptor is recycled back to the plasma membrane. Both RTKs and some cytoplasmic tyrosine kinases are also regulated by ubiquitin-mediated degradation at the proteasome.[99,100] In the case of the EGFr and Src, it is the activation of these proteins that initiates the degradation by recruiting an E3 ubiquitin ligase called Cbl via SH2 domain interactions.[101–104] This ensures that the proteasome selectivity degrades the active forms of the enzymes. Two other inhibitory mechanisms are also elicited by the very signaling pathways that they inactivate. For example, the activation of MAPK-signaling pathways results in the transcriptional activation of a class of enzymes called MAPK phosphatases (MPKs), which, as the name suggests, dephosphorylate and inactivate MAPKs.[5,105] Also, the JAK-Stat signaling pathway results in the production of the SOCS (suppressor of cytokine signaling) proteins, which have an SH2 domain and a region known as a SOCS box. The SOCS proteins are thought to inhibit signaling by binding to specific phosphotyrosine-containing motifs on receptors and the JAK kinases and perhaps initiating ubiquitin-mediated degradation.[6,106] Finally, the action of both phosphoprotein and phospholipid phosphatases can also serve to regulate signaling. Of particular importance is the phosphoinositide phosphatase and tumor suppressor known as PTEN, whose loss has been associated with malignancy in many cancers, particularly glioblastomas and prostate cancer.[93,107]

Selected Examples of Signal Transduction Pathways

Throughout this chapter, we have touched on the concept that many extracellular ligands engage multiple signaling pathways and that there are some common themes to the signaling outputs that emerge. For example, stimulation with most ligands results in profound changes in gene transcription by activating transcriptional regulators such as Fos, Myc, NFkB, Stats, Smads, hormone receptors, and so on. Many factors elicit changes in the cytoskeleton, polarity, and movement of cells. Alterations in metabolism, hormone responses, differentiation, and survival are other common outputs. In this section, a few examples of receptor-initiated signal transduction pathways will be given, illustrating the concepts that have been discussed throughout.

Receptor Tyrosine Kinase PDGFr

There are five PDGF ligands encoded by four different genes (A, B, C and D), and two different receptors encoded by unique genes (α and β).[108] Each ligand is a dimer, with known isoforms including AA, AB, BB, CC, and DD. PDGF AA can bind only to a homodimeric αα receptor, whereas AB, BB, and CC can bind both αα and αβ receptors. PDGF DD binds predominantly to ββ receptors. PDGF acts predominantly on cells on mesenchymal origin and promotes cell growth, migration, and survival. Alterations in PDGFr signaling play a role in sarcomas and gliomas.[109,110] Furthermore, chromosomal translocations that cause the constitutive activation of the kinase domain of PDGFr are found in some leukemias and lymphomas.

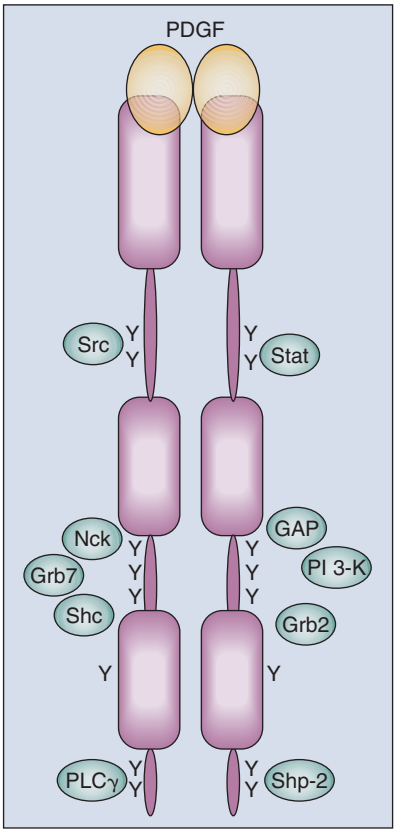

Figure 2-4 • Recruitment of SH2 domain-containing proteins by activated PDGF receptors. The figure illustrates how the ligand PDGF, which is a dimer, causes the dimerization and transphosphorylation of its receptor on a number of tyrosine residues, in the juxtamembrane region, in the kinase insert region, on the activation loop, and on the carboxy-terminal tail sequences. Each one of these phosphorylated tyrosines then binds selectively to SH2 domain-containing proteins, which then initiate a number of different intracellular signaling pathways. The selectivity of SH2 domain binding to each tyrosine is determined by the amino acid sequences immediately proximal to each tyrosine.

Once activated by dimerization and transphosphorylated on several tyrosine residues, the PDGFr recruits at least 10 different SH2 domain-containing signaling molecules to these sites (Fig. 2-4).[69,70,111] One class of binding proteins are members of the Src family of tyrosine kinases (SFKs). These enzymes become activated by this association and then phosphorylate a number of other signaling molecules. While the mechanistic details have yet to be worked out, one important effect of SFK activation is the stabilization of myc mRNA and subsequent transcription.[69] Another important signaling cassette to be recruited is the class IA PI 3-K, which associates directly with the receptor via the SH2 domains on its regulator subunit; the signaling cascades that were discussed earlier are then initiated. Recruitment and phosphorylation of the adaptor protein Shc, together with the subsequent binding of Grb2/Sos, allow the Ras/MAPK pathway to become activated. Other signaling effectors that are more selective for RTKs such as the PDGFr include phospholipase Cγ, the adaptor protein Nck, and the tyrosine phosphatase Shp2, as well as the negative regulators Ras-GAP and Cbl.

It is important to note that the example of signaling that is illustrated here—the recruitment of multiple signaling cascades both to the receptor itself and to adaptor proteins—is a general theme that is seen throughout RTK signaling. Specificity is provided by the nature of the phosphorylation sites on the receptor and the domain makeup of the adaptor proteins that are recruited, as well as the

complement of signaling proteins that are expressed in any given cell type. Furthermore, other receptors, such as integrins and GPCRs, use very similar strategies. In these cases, cytoplasmic tyrosine kinases (FAK and Src in the case of integrins and Src and Tec family members in the case of GPCRs) are responsible for generating the SH2 domain recruitment sites.

TGFβ Receptor

As we saw earlier, the receptors in this family are transmembrane serine/threonine kinases, with ligand stimulating the phosphorylation of the type I receptor by the type II subunit, which activates the intrinsic kinase activity of the type I subunit. The best-characterized intracellular effectors of TGFβ signaling are the Smad proteins.[112–116] There are three types of Smads: R-Smads, a common Smad (in vertebrates this is known as Smad4), and inhibitory Smads. The R-Smads and Smad4 have two conserved domains called MH1 and MH2, joined by linker sequences. In addition, the R-Smads have carboxy-terminal serine phosphorylation sites. On ligand binding, the receptors recruit and phosphorylate one or more R-Smads. The conformational changes that are induced by this phosphorylation release the R-Smads from the receptor and allow the formation of a trimeric complex of two R-Smads with Smad4. This complex translocates to the nucleus, where, along with coactivators such as CBP/p300 and factors such as FOXO and Forkhead, transcription is activated. The specificity of the transcriptional response is provided by the R-Smads that are present in the complex and thus the coactivators and transcription factors that are recruited. In turn, recruitment of individual R-Smads is determined by the exact nature of the heterotetramer receptors that are formed in response to the diverse TGFβ family ligands.[112] In the cases in which the ligand is TGFβ itself or activin, efficient recruitment of R-Smads to the receptor also requires an adaptor protein called SARA, which has a FYVE domain that interacts with PI 3-P, and a Smad binding site.[116,117] The inhibitory Smads interfere with signaling by binding to type I receptors and interfering with R-Smad recruitment.

Although the Smads are the only known mechanism by which TGFβ receptors modulate transcription, other signal transduction pathways also control Smad activation. For example, R-Smads are phosphorylated by MAPKs, which may prevent nuclear localization of the Smads and transcriptional responses. In contrast, phosphorylation by JNK enhances nuclear translocation and activity of Smad3. Other kinases that have been reported to phosphorylate Smads include cell cycle kinases such as Cdk2 and Cdk4, PKC, and CaMKII. In this way, signaling from other receptors can greatly influence the transcriptional responses to TGFβ receptor stimulation.[112]

TNF Receptor

The death receptors are the means by which extracellular signals are linked to the apoptotic machinery of the cell, a process known as *instructional apoptosis*. One of the best characterized of these receptors is called Fas (also known as CD95 or Apo1); it will be used as illustration.[65,118–120] Trimerization of Fas by its ligand clusters the receptor's death domains, leading to the recruitment of the protein FADD by death domain interaction. The death effector domain in FADD then binds to the inactive, zymogen form of caspase-8. The oligomerization of caspase-8 that ensues causes the self-activation of caspase-8 by proteolysis, resulting in the subsequent cleavage and activation of effector caspases such as caspase-9 and commitment to apoptosis.

Wnt Signaling

The last example to be considered is that of Wnt signaling through Frizzled and its coreceptors, the LRPs.[40] One of the most important signaling components in Wnt signaling is the β-catenin protein, which accumulates in the cells in response to the ligand and activates transcription by associating with the DNA-binding protein TCF.[121–123] In unstimulated cells, TCF is in a complex with the negative regulator Groucho and is transcriptionally inactive. In these same cells, β-catenin turns over rapidly, a consequence of its recruitment by a so-called destruction complex. This complex contains Axin, APC, and GSK3, a serine/threonine kinase. Phosphorylation of β-catenin by GSK3 causes β-catenin to become ubiquitinated and targeted for destruction by the proteasome. The binding of Wnt to its ligand causes the phosphorylation of LRP by GSK3 and CK1 and the recruitment of the Axin/APC/GSK3 complex to the receptor (Fig. 2-5). This is presumably sufficient to prevent the phosphorylation of β-catenin, thus allowing its concentration to rise, enter the nucleus to associate with TCF, and activate transcription. Another key intermediate in Wnt signaling is Dsh, which is required upstream of Axin/APC/GSK3. Dsh is also a cytoplasmic protein that becomes recruited to the Frizzle/LRP complex in response to Wnts, but the exact mechanism by which it participates in signaling is unknown at this time.

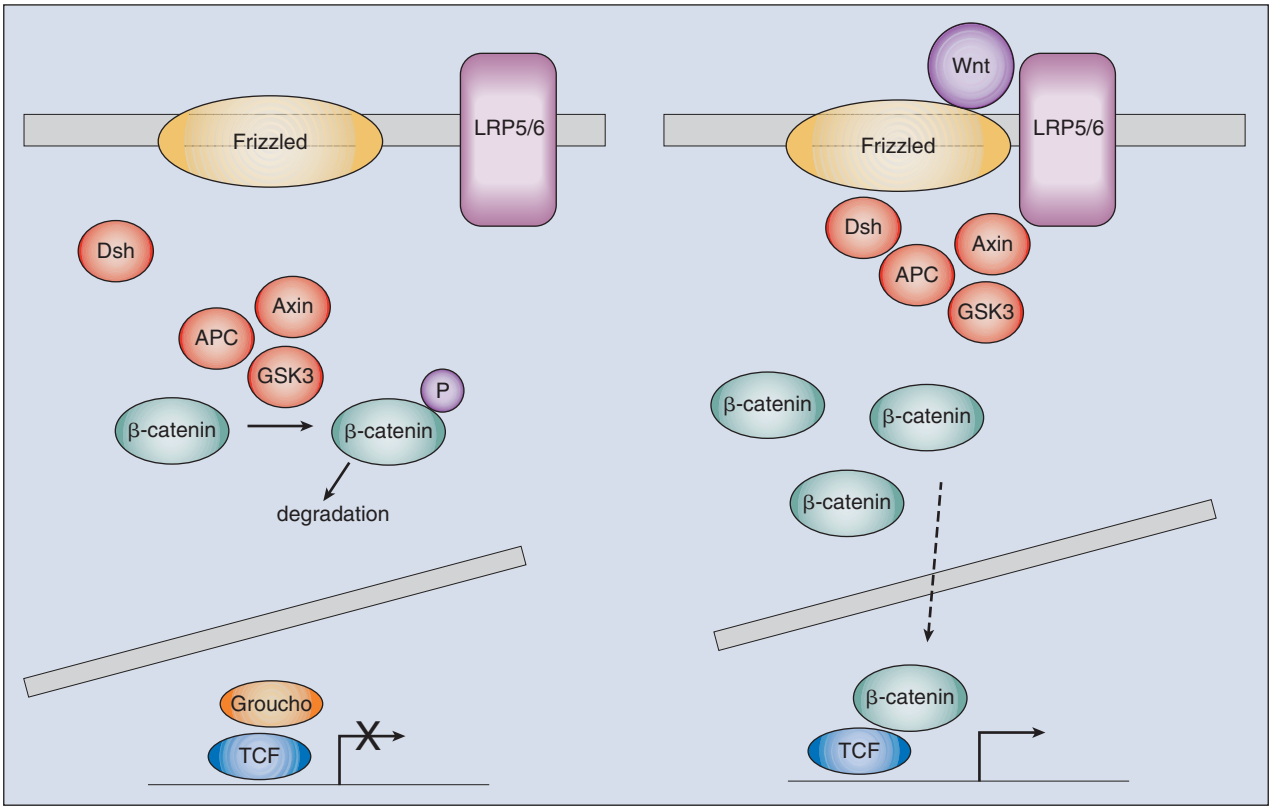
In an intriguing new twist to the story of Wnt signaling, it was recently found that Wnts can act as ligands for the atypical RTKs, Ryk, Ror1, and Ror2.[124–126] Little is yet known about the signal transduction pathways that are elicited by Wnt2 binding to these RTKs or about the cellular outputs they specify.

CLINICAL RELEVANCE AND APPLICATIONS

From research conducted over the last two decades, it is clear that many human cancers have their origins in dysregulated signaling pathways.[1,127,128] Some of the earliest oncogenic events to be discovered in humans were mutated and activated K-Ras, chromosomal translocations that result in the overexpression of Myc and the production of the Bcr-Abl tyrosine kinase, and chromosomal amplification of the RTK Her2. Since then, many other activating mutations in signaling pathway components have been discovered in cancer cells. Examples include activating mutations in the EGFr in some non-small-cell lung cancers,[129] in B-Raf in most melanomas as well as other tumor types,[82] in Jak2 in myelodysplastic syndromes,[130,131] and in PI 3-K, particularly in breast cancers.[90,91] Furthermore, chromosomal translocations involving the RTKs Kit, Flt3, and PDGFr are detected in gastrointestinal stromal tumors and some lymphomas. Other mechanisms that cancer cells use to promote their growth and survival include the overexpression of the antiapoptotic protein Bcl-2 in lymphoma,[132,133] activating mutations in G proteins in pituitary tumors,[13,134] the acquisition of insensitivity to the inhibitory growth effects of TGFβ while maintaining the positive signals in many carcinomas,[135–137] and the overexpression of estrogen or androgen receptors in breast and prostate cancers, respectively.[52,138–142]

The discovery of each of these activated signaling pathways has been rapidly followed by attempts by both the academic community and the pharmaceutical industry to develop new therapeutics targeting these events.[4,143–145] Some of these attempts have yet to be successful despite enormous effort; for example, the Ras GTPase has so far proved intractable to small molecule inhibition.[72,146] But for other targets, there have been successes, the most notable being the development of imatinib (target: Abl, PDGFr) and later dasatinib (target: Abl, SFKs) for the treatment of chronic myelogenous leukemia[147] (see Chapter 108). Other therapeutics that target signal transduction pathways include antiestrogens and antiandrogens for breast and prostate cancer, respectively[148,149]; trastuzumab for Her2-positive breast cancer[150]; gefitinib and erlotinib (target: EGFr) for lung cancer[151]; sorafenib (targets: VEGFr and Raf) for renal cell carcinoma[152]; and sunitinib (targets: VEGFr, PDGFr, Kit) for renal cell carcinoma and gastrointestinal stromal tumor.[153,154]

It can be anticipated that in the future, most cancers will be classified not just according to anatomic site of origin and histopathology, but also on the basis of the genetic alterations that are present in the tumor, including those in signaling pathways. New therapeutic modalities are likely to include strategies (small molecules, antibodies, microRNA, etc.) to target these activated signaling pathways.



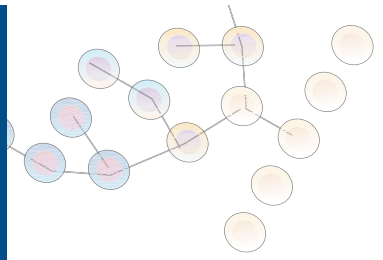


Figure 2-5 • Canonical intracellular signaling from Wnt receptors. In unstimulated cells, a complex of Axin, APC, and GSK (glycogen synthase kinase) phosphorylates β-catenin, which causes its degradation via the proteasome pathway. When Wnt ligand is present, Frizzled and Lrp associate and create binding site for axin, APC, and GSK3 in cooperation with disheveled (Dsh). Phosphorylation of β-catenin is thus prevented, which allows its accumulation and transport into the nucleus. Once in the nucleus, β-catenin displaces the association of Groucho with the transcriptional activator TCF, allowing transcription of several target genes. In some cancer cells, particularly from the colon, mutations in APC prevent the downregulation of β-catenin and thus allow constitutive TCF signaling.

3 The Cellular Microenvironment and Metastases

Amato J. Giaccia and Janine T. Erler

SUMMARY OF KEY POINTS

- Metastatic disease kills the majority of cancer patients.
- Gene mutations, the tumor microenvironment, and host cells drive the metastatic spread of tumor cells.
- Metastasis can be subdivided into four steps: invasion, intravasation, survival in circulation, and extravasation.
- Colonization of metastatic tumor cells requires the ability to proliferate in a foreign tissue and angiogenesis.
- The formation of a premetastatic niche is essential for the growth of extravasating metastatic tumor cells.
- Organ specificity of tumor metastases is determined both by blood flow and tissue-specific factors.
- Primary tumors possess stem cells that can recapitulate the tumor from a single cell, and a subset of these cancer stem cells may inherently possess altered gene expression changes with increased metastatic potential.
- Antimetastatic therapy will probably require the targeted inhibition of many pathways that control proliferation, invasion, and angiogenesis.

INTRODUCTION

Tumors are described as benign or malignant. Malignant tumors can spread by invasion and metastasis, whereas benign tumors cannot and remain localized. One of the hallmarks of cancer cells is their ability to grow and divide without undergoing senescence, provided they have sufficient oxygen, nutrients, and space. As tumors grow, oxygen and nutrients can quickly become limiting in large part as a result of an inadequate vascular supply. Cancer cells will adapt to these growth-limiting environments and also seek out fresh terrain to take up residence, where neither space nor nutrients are (initially) limiting. The spread of cancer from its primary site to secondary sites in the body is defined as metastasis, which comes from the Greek word meaning "change of state." These secondary sites may be located in a new organ or in a different region of the same organ. In reductionist terms, cancer cells metastasize by dislodging from the primary tumor, penetrating through lymphatic and blood vessels, and establishing new growth at a new site in normal tissue. Cancer cells must acquire the capability for invasion and metastasis to escape the primary tumor mass and colonize new terrain in the body where nutrients and space are not limiting. Acquisition of this capability for invasion and metastasis is another of the hallmarks of cancer[1] and is significantly influenced by changes in gene expression and by microenvironmental factors. It is the ability to spread to other tissues and organs that makes cancer a potentially life-threatening disease, in that metastases are responsible for 90% of cancer patient deaths.[2] Very few treatment options exist for patients with metastatic cancer, and furthering our understanding of the process of metastasis will aid in the development of new approaches to treat metastatic disease.[3]

MULTISTEP PROCESS OF METASTASIS

Metastasis is a multistep process (Fig. 3-1) consisting of a series of discrete biological processes. These steps allow primary tumor cells to invade the surrounding tissue, intravasate through blood vessels to enter the circulatory or lymph system, acquire mutations to survive fluctuating environmental changes, extravasate from the circulatory or lymph system into new tissue, proliferate at secondary sites, and develop a vascular system to support growth of the metastases. In some cases, metastases can also give rise to new metastases. There is a propensity for certain tumors to seed in particular organs in part as a result of blood flow. However, blood flow alone cannot explain the different patterns of metastases found for different primary tumors. The most popular theory to explain the patterns of metastases is the "seed and soil" theory put forth by Stephen Paget over a century ago in 1889.[4] Paget described tumor cells as "seeds" and the host environment as the "soil," and proposed that their interaction determines metastatic outcome.

Although the Paget theory is appealing, we know that metastasis is a very inefficient process, because very few cells that escape the primary tumor take up residence in new tissues. For this reason, the tumor cells that survive the process have been termed by Fidler as the "decathlon champions," because they excel at all the steps in the metastatic process.[5] Metastasis is strongly influenced by the interactions between tumor and host cells, and by both the immediate and extended tumor microenvironments. There is ever more evidence demonstrating that these interactions between tumor and host cells are key determinants for the success of metastatic growth and spread.

The Tumor Microenvironment Acts as a Selection Pressure for Metastatic Tumor Cells

The first step in tumorigenesis is transformation, where cells accumulate mutations in proto-oncogenes that result in dysregulated cell growth and increased life span, and loss of tumor suppressor genes that normally act to limit cell growth and viability. In addition, alterations in DNA damage sensing and repair pathways result in

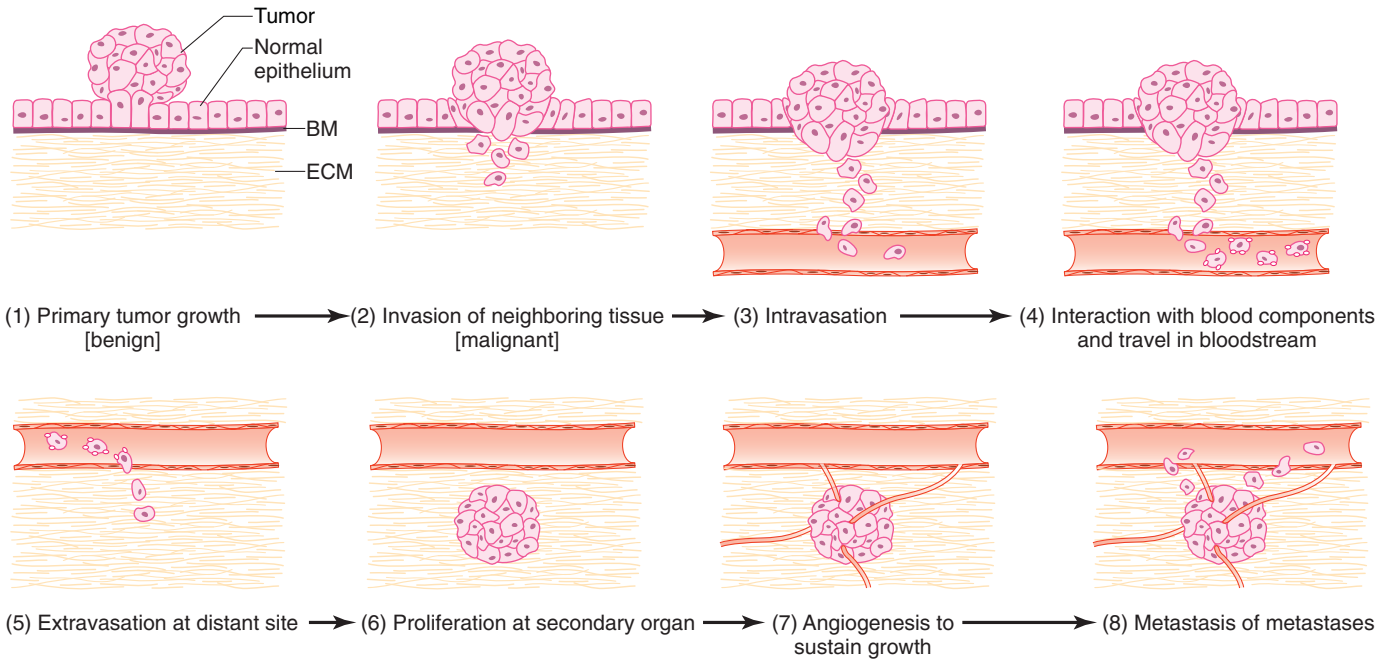

Figure 3-1 • Metastasis is a multistep process consisting of a series of discrete biological events. These allow primary tumor cells to invade the surrounding tissue, intravasate the circulatory system and survive this harsh environment, extravasate into new tissue, proliferate at secondary sites, and develop a vascular system to support growth of the metastases. See text for details. BM, basement membrane; ECM, extracellular matrix. (Adapted from Le QT, Denko NC, Giaccia AJ: Hypoxic gene expression and metastasis. Cancer Metastasis Rev 2004;23:293–310.)

decreased genomic stability and can promote tumor progression. In contrast to cellular transformation, tumor cells must overcome a different set of barriers to metastasize. These are external barriers created by the tumor microenvironment that limit tumor progression (Fig. 3-2). External forces include physical barriers such as extracellular matrix (ECM) components and basement membranes, as well as physiologic barriers such as limited oxygen (hypoxia) and nutrients, changes in pH, and immunologic barriers by the immune system.[2] Cells respond to external microenvironmental influences by altering gene expression such that they are able to adapt and survive. The tumor microenvironment thus exerts a selection pressure for cells capable of overcoming these barriers, driving tumor progression.

Tumor hypoxia is a potent microenvironmental influence and is associated with metastasis and poor survival in cancer patients.[6–9] Hypoxia selects for cells with low apoptotic potential[10–12] and increases genomic instability, allowing rapid mutational adaptations.[13,14] Hypoxia additionally increases the expression of genes involved in glucose transportation, angiogenesis, anaerobic metabolism, cell survival, invasion, and metastasis (a list is given in Table 3-1).[15,16] All of these changes allow cells to adapt to oxygen-deprived conditions and permit cells to escape these conditions by establishing new blood supplies or by physically moving from an oxygen-poor environment to an oxygen-rich environment. A large number of gene expression changes are mediated by hypoxia-inducible factor (HIF)-1, a helix-loop-helix transcription factor that is activated by oxygen-deprived conditions. HIF-1 is often found overexpressed in cancer cells as a result of the hypoxia microenvironment of solid tumors as well as oncogene and tumor suppressor gene mutations, and is associated with metastasis and poor survival.[17] Several HIF-1 targets have been shown to be mediators of metastasis, such as CXCR4, which promotes organ-specific metastasis in renal cancer,[18] and c-met, which increases tumor cell invasion (see section on Invasion).[19,20]

Hypoxia-regulated genes represent potentially specific therapeutic targets that should be highly tumor or metastases specific.[9,21] Recent studies have suggested that lysyl oxidase (*LOX*) is a hypoxia-induced gene that is a very promising target for metastatic disease. Research has demonstrated that inhibition of the secreted protein can prevent both invasion and metastatic growth.[22] In addition, LOX and other HIF-1α targets such as CA-IX have been shown to be independent markers of prognosis.[22–25]

Animal imaging studies have revealed that tumor cells can move rapidly along collagen fibers in the ECM that act as "highways" for metastasis.[26] This process is facilitated by host macrophage cells.[27] Furthermore, increased fiber deposition enhances ECM stiffness,

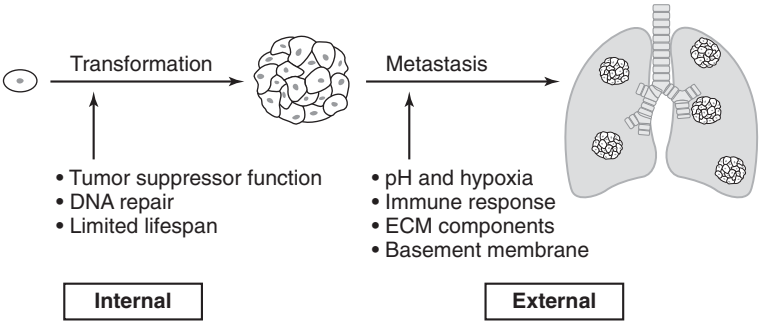

Figure 3-2 • Barriers for tumor progression. The first step in tumorigenesis is cellular transformation where cells must overcome several internal barriers. To metastasize, cells must overcome external barriers put in place by the tumor microenvironment. (Adapted from Gupta GP, Massague J: Cancer metastasis: building a framework. Cell 2006;127:679–695.)

which has been shown to increase cancer cell malignancy.[28] These events occur through activation of ERK and Rho by integrin clustering (see section on Cell Motility).[29] Production of reactive oxygen and nitrogen species by host immune cells and rapidly proliferating tumor cells not only increases genomic instability but has also been proposed to upregulate the expression of metastasis-promoting genes.[30]

Invasion

Changes in Cell Adhesion

The first step of metastasis is invasion. Cells must undergo changes in their cell-cell and cell-matrix adhesion interactions to dissociate themselves from the tumor.[31] Acquisition of an invasive phenotype requires changes in expression of genes that control cell-cell adhesion as well as proteolytic degradation of the ECM.[32] Cell-cell adhesions are mediated primarily by E-cadherin proteins expressed at junctions between cells.[31] Cadherins bind cells through protein-protein interactions at their extracellular domains, whereas their intracellular domains signal to catenins and the actin cytoskeleton. Changes in E-cadherin expression allow cells to detach from their neighbors and begin their migratory route toward the circulatory or lymphatic system to seek out new terrain. Reduced expression of E-cadherin is often observed in aggressive cancers through epigenetic silencing, proteosomal degradation, proteolytic cleavage, or mutation. In fact, inactivating mutations of E-cadherin have been shown to predispose

patients to gastric cancer, implicating E-cadherin as a tumor suppressor gene.[31]

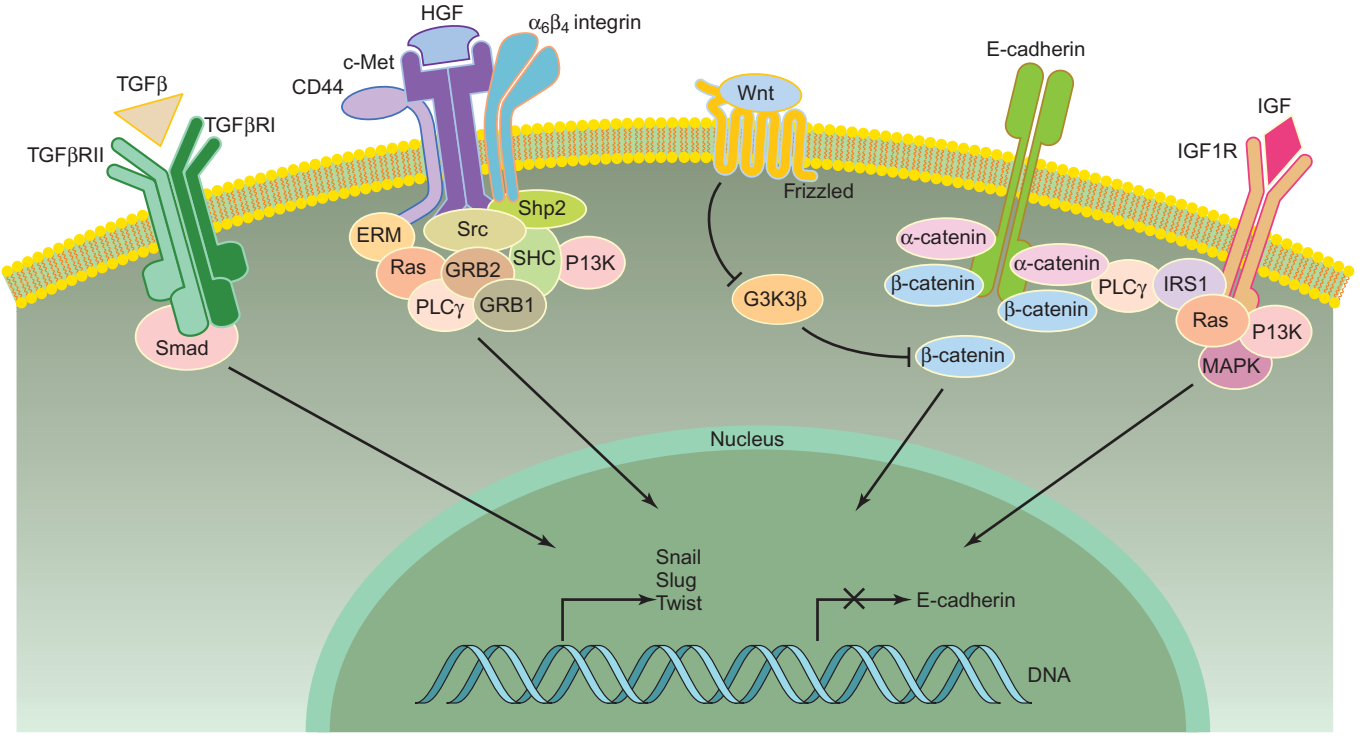
Loss of E-cadherin is highly associated with epithelial to mesenchymal transition (EMT), a program that is essential for numerous developmental processes.[33] The acquisition of the invasive phenotype has many similarities to EMT, including loss of cell-cell adhesion mediated by E-cadherin repression and an increase in cell mobility. During EMT, there is a switch from E-cadherin (an epithelial cell marker) to N-cadherin expression (a mesenchymal cell marker), which promotes cell-matrix adhesion instead of cell-cell adhesion.[33]

Several signal transduction pathways, such as the Ras-MAPK and Wnt pathways, have been shown to regulate EMT (Fig. 3-3). In particular, the Ras-MAPK pathway activates two related transcription factors known as Snail and Slug.[34,35] Both of these proteins act as transcriptional repressors of E-cadherin, and their expression induces EMT in cancer cells.[36] Studies have indicated that Slug is an independent prognostic parameter for poor survival in colorectal carcinoma patients.[37] Twist, another basic helix-loop-helix transcription factor that is necessary for proper embryonic development, has also been shown to induce EMT through the repression of E-cadherin.[38] Both Twist and Snail expression levels are elevated in breast cancer patients, and are associated with poor prognosis.[38,39] Dysregulation of Wnt signaling is common in many types of human cancers and regulates EMT in part through Snail activation, an important early step in metastasis.[40]

Cell Motility

Cancer cells are able to take advantage of many mechanisms to migrate and invade, including both individual and collective cell-migration strategies (Table 3-2).[32] Most cancer cells of epithelial origin undergo EMT and acquire invasive migration capacity to enter the circulatory or lymphatic system. Invasive migration is a dynamic and complex process involving changes in cell-matrix adhesion and the cytoskeleton (Fig. 3-4). Changes in cell-matrix adhesion are necessary for the leading edge of the cell to grab onto the matrix surrounding it and pull itself forward in a movement similar to an inchworm. This invasive migration can be viewed as cycles of adhesion and detachment, allowing the cell to bind, then detach after pulling forward. Cell-matrix adhesions are in large part regulated by integrin proteins. Integrins are heterodimers of one of 18 alpha and 8 beta transmembrane proteins that bind to specific components of the ECM.[41] They can transmit signals into or out of the cell and are important mediators of malignant transformation.

Integrins are stimulated when they come into contact with specific ECM substrates, or through growth factor-stimulated signaling where they interact with receptor tyrosine kinases.[42–44] For example, hepatocyte growth factor (HGF, also known as scatter factor) influences invasion by signaling through its receptor c-met.[45] Integrin stimulation also promotes formation of focal adhesion contacts, focal adhesion kinase (FAK) activation through phosphorylation, and formation of FAK-Src complexes.[44] It is noteworthy that Src mutations that have been implicated in tumor cell motility are often observed in human cancers such as adenocarcinoma of the colon.[46] Intracellular signaling mediated by FAK activates Rac, RhoC, cdc42, and other guanosine triphosphatases (GTPases) that mediate cellular changes required for invasion.[42] These include actin-myosin contraction that propels the cell forward, and recruitment of matrix metalloproteases (MMPs) to focal adhesion sites where they degrade the ECM,



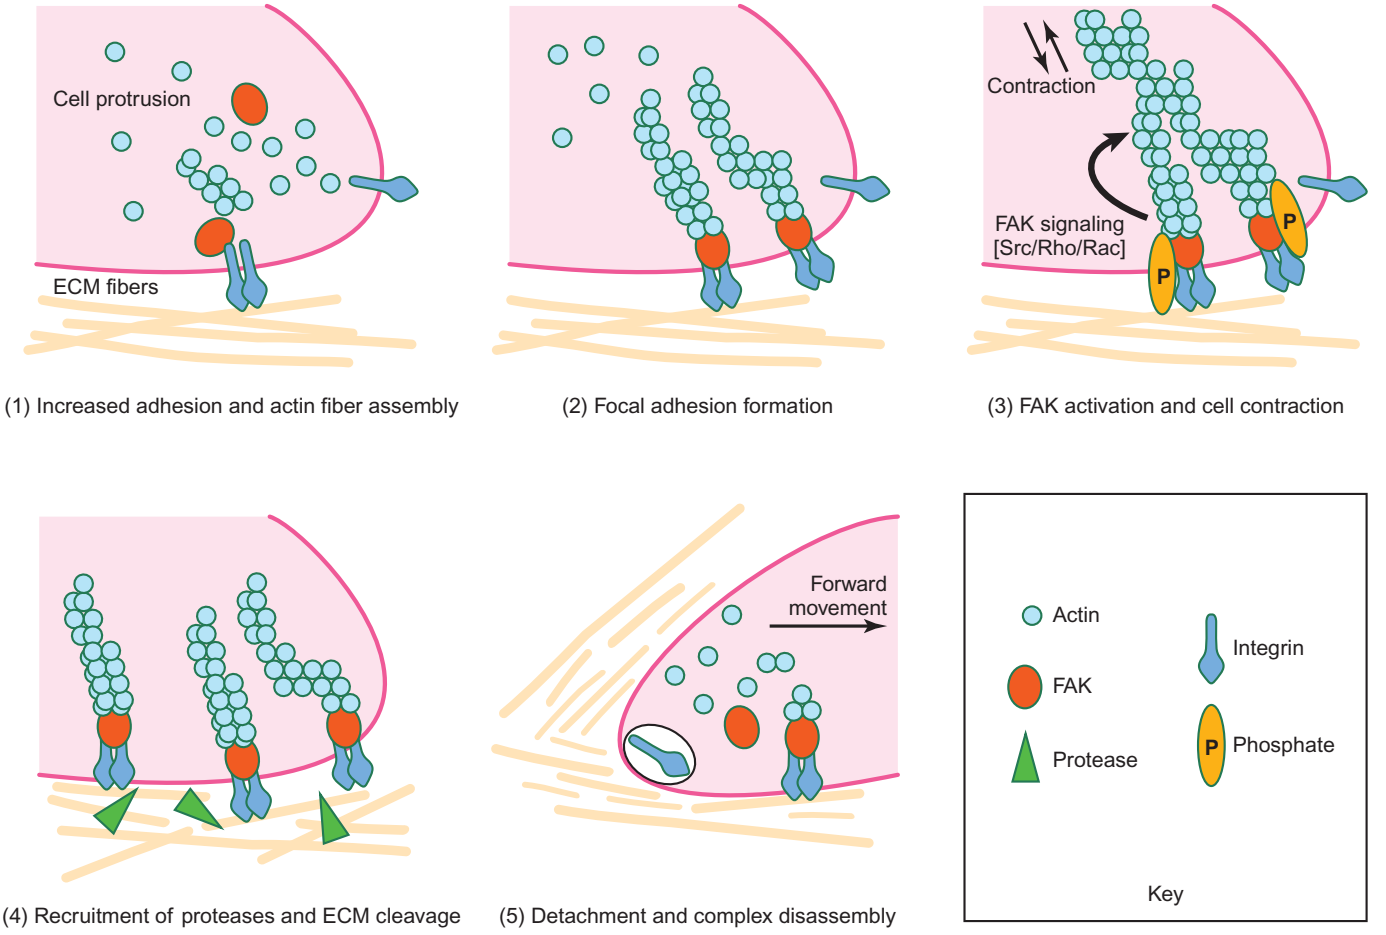


Figure 3-3 • Signaling pathways involved in epithelial to mesenchymal transition (EMT). EMT is a program of development of biological cells essential for numerous developmental processes. Tumor cell invasion has many phenotypic similarities to EMT, including a loss of cell-cell adhesion mediated by E-cadherin repression and an increase in cell mobility. Several signal transduction pathways have been shown to be involved in regulation of EMT. These include Ras-MAPK and Wnt. These pathways are activated by the binding of ligands to transmembrane receptors. These include: TGF-β binding to TGF-βRI and TGF-βRII; HGF binding to c-Met; Wnt binding to Frizzled; and IGF binding to IGF-1R. Activation of these pathways results in transcriptional repression of E-cadherin, and transcriptional activation of Snail, Slug, and Twist. These transcription factors regulate expression of genes involved in EMT. An important repressor of E-cadherin is β-catenin, which is normally targeted for degradation by GSK-3β. Activation of the Wnt pathway inhibits GSK-3β activity, resulting in stabilization of the β-catenin and translocation to the nucleus. (4) Recruitment of proteases and ECM cleavage

(5) Detachment and complex disassembly

Figure 3-4 • Invasive migration. Invasive migration is a dynamic and complex process involving changes in cell-matrix adhesion and the cytoskeleton. It begins with pseudopod protrusion at the leading edge. This increases cell-matrix interaction, stimulating integrin receptors. Integrin stimulation promotes formation of focal adhesion contacts, focal adhesion kinase (FAK) activation through phosphorylation, and formation of FAK-Src complexes. Intracellular signaling mediated by FAK activates Rac, RhoC, cdc42, and other GTPases that mediate cellular changes required for invasion. These include actomycin contraction that propels the cell forward, and recruitment of proteases to focal adhesion sites where they degrade the ECM, allowing the cell to glide forward when focal adhesion complexes are disassembled after contraction. The remodeled matrix tracks left behind the cell have been shown to facilitate movement of subsequent cells. (Adapted from Friedl P, Wolf K: Tumour-cell invasion and migration: diversity and escape mechanisms. Nat Rev Cancer 2003;3:362–374.)

allowing the cell to glide forward when focal adhesion complexes are disassembled after contraction.[32] In addition, the remodeled matrix tracks left behind the cell have been shown to facilitate movement of subsequent cells, similar to the generation of ski tracks by the first cross-country skier that allow following skiers to move more easily.[26]

Disruption of the Basement Membrane

The basement membrane provides a physical barrier between epithelial cells and the stroma. It is composed of numerous glycoproteins and proteoglycans that provide ligands for integrins permitting control of cell orientation and outside to inside signaling. Epithelial and stromal cells produce a mixture of these components that form a dense meshwork underlying the epithelial cells.

The basement membrane is not normally permeable to cells. Tumor cells overcome this barrier by altering the expression of their cell surface receptors such that they can now adhere to basement membrane components.[32,47,48] For example, tumor cells will increase expression of integrins that can bind laminin and collagen IV.[49] Increased CD44 expression permits cell binding to hyaluronan, a basement membrane proteoglycan, and is observed in several types of human cancer including metastatic colon carcinomas.[50] In addition, cancer cells modify the components of the basement membrane to ease penetration. For example, reduced laminin expression is observed in poorly differentiated human colon carcinomas.[51]

ECM protease activity is tightly regulated by proteins that inhibit their functions.[45,52] Tumor cells proteolytically disrupt the basement membrane by altering the balance between ECM proteases and their inhibitory proteins. For example, elevated MMP expression and activity increases degradation of the basement membrane. MMP-1 (also known as collagenase or gelatinase) degrades collagen IV and is increased in highly metastatic cancer cells.[53] MMP degradation of the ECM not only facilitates cell movement but additionally generates a large number of bioactive cleaved peptides, and releases growth factors and chemokines trapped within the ECM mesh.[52] For example, MMP activity releases active forms of proteoglycans including heparin, hyaluronate, and chondroitin sulfate.[54,55]

Intravasation

The entry of tumor cells into the circulation (intravasation) and the exit of tumor cells from the circulation (extravasation) to host tissue represent critical steps in the metastatic process. One clear difference between intravasation and extravasation has to do with the composition of the blood vessels. Tumor blood vessels are malformed and irregular, often possessing breaks in their thin lining that permit the easy access of tumor cells into the circulation. In contrast, the vasculature of normal tissue where tumor cells extravasate do not have these same features. This very observation suggests that the processes of intravasation and extravasation are distinct and probably require different gene functions. The abnormal vasculature found in tumors is the result of the dysregulated expression of proangiogenic growth factors, inhibition of antiangiogenic genes and pathways, recruitment of vascular progenitor cells from the bone marrow, and, in some cases, vascular memory by tumor cells.

Tumors typically do not possess abundant lymphatics and are under high interstitial pressure. Although tumors secrete lymphangiogenic factors such as vascular endothelial growth factor-C (VEGF-C), the development of lymphatics in tumors is also abnormal. In fact, the intravasation of tumor cells into lymphatics is probably easier than through vasculature in that lymphatic vessels function as a collection point for interstitial fluids.

Our knowledge of the genetic determinants involved in intravasation is limited. Gradients of chemo-attractant proteins such as chemokines have been proposed to guide cells toward the circulatory system.[26] In addition, tumor cells move along collagen fibers produced by invading cells, a process facilitated by host macrophages.[26] Whether or not genes such as *LOX* that are required for cross-linking collagen are involved in this process is still unknown. Interestingly, the transcription factor Twist that is implicated in EMT (as described previously) has also been shown to increase the ability of tumor cells to intravasate.[38] However, the underlying molecular mechanisms involved in promoting intravasation by Twist are as yet unknown.

Survival in the Circulatory System

Tumor cells that have successfully entered the bloodstream through intravasation theoretically have access to most organs in the body. However, before these tumor cells can extravasate into a target tissue they must first survive the environment of the circulatory system. Tumor cells in the circulatory system are subjected to immune attack, circulatory forces, and anoikis (apoptosis induced by loss of adhesion).[2] Circulating tumor cells bind to platelets to protect themselves from these dangers, thus increasing their chance of survival.[56–58] Tumor cells also bind to coagulation factors including thrombin, fibrinogen, tissue factor, and fibrin, creating emboli.[59] These tumor cell emboli are more resilient to both circulatory forces and immune attack, and have been shown to have greater metastatic potential than single tumor cells.[57] In the circulation, aggregates of tumor cells are termed homotypic clumps, because they are homogeneous in their cellular composition, whereas those associated with platelets are termed heterotypic clumps and may possess greater metastatic potential for the reasons described previously.[56,58]

The ability to resist apoptotic cell death is important at a variety of steps in the metastatic process. First, tumor cells must survive the lack of oxygen and nutrients in the primary tumor to be able to migrate and invade. This is particularly noteworthy, because hypoxia increases the metastatic potential of tumor cells. Apoptotic resistance in response to decreased oxygen and nutrients is achieved by loss of the *p53* tumor suppressor gene, increased expression of antiapoptotic members of the Bcl-2 family and decreased expression of proapoptotic members, and increased activity of the HIF transcription factor. Hypoxic tumor cells that are resistant to apoptosis have a greater probability of surviving for sufficient periods of time to intravasate into the circulation.

Apoptosis can also play a role in anoikis, death induced by loss of cell adhesion. Obviously, resistance to anoikis is important both in the early phases of invasion as well as during intravasation and circulation. Although a variety of receptor tyrosine kinases can impart resistance to anoikis,[59] most probably the formation of homotypic and heterotypic cell aggregates promotes resistance to anoikis as well.

Arrest and Extravasation

Much of our knowledge of tumor cell extravasation is patterned after leukocyte transmigration through endothelium. It is well known that leukocytes arrest before transmigration. Similarly, tumor cell arrest can occur passively through mechanical lodging or can be allowed by cell-surface molecules.[60–62] Endothelial cells are constantly shed from the blood vessel walls, creating temporary gaps to which tumor cells can more easily attach because basement membrane components are exposed.[63–65] Vessel wall damage also attracts platelets and tumor cells associated with platelets, which is enhanced by fibrinogen expression on the endothelial cell surface.[66,67] Fibrin blood clots at the sites of tumor cell arrest can further damage vessels, attracting more platelets and circulating tumor cells.[68] Increased blood coagulation is often observed in cancer patients as a result of elevated levels of thromboplastin, procoagulant A, and phosphatidylserine produced by tumor cells.[69,70] The most severe manifestations of this hypercoagulation state were described by Trousseau many years ago. The induction of the enzymes involved in this state can also be enhanced by changes in the tumor microenvironment.[71]

Tumor cell arrest is allowed by endothelial cell P- and E-selectins that bind to the tumor cells[72,73] and by tumor glycosylation patterns

and cell-cell adhesion molecules such as integrins and CD44.[74–78] Increased cell-surface expression of mucin carbohydrate is associated with increased metastatic potential in human colon carcinoma.[79] Tumor clump formation additionally facilitates tumor cell arrest by increasing the number of adhesive interactions. ECM components such as fibronectin and laminin enhance tumor cell arrest, and administration of targeting peptides to fibronectin and laminin can reduce metastatic formation.[80] Tumor cells may reside and grow within the intravascular space until the metastatic lesion physically breaks through the vessel.[81] Tumor cells may also extravasate by inducing endothelial cell retraction permitting cell attachment to the ECM.[81] It is highly noteworthy that VEGF increases vascular permeability and may permit extravasation through Src activation.[82,83] Thus, anti-VEGF therapy could potentially act to inhibit metastases by decreasing vascular permeability. In some cases, tumor cells direct their movement and invasion into new organ terrain by following migrating white blood cells and tissue motility factors.[84]

Proliferation

The final steps of metastasis involve the resumption of cell proliferation at the secondary site and induction of angiogenesis to supply oxygen and nutrients. Studies have shown that the host tissue can influence tumor growth through autocrine, paracrine, and endocrine signals. However, it is the net balance of positive and negative signals that determines metastatic proliferation. This can partially explain organ-specific metastasis, because only certain cells will be able to respond to tissue-specific proliferation-stimulating signals and leave their dormant state.[85] For example, insulin-like growth factor-1 (IGF-1), HGF, and transforming growth factor α (TGFα) are highly expressed in the liver,[86–88] and cancer cells from colon, breast, and bladder overexpress receptors for these ligands such as epidermal growth factor receptor (EGF-R)[89–93] and c-met receptor,[94] resulting in proliferation of metastatic cells in these tissues.

Angiogenesis

The formation of a new blood supply from pre-existing vasculature is stimulated by an angiogenic "switch" that occurs when the ratio of inducers to inhibitors is increased. Inhibitors of angiogenesis include ECM proteins thrombospondin and endostatin.[95–97] Angiogenic inducers include VEGF, platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), TGFβ, and ephrin, and their family members.[3] Of these, VEGF is the best characterized and has successfully been targeted through the use of monoclonal antibodies and soluble receptors.[98] VEGF increases angiogenesis by stimulating endothelial cells, mobilizing endothelial progenitor cells, stimulating outgrowth of pericytes that line the walls of mature blood vessels, and increasing vascular permeability allowing macromolecules to traverse endothelium.[99,100] Furthermore, VEGF is thought to be a key molecule for the homing of VEGFR-positive bone marrow-derived progenitor cells involved in premetastatic niche formation (see later discussion),[101] and for homing of VEGFR-positive tumor cells to metastatic sites.[102] Recruitment of bone marrow-derived circulating endothelial cells additionally increases angiogenesis.[103] Thus, angiogenesis is important both for primary tumor and metastatic tumor growth, making it an attractive target.

Metastasis of Metastases

Tumor cells that have successfully colonized secondary organs are capable of further metastasis and colonization of other organs. Cells within the metastatic tumors are subjected to similar microenvironmental stresses experienced by the primary tumor, and adapt to overcome these external barriers and seed new terrain. These cells from metastases may have an intrinsic colonization capability allowing them to constantly reseed both primary and secondary tumors.[104]

LYMPHATIC METASTASIS

The vascular and lymphatic systems have numerous connections,[105] and metastasizing tumor cells can easily pass from one system to another.[106,107] Invading tumor cells can additionally enter small lymphatic vessels directly and be passively transported to the lymph. Cancer cells may spread to lymph nodes near the primary tumor, known as the regional lymph nodes (RLNs). This is often referred to as nodal involvement, positive nodes, or regional disease. Tumor cells may become trapped in the first lymph node, or form distal nodal metastases referred to as "skip metastases" because they have bypassed the first draining lymph nodes in the area.[4] RLNs may become enlarged and are often removed to prevent cancer spread. Lymph node involvement and presence of micrometastases in the sentinel lymph node (the lymph node draining the tumor site) correlate with decreased survival.[108] Localized spread to RLNs near the primary tumor is not normally considered as metastasis per se, although it is also a sign of worse prognosis.[109,110] Some malignancies, such as sarcomas in contrast to breast carcinomas, do not spread to the RLNs before metastasizing to distant sites. Thus, node status does not always correlate with metastasis.[2]

COLONIZATION BY METASTATIC TUMOR CELLS

The patterns of colonization cannot solely be explained by circulatory routes above. The propensity for certain tumors to seed in particular organs was first discussed as the "seed and soil" theory by Stephen Paget over a century ago in 1889.[4] For example, prostate cancer often metastasizes to the bones, and colon cancer has a tendency to metastasize to the liver. Colonization is an extremely inefficient process that is heavily dependent on the interactions between "seeding" tumor cells and the "soil" microenvironment of the secondary site. Many factors including formation of a premetastatic niche and organ specificity determine these patterns of colonization.

Premetastatic Niche

Recent in vivo data have suggested that the formation of a premetastatic niche is essential for the growth of extravasating metastatic tumor cells.[101] Factors secreted by primary tumor cells stimulate mobilization of bone marrow-derived cells that enter circulation and reside in sites of future metastasis. These bone marrow-derived cells express VEGFR-1, c-kit, CD133, and CD134, and increase angiogenesis at the premetastatic sites. Targeted inhibition of VEGFR-1 prevented niche formation and subsequent metastatic progression. This tissue preconditioning may thus represent a key step that could be targeted therapeutically, although studies with anti-VEGF therapy fail to show significant benefit in preventing metastatic growth for long periods of time. The role of hematopoietic progenitor cells and other bone marrow-derived cells in tumor progression is reviewed by Kaplan and colleagues[111] and shown in Figure 3-5.

An additional function of the premetastatic niche is to guide metastases to specific organs. Kaplan and coworkers demonstrated that injection of secreted factors collected from cancer cells that metastasize to multiple organs could permit cancer cells that only metastasize to the lung when grown as subcutaneous tumors in mice, to display widespread metastasis through governing bone marrow-derived cell accumulation.[101] Elevated fibronectin expression by fibroblasts and fibroblast-like cells resident at premetastatic sites seems to be a critical factor in the development of the premetastatic niche. The key tumor-secreted factors that determine metastatic sites and mediate premetastatic niche formation have yet to be identified, although a role for tumor necrosis factor α (TNFα), TGF-β, and VEGF-α pathways has been demonstrated.[112]

MMPs may also play an important role in this process. For example, VEGF-R1 signaling has been shown to be required for

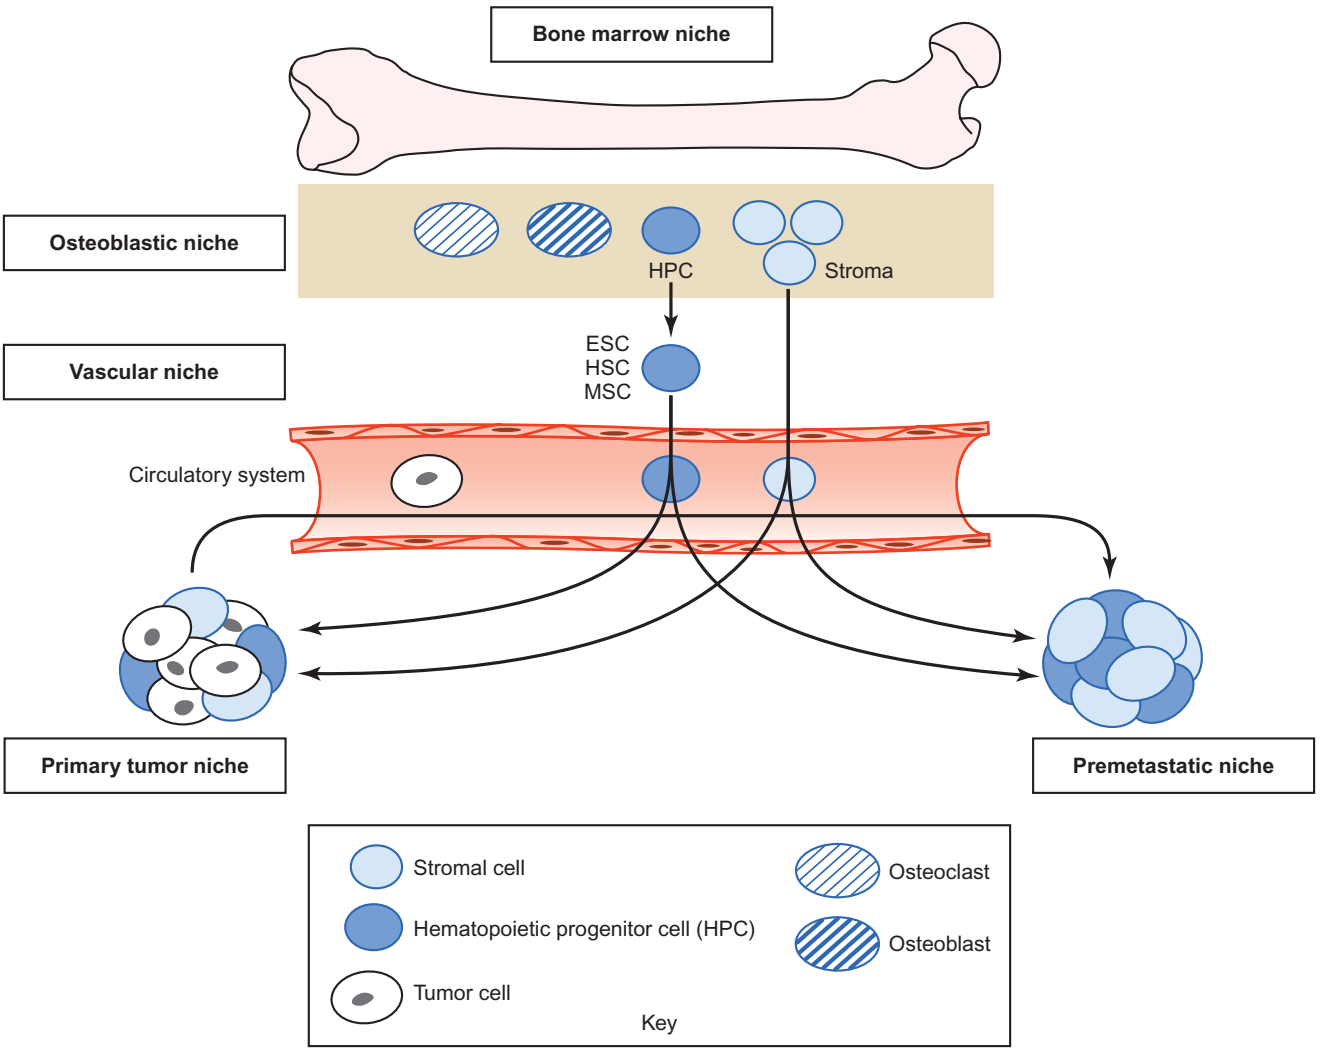

Figure 3-5 • The role of bone marrow-derived cells in tumor progression. Cells derived from the bone marrow niche are involved at many stages during tumor progression. Hematopoietic progenitor cells (HPCs), hematopoietic stem cells (HSCs), mesenchymal stem cells (MSCs), and stromal cells including macrophages and fibroblasts, permit tumor growth and development at primary and metastatic niches. (Adapted from Wong SY, Hynes RO: Lymphatic or hematogenous dissemination: how does a metastatic tumor cell decide? Cell Cycle 2006;5:812–817.)

premetastatic induction of MMP-9 expression in endothelial cells and macrophages of the lungs by distant primary tumors.[113] This is thought to make the lung microenvironment more compliant for invasion of metastasizing cells. This concept is supported by the finding that pericyte recruitment and angiogenesis are not observed in tumor-bearing mice with MMP-9 knockout bone marrow cells.[114] Furthermore, stromal-derived MMP-2 and MMP-9 have also been shown to contribute to establishment and growth of metastases.[115] Thus, whereas there is evidence that MMPs play multiple roles in metastases, clinical trials with MMP inhibitors have failed to show significant efficacy. In large part, this has been due to unexpected normal tissue toxicities and conflicting roles in metastases.

Organ Specificity

The organ distribution of metastases from a primary is not random. Minn and colleagues used bioluminescence imaging to reveal patterns of metastasis formation by human breast cancer cells in mice.[116] They also showed that individual cells from the pleural effusion of a breast cancer patient showed distinct patterns of organ-specific metastasis.[117] Single-cell progenies derived from this population demonstrated different abilities to metastasize to the bone, lung, or adrenal medulla. These studies indicate that there are particular requirements for metastasis to colonize specific organs. Some of the key molecules determining organ-specific metastasis have been identified and are briefly discussed in the following section.

Metastases to the Bone

There are two types of bone metastases: osteoblastic and osteolytic.[118,119] Osteoblastic metastases are observed in patients with advanced prostate cancer. Both the differentiation of osteoblastic precursors as well as the activity of osteoblast cells are stimulated by tumor and microenvironmental signals such as bone morphogenetic protein (BMP), FGFRs, and IGF-1R.[120] Runx-2 is a key transcription factor that regulates the differentiation of osteoblasts and osteoblastic precursor cells,[121] and represents a potential new target for inhibiting osteoblastic metastases by preventing osteoblastic precursor differentiation. In contrast, osteolytic metastases are observed in patients with breast cancer or multiple myeloma,[122,123] and in these patients interactions between tumor cells and the bone microenvironment result in bone resorption and metastatic growth due to the unique interplay between osteoblasts and osteoclasts (Fig. 3-6).[118,122] Parathyroid hormone-related protein (PTHrP) secreted by the tumor cells, stimulates osteoblasts to produce receptor activator of nuclear

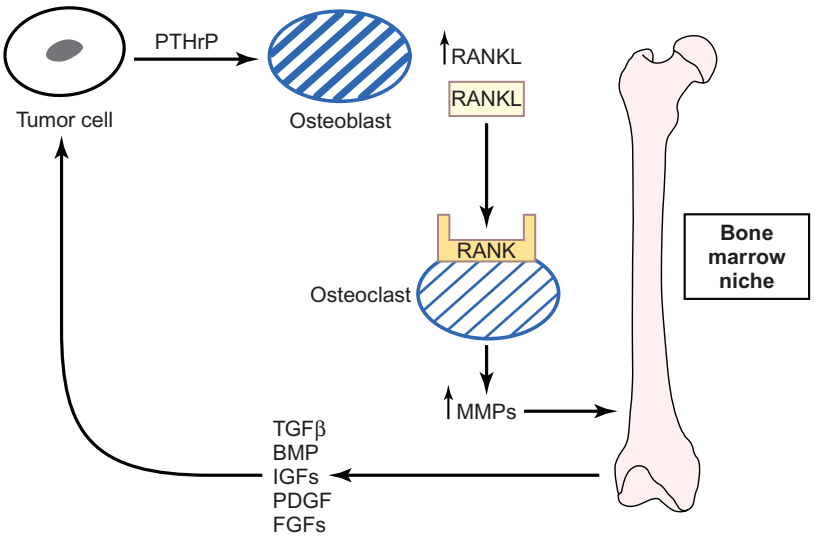

Figure 3-6 • The vicious cycle of osteoclastic bone metastasis. Interactions between the tumor cells and the bone microenvironment create a "vicious cycle" of osteolytic metastatic lesion development. Parathyroid hormone-related protein (PTHrP), secreted by the tumor cells, stimulates osteoblasts to produce RANK ligand (RANKL). Bone-resorbing osteoclast cells are activated by RANKL when it binds to the RANK receptor. The activated osteoclasts upregulate MMPs that degrade the bone matrix-releasing growth factors such as TGFβ, IGFs, PDGF, FGFs, and BMP. These factors stimulate tumor cells to release PTHrP, thus completing the vicious cycle. (Adapted from Steeg PS: Tumor metastasis: mechanistic insights and clinical challenges. Nat Med 2006;12:895–904.)

factor–κB (RANK) ligand (RANKL). Consequently, bone-resorbing osteoclast cells are activated by RANKL when it binds to the RANK receptor. Activated osteoclasts upregulate MMPs, which degrade the bone matrix-releasing growth factors such as TGFβ, IGFs, PDGF, FGFs, and BMP.[118,124,125] These factors stimulate tumor cells to release PTHrP, thus restarting this pathway of bone resorption. Gene profiling has identified other important mediators of osteoclastic bone metastases including CXCR4, MMP-1, CTGF, and osteopontin.[126] Tumor cells additionally induce osteoclast formation by overexpressing interleukins such as IL-8 and IL-11, and by downregulating macrophage colony-stimulating factor.[127,128] All of these latter factors represent new targets for metastases, although the importance of each factor in osteoclastic bone metastases requires further clarification.

Metastases to the Brain

Brain metastases are most commonly observed in patients with breast cancer, lung cancer, and melanoma. Vascular access to the brain is strictly regulated by the blood-brain barrier, an endothelial layer surrounding the brain connected by tight junctions and further lined by a basement membrane, pericytes, and astrocytes.[129] Macromolecules are not usually able to traverse the blood-brain barrier, and it remains unclear how tumor cells are able to penetrate the blood-brain barrier. However, once the tumor cells are within the brain parenchyma, glial cells permit establishment and growth of metastases by secreting chemokines, cytokines, and growth factors.[130] Other neurotransmitter hormones in the brain such as norepinephrine have also been reported to increase tumor cell motility and metastatic spread.[131]

Little is known about the key factors that determine colonization of the brain, mostly because there is a lack of good in vivo models of brain metastasis. Overexpression of Stat3 increases melanoma metastasis to the brain and increases invasion of the melanoma cells and angiogenesis, although the pathways modulated by Stat3 signaling require elucidation.[132] The dependence of brain metastases on VEGF has been demonstrated experimentally in animals through inhibition studies where VEGF neutralization reduces brain metastases.[133,134]

In general, patients with brain metastases have an extremely poor prognosis. It is of concern that there has been an increase in the incidence of brain metastases in patients whose systemic disease is well controlled.[135–137] For example, patients with breast tumors that overexpress Her-2 and who are treated with Her-2 targeting trastuzumab (see later discussion) have an incidence of brain metastases twice that of breast cancer patients who are treated with other agents.[135] This is thought to be because the brain offers a sanctuary when systemic disease is being controlled.[3] The development of drugs that can cross the blood-brain barrier and target brain metastases are of paramount importance in the development of new targeted therapies to tackle this problem. Currently, the best treatment for oligometastases to the brain is radiosurgery.

Metastases to the Lung

Pulmonary metastases are frequently observed in patients with sarcoma, breast, melanoma, gastrointestinal, and kidney cancers. Because cardiac output from the pulmonary artery circulates through the lungs, a high incidence of pulmonary metastases in cancer patients can be expected on the basis of blood flow alone. Metastases therefore often initiate in pulmonary arterioles and later traverse the basement membrane into the lung parenchyma. TGFβ and NF-κB facilitate this process in breast cancer,[138–140] as does osteopontin in hepatocellular cancer,[141] and ezrin in osteosarcoma and breast cancer.[142,143] In vivo studies have identified a gene expression signature for lung metastasis including several membrane-localized and secreted proteins that has been validated in breast cancer patients.[116] Interestingly, this group of genes was able to induce lung metastasis when expressed together but not individually, suggesting essential cooperation between proteins. Increased expression of antiapoptotic proteins such as Bcl-2 and Bcl-xl is also observed in lung metastases, facilitating survival and providing resistance to therapy.[144–148] These studies suggest that multiple targets must be inhibited with combination therapy to effectively inhibit lung metastases.

Metastases to the Liver

Liver metastases are observed in patients with breast, lung, and pancreatic cancers. However, liver metastases are most commonly found in patients with metastatic colorectal cancer, because the liver is the first capillary bed encountered by the metastasizing cells. The circulatory system of the liver, in particular the liver sinusoids, does not have a barrier limiting macromolecule flux, and it is well perfused and highly permeable, permitting metastasizing cancer cells to establish themselves and grow. Thus, tumor cell invasion and survival are probably the key determinants in metastatic colonization of the liver.[149] There are two types of liver metastases: a nonangiogenic "replacement" of liver cells with tumor cells that preserves the stroma,[150] and a "pushing" type of metastasis[3] whereby the liver stroma is not preserved and has higher levels of endothelial cell proliferation.[151,152] In light of the "pushing" type of metastases that stimulate angiogenesis, targeting the VEGF pathway experimentally in vivo has been shown to prevent liver metastases,[153–155] and is effective when combined with cytotoxic agents in patients with metastatic colon cancer.[156,157] Other molecules thought to be important in

colonization to the liver and that could be targeted therapeutically are COX-2,[158,159] integrins,[160] and Src.[161]

HOST-TUMOR CELL INTERACTIONS

Tumor progression requires collaboration between tumor and host cells. Research has revealed much cross-talk between cancer cells and bone marrow-derived host immune and stromal cells.[162] For example, disruption of TGFβ signaling in fibroblasts can induce stomach and prostate cancer in mice.[163] Mutations commonly found in cancer cells, such as *p53* and *PTEN* mutations, can also be found in cancer-associated stroma and have been hypothesized to be important during tumor progression.[164,165] In fact, gene expression profiling of activated fibroblasts in vitro generated a signature that could predict primary tumor metastasis.[166] For example, the chemokine CXCL12 is produced by breast cancer-associated fibroblasts[167] and increases tumor cell migration and recruitment of endothelial progenitor cells expressing CXCR4,[168] a CXCL12 receptor.

Cells that respond to tissue injury (such as leukocytes and lymphocytes) are often associated with tumor cells and enhance their progression, for example by assisting travel in the bloodstream. The tumor-suppressing activities of cells in charge of immune attack (such as natural killer cells and antigen-presenting cells) can be dampened by overexpression of tumor-derived immunosuppressive cytokines such as TGFβ and interleukins,[169–171] and by lack of necessary costimulatory signals from tumor cells.[172] Thus, host cells can directly promote tumor progression by secreting growth factors and cytokines that stimulate tumor metastases and suppress tumor immune surveillance.

Inflammation and Metastases

Ironically, cells involved in chronic inflammation facilitate tumor formation and progression, mostly mediated by NF-κB and COX-2.[173,174] In particular, infiltration of activated macrophages into tumors correlates with poor prognosis.[27,175] The tumor-suppressing and tumor-promoting roles of these tumor-associated macrophages (TAMs) are shown in Table 3-3. TAMs are especially attracted to regions of hypoxia, where they secrete abundant angiogenic inducers and proteases, including VEGF and MMPs,[175,176] that have been reported to enhance angiogenesis.[27] TAMs express high levels of the HIF-2 transcription factor that has been found to be an independent prognostic factor of outcome.[177] Interestingly, work by Cramer and associates[178] has shown that in fact HIF-2 is needed for myeloid cell infiltration and activation. Furthermore, TAMs release growth factors such as PDGF, EGF, and HGF, which enhance proliferation, survival, and invasion.[175] Mutation of the macrophage colony-stimulating factor-1 gene that affects macrophage differentiation has been shown to prevent metastasis in mice bearing aggressive breast cancer tumors.[179] Targeting TAMs may be a viable mechanism for antimetastatic therapies.[180]

Table 3-3 Conflicting Roles of Tumor-Associated Macrophages

Pro-Tumor	Anti-Tumor
Proangiogenic cytokines	Tumor cell lysis
Immunosuppressive cytokines	Immunostimulatory cytokines
Protumorigenic chemokines	Immunostimulatory chemokines
Reactive oxygen species (ROS)	ROS
Elevated MMPs, TF, and uPA	

MMPs, matrix metalloproteinases; TF, tissue factor; uPA, urokinase plasminogen activator.

Adapted from Condeelis J, Pollard JW: Macrophages: obligate partners for tumor cell migration, invasion, and metastasis. Cell 2006;124:263–266.

DORMANT CELLS

The prolonged survival of single cells or micrometastases with no apparent progression is referred to as dormancy.[181] Dormant cells are frequently observed in patients with prostate, melanoma, and breast cancer,[182–184] and are found to reside in the lungs, liver, and bone marrow. These micrometastases represent minimal residual disease that results from the inefficiency of metastasizing tumor cells to colonize organs properly following extravasation.[185] Incompatibilities between tumor cells and their tissue soil, or inability of tumor cells to generate sufficient angiogenesis result in cell-cycle arrest and dormancy.[181] What genes and pathways are important in controlling metastatic dormancy are unknown and are important to identify, because they represent a "metastatic tumor suppressor mechanism."

The presence of dormant tumor cells is associated with poor patient prognosis.[186] Isolation and reimplantation of dormant cells can generate primary tumors, demonstrating that these cells are viable.[185,187,188] In vivo experiments have indicated that growth of dormant metastatic cells can be activated by angiogenesis or removal of the primary tumor,[189] suggesting that limited levels of growth factors or cytokines may induce this dormant state. The angiogenic switch required for dormant cells to grow into tumors may be detectable by markers in the blood, such as VEGF, and could thus be used to monitor undetectable and asymptomatic disease in patients.[190] Interestingly, circulating tumor cells can be detected in breast cancer patients as long as 22 years after mastectomy.[191]

CANCER STEM CELLS AND METASTASIS

Stem cells are primal cells that retain the ability to renew themselves through cell division and can differentiate into a wide range of specialized cell types. They give rise to all tissues during embryogenesis and control tissue homeostasis in the adult. Cells with stem cell properties have been identified in some cancer types.[192–194] These cancer stem cells (CSCs) are able to self-renew and differentiate into multiple cell types and are believed to arise either by mutation of an adult stem cell or fusion of an adult stem cell with a CSC.[195] It is hypothesized that tumors arise from CSCs and that these cells persist in tumors as a distinct population that is responsible for disease relapse and metastasis. Because CSCs are the only cells capable of giving rise to new tumors by themselves, targeting this subpopulation may eradicate cancer.

The recent discovery of CSCs has revolutionized our way of thinking about cancer. Cancer is classically thought of as a disease of progression, facilitated through the accumulation of mutations and driven by microenvironmental signals. Whereas the stem cell microenvironment or niche is thought to be the key determinant for stem cell regulation, the role of CSCs in multistage tumor progression, particularly with respect to metastasis, is poorly understood. There may exist a subset of CSCs with the inherent property to metastasize (Fig. 3-7). Research into these metastatic CSCs is greatly anticipated.

ANTIMETASTATIC THERAPY

The literature is replete with genes that have been implicated in the metastatic process.[196,197] Because of the immense heterogeneity of metastatic cells, metastatic selective therapeutic targets have been difficult to identify and develop for targeted therapy. Clinically, there have been two success stories thus far: bevacizumab and trastuzumab. However, both agents affect both primary and metastatic tumor growth. Bevacizumab targets VEGF and has displayed activity in several metastatic cancer types, especially when administered in combination with cytotoxic compounds.[157] Other small-molecule inhibitors to VEGF-R have also shown some antimetastatic effectiveness. Trastuzumab is a recombinant monoclonal antibody to Her-2 that is very effective against metastatic breast cancer, again, particularly in combination with cytotoxic agents.[198] However, only 30% to 40%

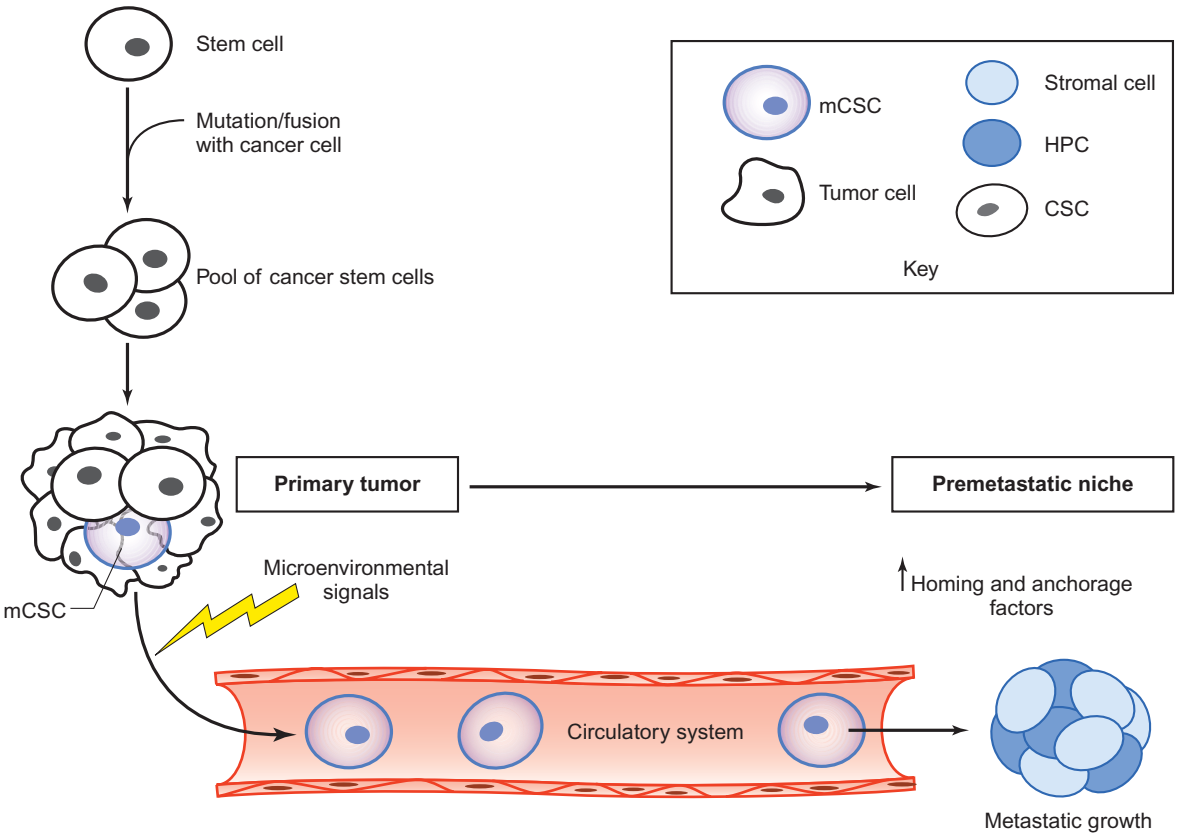

Figure 3-7 • The role of cancer stem cells (CSCs) in metastasis. CSCs are able to self-renew and differentiate into multiple cell types and are believed to arise either by mutation of an adult stem cell or fusion of an adult stem cell with a cancer stem cell. It is hypothesized that a pool of CSCs develops and gives rise to the primary tumor. A subpopulation of CSCs is believed to exist with the inherent property to metastasize. Microenvironmental signals stimulate primary tumor cells to secrete factors involved in premetastatic niche formation, and additionally stimulate invasion and dissemination of the metastatic CSCs (mCSCs). These mCSCs are attracted to homing and anchorage signals produced by bone marrow-derived cells at the premetastatic niche. (Adapted from Al-Hajj M, Clarke MF: Self-renewal and solid tumor stem cells. Oncogene 2004;23:7274–7282.)

of breast cancer patients overexpress Her-2 and are suitable for treatment.[198] In addition, whereas MMP inhibitors demonstrated good antimetastatic effects in vivo, these compounds failed in clinical trials, and additional research has revealed their conflicting roles in metastasis.[199]

A recent study by Gupta and associates[200] analyzed gene expression profiles of metastases from a breast cancer cell line, and identified four genes: epiregulin, which encodes a ligand that binds to the EGFR; cyclooxygenase, which encodes an enzyme that is involved in inflammatory responses and wound healing; and two MMPs that encode proteins involved in tissue remodeling and angiogenesis that affect both primary and metastatic tumor growth. The investigators found that inhibition of each gene individually through genetic knockdown resulted in a modest effect on lung metastases. In contrast, if combinations of these genes were inhibited, there was a significantly greater effect on the metastatic process, suggesting that combination therapy is more effective in controlling metastases. However, many of these reported genes, such as *Her-2/Neu* and *EGFR,* as described previously, affect both primary as well as metastatic tumor growth, somewhat obfuscating their roles as direct modulators of tumor metastases. What the field is desperately in need of is new candidate genes and proteins that specifically affect the metastatic process and have little effect on primary tumor growth.

One very promising target is LOX, a hypoxia-induced secreted protein involved in multiple stages of metastasis (Fig. 3-8).[201] LOX contributes to tumor cell invasion by cross-linking collagens in the ECM, which stimulates integrin-mediated cell-matrix adhesion and activation of FAK, and additionally provides a route ("highway") by which tumor cells may travel. Furthermore, LOX is involved in the formation and maintenance of the metastatic niche, allowing metastatic dissemination and growth. Targeting secreted LOX through antibody or small-molecule inhibition significantly reduced formation and growth of metastases to the lung, liver, bone, and brain, in several models of cancer. These data provide hope for the future, because there is an urgent need for new metastasis-targeting therapies.

CONCLUSION

Metastatic disease, not the primary tumor, kills the majority of cancer patients. For such an important determinant of long-term survival, progress has been slow in understanding the crucial genes and pathways that drive metastatic progression. The reasons for this slow progress have been numerous, including inadequate animal models that reflect the metastatic process in humans, failure to identify genes that specifically affect metastatic tumor growth, the complexity of host and metastatic tumor interactions, and premature clinical trials focusing on "attractive" gene targets. The future for metastasis research looks very promising in large part because we understand the mistakes of the past and are using multiple genomic and proteomic approaches to target what has for so long seemed to be an untractable problem. It is only when we are able to attack the problem of metastases that we will make significant inroads in our war against cancer.

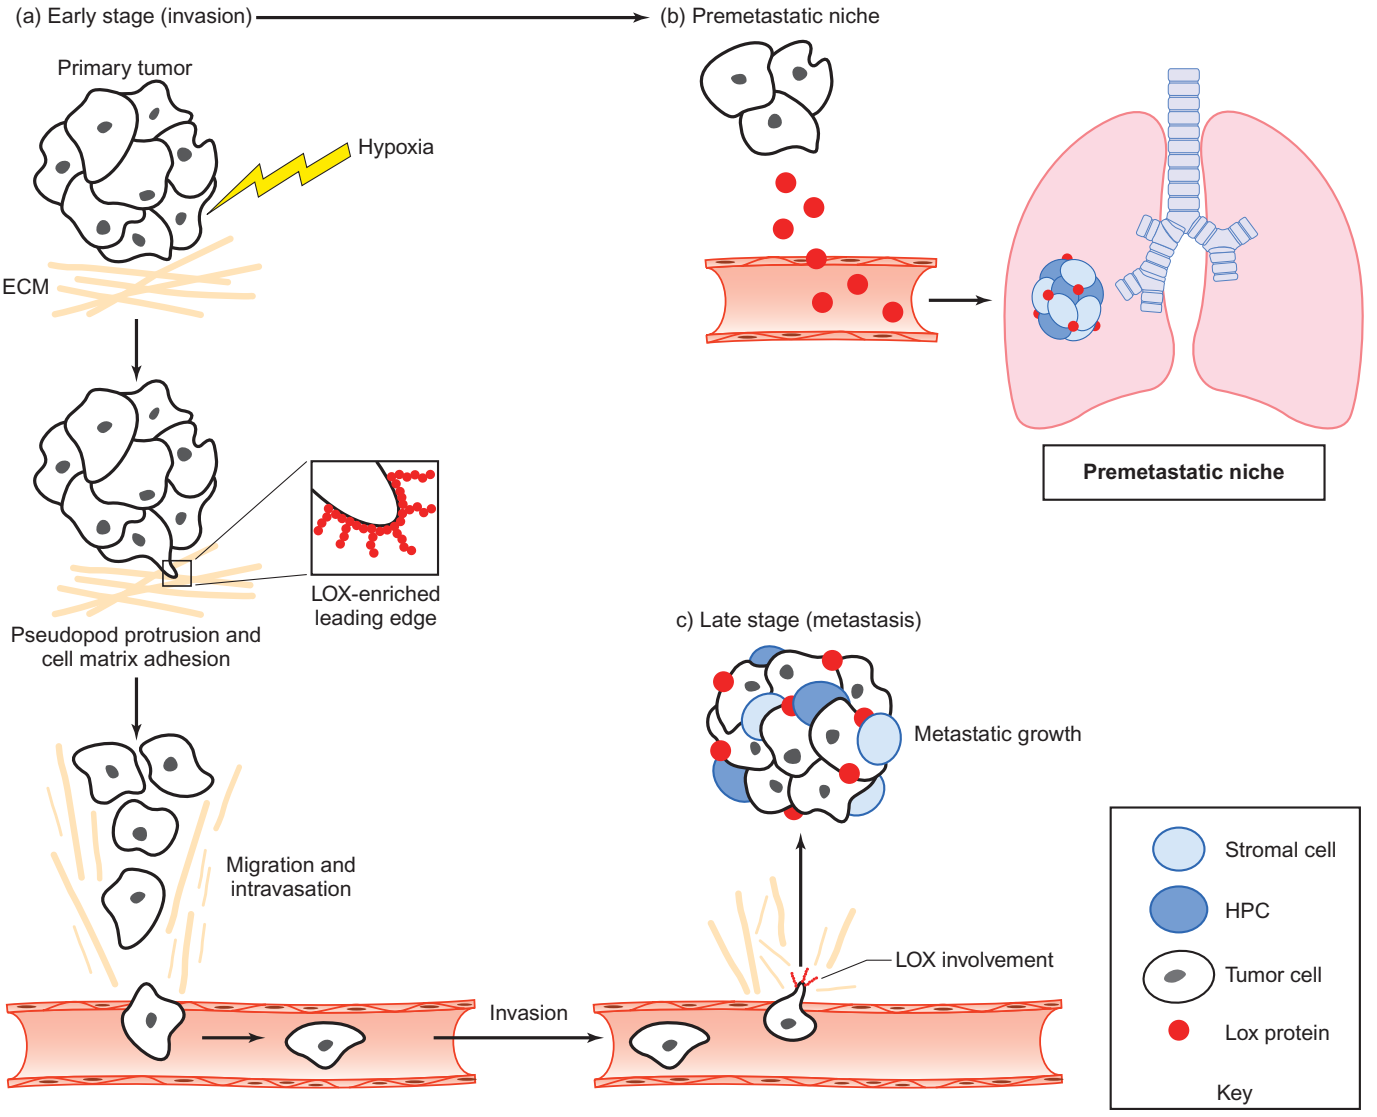

Figure 3-8 • The role of lysyl oxidase in metastasis. Lysyl oxidase (LOX) is a hypoxia-induced secreted protein involved in many stages of metastasis. LOX contributes to early-stage metastasis by increasing tumor cell invasion through the cross-linking of collagens in the ECM, which stimulates integrin-mediated cell-matrix adhesion and activation of focal adhesion kinase. LOX is expressed at the leading edge on invasive cells and extends along hairlike fibers in the ECM. Collagen cross-linking additionally provides a route ("highway") by which tumor cells may travel. LOX secreted by hypoxic cells in the primary tumor is involved in premetastatic niche formation at distant sites. Furthermore, LOX is involved in later stages of metastasis where cell-matrix adhesion interactions are again required for arrest and extravasation, and invasive migration. LOX is further required for the formation of a mature ECM, which is essential for metastatic tumor cell growth.

4 Control of the Cell Cycle

Jacqueline Lees

SUMMARY OF KEY POINTS

- Cells in most postnatal tissues are quiescent. Exceptions include cells of the hematopoietic system, skin, and gastrointestinal mucosa.
- The key challenges for proliferating cells are to make an accurate copy of the 3 billion bases of DNA (S phase) and to segregate the duplicated chromosomes equally into daughter cells (mitosis).
- Progression through the cell cycle is dependent on both extrinsic and intrinsic factors.
- Extrinsic factors include cell-to-cell contact, basement membrane attachments, and growth factor or cytokine exposure.
- The internal cell cycle machinery is controlled largely by oscillating levels of cyclin proteins and by modulation of cyclin-dependent kinase activity.
- One way in which growth factors regulate cell cycle progression is by affecting the levels of the D-type cyclins in the G_1 phase of the cell cycle.
- The restriction point of the cell cycle occurs in late G_1 and is the point beyond which the cell is committed to progress through the rest of the cell cycle. It is governed by a known tumor suppressor, the retinoblastoma protein.
- Cell cycle checkpoints are surveillance mechanisms that link the rate of cell cycle transitions to the timely and accurate completion of prior dependent events.
- Cells can arrest at cell cycle checkpoints temporarily to allow for (1) the repair of cellular damage; (2) the dissipation of an exogenous cellular stress signal; or (3) availability of essential growth factors, hormones, or nutrients.
- The major function of the p53 tumor suppressor protein is to induce cell cycle arrest, senescence, or death in response to cellular stress.
- Activation of the G_1, S, and G_2 phase checkpoints after DNA damage minimizes replication of damaged DNA templates or their segregation to daughter cells.
- Activation of the mitotic spindle checkpoint prevents defects in chromosome segregation and protects against aneuploidy.
- Disruption of cell cycle controls is a hallmark of all malignant cells. Disruption can manifest as alterations of growth factor signaling pathways, dysregulation of the core cell cycle machinery, and/or disruption of cell cycle checkpoint controls.
- Because cell cycle control is disrupted in virtually all tumor types, the cell cycle-related gene products that are mutated in tumors provide therapeutic targets that might preferentially affect tumor cells more than normal tissues.

INTRODUCTION

The majority of the cells in the adult body are arrested in a quiescent state, called the G_0 state. Most of these cells are terminally differentiated and never divide. However, specific populations retain the ability to proliferate throughout the adult life span, and this is essential for viability. For example, cells of the hematopoietic compartment and the gut have a high rate of turnover, and high rates of proliferation are therefore essential for the maintenance of these tissues. On average, about 2 trillion cell divisions occur in an adult human every 24 hours (about 25 million per second). The decision to proliferate or not is very tightly regulated. It is influenced by a variety of exogenous signals, including nutrients, mitogenic (e.g., epidermal growth factor and platelet-derived growth factor) and inhibitory (e.g., transforming growth factor-β) growth factors, and the interaction of the cell with its neighbors and with the underlying extracellular matrix. Each of these factors stimulates intracellular signaling pathways that can either promote or suppress proliferation. The cell integrates all of these signals, and if the balance is favorable, the cell will initiate the proliferation process. Anything that disrupts this balance can lead to either the reduction or expansion of a particular cell population. It is now clear that such changes are a hallmark of tumor cells. They carry mutations that impair signaling pathways that suppress proliferation and/or activate pathways that promote proliferation.

It is essential that proliferating cells copy their genomes and segregate them to the daughter cells with high fidelity. Over the past three decades, extensive effort has been placed on unraveling the basic molecular events that control this process. Studies in a variety of organisms have identified evolutionarily conserved machinery that controls eukaryotic cell cycle transitions through the action of key enzymes called cyclin-dependent kinases (CDKs). Eukaryotic cells have also evolved a series of surveillance pathways, termed *cell cycle checkpoints*, that monitor for potential problems during the cell cycle process. Human cells are continuously exposed to external agents (e.g., reactive chemicals and ultraviolet light) and to internal agents (e.g., by-products of normal intracellular metabolism, such as reactive oxygen intermediates) that can induce DNA damage. The cell cycle checkpoints detect DNA damage and activate cell cycle arrest and DNA repair mechanisms, thereby maintaining genomic integrity. Most, if not all, human tumor cells have mutations within key components of both the cell cycle machinery and checkpoint pathways. This has important clinical implications, as the presence of these defects can modulate cellular sensitivity to chemotherapeutic regimens that induce DNA damage. This chapter focuses on the

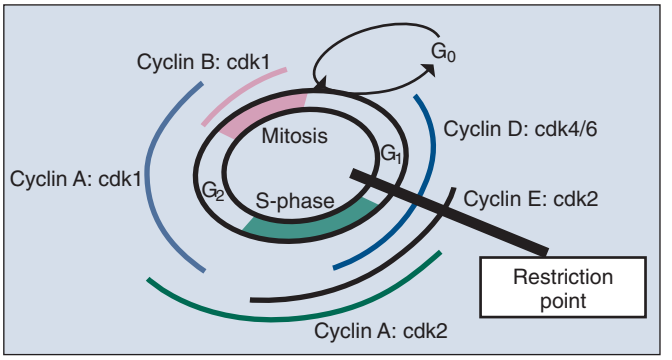

Figure 4-1 • The cell cycle. One round of cell division requires high-fidelity duplication of DNA during the S phase of the cell cycle and proper segregation of duplicated chromosomes during mitosis, or M phase. Before and after the S phase and M phase, the cell transits through "gap" phases, termed G_1 and G_2. The appropriate transition through these stages is controlled by the action of specific cyclin/CDK complexes.

mechanics of the cell cycle and checkpoint-signaling pathways and discusses how this knowledge can lead to the efficient use of current anticancer therapies and to the development of novel agents.

CELL CYCLE MACHINERY

Overview of Cell Cycle Phases

Cell proliferation proceeds through a well-defined series of stages (Fig. 4-1). First, the cell moves from the quiescent G_0 state into the first gap phase, or G_1, in which the cell is essentially readying itself for the cell division process. This involves a dramatic upregulation of both transcriptional and translational programs not only to yield the proteins that are required to regulate cell division but also to essentially double the complement of macromolecules so that one cell can give rise to two cells without a loss of cell size. This protein synthesis phase is frequently referred to as cell growth. Not surprisingly, this takes a significant amount of time (anywhere from 8 to 30 hours) and energy. Studies with cultured cells show that mitogenic growth factors are essential for continued passage through G_1. Specifically, if growth factors are withdrawn at any point during this phase, the cell will not divide. However, as it nears the end of G_1, the cell passes through a key transition point, called the *restriction point*, at which it becomes growth factor independent and is fully committed to undergoing cell division. Within an hour or two, the cell enters the synthesis phase, or S phase, in which each of the chromosomes is replicated once and only once. The cell then enters a second gap phase, called G_2, which lasts 3 to 5 hours, and then initiates mitosis, or M phase, in which the chromosomes are segregated. On completion of mitosis, the daughter cells can enter quiescence or initiate a second round of cell division, depending on the milieu.

Cyclin and Cyclin-Dependent Kinase Complexes

The CDKs constitute a large subfamily of highly conserved ser/thr kinases that are defined by their dependence on a regulatory subunit, called a cyclin.[1,2] Only a subset of these CDKs are specifically involved in cell cycle regulation. Yeast use a single CDK for cell cycle control that is called cdc2 in *Schizosaccharomyces pombe* and cdc28 in *Saccharomyces cerevisiae*. In contrast, mammals employ multiple CDKs.[3] The first identified human CDK, called CDK1 (originally *cdc2*), was cloned by virtue of its ability to complement a mutant *cdc2* yeast strain.[4] Subsequent studies identified additional human CDKs and determined that they regulate distinct cell cycle stages; CDK4 and CDK6 regulate passage through G_1, CDK2 regulates the G_1-to-S transition and S phase, and CDK1 controls G_2 and mitosis. The activity of these kinases is controlled by multiple regulatory mechanisms.[5,6] Most important, the CDKs act in association with a cyclin subunit that binds to the conserved PSTAIRE helix within the kinase.[3,5] Cyclin binding causes a reorientation of residues within the active sites that is essential for kinase activity.[3] The associated cyclin also determines the substrate specificity of the resulting cyclin-CDK complex. The cyclins are quite divergent, especially in their N-terminal sequences, but they all share a highly conserved 100-amino-acid sequence, called the *cyclin box*, that mediates CDK binding and activation. As their name implies, cyclins were originally identified as proteins whose expression was restricted to a particular stage of the cell cycle.[7] This is due to cell cycle-dependent regulation of both cyclin gene transcription and protein degradation. Notably, there is frequently a delay between the formation of a particular cyclin/CDK complex and the appearance of kinase activity (Fig. 4-2). This reflects considerable post-translational regulation of the cyclin/CDK complex.[8–11] First, kinase activation is absolutely dependent on phosphorylation of a threonine residue that is adjacent to the active site (thr 160 in CDK2). This is catalyzed by a kinase, called CDK-activating kinase (CAK).[11–13] In mammalian cells, phosphorylation occurs after cyclin binding. Although there appear to be at least two

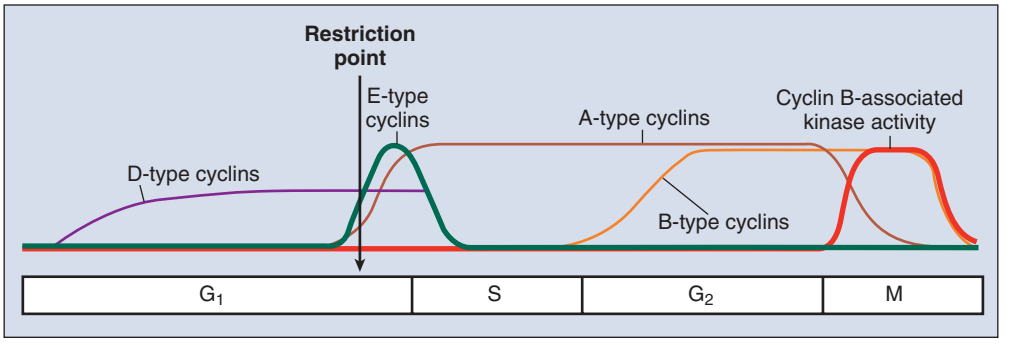

Figure 4-2 • The expression of the cyclin subunits in tightly linked to cell cycle phases. Extracellular stimuli, such as mitogenic growth factors and hormones, induce the expression of the D-type cyclins early in G_1. Cyclin E expression occurs late in G_1, synonymous with the restriction point, and its levels peak at the G_1-to-S transition and then decline during S phase. Cyclin A is induced a little later than cyclin E and is degraded at the metaphase of mitosis. The B-type cyclins are expressed primarily in G_2, and the levels remain high until the anaphase of mitosis. There is typically a delay between the expression of the cyclin protein and the appearance of cyclin-associated kinase activity that results from post-translational regulation. This is most pronounced in the case of cyclin B, for which activation of the cyclin B/CDK1-associated kinase activity does not occur until the G_2-to-M transition.

mammalian CAKs, the major CAK is a trimolecular complex composed of CDK7, cyclin H, and Mat1.[12–14] This kinase is constitutively active, and to date, there is no evidence that it is cell cycle regulated. Indeed, the CDK7-cyclinH-Mat1 complex is also required for the control of basal transcription via regulation of RNA polymerase II function.[12,15] Second, when it is first formed, the cyclin/CDK complex is frequently subject to inhibitory phosphorylation of Thr-14 and Tyr-15 residues within the CDK's active site by the Wee1 (Tyr-15) and Myt1 (Thr-14 and Tyr-15) kinases.[9] Activation of the cyclin/CDK complex is now dependent on the action of a dual-specificity phosphatase called Cdc25.[10] Mammalian cells have three different Cdc25 proteins, called Cdc25A, Cdc25B, and Cdc25C, which show some specificity for different cyclin/CDK complexes.[10]

The mammalian cyclins are divided into four distinct classes—D-type cyclins, E-type cyclins, A-type cyclins, and B-type cyclins—on the basis of both their sequence homology and the stage of the cell cycle at which they act (see Figs. 4-1 and 4-2).[16] Each of these classes has two or three paralogs (cyclin D1, D2, and D3; cyclin E1 and E2; cyclin A1 and A2; and cyclin B1 and B2). The relative roles of these paralogs are still unclear. In some cases, differences exist (e.g., in subcellular localization) that suggest that particular paralogs will have distinct activities or regulation. However, other studies (particularly the analysis of mouse models) show that there is considerable functional redundancy, or at least an ability to substitute for one another, between paralogs of a particular cyclin type.[17,18] For simplicity, we will focus largely on the core properties of the cyclin types.

The D-type cyclins represent an unusual class of cyclins.[16,19] First, they do not participate the cell division process itself. Instead, they play a critical role in determining whether a cell will divide under the direction of external cues. Second, their expression is not really cell cycle regulated; D-type cyclins are present at very low levels in quiescent cells, in large part because they are phosphorylated by an abundant G_0 kinase called GSK3β and then exported to the cytoplasm for degradation, but their expression is induced during G_1, and it persists through all subsequent cell cycle stages.[20] This G_1 induction is a direct consequence of mitogenic signaling. This inhibits expression of GSK3β and activates transcription of the D-type cyclins. Notably, individual mitogenic signaling pathways induce different D-type cyclins. For example, signaling by EGF/ras (via the AP-1 transcription factor) and Wnt/β-catenin (via the Tcf/Lef transcription factor) specifically induces cyclin D1, while c-myc specifically induces cyclin D2.[21–26] This specificity helps to ensure that the presence of multiple proproliferative signals gives rise to more D-type cyclins than a single mitogen does. Importantly, the analysis of mouse models shows that cyclins D1, D2, and D3 are functionally redundant; the key factor appears to be the total level of D-type cyclin that is present in the cell.[27] This promotes cell cycle entry through two distinct mechanisms. First, the D-type cells titrate inhibitory molecules, called CDK inhibitors, away from other CDK-kinase complexes and thereby promote their activation.[5,28,29] Second, cyclins D1, D2, and D3 associate with CDK4 and CDK6, and the resulting complexes phosphorylate the retinoblastoma protein (pRB), a key gatekeeper for cell cycle reentry.[30–34] We will discuss both the CDK inhibitors and pRB in more detail later because of their central importance in controlling cell cycle reentry and their frequent disruption in cancer.

E-type cyclins are expressed during late in G_1 under the control of the E2F transcription factors.[35,36] Cyclin E binds specifically to CDK2, and the resulting complex is required for cells to move through the G_1-to-S transition.[37–39] To date, several cyclin E/CDK2 substrates have been identified. Some cyclin E/CDK2 substrates play a positive role in cell cycle progression. For example, cyclin E/CDK2 phosphorylates NPAT, a transcription factor that mediates transcriptional activation of histone gene clusters.[40–42] The resulting increase in histone pools is essential for the appropriate packaging of newly replicated DNA in S phase cells. Cyclin E/CDK2 also induces the duplication of centrosomes that is required for formation of the mitotic spindle.[43–46] Other cyclin E/CDK2 substrates are key cell cycle inhibitors. First, cyclin E/CDK2 phosphorylates pRB at completely different sites from those that have already been modified by the cyclin D/CDK4/6 kinases, and this is sufficient to inactivate pRB's growth suppressive function.[31,34,47] Second, cyclin E/CDK2 phosphorylates the CDK inhibitor p27 on Thr-187.[48,49] This creates a high-affinity binding site for a ubiquitin ligase, called SCF, which plays a very important role in G_1/S control.[50–53] SCF has three core components: a RING finger protein, called Rbx1, which recruits the E2-ubiquitin conjugate; a cullin (Cul1); and Skp1 (Fig. 4-3).[52–54] Skp1 acts to recruit a family of proteins, called F-box proteins, that determine the target specificity of the SCF complex (see Fig. 4-3). In the case of p27, the F-box

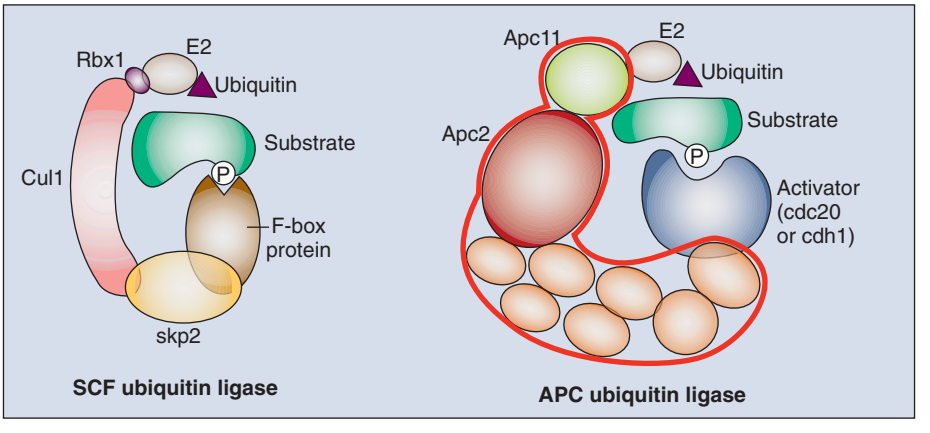

Figure 4-3 • Ubiquitin ligases. The SCF and APC ubiquitin ligases play a key role in enabling forward passage through key cell cycle transitions. These are both large complexes that include three core components: a scaffolding protein called a cullin, a protein that recruits the E2 and its associated ubiquitin molecule, and a specificity factor (called the F-box protein in SCF and the activator in APC) that recruits the substrate. SCF and APC catalyze polyubiquitination of their substrates, and this acts as a signal for substrate degradation by the 26S proteasome. SCF has numerous substrates whose degradation promotes passage through the early stages of the cell cycle, including $p27^{Kip1}$ (the restriction point) and cyclin E, E2F-1, and Cdt1 (S-phase). APC is essential for completion of mitosis (by promoting degradation of securin and the mitotic cyclins) and to allow origin licensing (by promoting degradation of geminin and thereby allowing accumulation of cdt1 during G_1).

protein is Skp2, and the SCF complex is therefore designated as SCF^{Skp2}.[55,56] Once SCF binds its substrate, it transfers a ubiquitin molecule to lysine residues within the target protein and subsequently to lysine residues in the ubiquitin molecule to create a polyubiquitin chain.[54] This polyubiquitin chain targets the substrate to the proteasome for degradation.[54] Notably, SCF is also responsible for the decline in cyclin E/CDK2 levels that is activated during S phase (see Fig. 4-2). First, cyclin E/CDK2 actually phosphorylates itself on multiple sites, creating a recognition site for $SCF^{Fbw7/Cdc4}$ and thereby ensuring its own destruction.[57,58] Second, cyclin A/CDK2 (the S phase kinase) phosphorylates E2F-1, the transcription factor that activates cyclin E transcription, and this is targeted for degradation by SCF^{Skp2}.[59–61] Together, these mechanisms restrict the action of cyclin E/CDK2 to a small window in the cell cycle.

The A-type cyclins are first transcribed during late G_1 under the control of the E2F transcription factors in a similar manner to that of cyclin E. However, in contrast to cyclin E, cyclin A associates with both CDK2 and CDK1 and it acts at two distinct cell cycle stages.[62,63] First, cyclin A/CDK2 is absolutely required for S phase progression. This was established by showing that injection of either cyclin A antisense constructs or antibodies was sufficient to block S phase progression.[62,64] Notably, cyclin A/CDK2 enters the nucleus at the start of S phase, and it is specifically localized at nuclear replication foci and therefore is thought to be actively involved in the firing of replication origins.[65] As was described previously, cyclin A/CDK2 is also required to phosphorylate E2F-1 and mediate its degradation, and this is required to prevent E2F1 from triggering apoptosis.[59–61] Second, cyclin A/CDK1 complexes act during G_2 and at the beginning of mitosis.[62] Here, they are thought to play a key role in initiating the condensation of chromatin and might also participate in the activation of the cyclin B/CDK1 complexes. Cyclin A/CDK2 is destroyed in the prometaphase of mitosis through the action of another ubiquitin ligase, called *anaphase-promoting complex* (APC).[66] APC is a much larger complex that SCF, but it also contains a RING finger protein, called Apc11, to recruit the E2-ubiquitin conjugate, a core cullin subunit (Apc2), and it binds a variety of activators that are required for APC activity and, in a manner comparable to that of the F-box proteins of SCF, establish substrate specificity (see Fig. 4-3).[54,66] In the case of cyclin A/CDK2, the activator is CDC20, and the APC complex is therefore designated as APC^{Cdc20}.

There are two B-type cyclins, B1 and B2, which show significant differences in their subcellular localization. The analysis of mutant mouse models shows that cyclin B2 loss has no detectable effect on development, while cyclin B1 is absolutely required for embryogenesis.[67] This indicates that cyclin B1 is the major B-type cyclin in vivo; therefore, we will restrict our discussion to this isoform. Cyclin B1 protein first appears at the beginning of G_2. It accumulates steadily through G_2 and associates specifically with CDK1.[63] However, the resulting cyclin B1/CDK1 complex is mostly sequestered in the cytoplasm, and it is retained in an inactive form throughout G_2 via the inhibitory phosphorylation of Thr-14 and Tyr-15 in CDK1's active site by the Myt1 and, to a lesser extent, Wee1 kinases.[68–70] Activation of cyclin B1/CDK1 occurs in a highly synchronous manner during the first stage (called prophase) of mitosis (see Fig. 4-2).[71] This activation is mediated by two changes. First, the activities of myt1 and wee1 are dramatically downregulated at the transition between G_2 and M. Second, there is a dramatic increase in the activity of the Cdc25A and C phosphatases that relieves the inhibitory phosphorylation of Thr-14 and Tyr-15.[10] These activity changes are triggered by the phosphorylation of Myt1, Wee1, Cdc25A, and Cdc25C. Three different kinases are thought to contribute to this phosphorylation: polo-like kinase, cyclin A/CDK1, and cyclin B1/CDK1 itself. The involvement of cyclin B1/CDK1 creates a powerful feedforward loop; once a small amount of cyclin B1/CDK1 is activated, it simultaneously inactivates its own inhibitors and activates its activators, enabling a rapid transformation of the entire cyclin B1/CDK1 pool from the inactive state to the active state. Once active, cyclin B1/CDK1 phosphorylates components of the centrosomes and initiates a process called *centrosome separation*, in which the centrosomes move to opposing poles of the nascent spindle, an event that is essential for formation of the mitotic spindle.[72] Cyclin B1/CDK1 then translocates across the nuclear membrane (which is still intact at this point in the mitosis) to orchestrate mitotic events.[73] Notably, cyclin B1/CDK1 is degraded at the end of metaphase (see Fig. 4-2).[74] This is triggered by the ubiquitination of cyclin B1 by the ubiquitin ligase APC and its subsequent recognition and degradation by the proteosome.[66,75,76] This downregulation of mitotic CDKs is required for cytokinesis (the separation of the daughter cells) and reentry into G_0/G_1.[74]

Cyclin-Dependent Kinase Inhibitors

The CDK inhibitors (CDKIs) play a key role in establishing the activity of the cyclin/CDK complexes in response to either external signals or internal stresses.[5] The CDKIs can be divided into two distinct families based on their biological properties. The first CDKI family is named INK4, based on their roles as inhibitors of CDK4. The INK4 family has four members called $p16^{INK4a}$, $p15^{INK4b}$, $p18^{INK4c}$, and $p19^{INK4d}$. These INK4 proteins specifically target CDK4 and CDK6 and not other CDKs. They preferentially target the monomeric CDK and prevent cyclin binding. Consistent with their inhibitory role, the alterations in the *INK4* genes are observed in human tumors.[77] *Ink4a* appears to be most the most frequently affected; it was identified as a tumor suppressor that is associated with familial melanoma, and it is inactivated by point mutation, deletion, and/or promoter methylation in approximately 30% of all human tumors.[78,79] In contrast, point mutations in $p15^{INK4b}$, $p18^{INK4c}$, and $p19^{INK4d}$ are rare, but promoter methylation of *Ink4c* has been detected in Hodgkin lymphomas and medulloblastomas, and reduced $p18^{INK4c}$ protein expression has been seen in a variety of tumor types.[80–84]

The second CDKI family is named CIP/KIP and includes three members: $p21^{Cip1}$ (also called $p21^{Waf1}$), $p27^{Kip1}$, and $p57^{Kip2}$.[5] These CIP/KIP proteins have two major activities. First, they associate with, and inhibit the activity of, the G_1/S and S phase kinases cyclin E/CDK2 and cyclin A/CDK2. Second, $p21^{Cip1}$ and $p27^{Kip1}$ bind to the D-type cyclins outside of the CDK binding site and actually promote assembly of cyclin D/CDK4/6 complexes.[85] These two activities are clearly paradoxical. However, they are critical in establishing how the cell decides whether or not to divide in response to external signals. In general, the expression and/or activity of CDKIs is promoted by growth suppressive signals and inhibited by pro-proliferative signals. For example, the inhibitory growth factor transforming growth factor-β induces transcription of $p15^{INK4b}$, while several mitogenic signaling pathways cause Akt to phosphorylate $p21^{Cip1}$ and $p27^{Kip1}$ and induce their cytoplasmic sequestration.[86–90] Importantly, signaling pathways have the opposite effect on the D-type cyclins: Growth suppressive signals inhibit their expression and activity while mitogens are activating. The opposing regulation of CDKIs and D-type cyclins controls cell cycle entry by creating a tipping point (Fig. 4-4). G_0/G_1 cells have low levels of D-type cyclins and high levels of CDKIs; thus, cell cycle entry is blocked. However, an increase in mitogenic signals boosts the levels of cyclin D, and this eventually exceeds the level of INK4 proteins, which are simultaneously declining. At this point, the D-type cyclins begin to bind to the CIP/KIP proteins. This helps the D-type cyclins to assemble into active cyclin D/CDK4/6 complexes and draws the CIP/KIP proteins away from the cyclin E/CDK2 complexes as they begin to accumulate. The cyclin D/CDK4/6 and cyclin E/CDK2 complexes cooperate in the phosphorylation and inactivation of the pRB protein. This appears to be the tipping point in commitment to cell cycle entry.

pRB Tumor Suppressor

The retinoblastoma protein (pRB) was originally identified by virtue of its association with hereditary retinoblastoma protein.[91] It behaves

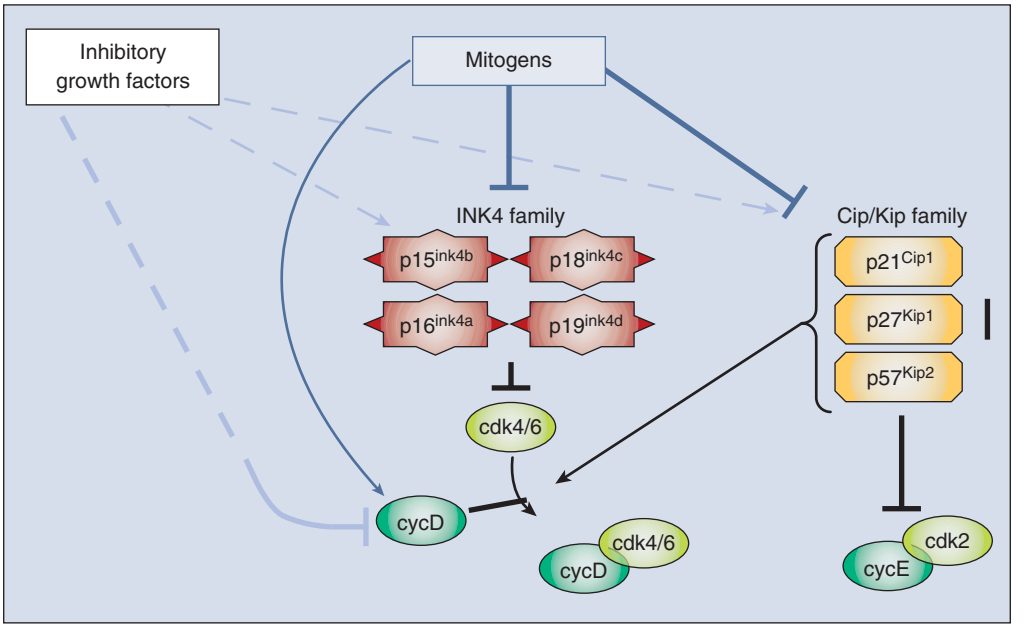

Figure 4-4 • The CDK inhibitors (CDKIs) play a key role in regulating the G_1-to-S transition. The levels of nuclear INK4 and Cip/Kip CDKIs are typically elevated by growth inhibitory stimuli and reduced by mitogenic stimuli. The INK4 family members bind specifically to CDK4 and CDK6 and inhibit their association with cyclin D. The Cip/Kip CDKIs interact with both the cyclin and CDK components and have highest affinity with the intact cyclin–CDK complex. Cip/Kip binds in a different way to cyclin D versus cyclin E complexes, and this has opposing effects on their activity. Cip/Kip binding enables formation of active cyclin D–CDK4/6 complexes. In contrast, Cip/Kip associates with cyclin E–CDK complexes and blocks their activity. Cyclin D complexes have a higher affinity for Cip/Kip than do cyclin E complexes. The mitogen-induced accumulation of D-type cyclins during G_1 titrates Cip/Kip from cyclin E–CDK2 and facilitates activation of both cyclin D–CDK4/6 and cyclin E–CDK2 kinases. Cyclin E–CDK2 can also phosphorylate p27 to promote its ubiquitin-mediated degradation.

as a classic tumor suppressor: Affected individuals inherit a germline mutation within one *Rb-1* allele, and loss of heterozygosity is seen in all of the tumors. Subsequent studies showed that the transforming ability of small DNA tumor viruses, including human papilloma virus, adenovirus, and simian virus, was dependent on the ability of virally encoded oncoproteins (E7, E1A, and SV40, respectively) to bind and inhibit pRB.[92] Moreover, the *RB-1* gene was found to be inactivated in approximately one third of all sporadic human tumors.[91] Thus, pRB is a major human tumor suppressor.

To date, numerous pRB-associated proteins have been identified.[93] However, studies in mouse models indicate that pRB's tumor suppressive activity is largely dependent on its ability to prevent cell cycle entry through inhibition of the E2F transcription factors.[94–96] The E2F proteins regulate the cell cycle-dependent transcription of numerous targets, including core components of the cell cycle control (e.g., cyclin E and cyclin A) and DNA replication (e.g., cdc6, CDT1, and the MCM proteins) machineries.[47,97–99] pRB regulates E2F through two distinct mechanisms. First, its association with E2F is sufficient to block its transcriptional activity.[100] Second, the pRB-E2F complex can recruit histone deacetylases (HDACs) to the promoters of E2F-responsive genes and thereby actively repress their transcription.[101–103] Cell cycle entry requires the sequential phosphorylation of pRB by cyclin D/CDK4/6 and cyclin E/CDK2 complexes and the consequent dissociation of pRB from E2F.[34,47,104] Importantly, tumors that retain wild-type pRB almost always carry activating mutations in *cyclin D1* or *CDK4* or inactivating mutations in the CDK4-inhibitor, *p16*.[104] This suggests that the functional inactivation of pRB, and the resulting deregulation of E2F, is an essential step in tumorigenesis.

Studies to date have identified eight *E2f* genes that encode nine different E2F proteins.[99] pRB and its relatives p107 and p130 (collectively called the pocket proteins) regulate a subset of the E2Fs: E2F1, E2F2, E2F3a, E2F3b, E2F4, and E2F5. These E2F proteins associate with a dimerization partner, called DP, and the resulting complexes function primarily as either activators (E2F1, E2F2, and E2F3a) or repressors (E2F4 and E2F5) of transcription under the direction of the pocket proteins.[47] Most classic E2F target genes are regulated by the coordinated action of these repressor and activator E2Fs (Fig. 4-5). In G_0/G_1 cells, the DP-E2F4 and DP-E2F5 complexes associate with the promoters of E2F-responsive genes and recruit p107 and p130, along with their associated HDACs, to actively repress their transcription.[105,106] At the same time, the activating E2Fs are bound by pRB, inhibiting their potential to activate transcription. Whether complexes containing pRB and activating E2Fs contribute to the repression of E2F target genes is still unclear.[107] In response to mitogenic signaling, CDK activity increases, and the phosphorylation of the pocket proteins causes them to release their associated DP-E2Fs. E2F4 and E2F5 dissociate from the DNA and translocate to the cytoplasm because they have potent nuclear export signals.[108,109] The free E2F complexes—DP-E2F1, DP-E2F2, and DP-E2F3—now occupy the promoters and activate their transcription. Thus, in every cell cycle, there is a coordinated switch from the repressive to the activating E2Fs that enables the simultaneous activation of genes promoting cell cycle progression. Since *cyclin E* is itself an E2F-responsive gene, this regulation creates a strong feedforward loop: The appearance of a small amount of the cyclin E/CDK2 kinase promotes pRB inactivation and further cyclin E expression. This signal is further amplified by cyclin E/CDK2's ability to phosphory-

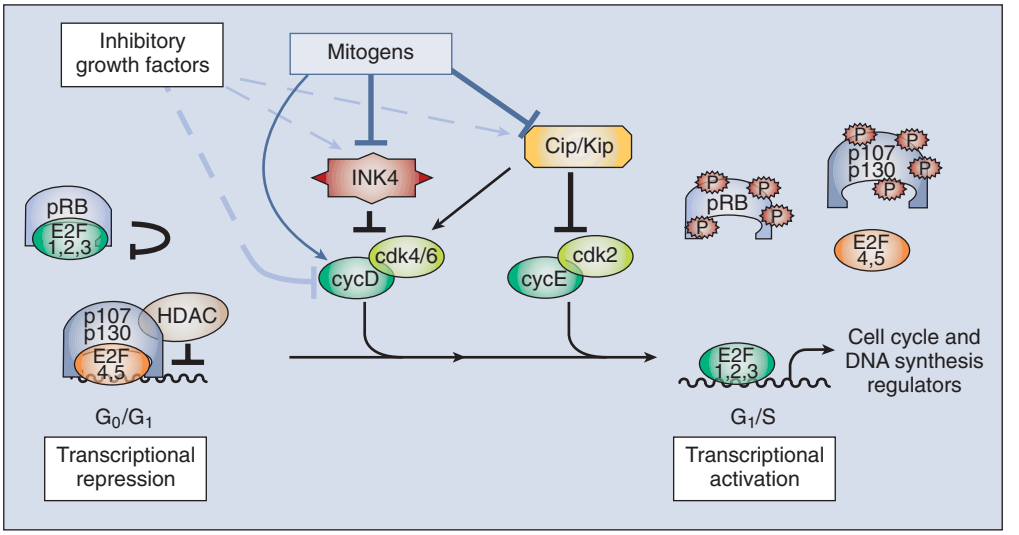

Figure 4-5 • The retinoblastoma protein (pRB) and the restriction point. The pocket proteins—pRB, p107, and p130—regulate a subset of the E2F family of transcription factors. The pocket proteins bind to these E2Fs during G_1 and suppress their activity through two mechanisms. First, pRB binds to E2F1, E2F2, and E2F3a (collectively called the activating E2Fs) and blocks their transcriptional activity. Second, p107 and p130 associate with E2F4 and E2F5 (together called the repressive E2Fs), and the resulting complexes recruit histone deacetylases (HDACs) to the promoters of E2F-responsive genes and actively repress their transcription. E2F-responsive genes encode core components of the cycle control and DNA replication machinery, and cell cycle entry is impossible without these products. Mitogenic signaling leads to the sequential activation of cyclin D–CDK4/6 and cyclin E/CDK2, and these phosphorylate the pocket proteins and release their associated E2Fs. This causes the repressive E2Fs to dissociate from E2F-responsive promoters and allows the activating E2Fs to bind and activate their transcription.

late p27 and signal its destruction. Importantly, pRB-inactivation is largely synonymous with the restriction point, defined as the point at which cells become committed to divide even in the absence of mitogenic stimuli.[110,111] Consistent with this model, the exogenous expression of any individual activating E2F in cell culture is sufficient to stimulate DNA synthesis in the absence of growth signals.[112–116]

DNA Replication

The DNA replication machinery is optimized to ensure that the genome is copied once—and only once—in each cell cycle.[117–120] This is achieved through a two-step process that first establishes a prereplication complex (pre-RC) at each origin of replication, a process that is frequently referred to as *origin licensing*, and subsequently transforms pre-RCs into the preinitiation (pre-IC) complex that activates DNA replication (Fig. 4-6). These two steps occur at distinct stages of the cell cycle to ensure that origins are only licensed once per cell cycle, and rereplication cannot occur. Pre-RC formation takes place during G_1. The first step in this process is the recruitment of the multiprotein complex called the *origin recognition complex* (ORC) to the origin DNA.[121,122] Although ORC binds a subset of genomic sites, there is no evidence that ORC exhibits sequence-specific DNA binding, and it is still unclear how ORC is recruited to specific sequences. Once bound, ORC recruits additional proteins including Cdc6, Cdt1, and finally the MCM complex, a helicase that is required to unwind the DNA strands to form the pre-RC. Once cells enter S phase, the transformation of the pre-RC to the pre-IC requires the activity of two kinases: a CDK (likely, but not yet proven, to be cyclin A/CDK2) and the Ddf4-dependent kinase, which is composed of the Dbf4 regulatory subunit and the Cdc7 kinase.[123,124] In mammals, the precise target(s) of these kinases is still unclear. However, the action of these kinases allows numerous additional proteins to associate with the pre-RC and form the pre-IC.[125] Assembly of the pre-IC is thought to trigger DNA unwinding by the MCM complex, recruitment of the DNA polymerases, and initiation of the replication process, frequently called origin firing.

The transformation of the pre-RC to the pre-IC can occur at different time points in S phase, depending on whether the origin fires early or late.[118–120] The system can tolerate this heterogeneity because the pre-RC is disassembled after firing and cannot reform until the subsequent cell cycle. This occurs through several mechanisms. The MCM complex travels with the replication fork in its role as the DNA helicase. There is also some evidence that phosphorylation of ORC1 reduces its ability to bind to origins. Finally, and most important, Cdt1 is prevented from participating in pre-RC formation outside of G_1 phase in two distinct ways. First, Cdt1 is marked for destruction by ubiquitination.[126] This is mediated by SCF^{Skp2} and particularly by an E4 ubiquitin ligase that includes Rbx1 (to recruit the E2-ubiquitin), a cullin (Cul4), Ddb1, and Dtl/Cdt2 (the substrate specificity factor).[127–129] Importantly, this Cul4-$Ddb1^{Dtl/Cdt2}$ complex functions independently of Cdt1 phosphorylation. Instead, Cdt1 is targeted only when proliferative cell nuclear antigen is present on the DNA, which occurs primarily as a consequence of the initiation of DNA replication.[130] Second, cells possess a protein called geminin that sequesters Cdt1 and prevents it from participating in pre-RC formation. Geminin is present specifically in S, G_2, and early M phase cells. However, the two major mitotic APC complexes, APC^{Cdc20} and APC^{Cdh1}, ubiquitinate geminin and thereby trigger its destruction. This creates a window between anaphase of mitosis and late G_1 (when APC^{Cdh1} is inactivated) in which geminin is absent and therefore Cdt1 is free to participate in pre-RC formation. The importance of both the Cul4-$Ddb1^{Dtl/Cdt2}$ complex and geminin is underscored by the finding that the loss of either one of these regulators is sufficient to trigger inappropriate Cdt1 accumulation and rereplication of the genome.[128,129,131,132]

Mitosis

The mitotic machinery is optimized to ensure that the replicated chromosomes are faithfully segregated to the daughter cells. This is achieved through the use of a specialized microtubule-based structure, the mitotic spindle, on which the original chromosomes and

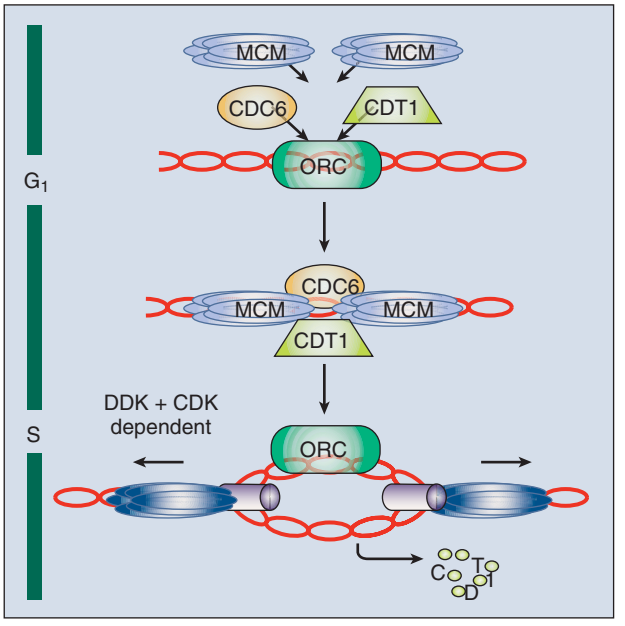

Figure 4-6 • Origin licensing and firing. The origin replication complex (ORC) associates with replication origins. During G_1, Cdc6 and Cdt1 are loaded on chromatin, and they in turn load the MCM complex on chromatin, at which point licensing is considered complete, and the multiprotein complex is called the pre-RC. Once cells pass the G_1-to-S transition, this complex is activated to form the pre-IC, and DNA replication is initiated. Activation requires both CDK and Ddf4-dependent kinase activity. It results in recruitment of numerous proteins and activation of the MCM complex, which unwinds the DNA. Subsequently, core components of the replication machinery, including DNA polymerase α and DNA polymerase ε, are recruited to initiation sites. The transition from pre-RC to pre-IC results in inhibition of cdt1 by ubiquitin-mediated degradation and geminin binding. Origin licensing cannot occur again until activation of APC at the end of mitosis allows accumulation of cdt1.

their newly replicated copies, called sister chromatids, align and are then partitioned to opposite poles of the cell. The appropriate side-by-side alignment of the sister chromatids, termed *biorientation*, is facilitated by the physical tethering of the sister chromatids to one another. This process, called *cohesion*, actually occurs in S phase in a manner that is coordinated with the replication process.[133,134] Cohesin is mediated by four proteins that together make up the cohesin complex. Two of these proteins, Smc1 and Smc3, have a long coiled-coil structure with a dimerization domain at one end that allows them to heterodimerize to form a V-like structure. Importantly, the remaining ends of Smc1 and Smc3 can associate with each another to form a functional ATP domain. This acts in an ATP-dependent manner to recruit two additional proteins, Scc1 and Scc3, that form a closed ring structure.[135] It is still unclear precisely how this ring links the sister chromatids; some investigators hypothesize that the cohesin complex encircles the chromosomes; others argue that the ring (which is known to be approximately 50 nM) is too small to surround complex chromatin structures. Regardless of the mechanism, the cohesin complex links the sister chromatids at the centromeres and at periodic intervals along the arms. The sister chromatids are essentially strung out and become entangled. Consequently, the chromosome structure must be modified before segregation. This occurs toward the end of G_2 and the beginning of mitosis. Largely on the basis of morphologic features, mitosis is divided into five different stages—prophase, prometaphase, metaphase, anaphase, and telophase (Fig. 4-7)—prior to separation of the daughter cells or cytokinesis.

Prophase is essentially a preparative stage. One of the major events is the modification of the DNA. In a process called *resolution*, the sister chromatids are untangled via the action of topoisomerase II.[133,134] Resolution requires removal of the chromosome arm cohesin through phosphorylation of Scc3 by polo-like kinase and histone H3 by the aurora B kinase. Importantly, the cohesin complex at the centromere is somehow protected from this modification by a protein called shugosin (Sgo).[136] This is the glue that keeps the sister chromatids together until the appropriate point in mitosis. In addition to resolution, the sisters undergo condensation, essentially packaging into a more compact chromatin structure. This process involves two multimeric complexes, condensin I and II, which also contribute to sister chromatid resolution, and it requires phosphorylation by mitotic CDKs.[133,134] During prophase, the nuclear envelope is still intact; consequently, differences in subcellular localization of the condensin and CDK complexes allow only condensin II and cyclin A/CDK1 (nuclear), and not condensin I and cyclin B/CDK1 (cytoplasmic), to initiate condensation. The second major event in prophase is the activation of the cytoplasmic cyclin B1/CDK1. This initiates formation of the mitotic spindle by triggering the centrosomes, which are located in the cytoplasm and are already nucleating microtubules, to segregate to the opposite poles of the nascent spindle. The active cyclin B1/CDK1 complex then translocates into the nucleus. Once there, it phosphorylates components of the nuclear envelope and triggers its breakdown.[137,138] This defines the transition from prophase to prometaphase.

During prometaphase, the condensation process is accelerated because condensin I and cyclin B/CDK1 now have access to the DNA. The sister chromatids become attached to spindle microtubules through a structure called the *kinetochore*, which is assembled onto centromeric DNA.[139] Microtubules nucleated from the centrosomes attach to the kinetochore through a process called *search and capture*, in which individual microtubules grow and shrink until they contact and bind the kinteochore.[140] Typically, one sister chromatid of the pair attaches first, and this attachment is further stabilized through the recruitment of additional microtubules from the same pole of the mitotic spindle to create a kinetochore fiber: highly bundled microtubules bound to the kinetochore. The sister chromatids oscillate in the cell until the second sister chromatid is captured by microtubules emanating from the other pole. These oscillations continue until all of the chromosomes are properly aligned on the metaphase plate during metaphase.

Metaphase is defined as the point at which all of the chromosome pairs are fully condensed, attached to the mitotic spindle, and aligned at the center—termed the *metaphase plate*. The pulling of the kinetochore fibers toward the poles creates tension through the cohesin complex at the kinetochores that indicates that the sister chromatids have achieved appropriate biorientation. The cell constantly monitors the attachments of microtubules to the chromosomes, and the tension that is generated by microtubules on the kinetochores ensures that the sister chromatids are properly aligned at the metaphase plate.[141] This is one of several cell cycle checkpoints, called the *mitotic spindle checkpoint*, that we will describe in more detail in the following sections.

Anaphase is characterized by the segregation of the chromosomes. This event is controlled by the mitotic ligase APC^{Cdc20}.[75,76,141–144] APC^{Cdc20} ubiquitinates, and thereby triggers the degradation of, a protein called securin that exists to bind and inhibit a protease called separase. Once released, separase cleaves the Scc1 component of the cohesin complex. This opens the cohesin ring, unlinking the sister chromatids and allowing them to be pulled to opposite poles. The spindle poles then move farther apart to ensure that the chromosomes are fully segregated. APC^{Cdc20} also activates the ubiquitination and degradation of geminin, allowing accumulation of Cdt1 for origin relicensing in the subsequent G_1 phase, and the mitotic cyclins, allowing loss of CDK kinase activity. This latter event is critical to the completion of mitosis and cytokinesis.

During telophase, the mitotic spindle disassembles, leaving a single centrosome and a single set of chromosomes with each nascent

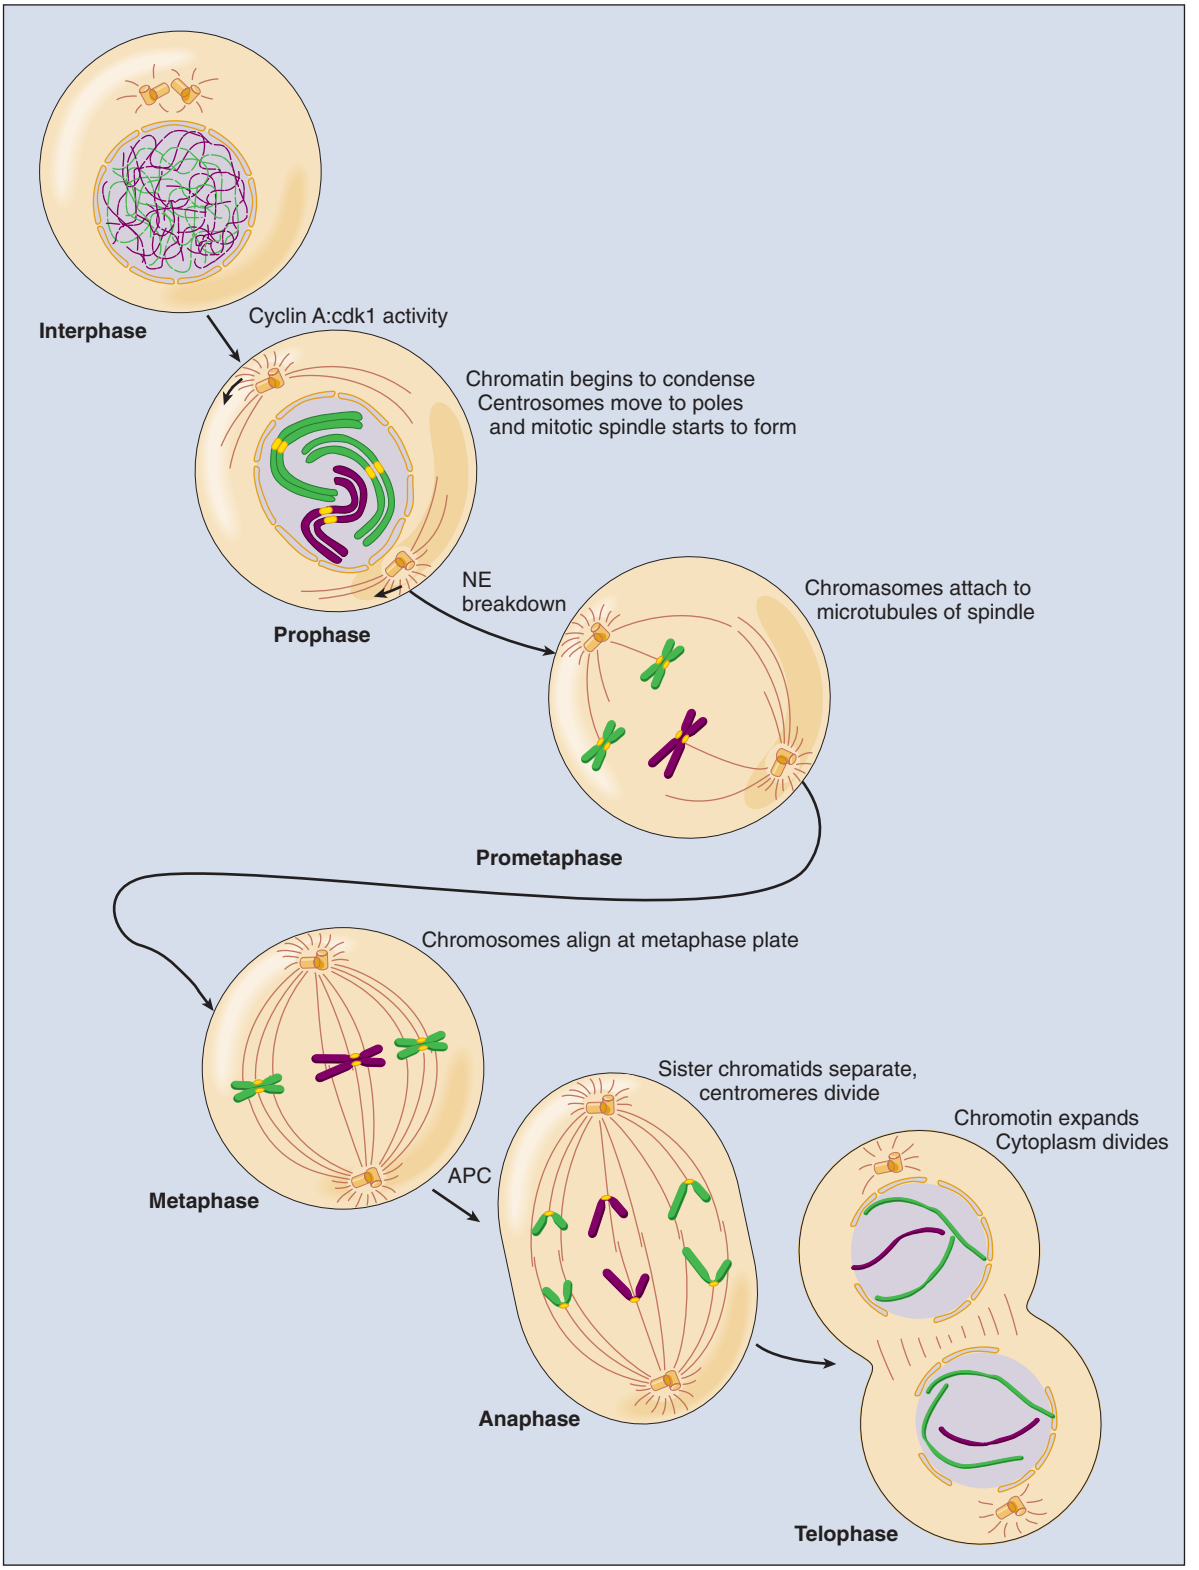

Figure 4-7 • Key stages of mitosis. As the parent cell enters prophase, the chromosomes begin to condense, and proteins associate to form the kinetochores. The centrosomes segregate to the poles to begin formation of the mitotic spindle. Nuclear envelope (NE) breakdown denotes the start of prometaphase. In this phase, the sister chromatids continue to condense, and they attach to spindle microtubules via their kinetochores. During metaphase, the sister chromatids align at the metaphase plate and eventually achieve appropriate biorientation. At the onset of anaphase, the sister chromatids separate and move toward the poles of the spindle. During telophase, the parent cell is divided into two daughter cells by cytokinesis.

daughter cell. As the DNA begins to decondense the nuclear envelope reforms around the segregated chromosomes to create two nuclei. These events are dependent on the loss of CDK kinase activity and the dephosphorylation of CDK substrates.

Finally, the cell undergoes cytokinesis, or cytoplasmic division. This involves formation of an actin- and myosin-containing structure, called the *contractile ring*, on the inner face of the cell membrane. The position of the contractile ring is carefully controlled. For most mammalian cells (ones that are not undergoing asynchronous division), the ring begins to form in anaphase and its position is established by the position of the metaphase plate. As the membrane grows, the contractile ring contracts steadily to form a constriction, termed the *cleavage furrow*, which ultimately separates the two nuclei and forms the two daughter cells. These cells can adopt either a G_0 or a G_1 state, depending on the extrinsic signals that exist.

CELL CYCLE CHECKPOINTS

At key transitions during eukaryotic cell cycle progression, signaling pathways monitor the successful completion of events in one phase of the cell cycle before proceeding to the next phase. These regulatory pathways are commonly referred to as *cell cycle checkpoints*.[145–147] In a broader context, cell cycle checkpoints are signal transduction pathways that link the rate of cell cycle phase transitions to the timely and accurate completion of prior dependent events. Checkpoint surveillance functions are not confined to monitoring normal cell cycle progression; they are also activated by both external and internal stress signals. To minimize the possibility of errors, checkpoints exist at four different points in the cell cycle: G_1/S, intra-S, G_2/M, and at the metaphase to anaphase transition (called the *spindle checkpoint*).

The best-studied of the cell cycle checkpoints are those that monitor the status and structure of chromosomal DNA during cell cycle progression.[147–149] In particular, cells scan the chromatin for partially replicated DNA as well as DNA strand breaks and other DNA lesions that can result from both extrinsic (e.g., chemicals, ionizing or ultraviolet radiation) and intrinsic (e.g., by-products of intracellular metabolism) DNA-damaging agents. The checkpoint pathways include sensor proteins that detect these DNA lesions and simultaneously trigger two processes: They recruit additional complexes to repair the DNA and activate signaling pathways that induce a temporary cell cycle arrest. In certain situations, which are determined by the cell type and the degree of damage, the checkpoint pathways can induce permanent cell cycle arrest (a process called *senescence*) or apoptosis.

The central components of the DNA damage response (DDR) are two members of the phosphoinositide 3-kinase-related kinase family: ATM and ATR.[147,148] ATM was original identified by virtue of its mutation in a hereditary syndrome, ataxia-telangiectasia, which is associated with radiation hypersensitivity and cancer predisposition.[150] ATR is also associated with a hereditary syndrome called Seckel syndrome. Early studies suggested that ATM and ATR played distinct roles in the response to double-stranded DNA breaks (ATM) versus replicative defects and single-stranded breaks (ATR). However, we now know that the regulation is more complex; there is considerable cross-talk between ATM and ATR, and they share many mediators and effectors, but the precise composition and role of the DDR complexes vary depending on both the type of the damage and the stage of the cell cycle.[151] In this chapter, we focus primarily on how the DDR activates cell cycle checkpoints (Fig. 4-8). However, it is important to note that many of the components of the core DDR machinery are affected in hereditary disease syndromes and/or

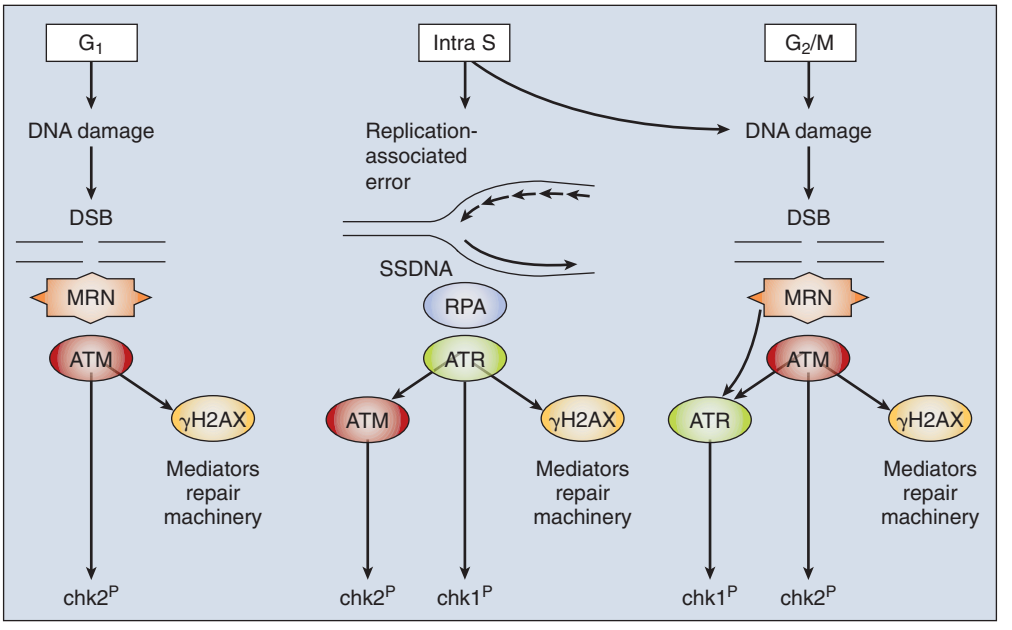

Figure 4-8 • ATM/ATR signaling is activated by DNA damage and replication stress. The cell constantly monitors the chromatin for lesions, using complex signal transduction pathways that center on the ATM and ATR kinases. The precise mechanism of response varies according to the type of DNA damage and the cell cycle stage. Double-stranded breaks (DSBs) are the most deleterious form of DNA damage. DSBs are recognized by the MRN complex that consists of Mre11, Rad50, and Nbs1. This complex recruits ATM to the site of damage. ATM phosphorylates histone H2AX, to form γH2AX, and this creates a binding platform for additional proteins that propagate the DNA damage response and activate repair. For S and G_2 phase cells, but not G_1 cells, ATR is also recruited to the damage site. ATR and/or ATM signal to their effector kinases—CHK1 and CHK2—respectively, to influence cell cycle progression as described in Figure 4-9. Errors in DNA replication can also activate the DNA damage response machinery through the presence of single-stranded DNA (ssDNA) that is a hallmark of the replication fork. The ssDNA is coated with RPA and bound by ATR. Active ATR then recruits the DNA damage and repair machinery, including ATM, leading to the sequential activation of CHK1 and then CHK2.

abrogated in human tumors (e.g., NBS1, BRCA1, BRCA2, and the Franconi's anemia proteins).

G_1/S Checkpoint

In G_1 cells, double-stranded DNA breaks (DSBs) are the most common and most deleterious type of DNA damage. These DSB breaks are recognized by the multifunctional Mre11-Rad50-Nbs1 (MRN) complex.[147] This complex recruits ATM to the site of damage. It is still unclear whether ATM activation occurs before or in response to MRN binding. The active ATM then recruits proteins to modify the chromatin at the region of the break and activate repair and signaling. As a first step in this process, ATM phosphorylates histone H2AX, to form γH2AX. This helps to hold the damaged ends together and acts as a binding platform for additional factors, including Mdc1, 53BP1, and BRCA1, as well as more MRN and ATM. In contrast to the S and G_2 response, there is no recruitment of ATR to DSB in G_1 cells; therefore, ATM is solely responsible for checkpoint activation. The recruitment of additional ATM amplifies the signal, and ATM acts via phosphorylation and activation of the effector kinase CHK2.[152,153]

CHK2 influences G_1 cell cycle arrest via two mechanisms (Fig. 4-9). First, it phosphorylates all three members of the Cdc25 family. Phospho-Cdc25A is ubiquitinated by the $SCF^{Trcp\beta}$ and degraded, while phospho-Cdc25B and phospho-Cdc25C are bound and sequestered by a cytoplasmic protein called 14–3-3.[10,154,155] This is a rapid response that can take effect within minutes after DNA damage, and it has a widespread effect on cell cycle progression by preventing activation of all CDK2 and CDK1 complexes. In the case of the G_1/S checkpoint, cyclin E/CDK2 is the relevant target. Second, CHK2 phosphorylates p53, a critical regulator of cell cycle checkpoints.[156] In normal, nonstressed cells, p53 protein is maintained at low steady-state levels because it has a very short half-life. This half-life is a result of rapid ubiquitination of p53 by HDM2 (the human ortholog of murine MDM2 protein) and its consequent degradation. The importance of MDM2 for maintenance of appropriate p53 levels in vivo is highlighted by the fact that absence of MDM2 in knockout mice results in early embryonic lethality that is rescued by a dual knockout of MDM2 and p53.[157] Phosphorylation of p53 by CHK2 is sufficient to prevent its association with HDM2/MDM2.[158] This leads to an accumulation of p53, which functions as a transcriptional activator. p53 induces expression of many genes. One of the key targets for the G_1/S (and also G_2/M) checkpoint is the CDK inhibitor $p21^{Cip1}$.[159,160] This p53-mediated arrest takes longer to develop than Cdc25 response (because it requires transcription and protein synthesis) but appears to be much more robust. Moreover, in addition to inducing cell cycle arrest, p53 has the capacity to induce apoptosis through the transcriptional activation of proapoptotic regulators (e.g., the BH3-only proteins PUMA and NOXA).[161] How p53 chooses to activate arrest versus apoptosis targets is not fully understood, but it is clearly influenced by both the cell type and the level of damage.[161]

Importantly, p53 is also activated by other stress signals (see Fig. 4-9). In particular, it is now well established that numerous oncogenes trigger a stress response (called *oncogene-induced stress*) that leads to the activation of p53.[162–165] The emerging view is that this occurs through two distinct mechanisms. First, oncogene activation is thought to yield replicative stress that activates p53 via activation of CHK kinases and phosphorylation of HDM2/MDM2 as just described.[166,167] Second, many oncogenes activate transcription of *Arf*.[168] This gene is encoded by the *INK4a/Arf* locus, and it actually shares two coding exons, which are read in alternate reading frames (hence the name ARF), with the $p16^{Ink4A}$ tumor suppressor.[169] The *Arf* protein product, called $p14^{Arf}$ in humans and $p19^{Arf}$ in mouse, binds to HDM2/MDM2 and prevents it from regulating p53.[170–174] As with the DDR, this frees p53 to activate the transcription or proarrest or proapoptotic targets. The central importance of this p53 pathway is underscored by the finding that the majority of human tumors carry mutations in p53, have upregulated HDM2 (typically by gene amplification), or have inactivated $p19^{Arf}$.[169] This is very analogous to the selective pressure to deregulate pRB pathway components (pRB, cyclin D/CDK4, and $p16^{Ink4A}$) that was discussed previously.[104] Together, the pRB and p53 pathways are critical gatekeepers of G_1-to-S progression in normal cell cycle and stress response.

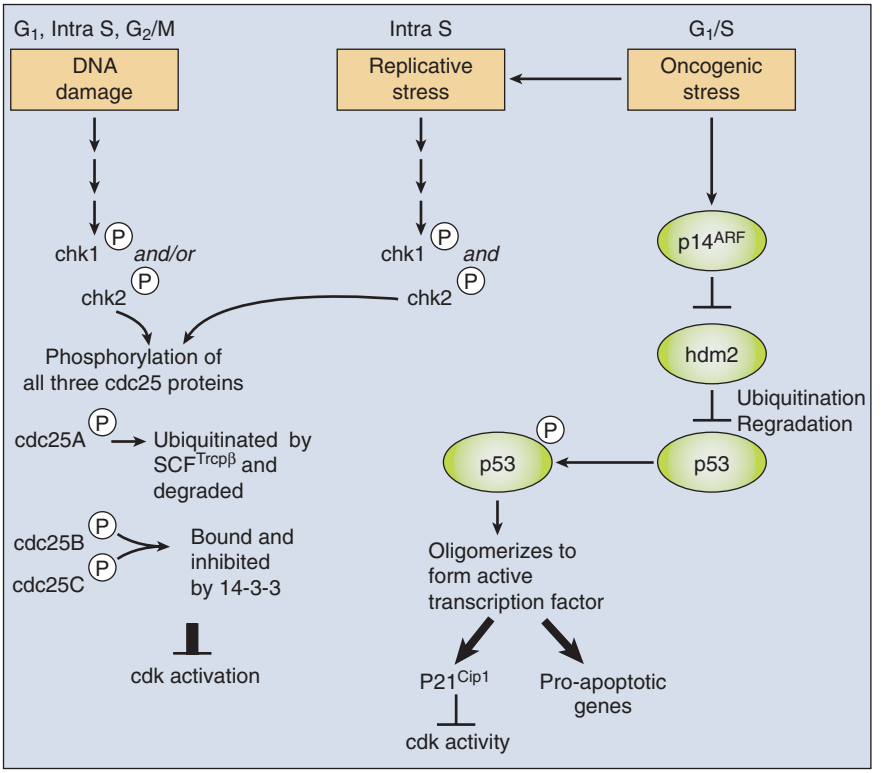

Figure 4-9 • DNA damage, replicative stress, and oncogenic stress induce cell cycle arrest. DNA damage and replication stress lead to the rapid phosphorylation and activation of the CHK1 and/or CHK2 kinases. These enforce cell cycle arrest through two mechanisms. CHK1 and CHK2 both phosphorylate the cdc25 phosphatases, and this triggers their ubiquitination and degradation (cdc25A) or binding and inhibition by 14-3-3 (cdc25B and cdc25C), thereby preventing activation of either cyclin/CDK2 or cyclin/CDK1 kinases. CHK1 and CHK2 also phosphorylate p53 and prevent it from being targeted by HDM2 for ubiquitin-mediated degradation. As a result, p53 accumulates and activates transcription of $p21^{Cip1}$, inhibiting CDK2 and CDK1 kinase complexes, or proapoptotic genes. Oncogenic stress also leads to cell cycle arrest by activating replicative stress and/or inducing transcription or the $p14^{Arf}$ tumor suppressor and suppressing HDM2-mediated inhibition of p53.

As an additional DNA damage response in G_1 cells, genotoxic agents also inhibit origin licensing by way of an ATM/ATR-independent process. This is achieved through regulation of Cdt1.[127–129,175] As was described previously, Cdt1 is required for pre-RC formation. In an undamaged cell, Cdt1 is available during G_1 but is inhibited after origin firing by degradation (mediated by the SCFskp2 and Cul4-Ddb1-Dtl/Cdt2 ubiquitin ligases) and geminin binding. As a key feature of this regulatory system, Cdt1 is completely resistant to Cul4-Ddb1-Dtl/Cdt2 in the G_1 phase. However, DNA damage allows Cul4-Ddb1-Dtl/Cdt2 complex to ubiquitinate Cdt1 and induce its degradation. This process requires binding of Cdt1 to proliferative cell nuclear antigen, but the mechanism by which this induces Cdt1 ubiquitinylation is not understood. Importantly, the degradation of Cdt1 is extremely rapid, occurring within minutes of the DNA damage. As a result, origin licensing is completely blocked until the damage is repaired and Cdt1 is resynthesized.

Intra-S Phase Checkpoint

One of the major goals of cell cycle checkpoints is to prevent the deleterious consequences of replicating damaged DNA. Therefore, S phase cells must respond virtually instantaneously to DNA damage to halt initiation of new replication forks throughout the S phase.[149] The most deleterious damage is DSBs. These can occur through the action of DNA damaging agents (from either extrinsic or intrinsic sources) or as a consequence of the replication process itself, for example, if the replication fork passes through nicked DNA or replication stalls at sites of DNA damage. The cell senses the damage in different ways depending on whether or not the lesion is associated with replication. Ultimately, both ATM and ATR are recruited to the site of damage, but the order of binding is different.[149,151] Replication-linked DSBs are distinguished by the presence of single-stranded DNA, a hallmark of the replication process. The single-stranded DNA is coated by RPA and bound by ATR and its regulator subunit ATRIP, even during the normal replication process. In response to DNA damage, the ATR kinase is activated, and it then recruits a variety of complexes that mediate both repair and checkpoint activation, including ATM. In contrast, nonreplication-associated DSBs initially recruit and activate ATM through the MRN-dependent process described previously for G_1/S checkpoint. However, in S phase cells, DSB resection causes the formation of single-stranded DNA (through the action of the MRN endonuclease), and this is then bound by RPA and ATR/ATRIP.[149,151] Thus, in S phase cells, ATR and ATM jointly orchestrate the DDR. ATR contributes to the checkpoint response in a similar manner to ATM: It activates an effector kinase, called CHK1, which can also phosphorylate the cdc25 proteins and p53.[176–179]

G_2 Checkpoint

The G_2 checkpoint is required to prevent the passage of DNA lesions to two daughter cells during mitosis.[147,180] DSBs are detected exactly as we described previously for the S phase nonreplication-associated DSBs. Similarly, the ATR/CHK1 and ATM/CHK2 pathways enforce arrest through inhibition of G_2 and mitotic CDK complexes via the rapid removal of the cdc25 phosphates and the p53-dependent induction of the $p21^{Cip1}$ CDKI.

Spindle Checkpoint

The preceding sections focused on the steps the cell takes to prevent the propagation of DNA errors to the daughter cells. In contrast, the spindle checkpoint acts to ensure that there is appropriate partitioning of the chromosomes.[181] We have already introduced the concept that chromosome segregation is prevented until all of the condensed sister chromatid pairs are aligned at the metaphase plate with the appropriate biorientation. This is actually controlled by a signaling network that constitutes the spindle checkpoint (Fig. 4-10). The core components of the spindle checkpoint—called MAD1, MAD2, BUBR1, and BUB1 in humans—were originally identified through screens in yeast for "mitotic arrest deficient" (MAD) and "budding uninhibited by benzimidazole" (BUB) mutants.[181] These proteins become active in the prometaphase of mitosis (see Fig. 4-10). They

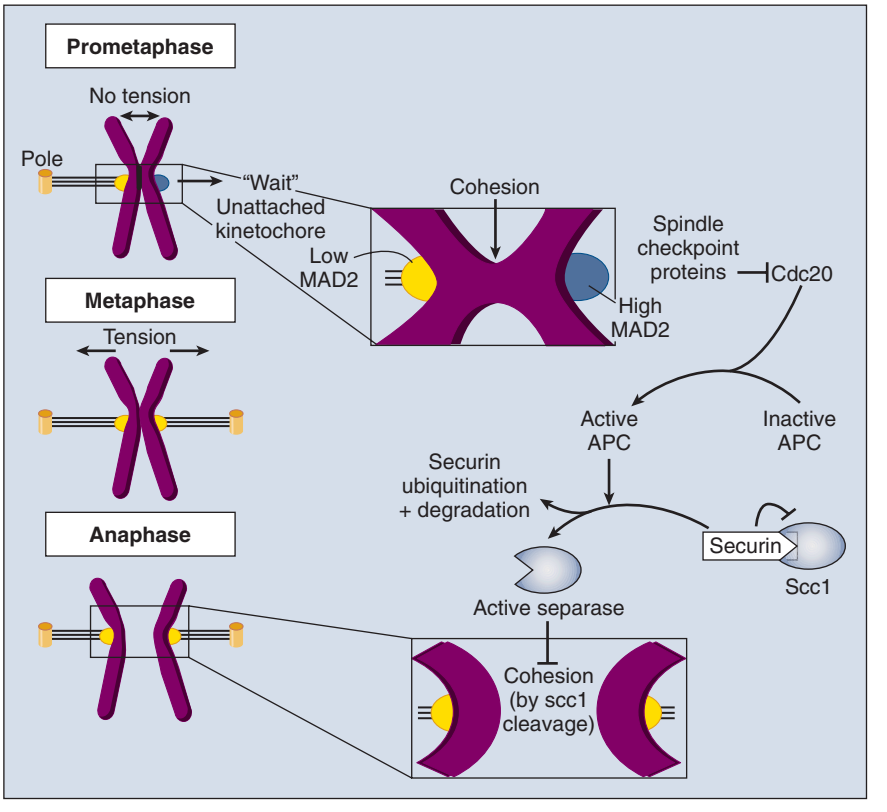

Figure 4-10 • The spindle checkpoint. Improper chromosome alignment on the mitotic spindle, disruption of microtubule dynamics, or unattached kinetochores can activate the spindle checkpoint. Spindle checkpoint signaling is mediated by the Bub1, Bub3, BubR1, and Mad2 proteins, which all localize to kinetochores. These core spindle checkpoint regulators prevent the activator protein Cdc20 from binding to APC and therefore protects securin, a major APC^{cdc20} target, from ubiquitin-mediated degradation. As a result, securin remains bound to separase, and this prevents cleavage of Scc1 and loss of centromeric cohesin. The spindle checkpoint is relieved at the end of the metaphase by the appropriate biorientation of the sister chromatids at the metaphase plate. The sensing mechanism involves detecting tension through the cohesin complex at the kinetochores that is created by the pulling of the spindle fibers toward the poles. Mad2 then dissociates from the attached kinetochore, and this allows cdc20 to activate APC and trigger sister chromatid segregation.

associate with the kinetochore and, in the absence of biorientation, prevent the CDC20 activator from binding to the APC. As a result, separase is sequestered by securin and unable to cleave the centromeric cohesin (see Fig. 4-10). It is still unclear precisely how the spindle checkpoint is inactivated by appropriate biorientation. However, it involves monitoring the tension through the cohesin complex at the kinetochores (created by the pulling of the spindle fibers toward the poles) and the dissociation of MAD2 from the attached kinetochore (see Fig. 4-10). Because aneuploidy is a shared feature of many cancer cells, there has been considerable speculation that disruption of the spindle checkpoint could occur during tumor progression.[182–184] Notably, inactivating mutations in *Bub1* have been identified in human colon carcinoma cell lines, which are known to have a high degree of aneuploidy.[185] Moreover, haploinsufficiency of Mad2 has been shown to cause elevated rates of lung tumor development in $Mad2^{+/-}$ mice compared with age-matched wild-type mice.[186] However, it is still an open question whether spindle checkpoint defects make a significant contribution to tumor development.

CELL CYCLE DEREGULATION IN HUMAN CANCERS

Molecular analysis of human tumors demonstrates that alterations in components of the cell cycle machinery and checkpoint-signaling pathways occur in the majority of human tumors (Table 4-1). This finding underscores how important maintenance of cell cycle control is in the prevention of human cancer. The alterations in the cell cycle machinery that occur most frequently include loss or mutation of the pRB tumor suppressor; overexpression of cyclins, CDKs, and Cdc25 phosphatases; and loss of expression of CDKIs. The most frequently altered cell cycle checkpoint-signaling molecule is the p53 tumor suppressor. Proteins that reside upstream of p53 (including ATM and CHK2) are also targeted for mutation in human tumors, and their discovery and analysis have greatly deepened our insight into DNA damage response-signaling pathways. Mutations that affect the pRB pathway have been identified in the majority of human cancers.[91,187] The *RB-1* gene was originally identified by virtue of its mutation in both familial and sporadic retinoblastoma, but it is defective in many other tumor types, especially osteosarcoma and lung cancer. Indeed, more than 90% of small-cell lung cancers have mutant *RB-1*, suggesting that disruption of the pRB pathway (through the genetic or epigenetic targeting of *RB-1* or upstream signaling components) is a requirement for the genesis of lung cancer.[188] It is important to note that inactivation of the parallel and interconnecting $p14^{Arf}$-p53 axis is also essential in functionally pRB-deficient lung cells to bypass efficient apoptosis.[169] In breast cancer, loss of normal pRB function due to *RB-1* mutation is observed in 20% of tumors.[189] In the 80% of breast carcinomas that lack *RB-1* mutations, alterations in components of the signaling pathways that regulate pRB are frequently found, including cyclin D1 and cyclin E overexpression and *cdk4* and *cdk6* gene amplification.[190–192] Nearly 50% of invasive breast cancers have elevated cyclin D expression compared with surrounding normal breast epithelium, while transgenic mice with overexpression of human cyclin D1 or cyclin E in mammary gland cells develop mammary adenocarcinomas.[193–195] Similarly, *cdk4* and *cdk6* gene amplification occurs in breast cancers, sarcomas, gliomas, and melanomas.[196]

Table 4-1 Mutations of Cell Cycle Checkpoint Regulators in Human Tumors*

Gene/Protein	Tumors Associated with Mutations or Altered Expression	Hereditary Syndromes Associated with Germline Mutations
ATM	Breast carcinomas, lymphomas, leukemias	Ataxia-telangiectasia
Bub1	Colorectal carcinomas	NR
BRCA1	Breast and ovarian carcinoma	Familial breast and ovarian cancer
Cdc25A	Carcinomas of breast, lung, head and neck, and lymphoma	NR
Cdc25B	Carcinomas of breast, lung, head and neck, and lymphoma	NR
Cdk4	Wide array of cancers	NR
Cdk6	Wide array of cancers	NR
Chk1	Colorectal and endometrial carcinomas	NR
Chk2	Carcinomas of breast, lung, colon, urogenital tract, and testis	Li-Fraumeni syndrome
Cyclin D1	Wide array of cancers	NR
Cyclin D2	Lymphoma and carcinomas of the colon, testis and ovary	NR
Cyclin D3	Lymphoma, pancreatic carcinoma	NR
Cyclin E	Wide array of cancers	NR
MDM2	Soft tissue tumors, osteosarcomas, esophageal carcinomas	NR
MRE11	Lymphoma	Ataxia-telangiectasia-like disorder
NBS	Lymphomas, leukemias	Nijmegen breakage syndrome
$p15^{INK4b}$	Wide array of cancers	NR
$p16^{INK4a}$	Wide array of cancers	Familial melanoma
$p27^{KIP1}$	Wide array of cancers	NR
p53	Wide array of cancers	Li-Fraumeni syndrome
$p57^{KIP2}$	Bladder carcinomas	NR
p130	Wide array of cancers	NR
pRB	Wide array of cancers	Familial retinoblastoma

NR, not reported.
*Only alterations that are present in more than 10% of primary tumors are represented.

Modifications of CDKIs that act upstream of pRB activity are also commonly found in human tumors. The CDK inhibitor $p27^{Kip1}$ is often aberrantly expressed in human breast cancer, and reduced $p27^{Kip1}$ protein levels are correlated with more aggressive breast tumors.[197,198] Likewise, decreased expression of the CDK inhibitor $p57^{Kip2}$ is found in human bladder cancers.[199] Germline mutations in $p16^{INK4a}$ predispose individuals to melanoma, while deletion of $p15^{INK4b}$ and $p16^{INK4a}$ is linked to the pathogenesis of lymphomas, mesotheliomas, and pancreatic cancers.[78,79,196,200] In tumor types in which $p15^{INK4b}$ and $p16^{INK4a}$ are not deleted, methylation of the gene locus leads to transcriptional repression and loss of gene expression. In some tumors, hypermethylation prevents expression of both $p16^{INK4a}$ and $p14^{Arf}$, which are encoded by alternative reading frames of the *Ink4a/Arf* locus.[199] Both Cdc25A and Cdc25B phosphatases are overexpressed in more than 30% of primary breast tumors, 40% to 60% of non-small-cell lung cancers, 50% of head and neck tumors, and a significant fraction of non-Hodgkin's lymphomas.[10,201,202] Elevation of these oncogenic phosphatases can result in increased activation of CDK and override of checkpoint arrest.

p53 mutation is the most frequently observed mutation in the majority of human tumors. The importance of p53-dependent signaling in tumor suppression is underscored by the frequency of mutation in sporadic tumors and the finding that germline mutations of *p53* result in Li-Fraumeni syndrome, a highly penetrant familial cancer syndrome that is associated with significantly increased rates of brain tumors, breast cancers, and sarcomas.[203,204] In human tumors that lack p53 gene mutation, p53 function may be disrupted by alterations in cellular proteins that modulate the levels, localization, and biochemical activity of p53. For example, in some tumors with wild-type *p53* alleles, MDM2 gene amplification occurs, resulting in MDM2 protein overexpression and subsequent p53 inactivation.[205] In human papillomavirus-induced cervical carcinoma, *p53* is typically not mutated; however, the human papillomavirus E6 protein binds p53 and targets it for degradation, abrogating p53-dependent signaling.[206]

Mutation in components of the DNA damage response pathway also leads to enhanced tumorigenesis, as was discussed previously. For example, *ATM* mutations occur in ataxia-telangiectasia, a disorder in which patients have increased sensitivity to radiation and an elevated incidence of leukemias, lymphomas, and breast cancer.[150,207] ATM-null mice exhibit growth retardation, neurologic dysfunction, infertility, defective T lymphocyte maturation, and sensitivity to ionizing radiation.[208,209] The majority of ATM-deficient animals develop malignant lymphomas by 4 months of age, while $ATM^{-/-}$ fibroblasts have abnormal radiation checkpoint function after exposure to ionizing radiation.[208,209] The DNA double-strand break repair gene *MRE11* is mutated in individuals with an ataxia-telangiectasia-like disorder.[210] Mutations of *Chk2* and *Chk1* also arise in human cancers. *Chk2* mutations have been reported in several cancers, including lung, while *Chk1* mutations have been observed in human colon and endometrial cancers.[211,212] In addition, heterozygous alteration of *Chk2* occurs in a subset of individuals with Li-Fraumeni syndrome who lack p53 gene mutations.[213] These findings support the theory that in human tumors in which *p53* is intact, the function of this tumor suppressor might be disrupted by alterations in cellular proteins that modulate the levels or activity of p53. In addition, the breast cancer susceptibility tumor suppressors BRCA1 and BRCA2 are known to participate in the DNA damage response and repair.[214] Similarly, the Fanconi's anemia proteins, which were originally identified by virtue of their association with a recessive development disorder called Fanconi's anemia, which is associated with increased cancer predisposition (particularly acute myeloid leukemia), also function in the DNA damage response.[214]

The spindle checkpoint disruption has also been linked to the pathogenesis of several human tumors. *BUB1* mutations have been identified in human colon carcinoma cells, and Bub1 mutation facilitates the transformation of cells that lack the breast cancer susceptibility gene, BRCA2.[185,215] Moreover, Michel and colleagues demonstrate that $Mad2^{+/-}$ mice have significantly higher rates of lung tumor development than do age-matched wild-type mice.[186]

THERAPEUTIC MANIPULATION OF CELL CYCLE CONTROLS

Research over the past two decades has shown that alterations in cell cycle machinery and checkpoint signaling lead to tumorigenesis. These findings have important implications for the optimization of current therapeutic regimens and for the selection of novel cell cycle targets for the future development of anticancer agents. A leading goal of cancer-based research is to identify compounds that will target key cell cycle controls in a tumor-specific manner.

Targeting Cyclin-Dependent Kinase Activity

There has been considerable debate about whether inhibition of CDK activity is a rational strategy for anticancer therapies. CDK activity is frequently elevated in human tumors, but it is also required to maintain specific cells populations in the adult (e.g., the hematopoietic compartment and gut) that are essential for viability. Thus, the key issue is whether there is sufficient difference in the CDK activity in tumor versus normal cells to create a therapeutic window. Over the last few years, the analysis of CDK and cyclin mouse models has yielded considerable insight into this question but has also raised additional questions.[18] On the positive side, studies in mouse models clearly show that tumors can be more dependent on CDK activity, or at least a specific CDK activity, than normal tissues can. For example, loss of D-type cyclins has been shown to have little or no effect on the development and maintenance of many tissues, but loss of cyclin D-associated kinase activity can greatly suppress the development of certain tumor types, depending on the tissue and the identity of the initiating oncogenic lesions.[22,29,216] On the negative side, the mouse models also show that the cell cycle machinery is extremely robust; it adapts easily to the loss of CDKs or cyclins by using other CDKs or cylins to substitute for the missing activity. For example, CDK2 knockout mice are fully viable because CDK4/6 and CDK1 now form novel cyclin/CDK complexes and assume roles that are normally specific to CDK2.[217–219] This raises the possibility that tumor cells will rapidly develop resistance to CDK-inhibitory drugs by simply adapting their cell cycle machinery. In light of these complexities, efforts have been placed on generating pharmacologic inhibitors of CDKs that either are CDK-specific or have pan-CDK activities. Numerous small molecule inhibitors have been developed, and many are in clinical trials.[220,221]

One of the first compounds to be tested, flavopiridol, is a pan-CDK inhibitor that inhibits CDK4/6, CDK2, and CDK1 kinase activity. Consistent with this broad action, flavopiridol arrests cells at G_1/S (in a pRB-dependent manner) and G_2/M. This antiproliferative activity against a variety of human cancer cell lines produced favorable clinical responses in phase I and phase II studies of patients with renal, colorectal, gastric, lung, and esophageal carcinomas.[222–224] Notably, it was also determined that if target cells are first induced to induced to enter S phase, then treatment with flavopiridol had significant cytotoxic effects.[221] This arises through two mechanisms. First, flavopiridol inhibits the action of cyclin A/CDK2 and thereby prevents the phosphorylation of E2F1 and its subsequent degradation.[59,61] The persistence of E2F1 in late stages of the cell cycle is known to trigger apoptosis, and this effect shows strong specificity for tumor cells versus normal cells, presumably because of higher E2F1 levels. Second, flavopiridol suppresses the activity of CDK7 (which functions both as a component of both CAK and as a RNA polymerase II CTD kinase that promotes transcriptional elongation) and CDK9 (which acts in association with cyclin T to form another CTD kinase called P-TEFb).[225,226] Inhibition of CDK7 and CDK9 suppresses mRNA synthesis, and this leads to a rapid loss of

transcripts that have short half-lives, including many cell cycle regulators (e.g., cyclins) and antiapoptosis regulators. As a result of these observations, clinical trails have been conducted using sequential treatment of an S phase chemotherapeutic agent, gemcitabine, and then flavopiridol.[221] On a similar theme, sequential treatment with paclitaxel (which inhibits mitotic spindle function) and then flavopiridol also yields cytotoxic synergy.[221] In this case, flavopiridol is acting by inhibiting cyclin B/CDK1 and thus prevents phosphorylation and stabilization of a protein, called *survivin*, that is required to maintain the spindle checkpoint. Thus, the cells proceed through cytokinesis and enter G_1 without segregating their chromosomes, and this triggers apoptosis. Phase I and phase II trials have been conducted with paclitaxel and flavopiridol, and currents efforts are focused on optimizing the dosage and the time interval of administration.[221] More selective CDK inhibitors are also being analyzed.[220,221] These include small molecules that show a strong selectively for CDK2 and CDK1 or are highly specific for CDK4/6. Cell- and animal-based studies show that these drugs yield the anticipated affects. For example, the CDK4/6 inhibitor PD0332991 yields a G_1/S arrest in an pRB-dependent manner, and it can yield regression of xenografts generated from pRB-positive cell lines.[227] Many of these drugs have yet to be tested in clinical trials.

Targeting DNA Damage Response Proteins

In the last decade, there has been a growing appreciation that many tumors cells carry mutations that disrupt their DNA damage response (DDR). This is a major factor in establishing the resistance of tumors to chemotherapeutic agents, many of which work by causing DNA damage and triggering apoptosis through induction of DNA damage pathways. Therefore, considerable attention has focused on designing cancer treatments that would be effective in cells with an impaired DDR. Since it is hard to restore the function of mutant or missing proteins, the prevailing strategy is to identify drugs that would synergize with the defective DDR to selectively kill the tumor cells and not the normal cells. For example, inhibitors of poly(ADP-ribose) polymerase selectively kill cells that lack either BRCA1 or BRCA2.[228–230] The rationale for this is that these proteins provide two alternative repair mechanisms in response to DNA damage: homologous recombination (BRCA1 and BRCA2) and base excision repair (poly(ADP-ribose) polymerase). Therefore, loss of one but not both of these pathways can be tolerated. As a second example, inhibition of CHK1 sensitizes *p53* mutant cells to DNA damage.[220] Since *p53* is mutated in approximately half of all human tumors and the absence of p53 is a major predictor of poor response to classic chemotherapeutic agents, considerable efforts are being made to develop small molecular inhibitors of CHK1.

SUMMARY

Over the past several decades, investigators have uncovered a wealth of information about the proteins that control cell growth and division in human cells. A key finding is that deregulation of the cell cycle machinery and/or checkpoints is a universal alteration that has been identified in human cancer.[104,231] Although numerous genetic alterations can result in loss of normal checkpoints, the hope is that common strategies will be developed against a wide variety of cancers. Even though several of the currently used anticancer therapies target nonselective and non-mechanism-based targets, their effectiveness, albeit limited in many cases, is likely due to the fact that they ultimately target cell cycle regulatory or DDR-signaling pathways, the status of which is different in normal cells versus tumor cells. Identifying all the components of the cellular machinery that control the cell cycle both positively and negatively is vital to the continued development of anticancer agents that can preferentially eliminate cancer cells and minimize the toxicity to normal tissues. The information that is generated by the genomic and proteomic approaches using eukaryotic model systems will continue to reveal new cell cycle regulatory molecules. As our understanding of cell cycle regulation and checkpoint signaling improves, the goal is to use this knowledge in the design of mechanism-based therapeutics that will bring anticancer therapy to a new level. There can be little doubt of the value of targeting the cell cycle in drug discovery.

5 Cell Life and Death

Rebecca L. Elstrom and Craig B. Thompson

SUMMARY OF KEY POINTS

- Apoptosis control mechanisms seem to be impaired in virtually all tumors, suggesting that a required step in carcinogenesis is to disengage the apoptotic machinery.
- Two basic pathways of apoptosis have been described: the extrinsic or death receptor-mediated pathway and the intrinsic or mitochondrial pathway.
- The fate of a cell is determined by the balance of proapoptotic and antiapoptotic factors within the cell.
- Oncogenic transformation promotes proapoptotic pathways. Cancer cells must disable tumor suppressor molecules and/or activate survival signals to evade programmed cell death.
- Therapeutic strategies aimed at restoring tumor suppressors and interfering with survival factors are playing increasingly important roles in antineoplastic treatments.
- There is a growing understanding of the role of alternative forms of cell death, particularly necrosis, in the response of cancer cells to treatment.

INTRODUCTION

The evolution of a normal cell into cancer involves disruption and deregulation of several basic cellular processes. Multicellular organisms, in their evolution from simple, single cells, have developed redundant controls through which the homeostasis between different cell types is maintained. One of the safeguards that prevents excess cell accumulation is the presence of cell-intrinsic programs that can induce programmed cell death, the best studied being apoptosis. The growing understanding that transforming mutations can activate this intrinsic death response has emphasized the importance of this process in preventing cancer cell development. Apoptosis control mechanisms seem to be impaired in virtually all tumors, suggesting that a required step in carcinogenesis is to disengage the apoptotic machinery.

The concept that genes regulating cell death could play a role in tumorigenesis arose in the mid-1980s, when investigators first discovered that a translocation commonly found in follicular lymphoma, between chromosomes 14 and 18, brings a region on chromosome 18 called breakpoint cluster region 2 (*Bcl-2*) into close proximity with the immunoglobulin heavy chain enhancer on chromosome 14, resulting in overexpression of the *Bcl-2* gene.[1] Later work showed that the Bcl-2 gene product promotes oncogenesis by a novel mechanism.[2,3] Instead of inducing cell proliferation or invasion, the Bcl-2 protein inhibits the normal programmed death of B cells, resulting in the failure to eliminate the clonal B cells as they accumulate in excess. These findings demonstrated for the first time that disarming death pathways within a cell could predispose to development of malignancy.

Since the description of *Bcl-2,* extensive progress has been made in understanding both the mechanisms of apoptosis and the ways in which this process contributes to tumorigenesis. The identification of a family of genes related to *Bcl-2* that contribute to the balance between life and death, together with the discovery of the critical role of mitochondria in cellular homeostasis and apoptosis, have broadened our understanding of the dynamic interplay of forces determining the fate of cells.

In addition to progress in elucidating apoptotic mechanisms and deregulation, there has been an increasing understanding of the role of nonapoptotic mechanisms of cell death in both organismal homeostasis and pathogenic states such as cancer. Necrosis, a death process traditionally considered as unregulated and catastrophic, may instead represent a regulated event that contributes to organismal development and homeostasis. Autophagy, in which a cell "eats itself," is also under investigation as a form of nonapoptotic cell death, although the function of this process, whether to induce death or, conversely, to maintain survival, is controversial.

Harnessing these forces will improve our capability not only to understand the mechanisms by which normal cells become malignant but also to prevent and treat cancer in humans.

FUNDAMENTAL SCIENCE

Cell death occurs by two general classes of mechanism: apoptosis, or programmed cell death, and necrosis. Autophagy has been proposed as a third potential mechanism of cell death, although the physiologic functions of this process remain under study.

The process of apoptosis involves a cell-intrinsic suicide program that not only kills the cell but also stimulates the clearance and complete degradation of the corpse without inducing an inflammatory reaction. Apoptosis differs from other forms of cell death, such as necrosis, in that clearance of the cell is controlled through the activity of caspases—cysteine proteases with aspartate specificity that normally exist in an inactive, zymogen form. The initiator caspases 8 and 9 are activated by cellular signals and subsequently cleave downstream effector caspases, such as caspases 3, 6, and 7. These effector caspases set into motion the degradation of cellular components such as structural proteins, cell cycle machinery, and DNA. These processes result in the characteristic morphology of apoptotic cells, membrane blebbing, cell shrinkage, and DNA fragmentation. The end result is the disposal of the cell in a controlled manner, allowing turnover and phagocytosis without the inflammatory reaction to intracellular substances that accompanies death by necrosis.

As noted in the preceding discussion, the caspase cascade is initiated through specific cellular signals. These signals come through one of two major pathways: the extrinsic, receptor-mediated pathway, or the intrinsic, mitochondrial pathway. Although these pathways often are considered separately, extensive cross-talk exists between them.

Cell Death by Murder

In some cases, apoptosis is initiated through ligation of specific cell-surface receptors, the death receptors (Fig. 5-1). These molecules are members of the tumor necrosis factor receptor (TNFR) family. The best studied of these include Fas and TNFR1.[4,5] These receptors exist as trimers at the cell surface that are activated on binding of ligand, Fas ligand, and TNF, respectively. The intracellular domains of these receptors contain death domains which, on activation of the receptor, can recruit a death-inducing signaling complex, which leads to activation of a caspase cascade. The Fas death domain binds the Fas-associated death domain (FADD) adapter protein, which directly recruits caspase 8 and allows its cleavage and activation.

Activation of TNFR1, on the other hand, has multiple potential downstream effects.[6] TNFR1 binds the TNFR-associated death domain (TRADD) adapter protein, which in turn might recruit FADD, resulting in caspase 8 activation and apoptosis, as with Fas. TRADD also, however, can bind TNFR-associated factor-2, which may recruit inhibitor of apoptosis proteins (IAPs), which bind the death-inducing signaling complex and inhibit activation of caspase 8. Alternatively, TNFR-associated factor-2 may recruit components of the mitogen-activated protein kinase (MAPK) cascade, leading to activation of Jun-N-terminal kinase (JNK) and c-jun. Although in some systems JNK seems to promote TNFR1-induced apoptosis, these findings are inconsistent, and the role of JNK in receptor-mediated apoptosis is controversial. Finally, TRADD can bind receptor-interacting protein (RIP), resulting in activation of NF-κB, which antagonizes the apoptotic program. NF-κB is a transcription factor that activates expression of survival molecules such as IAPs and c-FLIP, a direct inhibitor of caspase 8 activation.[7] IAPs were first described in baculoviruses, where they were shown to inhibit apoptosis of host cells following viral infection.[8] Homologs such as XIAP and c-IAP-1 and -2 have since been identified in mammals; they seem to function by inhibiting caspase activation in both the death receptor and mitochondrial pathways.[9–11]

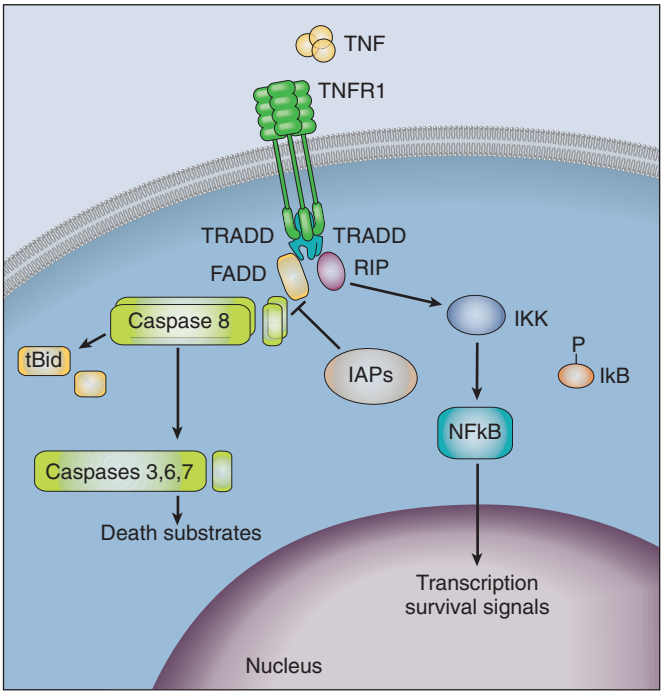

Figure 5-1 • Death receptors can initiate apoptosis or promote cell survival. On ligation of the death receptor, adaptors are recruited. For TNFR1, the outcome of ligand binding depends on the state of the cell. TRADD might bind the FADD molecule, which recruits caspase 8, resulting in its oligomerization and activation. Active caspase 8 in turn cleaves and activates effector caspases and the BH3-only molecule Bid, initiating an apoptotic cascade. This process is inhibited by IAPs. Alternatively, binding of TNFR1 might induce recruitment of RIP and IκB kinase (IKK), resulting in release of the NF-κB transcription factor from its inhibitor, IκB. NF-κB then enters the nucleus, activating transcription of survival genes such as IAPs, therefore antagonizing the proapoptotic factors.

Another ligand-receptor pair that functions in both immune regulation and control of cancer is the TNF-related apoptosis-inducing ligand, TRAIL, and its receptors, TRAIL-R1/DR4 and TRAILR2/DR5.[12,13] TRAIL induces apoptosis in a variety of transformed cells but is much less toxic to normal cells than to abnormal ones. The intracellular signaling pathways induced by TRAIL are similar to those of the TNFR1. TRAIL is expressed as a cell-surface molecule on natural killer cells, and it can inhibit tumor growth.[14] TRAIL also binds to decoy receptors TRAILR3/DcR1 and TRAIL-R4/DcR2, which sequester TRAIL from the signaling receptors, blocking TRAIL-induced apoptosis.[15,16] Expression of these decoy receptors might provide the mechanism by which normal cells escape TRAIL-induced death, in that many tumor cells show lower expression of the decoy receptors.

Cell Death by Suicide

The importance of mitochondria in apoptosis was demonstrated in 1996, when Liu and colleagues[17] demonstrated that cytochrome *c,* a component of the electron transport chain normally contained in the mitochondrial intermembrane space, could initiate programmed cell death when present in the cytosol. This finding led to the demonstration that the intrinsic, or mitochondria-dependent, cell death program resulted from loss of mitochondrial integrity with release of intermembrane space contents (Fig. 5-2). Cytochrome *c,* on release into the cytosol, forms a complex with Apaf-1 and adenosine triphosphatase (ATP). This complex, known as the apoptosome, binds and activates procaspase 9.[18] Other mitochondrial contents also participate in apoptosis. For example, Smac/DIABLO,[19,20] Htra2,[21] apoptosis-inducing factor (AIF), and endonuclease (endo) G also contribute to the cell death program.[22–24] Inhibitory proteins such as XIAP and cIAPs-1 and -2 bind to the apoptosome and inhibit activation of caspases. Smac/DIABLO and Htra2 function by inhibiting the inhibitors, which allows apoptosis to proceed. The progression of the cell death program seems to depend on the relative ratios of apoptosis promoters and inhibitors. Evidence suggests that AIF, on the other hand, might function independently of caspase activity. Upon release from mitochondria, AIF translocates to the nucleus, where, in cooperation with endo G, it can initiate large-scale fragmentation of DNA.

Controversy exists over the mechanism by which mitochondria lose integrity, resulting in release of their contents and initiation of the caspase cascade. General mechanisms proposed include mitochondrial dysfunction leading to matrix swelling and outer membrane rupture. Alternatively, loss of mitochondrial integrity could involve formation of specific pores large enough to release the intermembrane components. Another controversy exists over the importance of caspases in the actual death of cells following mitochondrial compromise as opposed to their role of simply orchestrating cellular disposal. Some investigators have shown that once mitochondria lose integrity, cells will die even in the absence of caspase activation.[25] This finding is consistent with the idea that release of mitochondrial contents proceeds from large-scale catastrophe to the mitochondria, with cellular viability impossible in the absence of mitochondrial function. Others have suggested that, under some circumstances, cells can recover even after cytochrome *c* release if caspases are held in check.[26] The function of IAPs in preventing apoptosome activity suggests that in some cases death can be prevented, but the role of caspases probably varies with different apoptotic stimuli.

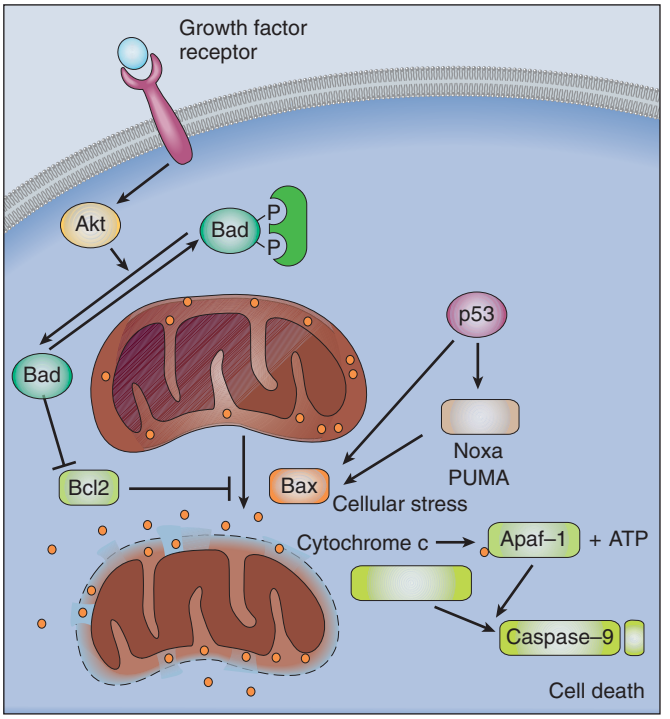

Figure 5-2 • Mitochondria-dependent apoptosis. Under conditions of cellular stress, the proapoptotic molecules Bax and/or Bak oligomerize at the mitochondria and induce release of mitochondrial contents, including cytochrome *c*. Cytochrome *c* then binds Apaf-1, and in combination with ATP forms the apoptosome. The apoptosome induces cleavage and activation of caspase 9, which activates a caspase cascade culminating in cell death. This process might be stimulated by DNA damage, which results in activation of p53, which, among several functions, promotes transcription of the BH3-only molecules Noxa and PUMA. The apoptotic pathway is antagonized by Bcl-2, which can block cytochrome *c* release and mitochondrial dysfunction. Growth factor stimulation might also antagonize apoptosis, in part through activation of such survival factors as Akt, which can phosphorylate and inactivate proapoptotic molecules such as the BH3 protein, Bad.

Bcl-2 Family

Bcl-2 family proteins play a key role in regulation of mitochondrial integrity and programmed cell death. The Bcl-2 family includes proteins with both antiapoptotic and proapoptotic function. Bcl-2, the first identified member of this family, acts to prevent apoptosis, as do Bcl-XL and Mcl-1. Bax and Bak antagonize the function of the antiapoptotic family members and are critical in promoting apoptosis through the mitochondrial pathway. All these family members have multiple domains, termed Bcl-2 homology (BH) domains. A third type of Bcl-2 family member, exemplified by Bad, Bim, and others, consist of a single BH domain and are termed BH3-only molecules. The BH3-only family members also play a key role in promoting apoptosis.

Extensive progress has been made in understanding the mechanisms by which these Bcl-2 family members regulate mitochondrial integrity and apoptosis, although many questions remain. The antiapoptotic molecules Bcl-2 and Bcl-XL localize to the mitochondria and maintain mitochondrial integrity. This could occur through promotion of exchange of metabolic substrates across the mitochondrial membrane, allowing maintenance of respiration.[27] Alternatively, antiapoptotic Bcl-2 family members might bind and inhibit the function of proapoptotic family members.[28] The multidomain proapoptotic molecules, Bax and Bak, are required for mitochondrial apoptosis initiated through most stimuli.[29] Mice with targeted knockouts of either of these molecules show largely normal apoptotic function, but loss of both Bax and Bak results in a severe defect in apoptosis.[30] This finding suggests that although these two molecules might have largely redundant functions, presence of one or the other is critical to allowing apoptosis to proceed. The BH3-only molecules, in contrast, seem to have a signaling function. Various apoptotic stimuli induce expression and/or activation of specific BH3-only family members, which translocate to the mitochondria and initiate Bax/Bak-dependent apoptosis (Fig. 5-3). They could operate either by activating Bax and Bak or by inhibiting the antiapoptotic function of Bcl-2 and Bcl-Xl. It has been suggested that different members of this group could have distinct functions—some directly binding and activating Bax/Bak, and others indirectly activating these proapoptotic molecules by binding and antagonizing Bcl-2/Bcl-XL.[31]

The BH3-only protein Bid provides an example of cross-talk between the receptor-mediated and mitochondrial pathways of apoptosis. Bid is a target of active caspase 8.[32,33] Once cleaved, this truncated form of the protein, tBid, can translocate to mitochondria, inducing cytochrome *c* release and amplification of the apoptotic signal. Although in some cell types death receptor engagement can kill cells independently of mitochondrial participation, in other cell types, this amplification step is critical to effect cell death.

Necrosis

In contrast to apoptosis, necrosis has largely been considered an uncontrolled, default form of cell death. Morphologically, necrosis is characterized by swelling of organelles and loss of plasma membrane integrity, and it can be induced by exposure of cells to overtly pathologic conditions such as extreme temperature or pH, or mechanical force. Increasingly, however, it is being recognized that at least in many cases, necrosis can occur through a highly regulated process, dependent, as in apoptosis, on specific signaling pathways. The critical components of this process include effectors that induce irreversible bioenergetic compromise in the cell, and those that result in release of inflammatory mediators from the cell, inducing a host response.

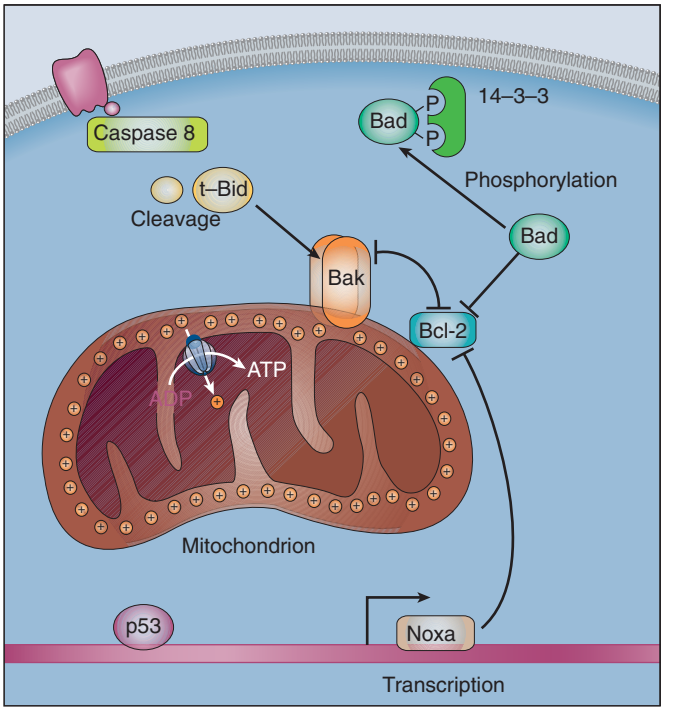

Figure 5-3 • BH3-only proteins initiate apoptosis. Several BH3-only proteins exist and could function in various ways to promote apoptosis. Bid is cleaved by caspase 8 on death receptor stimulation and subsequently translocates to mitochondria, where it can activate oligomerization of Bax and Bak. Other proteins, such as Bad and Noxa, function by inhibiting antiapoptotic Bcl-2 molecules. Noxa is transcriptionally regulated by p53, and Bad is regulated by inhibitory phosphorylation, which is growth factor dependent.

Necrosis can be activated both by death receptor signaling and by cell-intrinsic events. The absence of specific caspase activities, such as caspase 8, or the presence of apoptosis inhibitors, such as may be present in viral infection, may block apoptotic death in response to TNFR or Fas ligand stimulation, but induce a necrotic program. The regulated nature of this necrotic stimulus is illustrated by the fact that blocking the activity of the RIP kinase blocks necrotic cell death.[34]

Programmed necrosis may also be an important way in which organisms dispose of cells that have accumulated DNA damage. Although cells sustaining DNA damage in many cases die an apoptotic death, a functioning apoptotic pathway is not required for DNA damage–induced death. Zong and colleagues have shown that the activation of poly(ADP-ribose) polymerase (PARP) in response to DNA damage plays a critical role in the death of actively growing cells sustaining such damage.[35] PARP binds to DNA strand breaks, catalyzing the synthesis of poly(ADP-ribose) polymers on histones, promoting recognition of strand breaks by DNA repair enzymes. β-nicotinamide adenine dinucleotide (NAD) is a critical substrate of this reaction, and therefore PARP activation leads to depletion of NAD from the cytosol. Because cytosolic NAD is required for glycolytic metabolism, this consumption of NAD in response to DNA damage compromises the production of ATP in cells that are dependent on glycolysis, rather than mitochondrial metabolism, for energy production, such as rapidly proliferating cells and most cancer cells. In contrast, vegetative cells, deriving the bulk of their ATP from oxidative phosphorylation, remain bioenergetically intact. This necrotic death via PARP activation does not depend on apoptotic mediators such as Bak and Bax.

The activation of programmed necrosis might act as a warning system to the organism, resulting in release of proinflammatory mediators and activation of the immune system. This could be of particular benefit in the cases discussed previously, viral infection and cancer, in allowing the organism to mount an effective, global response to the insult.

Autophagy

Autophagy is a cellular process in which cytoplasmic components, including proteins and organelles, are sequestered into acidic vacuoles for degradation. The degradation products then become available as a source to support biosynthesis and energy production. Autophagy is promoted by metabolic stress and forms a response to metabolic emergencies within the cell.

The role of autophagy in cell death is not clear and is under active investigation. Some have hypothesized that autophagy is in and of itself a mechanism of cell death. Other investigators, however, have suggested that autophagy is instead a protective mechanism, allowing the cell to maintain bioenergetic integrity in the face of an inability to access nutrients. In this scenario, death would occur as a result of the depletion of intracellular resources, despite, not because of, autophagy.

Support for both these hypotheses can be found in the experimental literature. Lum and colleagues demonstrated that cells deprived of growth factors, leading to a defect in nutrient uptake, could maintain survival through activation of autophagy.[36] Inhibition of autophagy induction in this system led to rapid cell death. On the other hand, the loss of beclin-1, a gene product necessary for the induction of autophagy in mammals, predisposes to cancer in animal models,[37,38] and loss of beclin-1 is seen in some tumor types. The mechanism by which beclin-1 functions as a tumor suppressor is unclear, however. Beclin-1 associates with Bcl-2 and therefore might have a more direct role in apoptosis. Further investigation will be needed to clarify the role of autophagy in cancer.

APOPTOSIS IN CANCER

The events that can lead to mitochondrial apoptosis are varied. These include loss of normal survival-promoting extrinsic signals, DNA damage, metabolic stress such as hypoxia and nutrient limitation, oncogenic stresses, and toxins. Under normal circumstances, cells require extrinsic signals to promote cellular homeostasis and survival. These signals include growth factors and cell-cell or cell-matrix contact. Survival signals demonstrate to the cell that it is in an appropriate location and that cells like it are present in an appropriate number. Loss of these signals can occur if the cell finds itself in an ectopic position (loss of cell-cell or cell-matrix contact) or when specific cell types are in excess numbers (causing competition for growth factors), resulting in apoptosis.

Oncogenes as Triggers of Apoptosis

Oncogenic stresses, such as activation of Myc or loss of Rb with subsequent uncontrolled activation of the cell cycle machinery, can induce apoptosis. The mechanisms by which this occurs are not clear, but it is well demonstrated that oncogenesis through these pathways requires the additional step of inhibition of programmed cell death. In that Myc promotes activity of biosynthetic pathways, one possibility is that it promotes metabolic stress.[39,40] Other oncogenic stresses, such as loss of the Rb tumor suppressor or DNA damage, promote activity of the tumor suppressor p53.[41]

Research performed in recent years has demonstrated clearly the importance of apoptotic pathways in control of tumorigenesis. Cancer cells, through inappropriate growth and proliferation, outstripping of resources, and translocation to environments to which they are not adapted, subject themselves to death triggers and therefore must disable the apoptotic response to survive. A critical point in understanding the role of apoptosis in cancer is that lack of death alone does not suffice to make a cancer cell. Rather, tumors must activate proliferative, growth, and invasion programs—the targets of traditional oncogenes. It is these programs and their tendency to overwhelm the cell's survival signals that place the cell under apoptotic stress. Disabling of apoptotic pathways makes the cancer cells intrinsically defective in initiation of programmed cell death; such disabling promotes resistance to antineoplastic therapy but also suggests that many cancer cells live constantly "on the edge" of death. It is possible that restoration of apoptotic function could suffice for, or at least contribute to, the elimination of a tumor.

Tumor Suppressors Promote Apoptosis

p53

p53 is one of the best studied tumor suppressors, and its function is lost in at least half of human solid tumors. p53 activity is induced through stabilization of the protein in response to various oncogenic signals (including DNA damage), resulting in inhibition of cell growth through either cell cycle arrest or induction of apoptosis.[42] The specific mechanisms by which one or the other response occurs are not completely clear but could include duration of activity or the prevailing state of the cell. The activity of p53 seems to be mediated largely through its ability to act as a transcription factor, playing the roles of both transcriptional activator and repressor for different targets.

p53 activity and levels are controlled in large part by its upstream regulator, MDM2. MDM2 protein binds p53 and exports it from the nucleus, blocking its ability to act as a transcriptional regulator. MDM2 also targets p53 for proteasome-dependent degradation through its activity as a ubiquitin ligase. MDM2, in turn, is inhibited in its inhibition by p14ARF. In the absence of loss of p53 itself, overexpression of MDM2 can act as an oncogene, functionally suppressing p53 activity. MDM2 is overexpressed in multiple human tumor types, including lung cancer, brain cancers, and breast cancers.[43,44] p14ARF, conversely, has been shown to be lost in various tumors, including colon cancers.[45] Abnormalities of these upstream regulators tend to occur in tumors that retain wild-type p53, dem-

onstrating that dismantling of the p53/MDM2/p14ARF pathway plays a key role in tumorigenesis.

In addition to regulation by MDM2, post-translational modifications of p53 also influence its biologic activity. Phosphorylation and acetylation affect p53 stabilization and DNA-binding activity, and it seems that both these modifications promote p53 function. Mutant p53 proteins found in cancer cells are in some cases highly acetylated and phosphorylated, leading to stabilization and accumulation of the mutant protein.[46] This stabilized mutant protein can then act as a dominant negative, forming inactive complexes with residual wild-type protein.

The antitumor activity of p53 is mediated largely through its transcriptional effects. p53-dependent genes play multiple roles in apoptosis. For example, several proapoptotic Bcl-2 family members are transcriptionally activated by p53, including Bax and the BH3-only proteins Noxa and PUMA.[47,48] Expression of Apaf-1, another important element in the mitochondrial pathway, is induced through p53 activity. p53 promotes death receptor pathways through activation of Fas transcription, and it inhibits survival signaling through induction of PTEN (see later discussion).[42] Although this list of antitumor effects of p53 is far from exhaustive, the foregoing examples provide insight into the importance of this pathway in blocking tumorigenesis. Nontranscriptional roles for p53 in apoptotic regulation have also been proposed, including direct binding and inhibition of the activity of Bcl-X_L and Bcl-2.[49–51]

Proapoptotic Bcl-2 Family Members

In contrast to the oncogenic effects of the antiapoptotic Bcl-2 family members, proapoptotic family members, particularly Bax, have been implicated as tumor suppressors. Bax and its functional homolog, Bak, are critical in mediating apoptosis through the mitochondrial pathway induced by many cellular stresses.[30,46] Experimental models have suggested that Bax and Bak have p53-independent function in suppression of tumorigenesis and act as tumor suppressors.[52] In one study, murine cells expressing adenoviral E1A, a proliferative factor, and dominant negative p53 were unable to form tumors in mice. Additional loss of Bax and Bak, however, resulted in the formation of highly invasive tumors, emphasizing the capability of these molecules to inhibit carcinogenesis. Furthermore, mutations in Bax and Bak have been identified in many colon and gastric cancers.[53,54]

BH3-only proteins could also be important in preventing tumorigenesis. Although evidence implicating them as bona fide tumor suppressors is scant, BH3-only proteins play a role in the response to apoptotic stimuli of various death pathways, including p53 and death receptors.

PTEN

The activity of the survival pathway mediated through PI3K and Akt, discussed subsequently, is antagonized by phosphatase and tensin homolog on chromosome 10 (PTEN), a dual-specificity (protein and lipid) phosphatase that degrades phosphatidylinositol-3,4,5-triphosphate [Ptd(3,4,5)P3] back to the bisphosphate form, terminating the signal of PI3K. PTEN was discovered in the search for a tumor suppressor on chromosome 10 that is frequently lost in glioblastoma and prostate cancer. Since its discovery, researchers have shown that PTEN acts as a negative regulator of Akt.[55] Tumorigenesis in response to loss of PTEN depends in part on deregulation of Akt activity.[56]

The frequency of PTEN loss in human tumors is exceeded only by that of p53. PTEN function is abnormal in the majority of glioblastomas and prostate cancers and has been described in many other human cancers, including breast cancer and endometrial cancer. Furthermore, mice bearing an inactive allele of PTEN develop tumors in multiple organ systems.[57,58] The loss of a single allele of PTEN seems to be sufficient to promote tumorigenesis, as haploinsufficient mice frequently do not lose the second allele upon development of tumors, and loss of the second allele is a late event in many tumors.

Survival Factors Prevent Apoptosis in Cancer Cells

Antiapoptotic Bcl-2 Family Members

The central role of Bcl-2 family members in control of apoptosis suggests that these proteins may be appropriate targets of dysregulation in tumorigenesis, and, as predicted, many tumors show alterations in these proteins. The earliest description of antiapoptotic activity in cancer was that of overexpression of Bcl-2 in follicular lymphoma. This overexpression is brought about by the t(14;18) translocation, which brings the Bcl-2 gene locus into juxtaposition with the immunoglobulin heavy-chain enhancer, an abnormality found in at least 85% of follicular lymphomas. Since this discovery, Bcl-2 overexpression has been found in a multitude of different cancers, including other types of lymphoma and solid tumors such as breast cancer.[59]

The importance of Bcl-2 in the pathogenesis of cancer has also been demonstrated in experimental models. For example, mice expressing transgenic c-Myc in B cells develop lymphoma with a long latency period, suggesting the need for other transforming mutations for tumorigenesis. Coexpression of Bcl-2 markedly shortens the latency period, demonstrating synergy of these two molecules in lymphomagenesis.[2] Myc activation in cell lines induces apoptosis, in part through activation of p53. These experiments imply that a critical step in Myc-induced transformation is inhibition of apoptosis, and that Bcl-2 can provide this function. Bcl-Xl, another antiapoptotic family member with function similar to Bcl-2, also seems to play a role in both experimental and naturally occurring human tumors.[60–62]

Mice expressing transgenic Bcl-2 and Bcl-XL illustrate the important concept that inhibition of apoptosis alone does not induce tumorigenesis. Enforced expression of these molecules in B lymphocytes of mice leads to accumulation of lymphocytes, but lymphoma develops only rarely.[63] Instead, Bcl-2 and Bcl-XL facilitate lymphomagenesis by inhibiting the death that normally accompanies oncogenic activation. Likewise, lymphocytes bearing the t(14;18) can be detected in some healthy people with no evidence of lymphoma.[58] Taken together, these points of evidence emphasize that although suppression of apoptosis is an important step in transformation, it is not sufficient to drive carcinogenesis.

NF-κB

Another pathway through which tumor cells might suppress apoptosis is the nuclear factor-κB (NF-κB) pathway. As discussed previously, activation of NF-kB during death receptor stimulation sets into motion a transcriptional program that inhibits apoptosis and promotes survival. NF-κB, under normal circumstances, is held in check by binding of the inhibitor of NF-κB, IκB. NF-κB is released on phosphorylation of IκB through activity of two IκB kinases, IKK-α and IKK-β.[64] Phosphorylation targets IκB for ubiquitination and degradation by the 26S proteasome, releasing NF-κB to translocate to the nucleus and activate its target genes (Fig. 5-4). Oncogenic stimuli, as well as survival signals, promote NF-κB activation. For example, Ras-mediated transformation stimulates transcriptional activity of NF-κB.[65] Furthermore, the Bcr-Abl fusion protein, a causative mutation in chronic myeloid leukemia, activates NF-κB by promoting nuclear translocation.[66] Virally induced transformation by human leukemia/lymphoma virus type 1 is dependent in part on Tax-mediated activation of IKKs.[67]

The proto-oncogene *Bcl-3* was identified on one arm of a translocation found in some lymphoid malignancies, t(14;19). This translocation brings the *Bcl-3* gene in proximity to the immunoglobulin heavy-chain enhancer, resulting in its overexpression. The *Bcl-3* gene encodes a member of the IκB family, but this gene product seems to function differently from other IκBs.[68] Specifically, Bcl-3 localizes to the nucleus and modifies the function of NF-κB subunits.[69] When overexpressed in normal T cells, Bcl-3 promotes survival following cellular activation, and expression seems to be induced on treatment

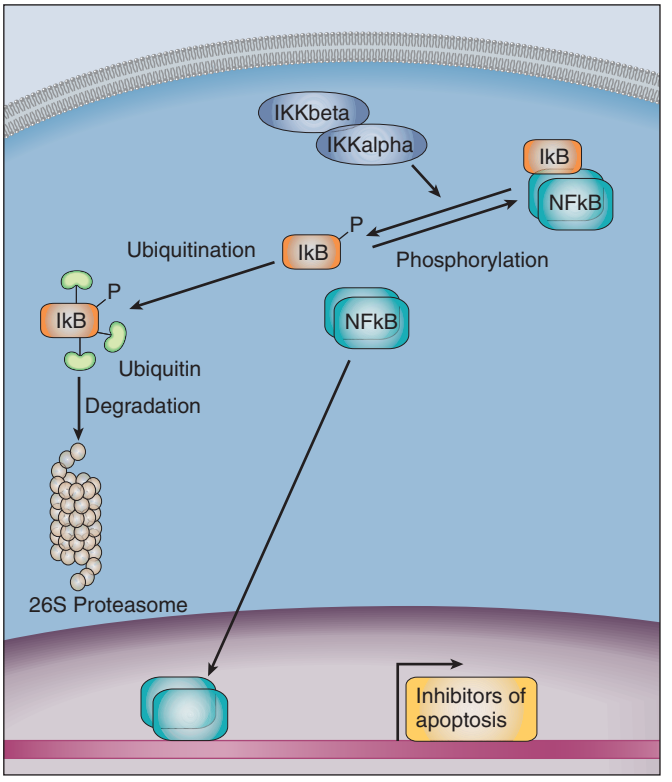

Figure 5-4 • NF-κB is a transcriptional activator of multiple antiapoptotic genes. Under resting conditions, NF-κB is bound by its inhibitor, IκB, which prevents its transcriptional activity by maintaining it in the cytoplasm. Activation signals stimulate activity of IκB kinases (IKK), which phosphorylate IκB. Phosphorylated IκB can then be ubiquitinated and targeted to the proteasome for degradation. This process releases NF-κB to enter the nucleus, where it activates transcription from its target promoters.

with immunologic adjuvants, suggesting a physiologic survival role for it in the immune system.[70] Mice expressing a *Bcl-3* transgene in B lymphocytes do not develop lymphoma, but they do show accumulation of B cells and hyper-responsiveness of the immune system, similar to the findings in *Bcl-2* transgenic mice.

PI3K/Akt

Many tumors lose extracellularly derived survival signals during pathogenesis, either by outstripping limited growth factors or by translocating to inappropriate environments. One signaling pathway that has been implicated in provision of survival signals is the phosphatidylinositol-3-kinase (PI3K) pathway.[71,72] Many growth factors, including interleukin-2, interleukin-3, platelet-derived growth factor, and insulin-like growth factor, signal in part through PI3K. PI3K phosphorylates phosphatidylinositide-4,5-bisphosphate (Ptd(4,5)P2) to Ptd(3,4,5)P3, which acts as a second messenger, activating downstream effectors such as the serine/threonine kinase Akt, also known as protein kinase B (PKB; Fig. 5-5). Akt seems to be a critical survival factor in many cell types, and its activity might promote survival through multiple functions, such as phosphorylation and inactivation of the BH3-only protein Bad, and through the Forkhead family transcription factor FKHRL1.[73] In addition, Akt acts in the insulin signaling pathway to promote glucose uptake, and it seems to play a similar role in non-insulin-responsive cells, promoting glucose uptake and glycolysis upon growth factor stimulation. It has been proposed that this metabolism-promoting effect of Akt might protect mitochondrial integrity through maintenance of substrate availability, thereby preventing apoptosis (Box 5-1).[74,75]

Another important mediator in the PI3K/Akt pathway is the mammalian target of rapamycin (mTOR). Akt indirectly activates mTOR through inhibitory phosphorylation of the TSC1/TSC2 complex,[76] leading to a complex interplay of proteins culminating in mTOR activation. Once active, mTOR promotes protein translation, leading to cell growth and proliferation. The complexity of this pathway, however, including multiple interacting protein partners and feedback mechanisms, makes it clear that the exact effects of mTOR activity on cell fate and cancer development require further elucidation.

Multiple studies have demonstrated the importance of Akt activity in tumorigenesis, either through amplification of one of the three AKT genes, or through loss of PTEN function. Amplification of *Akt* results in a similar phenotype to PTEN loss and has been found in gastric cancers, breast cancers, and other tumor types.[77–79] Furthermore, animal models also have demonstrated the role of Akt in tumorigenesis. Mice expressing constitutively active Akt in T cells develop thymic lymphoma at a high rate.[80] Furthermore, inhibition of mTOR activity diminishes tumor formation in mice heterozygous for PTEN, demonstrating the importance of mTOR in tumorigenesis mediated by this pathway.[81]

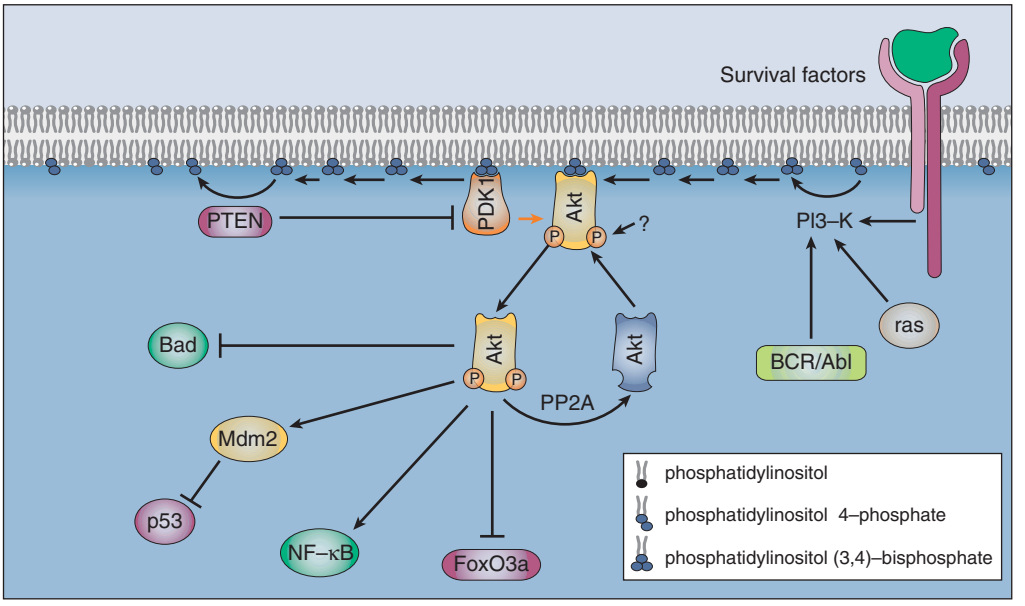

Figure 5-5 • The PI3K-Akt pathway is activated by multiple growth factor receptors and oncogenes and plays a critical role in promoting cell survival. PI3K is activated by growth factor stimulation or intracellular signals such as activated Ras or the oncogene *BCR-Abl*. Active PI3K phosphorylates phosphatidylinositols to phosphatidylinositol-3,4,5-triphosphate (PIP3) at the plasma membrane. PIP3 recruits Akt and its activating kinases, PDK1 and an uncharacterized PDK2, to the membrane, where Akt is phosphorylated and activated. Akt then promotes survival functions such as Bad and Forkhead inactivation, activation of NF-κB and MDM2, and glucose metabolism. PI3K activity is antagonized by the phosphatase PTEN, which degrades PIP3.

Box 5-1. METABOLIC DEREGULATION IN CANCER

Cells that lose survival signals fail to maintain themselves and undergo progressive atrophy. Loss of survival-inducing signal transduction leads to downregulation of cell-surface nutrient transporters (e.g., glucose transporters) and to a decreased rate of glucose metabolism, as indicated by decreased levels of hexokinase and phosphofructokinase, two key regulatory enzymes in the glycolytic pathway.[69,100–102] The loss of glycolytic products reduces delivery of substrate to the mitochondria, resulting in mitochondrial damage.

Nutrient limitation might have similar metabolic effects when cells accumulate in excess of the existing vascular supply.

In the 1920s, Warburg observed that cancer cells metabolize glucose at a higher rate than their normal counterparts. Furthermore, he found that the malignant cells relied on glycolysis for a disproportionate amount of their ATP production, with comparatively little energy produced by oxidative phosphorylation. Warburg hypothesized that this shift to aerobic glycolysis resulted from defects in mitochondrial function in the cancer cells.

Other researchers have subsequently confirmed Warburg's findings of increased aerobic glycolysis in cancer cells. The high rate of glucose uptake in tumors has formed the basis of a novel imaging modality, positron emission tomography (PET), using a fluorine-18-labeled glucose analog. A study evaluating PET scanning in lymphoma showed that more than 90% of lymphomas—including very indolent tumors—metabolize glucose at an abnormally high rate.[103] Although several research groups have found mutations in genes that encode mitochondrial enzymes in cancer cells, the fact that normal lymphocytes are unable to maintain glucose uptake and glycolysis in the face of dropping ATP levels suggests an alternative hypothesis. In this scenario, normal cells lack the ability to take up sufficient glucose to maintain themselves and instead are dependent on extrinsic signal transduction to maintain the expression and function of nutrient transporters. As a corollary, mutations that activate such signaling pathways could permit the cell to take up glucose in excess of that needed for bioenergetic or synthetic activities. Under such conditions, cells would secrete the excess glucose as lactate and have sufficient bioenergetic reserves to support entry into and progression through the cell cycle.

These findings raise the possibility that cancer cells, in the process of transformation, turn on signaling pathways that allow autonomous access to nutrients and metabolic pathways, rendering the cells independent of the extracellular signals normally required to maintain nutrient uptake. This facilitated access to nutrients would provide substrate to mitochondria, allowing maintenance of mitochondrial function and suppression of apoptosis even in the absence of growth factor signaling. If this hypothesis is true, autonomous access to nutrients is probably accomplished in multiple ways by different tumors.

One potential contributor to this goal is Akt. Akt is critical in the insulin signaling pathway to activate glucose uptake in insulin-responsive tissues, and it seems to play a similar role in non-insulin-responsive cells on growth factor stimulation. Although the role of *Akt* as an oncogene might include several functions, it clearly has the potential to promote glucose transporter expression and activity of glycolytic enzymes.

The role of metabolic control in tumorigenesis is poorly understood. Elucidation of this fundamental process in cancer might offer greater appreciation for the mechanisms of carcinogenesis.

Furthermore, the recognition of the importance of metabolic control in cancer could offer new therapeutic targets, improving our chances of defeating cancer in the future.

Epigenetic Gene Silencing

Inhibition of expression of tumor suppressor genes through epigenetic mechanisms is emerging as an important mechanism by which tumor cells might disable proapoptotic pathways. Promoter methylation at CpG islands could repress transcription of genes in the absence of mutation (Fig. 5-6). In addition, histone deacetylation might also turn off gene expression, possibly by inhibiting access of transcription factors (TF). For example, Soengas and associates[82] have shown that many melanoma cells (both primary tumors and cell lines) suppress Apaf-1 expression. This results in inhibition of p53-dependent apoptosis in these cells and renders them resistant to chemotherapy. Apaf-1 suppression is mediated not by mutation of *Apaf-1* but instead through methylation, because treatment with the methylation inhibitor 5-azacytidine restores both Apaf-1 expression and chemosensitivity. Methylation seems to play an important role in suppression of tumor suppressors in other tumors as well. For example, childhood neuroblastomas show loss of expression of caspase 8 through methylation of its promoter at high frequency.[83] Finally, promoter methylation of the *p14ARF* locus might suppress its expression in multiple tumor types.[84]

Acetylation of histones can also repress transcription of genes important in regulation of cell death. Global changes in histone acetylation have been found in cancer cells and are hypothesized to contribute to aberrant gene expression promoting survival and malignancy.[85]

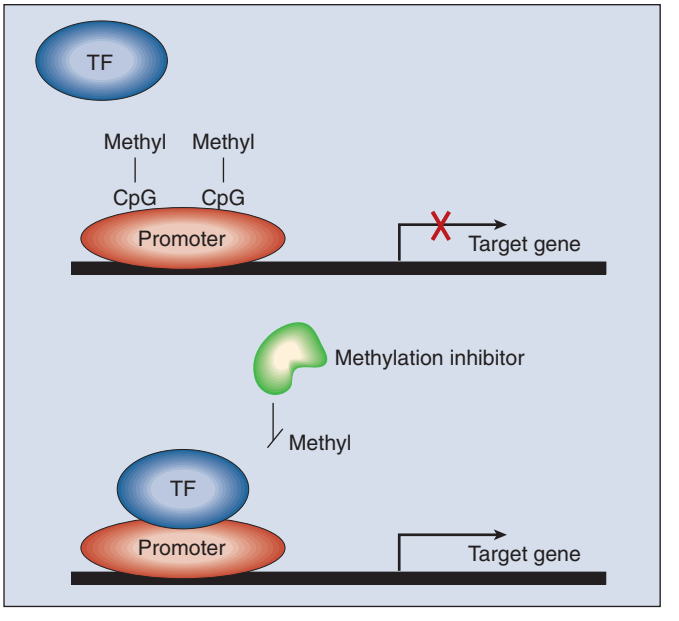

Figure 5-6 • Epigenetic gene silencing is a mechanism by which cancer cells turn off tumor suppressor gene expression. In the process of development or oncogenesis, genes might be silenced through promoter methylation. In tumors, promoters of tumor suppressor genes such as *Apaf-1* and caspase 8 are frequent targets of methylation. Methylation inhibitors such as 5-azacytidine reactivate expression of these tumor suppressor genes, potentially contributing to anticancer therapy.

MANIPULATING CELL DEATH IN CANCER TREATMENT

As discussed previously, cancer cells must dismantle or inhibit apoptotic pathways to maintain their transformed phenotype. Many trans-

formation-inducing mutations also have the effect of promoting programmed cell death, and cells are unable to pass through these initial changes to become cancer unless apoptosis is inhibited. This fact has two correlates. First, most traditional cancer chemotherapies act through induction of apoptosis, and the intrinsic apoptotic defects of these cells could make them inherently resistant to chemotherapy. On the other hand, cancer cells are constantly living "on the edge," pushed beyond the normal limits of cell viability. This fact might make tumor cells profoundly susceptible to apoptosis if either the defect can be corrected or another death pathway can be activated. This reasoning is the basis of the many attempts currently in progress to design therapies that will attain one of these objectives.

Restoration of Apoptotic Capability

Restoration of lost apoptotic pathways can be accomplished by several methods. First, if a proapoptotic gene, such as *p53,* is mutated, gene therapy provides a direct way in which to restore expression of the missing protein. One approach has been to attempt to deliver the gene in question via an adenoviral vector, for example with *p53* in tumors of the head and neck, and in lung tumors[86,87]; some success has been seen with intratumoral injections. Systemic therapy poses an additional challenge, however, in terms of both feasibility and safety. The effect of gene therapy with *p53* would be expected to be seen only in cells in which the transgene is expressed, requiring that every cell be infected by the vector. Furthermore, the safety of adenovirus vectors remains at issue.

Another, similar approach has been to target cancer cells lacking *p53* by taking advantage of the fact that adenovirus must inactivate *p53* to replicate in cells. Usually this is accomplished through the activity of the virus's E1Bp55 protein, which binds and inactivates p53. A virus that lacks E1Bp55 is unable to replicate in normal cells. Cancer cells that lack *p53* present a viable target, however, allowing the virus to accomplish its lytic life cycle and killing the cell. This approach is being used clinically with the drug ONYX-015, which, similar to *p53* gene therapy, has shown success with intratumoral injection in combination with chemotherapy in head and neck cancers.[88] Once again, systemic delivery seems more problematic.

In a strategy that is growing in importance in cancer therapy, small molecules targeting the p53 pathway have been designed to restore p53 function. One approach takes advantage of the fact that, in most cancers, *p53* is inactivated not by deletion but rather through a point mutation that results in accumulation of inactive protein. CP-31398 is a drug found in a screen for therapeutic agents that restore wild-type conformation to mutant p53 in tumor cells.[89] Since its identification, researchers have found conflicting data regarding its ability to restore p53 function in tumor cells, with some studies finding evidence of restoration of p53 function but others reporting nonspecific toxicity.[90,91]

Another approach has been to target the interaction of p53 with the inhibitory molecule MDM-2. Small-molecule inhibitors have been identified and have shown promise in preclinical studies.[92] Early-phase clinical studies using this approach are expected to be underway shortly.

The realization that many cancer cells turn off expression of proapoptotic genes by epigenetic mechanisms has provided another approach to the restoration of tumor suppressor function. Histone deacetylase inhibitors have entered clinical trials and have shown evidence of activity.[93,94] One of these, suberoylanilide hydroxamic acid, has shown activity in several tumor types and has been approved for use in cutaneous T-cell lymphomas. DNA methylation inhibitors are also in development.[95] The lack of specificity of these treatments raises theoretical concerns that genes which have been silenced in differentiation (e.g., *hTERT,* the human telomerase gene that might play a role in tumor promotion) or other tumor-promoting genes could be turned on through demethylation or deacetylation. Silencing of TRAIL decoy receptors through methylation has been demonstrated in cancer cells.[96] The end result of these therapies could depend on the balance of genes silenced through epigenetic mechanisms in each cancer, but early clinical trials are promising.

Inhibition of Survival Factors

Small-molecule inhibitors might show promise in the inhibition of survival factors expressed in cancer cells. The 26S proteasome is important in myriad cellular pathways, but its importance in activation of NF-κB, through degradation of IκB, has raised the possibility that inhibition of proteasomal degradation could have proapoptotic effects in cancer cells. Akt has also been reported to phosphorylate the tumor suppressor genes *TSC1* and *TSC2* and target them for proteasomal degradation.[97] Bortezomib, a proteasomal inhibitor, has shown activity in several hematologic malignancies, notably multiple myeloma,[98] in which it has been approved by the FDA for use, and mantle cell lymphoma. The activity of bortezomib as a sensitizing agent, lowering the threshold for apoptosis in response to other cytotoxic agents, is also under active investigation.

Small-molecule inhibitors targeting several other components of survival pathways are under development. Inhibitors of mTOR and Akt are currently in clinical trials, and a small-molecule inhibitor of Bcl-2 is undergoing preclinical testing at the time of this writing.[99] Inhibitors of IAP molecules are also drawing interest and under preclinical development.

Antisense strategies have been explored to target antiapoptotic molecules. Antisense oligonucleotides act by binding to specific messenger RNAs, forming double-stranded RNA complexes.These complexes might inhibit expression of the target messenger RNAs, either by blocking translation or through targeting them for destruction by the cell through recognition of abnormal double-stranded RNA. The most developed of these antisense oligonucleotides is one targeted against *Bcl-2,*[100–102] oblimersen, also known as Genasense. Trials in hematologic malignancies and in several solid tumors have shown some activity and it might be particularly useful as a sensitizing agent when used in combination with other cytotoxic therapies.

Death Receptor Activation

As discussed in previous sections, death receptor signaling seems to play an important role in some tumors. Initial studies examined the use of Fas and TNF as death-inducing ligands. Yet, although these molecules demonstrated antitumor activity, their utility as therapeutic agents has been compromised by toxicity, with both normal cells and malignant cells targeted for death.

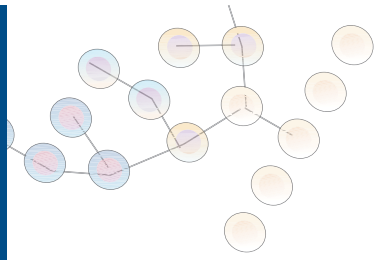
Investigations of TRAIL have raised the possibility that this ligand might be more selective for tumor cells. Most normal cells express decoy receptors that sequester TRAIL, preventing it from sending an intracellular death signal. Tumor cells seem to be uniquely sensitive to the apoptotic stimulus of TRAIL; one reason might be downregulation of decoy receptor expression, possibly by promoter methylation.[87] Studies in mice and nonhuman primates have demonstrated minimal toxicity to normal cells with administration of TRAIL.[103,104] When researchers examined the effects of TRAIL on human hepatocytes in vitro, however, it was found to cause significant cell death, raising the question whether TRAIL, like its counterparts Fas and TNF, might be too toxic for use in humans at therapeutic doses.[105] Early-phase clinical trials of TRAIL are underway.

Induction of Necrosis

The recognition of necrosis as a regulated, physiologic process raises the possibility that induction of necrotic cell death might present advantages in targeting cancer cells. Some currently used therapeutics might act in large part through inducing necrosis, and a strategy priming cells for necrotic cell death could contribute to the effectiveness of these treatments. As discussed previously, the metabolic state of a cancer cell seems to predispose it to necrosis in response to DNA damage through loss of the ability to produce ATP through glycolysis. Cancer cells might be sensitized to the effects of DNA-damaging

agents if also treated with agents that interfere with glycolysis. Whereas all cells depend to some extent on glycolytic metabolism, a modest inhibition of glycolysis in cells that are highly dependent on this pathway could potentially enhance the effects of DNA damage-based treatments. Other strategies to induce necrosis, such as induction of reactive oxygen species and promotion of RIP activity, might also be optimized as our understanding of these pathways increases. A potential advantage of necrosis as a treatment strategy lies in the potential to promote an immune reaction, and therefore possibly recruit the immune system to assist in fighting the tumor.

SUMMARY



Understanding of mechanisms of cell death and their importance in tumorigenesis is evolving rapidly. Our interpretation of these findings will certainly undergo revision as more information constantly becomes available. The current appreciation for these processes, however, already has provided opportunities for advancement of patient care.

In the future, research further clarifying the basic mechanisms of programmed cell death—including events mediating mitochondrial demise along with a better understanding of the nature of death signals—will continue to improve our arsenal of potential weapons against cancer. As has been found with traditional antineoplastic therapies, success will most likely be found with a combination of therapeutic approaches. These might include the addition of apoptosis-based therapies to traditional agents, combining proapoptotic with antisurvival approaches, along with strategies to manipulate both forms of cell death that await development as knowledge of these complex processes evolves.

6 Cancer Immunology

Drew M. Pardoll

SUMMARY OF KEY POINTS

- Cancer cells develop, grow, invade, and metastasize in the context of an organized microenvironment. This is reflected by the fact that for many cancers the majority of cells within the tumor mass are nontransformed.
- The relationship between the tumor cells and the nontransformed cells composing the tumor microenvironment is dynamic and active.
- The immune system is a major component of the tumor microenvironment, and therefore, the tumor must actively organize the immunologic component of its microenvironment.
- Because the immune response—particularly that mediated by killer T cells and cells of the innate immune system—can be a potent enemy to the tumor, a successful cancer must develop mechanisms to instruct the immune system to "tolerate" its existence, particularly when it is invading through tissue barriers and metastasizing to many organ sites.
- If a tumor fails to develop these tolerance induction and immunologic resistance mechanisms, the immune system will eliminate it.
- Oncogenic pathways in the tumor not only mediate cell growth, metabolic activity, and antiapoptotic activity, they also mediate interactions with the immune system.
- Ultimately, tumors do more than merely inhibit effecter functions of the immune system that can be detrimental to them. Tumors can in fact alter immunologic activity to promote tumor growth and development.
- We are now beginning to understand the molecular and cellular basis for tumor–immune system interactions, providing specific molecular targets for immunologic intervention.

OVERVIEW

Historically, interest in cancer immunology stemmed from the perceived potential activity of the immune system as a weapon against cancer cells. In fact, the term "magic bullet," commonly used to describe many visions of cancer therapy, was coined by Paul Ehrlich in the late 1800s in reference to antibodies targeting both microbes and tumors. Central to the concept of successful cancer immunotherapy are the dual tenets that tumor cells express an antigenic profile distinct from their normal cellular counterparts and that the immune system is capable of recognizing these antigenic differences. Support for this notion originally came from animal models of carcinogen-induced cancer in which it was demonstrated that a significant number of experimentally induced tumors could be rejected upon transplantation into syngeneic immunocompetent animals.[1–4] Extensive studies by Prehn on the phenomenon of tumor rejection suggested that the most potent tumor rejection antigens were unique to the individual tumor.[5]

As cancer genetics and genomics has exploded over the past decade, it is now quite clear that altered genetic and epigenetic features of tumor cells indeed result in a distinct tumor antigen profile. Overexpression of "oncogenic" growth factor receptor tyrosine kinases such as HER2/Neu and epidermal growth factor receptor (EGFR) via epigenetic mechanisms has provided clinically relevant targets for one arm of the immune system—antibodies.[6,7] Indeed, monoclonal antibodies are the largest growing single class of cancer therapeutics based on successful new U.S. Food and Drug Administration approvals. In striking contrast, cellular immunotherapy of cancer has been quite disappointing in establishing therapeutic success in clinical trials thus far. Emerging insights about the nature of the interaction between the cancer and the immune system have led us to understand why cell-based cancer immunotherapy approaches such as therapeutic vaccines have been less potent against established cancer than originally imagined. In general, we have learned that tumors use mechanisms of tolerance induction to turn off T cells specific for tumor-associated antigens. Oncogenic pathways in tumors result in the elaboration of factors that organize the tumor microenvironment in ways that are quite hostile to antitumor immune responses.

Not only is the cancer capable of inducing potent tolerance among tumor-specific T cells, we now know that there are distinct forms of inflammatory and immune responses that are procarcinogenic. Thus, two frontiers in cancer immunology are the elucidation of how the tumor organizes its immune-microenvironment as well as the nature of immune responses that are anticarcinogenic versus procarcinogenic. As the receptors, ligands, and signaling pathways that mediate immune tolerance and immune-induced procarcinogenic events are elucidated, these factors and pathways can be selectively inhibited by both antibodies and drugs in a way to shift the balance to antitumor immune responses. This chapter will outline the major features of tumor–immune system interactions and set the stage for molecularly based approaches to manipulate immune responses for successful cancer therapy.

HOW DO TUMORS DIFFER FROM SELF TISSUES?

Tumors differ fundamentally from their normal cell counterparts in both antigenic composition and biologic behavior. Genetic instability, a basic hallmark of cancer, is a primary generator of tumor-specific antigens. The most common genetic alteration in cancer is mutation,

which arises from defects in DNA damage repair systems of the tumor cell.[8–15] Recent estimates from genome-wide sequencing efforts suggest that every tumor contains a few hundred mutations in coding regions.[16] Additionally, deletions, amplifications, and chromosomal rearrangements can result in new genetic sequences resulting from juxtaposition of coding sequences not normally contiguous in untransformed cells. The vast majority of these mutations occur in intracellular proteins, and thus, the "neoantigens" they encode would not be readily targeted by antibodies. However, the major histocompatibility complex (MHC) presentation system for T-cell recognition makes peptides derived from all cellular proteins available on the cell surface as peptide-MHC complexes capable of being recognized by T cells. Based on analysis of sequence motifs, it is estimated that roughly one-third of the mutations identified from genome sequencing of 22 breast and colon cancers[16] were capable of binding to common human lymphocyte antigen (HLA) alleles based on analysis of sequence motifs (J.P. Allison, personal communication).

In accordance with the original findings of Prehn,[5] the vast majority of tumor-specific antigens derived from mutation as a consequence of genetic instability are unique to individual tumors. The consequence of this is that antigen-specific immunotherapies targeted at most truly tumor-specific antigens would by necessity be patient specific. However, there are a growing number of examples of tumor-specific mutations that are shared. The three best-studied examples are the Kras codon 12 G→A (found in roughly 40% of colon cancers and >75% of pancreas cancers), the BRAF V599E (found in roughly 70% of melanomas) and the p53 codon 249 G→T mutation (found in ~50% of hepatocellular carcinomas).[17–20] As with nonshared mutations, these common tumor-specific mutations all occur in intracellular proteins, and therefore require T-cell recognition of MHC-presented peptides for immune recognition. Indeed, both the Kras codon 12 G→A and the BRAF V599E mutations result in "neopeptides" capable of being recognized by HLA class 1- and class II-restricted T cells.[21–24]

The other major difference between tumor cells and their normal counterparts derives from epigenetics.[25] Global alterations in DNA methylation as well as chromatin structure in tumor cells results in dramatic shifts in gene expression. All tumors overexpress hundreds of genes relative to their normal counterparts, and in many cases, turn on genes that are normally completely silent in their normal cellular counterparts. Overexpressed genes in tumor cells represent the most commonly targeted tumor antigens by both antibodies and cellular immunotherapies. This is because, in contrast to most antigens derived from mutation, overexpressed genes are shared among many tumors of a given tissue origin or sometime multiple tumor types. For example, mesothelin, which is targeted by T cells from vaccinated pancreatic cancer patients,[26] is highly expressed in virtually all pancreatic cancers, mesotheliomas, and most ovarian cancers.[27,28] Whereas mesothelin is expressed at low to moderate levels in the pleural mesothelium, it is not expressed at all in normal pancreatic or ovarian ductal epithelial cells.

The most dramatic examples of tumor-selective expression of epigenetically altered gene are the so-called cancer-testis antigens.[29] These genes seem to be highly restricted in their expression in the adult. Many are expressed selectively in the testis of males and are not expressed at all in females. Expression in the testis seems to be restricted to germ cells, and some of these genes actually seem to encode proteins associated with meiosis.[30–32] Cancer-testis antigens therefore represent examples of widely shared tumor-selective antigens whose expression is highly restricted to tumors. Many cancer-testis antigens have been shown to be recognized by T cells from nonvaccinated and vaccinated cancer patients.[29] From the standpoint of immunotherapeutic targeting, a major drawback of the cancer-testis antigens is that none appear to be necessary for the tumors' growth or survival. Therefore, their expression seems to be purely the consequence of epigenetic instability rather than selection, and antigen-negative variants are easily selected out in the face of immunotherapeutic targeting.

A final category of tumor antigen that has received much attention encompasses tissue-specific antigens shared by tumors of similar histologic origin. Interest in this class of antigen as a tumor-selective antigen arose when melanoma-reactive T cells derived from melanoma patients were found to recognize tyrosinase, a melanocyte-specific protein required for melanin synthesis.[33,34] In fact, the most commonly generated melanoma-reactive T cells from melanoma patients recognize melanocyte antigens.[35] Although one cannot formally call tissue-specific antigens tumor specific, they are nonetheless potentially viable targets for therapeutic T-cell responses when the tissue is dispensable (e.g., prostate cancer or melanoma).

From the standpoint of T-cell targeting, tumor antigens upregulated as a consequence of epigenetic alterations represent "self-antigens" and are therefore likely to induce some level of immune tolerance. However, it is now clear that the stringencies of immune tolerance against different self-antigens differ according to tissue distribution and normal expression level within normal cells. The mesothelin antigen described previously is such an example. In a recent set of clinical pancreatic cancer vaccine studies, mesothelin-specific T-cell responses were induced by vaccination with genetically modified pancreatic tumor cell vaccines and induction of mesothelin-specific T cells correlated with ultimate disease outcome. Given that the immune system is capable of differential responsiveness determined by antigen levels, it is quite possible to imagine generating tumor-selective immune responses against antigens whose expression level in the tumor is significantly greater within normal cells in the tumor-bearing host. Additionally, upregulated antigens that provide physiologically relevant growth or survival advantages to the tumor are preferred targets for any form of therapy, because they are not so readily selected out.

Beyond the antigenic differences between tumor cells and normal cells, there are important immunologic consequences to the distinct biologic behavior of tumor cells relative to their normal counterparts. Whereas uncontrolled growth is certainly a common biologic feature of all tumors, the major pathophysiologic characteristics of malignant cancer responsible for morbidity and mortality are their ability to invade through natural tissue barriers and ultimately to metastasize. Both of these characteristics, never observed in nontransformed cells, are associated with dramatic disruption and remodeling of tissue architecture.

Indeed, the tumor microenvironment is quite distinct from the microenvironment of normal tissue counterparts. One of the important consequences of tissue disruption, even when caused by noninfectious mechanisms, is the elaboration of proinflammatory signals. These signals, generally in the form of cytokines and chemokines, are potentially capable of naturally initiating innate and adaptive immune responses. Indeed, the level of leukocyte infiltration into the microenvironment of tumors tends to be significantly greater than the leukocyte component of their normal tissue counterparts. Cancers are therefore constantly confronted with inflammatory responses as they invade tissues and metastasize. In some circumstances these inflammatory and immune responses can potentially eliminate a tumor—so called immune surveillance. However, as will be discussed, oncogenic pathways in the tumor seem to organize the immunologic component of the microenvironment in a fashion that not only protects itself from antitumor immune responses, they can qualitatively shift immune responses to those that actually support and promote tumor growth. Thus, just as with Annekin Skywalker, the tumors can entice the immune system to the dark side. It is these elements of the cancer–immune system interaction that will be the central targets of future immunotherapeutic strategies.

EVIDENCE PRO AND CON FOR IMMUNE SURVEILLANCE OF CANCER

The fundamental tenet of the immune surveillance hypothesis, first conceived nearly a half-century ago,[36,37] is that a fundamental role of

Box 6-1. HOW IMPORTANT IS IMMUNE SURVEILLANCE OF CANCER?

Few questions in cancer immunology have been more controversial than the immune surveillance hypothesis. First put forward by Lewis Thomas over a half century ago, the original immune surveillance hypothesis proposed that a natural role for the immune system was to survey the body for tumors similarly to the way the immune system surveys the body for invading foreign pathogens. Tumors were proposed to be distinguished from self-tissues by virtue of expression of tumor-specific antigens (TSAs). One aspect of this hypothesis that has held up to experimental testing has been the existence of TSAs. We now know that the genetic instability of tumor cells generates genetic and epigenetic changes that translate to antigens capable of being recognized by the immune system. However, because tumors seem to have developed mechanisms to subvert immunogenicity and tolerize the immune system, it is generally no longer believed that immune surveillance represents a major endogenous defense against tumorigenesis. It is likely that guardians of the genome that sense DNA damage, such as the ATR/ATM/p53 system, are much more fundamental mechanisms to protect against transformation. However, certain specialized components of the immune system, such as interepithelial lymphocytes activated by stress-induced ligands, may indeed play a complementary role in immune surveillance among specific epithelial tissues that are frequently exposed to carcinogenic stress. The best example is the intraepithelial lymphocytes within cutaneous epithelium that is constantly exposed to carcinogenic ultraviolet irradiation. A more moderate view of immune surveillance has been summarized by the hypothesis of Schreiber and colleagues that tumors "edit" themselves to either become resistant to immunologic surveillance or upregulate pathways (such as the STAT3 pathway) that actively induce tolerance among components of the immune system capable of recognizing TSAs.[57–59]

the immune system is to survey the body for tumors as it does for infection with pathogens, recognizing and eliminating them based on their expression of tumor-associated antigens (Box 6-1). In animal models, carcinogen-induced tumors can be divided into those that grow progressively (termed progresser tumors) and those that are rejected after an initial period of growth (termed regresser tumors).[1,2] The phenomenon of regresser tumors was thought to represent an example of the ongoing process of immune surveillance of cancer. A corollary to the original immune surveillance hypothesis is that progresser tumors in animals (presumed to represent clinically progressing cancers in humans) fail to be eliminated because they develop active mechanisms of either immune escape or resistance (Fig. 6-1).

A fundamental prediction of the immune surveillance hypothesis is that immunodeficient individuals would display a dramatic increase in tumor incidence. After an extensive analysis of spontaneous tumor formation in immunodeficient nude mice, which have atrophic thymi and therefore significantly reduced numbers of T cells and T-cell-dependent immune responses, no increased incidence of tumors was observed.[38–42] These studies were taken as a major blow to the immune surveillance hypothesis. However, a caveat to the interpretation of these results is that nude mice still produce diminished numbers of T cells via thymus-independent pathways and therefore can mediate some degree of T-cell-dependent immunity. In addition, nude mice frequently display compensatory increases in innate immunity that, as in the following discussion, may represent a potent form of antitumor immunity and could contribute to immune surveillance of cancer.

Epidemiologic studies of patients with heritable immunodeficiencies revealed a significantly increased risk of certain cancers that are distinct from the epithelial cancers commonly observed in normal immunocompetent adults.[43–45] Many of these cancers are also observed in transplant patients on chronic pharmacologic immune suppression as well as in human immunodeficiency virus/acquired immunodeficiency syndrome patients whose immune system is depressed. The most common cancers in these individuals include lymphoplastic lymphomas as well as Kaposi's sarcoma; however, certain epithelial cancers, such as stomach cancer, were also observed at increased frequency. A unifying theme for the majority of cancers observed in immunodeficient individuals is their microbial origin. The majority of lymphoplastic lymphomas are Epstein-Barr virus-associated lymphomas,[46] and Kaposi's sarcoma is a result of infection with the herpesvirus KSHV (Kaposi's sarcoma herpesvirus).[47] Other virus-associated cancers such as cervical cancer (from human papillomavirus [HPV])[48,49] are also observed at increased frequency. It is now appreciated that stomach cancer is associated with ulcer disease related to infection with the bacterium *Helicobacter pylori*.[50,51] From these studies, the notion emerged that immune surveillance indeed protects individuals against certain pathogen-associated cancers by either preventing infection or altering chronic infection by viruses and other microbes that can eventually induce cancer. These studies were taken to represent evidence that the common non-pathogen-associated cancers most commonly seen in adults in developed countries (e.g., prostate cancer, colon cancer, lung cancer) are not subject to immune surveillance.

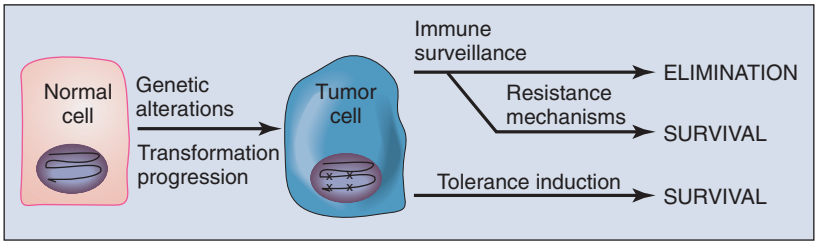

Figure 6-1 • The balance among immune surveillance, resistance, and tolerance. Transformation of normal cells to cancer cells involves the creation of true neoantigens resulting from mutation as well as upregulation of self-antigens resulting from epigenetic forces. Successful immune surveillance of tumors based on recognition of these tumor-specific antigens would lead to tumor elimination at early stages. Clinically relevant tumor survival and progression requires that tumors develop resistance mechanisms that inhibit tumor-specific immune responses to kill tumor cells. Alternatively, if the tumor develops mechanisms to induce immune tolerance to its antigens, antitumor effector responses do not develop. Evidence is accumulating that tumors actively develop immune resistance mechanisms as well as immune tolerance mechanisms to survive despite displaying antigens capable of recognition by the immune system.

Two caveats to this interpretation must be noted, however. First, detailed epidemiologic analyses of immunodeficient individuals were performed at a time when these patients rarely lived beyond their 20s and 30s, when cancer incidence normally increases most significantly. It is therefore possible that a more subtle cumulative increased incidence of common non-pathogen-associated cancers would have been observed had these individuals lived further into adulthood. Indeed, more recent analyses definitively demonstrate an increased incidence of some non-pathogen-associated cancers, in immunodeficient individuals, particularly melanoma.[52]

In addition to epidemiologic data, dramatic anecdotal examples are difficult to ignore. There have been reports that patients receiving kidneys from a cadaver donor that had been in complete remission from a melanoma before organ donation each rapidly developed metastatic melanoma of donor origin after the transplant.[53–55] These results indicate that at least for some non-pathogen-associated tumors, the immune system can play a significant role in maintaining the micrometastatic disease in a dormant state. Whether this principle applies to other non-pathogen-associated human tumors besides melanoma remains to be demonstrated.

Several recent studies reevaluating tumor immune surveillance in genetically manipulated mice have revealed clear-cut evidence that various components of the immune system can at least modify, if not eliminate, both carcinogen-induced and spontaneously arising cancers. In a series of studies by Schreiber and colleagues reexamining cancer incidence in mice rendered immunodeficient via genetic knockout of either the *RAG2* gene (deficient in both B and T cells), the γ-interferon receptor gene, *STAT 1* gene, or the *type 1 interferon receptor* gene.[56–59] When these knockout mice are either treated with carcinogens or crossed onto a cancer-prone *p53* knockout background, the incidence of cancers was modestly but significantly increased relative to nonimmunodeficient counterparts when observed over an extended period (longer than 1 year). Transplantation studies demonstrated that direct γ-interferon insensitivity by the developing tumors played a significant role in the defect in immune surveillance. Interestingly, in contrast to γ-interferon receptor knockout mice, the mechanism for increased tumor incidence in tumors in *type 1 interferon receptor* knockout mice did not involve sensitivity by the tumor to type 1 interferons but rather reflected the role of the type 1 interferons in induction of innate and adaptive immunity. Even animals not crossed onto a cancer-prone genetic background or treated with carcinogens developed an increased incidence of invasive adenocarcinomas when observed over their entire life span.

Furthermore, γ-interferon, *RAG2* double-knockout mice developed a broader spectrum of tumors than *RAG2* knockout mice. All of the tumors that arise in these genetically manipulated immunodeficient animals behave as regresser tumors when transplanted into immunocompetent animals. These findings indeed suggest that tumors that arise in immunodeficient animals would have been eliminated had they arisen in immunocompetent animals.

The relatively subtle effects on tumorigenesis, requiring observation over the life span of the animal, suggest that the original concept of immune surveillance of tumors arising on a daily basis is in fact not correct. Instead, it is clear that the presence of a competent immune system "sculpts" the tumor through a process that has been termed immunoediting. One of the caveats in the interpretation of these studies comes from the work of Enzler and Dranoff, who studied mechanisms of increased tumorigenesis in granulocyte-macrophage colony-stimulating factor (GM-CSF), γ-interferon double-knockout mice.[60] Although they observed an increase in gastrointestinal and pulmonary tumors, they noted that such animals harbored infection with a particular bacterium not normally observed in immunocompetent animals. Maintenance of these double-knockout mice on antibiotics essentially eliminated the increased rate of tumor formation. Thus, it is possible that some of the increased tumor rates in genetically immunodeficient animals could be related to unappreciated chronic infections that develop in these animals, which are not housed under germ-free conditions. Nonetheless, although the classic concepts of immune surveillance of cancer remain unsupported by experimental evidence, studies on tumorigenesis in genetically manipulated immunodeficient mice indeed suggest that developing tumors must actively adapt themselves to their immune microenvironment to exist within the context of a competent immune system.

INNATE IMMUNITY, EPITHELIAL IMMUNITY, AND TUMOR IMMUNE SURVEILLANCE

Although much emphasis has been placed on the role of adaptive immunity, particularly of conventional T cells in immune surveillance of cancer, a confluence of more recent findings points to innate immunity and epithelial immunity in the immunologic sensing of carcinogenic events in the skin, gut, and possibly other sites. Much of the evidence focuses on the NKG2D receptor. NKG2D was originally defined as an activating natural killer (NK) receptor.[61–63] Most NK receptors seem to be inhibitory when engaged; this inhibition is often associated with ITIM (immunoreceptor tyrosine kinase-based inhibitory motif) domains in the cytoplasmic tails. ITIMs provide docking sites for phosphatases that oppose the activity of tyrosine kinases involved in lymphocyte activation. NK activation status is a balance between engagement of activating and inhibitory receptors. NKG2D, the best-studied activating receptor on NK cells, is somewhat unusual in that it does not contain an ITAM (immunoreceptor tyrosine kinase-activating motif) and is associated with an adaptor molecule, DAP 10, which contains neither conventional ITIMs nor ITAMs.[64] Instead, DAP 10 contains a KYXXM motif that seems to bind to phosphatidyl inositol (PI) 3 kinase upon phosphorylation of the tyrosine in this motif. NKG2D is expressed on all NK cells as well as on some αβ and γδ T cells. Beyond NK cells, NKG2D is expressed at high levels on a number of subsets of interepithelial lymphocytes (IELs).

IELs represent a distinct population of lymphocytes residing in epithelial tissues that display features of both adaptive and innate immune responses.[65–69] They are thought to represent a major first line of defense against pathogens attempting to invade across epithelial linings exposed to the environment (i.e., skin, gut, respiratory tract). Fifty percent of the IELs of the gut express the γδ T-cell receptor (TCR), which is normally expressed by less than 3% of circulating T cells, whereas the other 50% express the common αβ TCR. γδ TCR-expressing IELs in different compartments express a very restricted repertoire and are thought to recognize certain types of microbial antigens or potentially self-antigens associated with stress or inflammatory responses to microbial infection. Even the αβ TCR-expressing IELs have an extremely restricted TCR repertoire similar to invariant NK T cells. A significant subset of gut IELs express a particular $V_\alpha V_\beta$ and are thought to recognize a limited subset of microbial or self nonpeptide antigens presented by nonclassical class 1 MHC molecules. Thus, NKG2D expression marks diverse subsets of lymphocytes that, though expressing different families of recognition receptors, act as components of innate immunity in that they recognize a stereotypical set of antigens associated with infection or stress (see later discussion).

The first evidence that the NKG2D receptor might play a role in tumor immune surveillance came from the finding that normal colonic epithelium as well as a significant proportion of tumors could express the two defined human ligands for NKG2D: MICA and MICB. MICA and MICB, which represent nonclassical MHC class I-type molecules whose structure demonstrates no antigen-binding groove characteristic of most MHC molecules, are stress-induced proteins whose genes contain stress response elements in their promoters.[70,71] Raulet and colleagues have demonstrated that upregulation of MICA/B is induced through the ATM/ATR/Chk1 pathway of DNA damage recognition.[72] An analysis in human cancer suggested a correlation between expression of MICA/B and infiltration of certain subsets of γδ T cells that express NKG2D. Initially it was proposed

that MICA and MICB were direct ligands for specific γδ receptors themselves as well as NKG2D,[73,74] but this idea is controversial.

MICA and MICB do not have any murine orthologs, but murine NKG2D does bind to products of the retinoic acid-inducible gene family, RAE-1α-RAE-1ε, as well as the product of the *H60* gene. ULBP3 is an additional NKG2D ligand to be described.[75,76] These NKG2D ligands seem to be involved in immune recognition and possibly tumor surveillance in mice.[77–79] Recognition and killing of murine skin keratinocytes or intestinal epithelial cells by γδ IELs require expression of NKG2D ligands and are blocked by anti-NKG2D antibodies. Trasnfection of murine tumors with genes encoding NKG2D ligands renders them susceptible to NKG2D-dependent killing by NK cells. Emerging data on NKG2D function on IELs together with the potentially stress-induced nature of its ligands suggests that the IEL system of immune surveillance may indeed be relevant to carcinogenesis as well as infectious challenges.[80] The major initiating event of carcinogenesis in the skin—ultravioleet light—is a potent source of DNA damage that, as mentioned previously, has been shown to induce NKG2D ligands via the ATM pathway. Thus, in addition to endogenous killers of genome-damaged cells, such as p53, IELs and NK cells may represent an extrinsic sensor of DNA damage and genotoxic stress via recognition of cells that have upregulated NKG2D ligands (Fig. 6-2).

As with the case of classic immune surveillance mediated by classical T cells, the emergence of a clinically evident cancer implies that the tumor has developed a mechanism to circumvent or evade any innate immune surveillance systems. In the case of the NKG2D system, Spies and colleagues have provided suggestive evidence that tumors can shed MICA/B in a soluble form as a means of evading NKG2D-dependent recognition. They demonstrated that certain tumors are associated with high levels of shed MICA/B and that soluble MICA/B binds to and downmodulates NKG2D on NK cells, thereby acting as an antagonist to NKG2D activation via cell surface-bound MICA/B.[81] Although this mechanism remains to be proven as a true evasion system for NKG2D-dependent tumor recognition, it points out the diversity of mechanisms that tumors utilize to evade immune recognition. It also points out straightforward approaches to block these evasion systems. If indeed soluble MICA/B does represent a mechanism for tumor immune evasion of innate immune recognition, antibodies that would bind to and clear soluble MICA/B but not block the interaction between cell membrane MICA/B and NKG2D on NK cells could potentially restore the capacity of NK cells to recognize MICA/B-expressing tumors.

IMMUNE TOLERANCE AND IMMUNE EVASION—THE HALLMARK OF A SUCCESSFUL TUMOR

Although controversy over the ultimate role of immune surveillance in natural modulation of cancer development and progression will

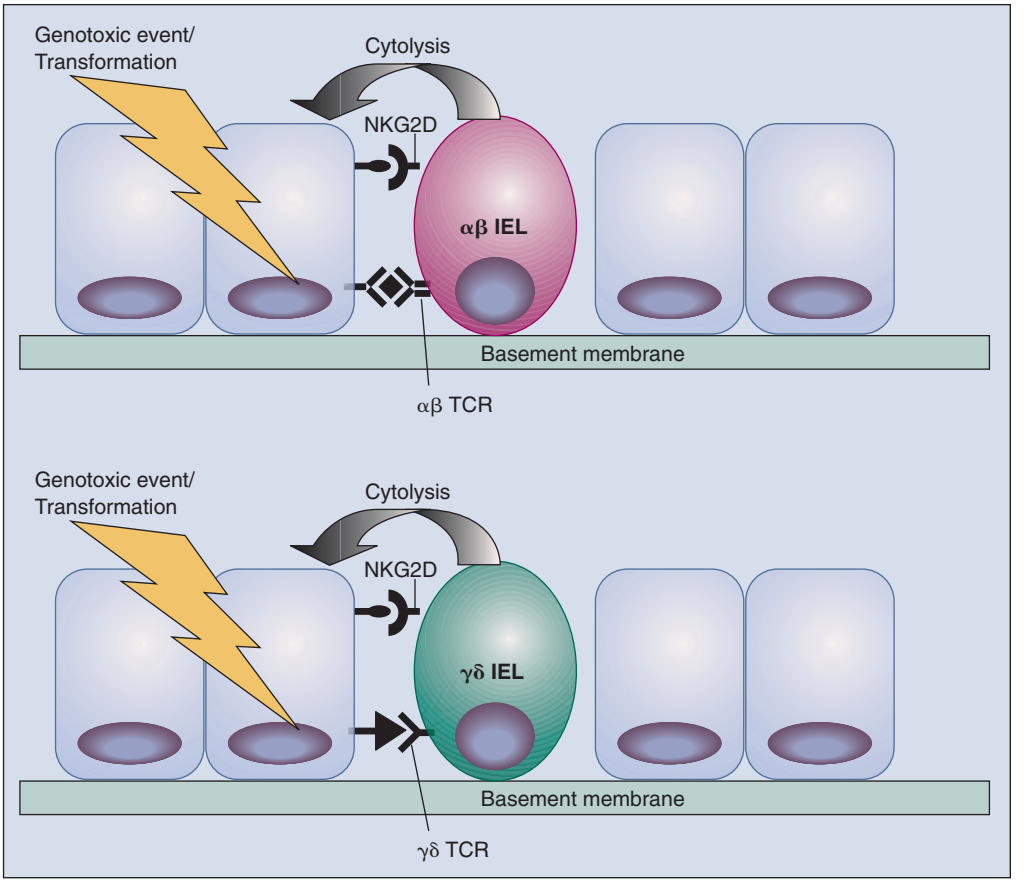

Figure 6-2 • Epithelial linings contain intraepithelial lymphocytes that can recognize epithelial cells undergoing genotoxic stress. Intraepithelial lymphocytes (IELs) fall into two categories: those that express the classical αβ T-cell receptor (TCR) that recognizes peptide-MHC complexes on the cell surface and those that express the γδ TCR, whose ligands are less well characterized. IELs also express the NKG2D receptor, which serves as a costimulatory receptor for activation of IELs. The ligands for NKG2D, MICA, and MICB in humans and RAE1α–RAE1ε, H60, and ULBP-3 in mice, are induced by genotoxic stress via the ATM/ATR pathways. This is a mechanism by which IELs can survey for damaged epithelial cells due to irradiation (skin) or mutagens that can cause transformation.

undoubtedly continue into the future, one can summarize the current state of knowledge as supporting the notion that natural immune surveillance plays a much smaller role than originally envisioned by Thomas and Burnet. However, developing tumors need to adapt to their immunologic milieu in a manner that either turns off potentially harmful (to the tumor) immune responses or creates a local microenvironment inhibitory to the tumoricidal activity of immune cells that could inadvertently become activated in the context of inflammatory responses associated with tissue invasion by the tumor. These processes—tolerance induction and immune evasion—have become a central focus of cancer immunology efforts and will undoubtedly provide the critical information necessary for development of successful immunotherapies that break tolerance to tumor antigens and break down the resistance mechanisms operative within the tumor microenvironment (see Fig. 6-1).

Evidence from both murine tumor systems as well as human tumors strongly demonstrates the capacity of tumors to induce tolerance to their antigens. This capacity to induce immune tolerance may very well be the single most important strategy that tumors use to protect themselves from elimination by the host's immune system. Tolerance to tumors seems to operate predominantly at the level of T cells; B-cell tolerance to tumors is less certain, because there is ample evidence for the induction of antibody responses in animals bearing tumors as well as human patients with tumors. However, with the exception of antibodies against members of the EGFR family, there is little evidence that the natural humoral response to tumors provides significant or relevant antitumor immunity. In contrast, numerous adoptive transfer studies have demonstrated the potent capacity of T cells to kill growing tumors, either directly through cytotoxic T-lymphocyte (CTL) activity, or indirectly through multiple CD4-dependent effector mechanisms. It is thus likely that induction of antigen-specific tolerance among T cells is of paramount importance for tumor survival.

The first direct evidence for induction of T-cell tolerance by tumors was provided by Bogen and colleagues, who examined the response of TCR-transgenic T cells specific for the idiotypic immunoglobulin expressed by a murine myeloma tumor.[82,83] They first demonstrated induction of central tolerance to the myeloma protein followed by peripheral tolerance. Using influenza hemagglutinin as a model tumor antigen, Levitsky and colleagues demonstrated that adoptively transferred hemagglutinin-specific TCR-transgenic T cells were rapidly rendered anergic by hemagglutinin-expressing lymphomas and hemagglutinin-expressing renal carcinomas.[84,85] Tolerance induction has been demonstrated in both the CD4 and CD8 compartment. In general, initial activation of tumor-specific T cells is commonly observed; however, the activated state of T cells is typically not sustained with failure of tumor elimination as a frequent consequence.

Tolerance induction among tumor antigen-specific T cells is an active process involving direct antigen recognition, although in some murine systems, tolerance to tumors seems to be associated with failure of antigen recognition by T cells—that is, the immune system "ignores" the tumor.[86,87] Beyond studies on transplantable tumors, more recent analyses of immune responses to tumor antigens in tumor-transgenic mice developing spontaneous cancer have further emphasized the capacity of spontaneously arising tumors to induce tolerance among antigen-specific T lymphocytes. In a model of prostate tumorigenesis, Drake and associates evaluated CD4 responses to hemagglutinin in double-transgenic animals expressing hemagglutinin and simian virus 40 (SV40) T antigen under control of the prostate-specific probasin promoter.[88] Development and progression of prostate tumors did not result in enhanced activation of adoptively transferred hemagglutinin-specific T cells. Tolerance to hemagglutinin as a normal prostate antigen occurred largely through ignorance, because there was no evidence for antigen recognition by hemagglutinin-specific T cells. However, increased recognition was observed upon either androgen ablation (which causes massive apoptosis within the prostate) or development of prostate cancer. Nonetheless, enhanced antigen recognition was not accompanied by activation of effector functions such as γ-interferon production. Analysis of the consequences of transformation in additional tumor-transgenic mouse systems has also been performed.

Willimsky and Blankenstein evaluated T-cell responses and rejection in a model of sporadic induction of tumors associated with expression of a tumor-specific antigen only at the time of transformation.[89] They found that preimmunization of mice against the tumor-associated antigen prevented the development of tumors. However, nonimmunized mice developed spontaneous tumors without any significant evidence of natural immune surveillance in the absence of preimmunization. They further demonstrated that an initial antigen-dependent activation of tumor-specific T cells could be observed at the time of spontaneous tumor induction but that this recognition ultimately resulted in an anergic form of T-cell tolerance similar to that observed by Drake and colleagues in the prostate system.

The capacity of spontaneously arising tumors to tolerize T cells has not been uniformly observed. A contrasting result by Ohashi and colleagues was observed when lymphocytic choriomeningitis virus (LCMV) GP33-specific TCR-transgenic CD8 T cells were adoptively transferred into double-transgenic mice expressing both SV40 T antigen and LCMV GP33 under control of the rat insulin promoter.[90] These animals develop pancreatic islet cell tumors that express GP33. These investigators found that as tumors progressed in the mice, enhanced T-cell activation occurred. CD8 T-cell activation was demonstrated through bone marrow chimera experiments to occur exclusively via cross-presentation in the draining lymph nodes. Despite the activation of tumor-specific T cells, the tumors grew progressively, indicating that the degree of immune activation induced by tumor growth was insufficient to ultimately eliminate the tumors. These results suggest that developing tumors can induce immune responses but may titrate their level of immune activation to one that ultimately does not "keep up" with tumor progression. Such a circumstance is one that is highly susceptible to the immunoediting concept put forward by Schreiber and colleagues, in which the tumor edits itself genetically to maintain a sufficient level of resistance to induced immune responses.

In the case of the LCMV GP33 T antigen-transgenic mice, because neither anergic nor deletional tolerance was observed, animals treated with the dendritic cell (DC) stimulatory anti-CD40 antibody demonstrated significant slowing of tumor growth. Thus, it may be possible under some circumstances to shift the balance between tumor immune evasion and tumor immune recognition by agents that affect the overall activation state of either antigen-presenting cells (APCs) or T cells (see later discussion).

It has been more difficult to obtain definitive evidence that human cancers tolerize tumor-specific T cells, because humans cannot be manipulated the way mice are. However, the T cells that are grown out from patients with cancer tend to be either of low affinity for their cognate antigen or recognize antigens that bind poorly to their presenting HLA (human MHC) molecule, resulting in inefficient recognition by T cells. Recently, the first crystal structure of the TCR-peptide-MHC trimolecular complex has been solved for an MHC class II-restricted human tumor antigen.[91] Interestingly, the orientation of the TCR, which is of low affinity for the peptide-MHC complex, is distinct from trimolecular complexes for viral (foreign) antigens and is partially similar to trimolecular complexes for a self-antigen. Thus, there may be fundamental structural features of tumor antigen recognition that lie between those of foreign-antigen and self-antigen recognition.

As will be discussed later, one of the features of the tumor microenvironment that is probably central to the capability of tumors to tolerize tumor-specific T cells is the immature or inactive state of tumor-infiltrating DCs. DCs are the major APCs that present peptides to T cells to initiate adaptive immune responses. In the context of infection, microbial ligands or endogenous "danger signals" associated with tissue destruction activate DCs to a state whereby they

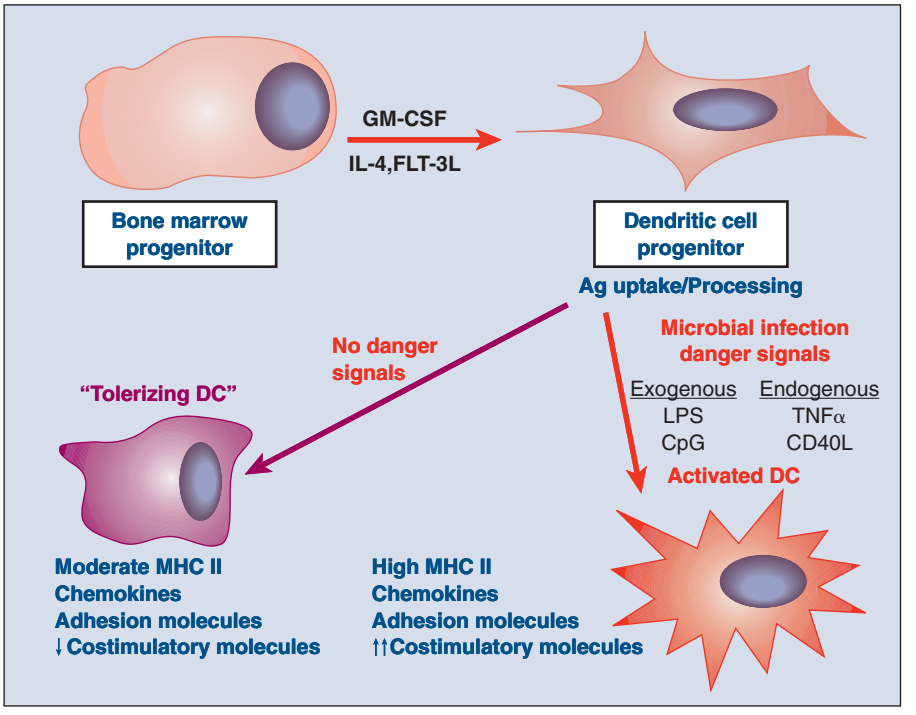

Figure 6-3 • Dendritic cells (DCs) can either activate adaptive immunity or tolerize T cells depending on their state of maturation. DC progenitors develop from hematopoietic (bone marrow-derived) progenitors under the influence of various cytokines, particularly GM-CSF. Under circumstances of microbial infection, specific pathogen-associated molecular patterns (termed PAMPs) engage pattern recognition receptors (PRRs), leading to release of proinflammatory danger signals that induce DC maturation. DC maturation leads to upregulation of costimulatory molecules, MHC, and chemokines that result in activation of T cells to effector cells (*right*). In the absence of these "danger signals," DCs follow a default pathway (*left*) in which they become "tolerizing DCs" that present antigen (Ag) to T cells in the absence of costimulatory signals. This represents a steady-state pathway for continuous presentation of self-antigens. The consequence is that these T cells are turned off (anergy), inducing tolerance.

present antigens to T cells together with costimulatory signals that induce T-cell activation and development of effector function. However, in the absence of microbial products or danger signals, DCs remain in an immature state in which they can still present antigens to T cells but without costimulatory signals. These immature DCs function as "toleragenic" DCs, inducing a state of antigen-specific T-cell unresponsiveness (termed anergy; Fig. 6-3). It is thought that steady-state presentation of self-antigens by immature DCs is an important mechanism of peripheral self-tolerance. Thus, if a tumor is able to produce factors that inhibit local DCs from becoming activated in response to the endogenous danger signals associated with tissue invasion, it could shift tumor-specific T cells from a state of activation (Fig. 6-4A) to one of tumor-specific tolerance (Fig. 6-4B).

REGULATORY T CELLS AND CANCER

Over the past 10 years, regulatory T (T_{reg}) cells have emerged as a central player in maintenance of the tolerant state as well as general downregulation of immune responses to pathogens.[92,93] Not surprisingly, they seem to play a role in tolerance to tumor antigens as well as in the resistance of tumors to immune-mediated elimination.[94,95] In contrast to the ephemeral CD8 suppressor cells of the 1970s that failed to withstand experimental scrutiny, the more recently defined $CD4^+$ regulatory T cells are characterized by expression of a central master regulatory transcription factor—FoxP3—whose role in the gene expression programs of regulatory T cells is being actively studied.[96] Although $CD4^+$ regulatory T cells selectively (but not specifically) express several cell membrane molecules, including

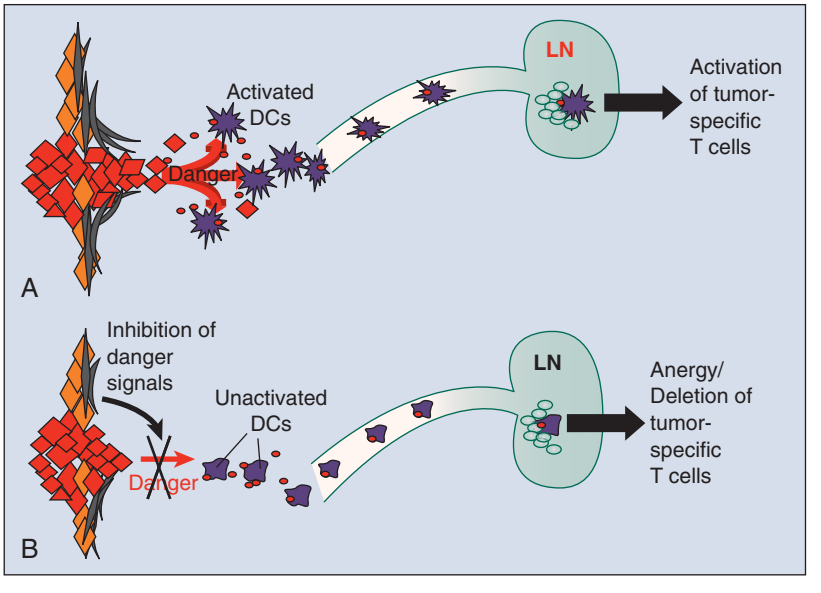

Figure 6-4 • Inhibition of DC activation in the tumor microenvironment can shift tumor-specific immune responses from activation to tolerance. Based on the scenario presented in Figure 6-3, if a tumor is able to produce factors that inhibit local DCs from becoming activated in response to the endogenous danger signals associated with tissue invasion, it could shift tumor-specific T cells from a state of activation (**A**) to one of tumor-specific tolerance (**B**). LN, lymph nodes.

CD25, neuropilin, GITR, and LAG3,[92,97–99] their overall genetic program and inhibitory capacity is absolutely dependent on sustained expression of FoxP3.[100,101]

Mechanisms of immune suppression by regulatory T cells vary and include production of inhibitory cytokines such as interleukin-10 (IL-10) and transforming growth factor-β (TGF-β).[102–104] In keeping with the emerging appreciation that tumors are by nature highly toleragenic, numerous murine studies have demonstrated that T_{reg} cells expand in animals with cancer and significantly limit the potency of antitumor immune responses—either natural or vaccine induced. For example, in a study by Sutmuller and coworkers a combination of GM-CSF–transduced tumor vaccine plus anti-CTLA4 antibodies was much more effective at eliminating established tumors when animals were treated with anti-IL-2 receptor α antibodies to eliminate $CD4^+$ T_{reg} cells.[105]

It is now appreciated that treatment with low-dose cytoxan is a relatively simple and reasonably effective way to temporarily eliminate cycling T_{reg} cells.[106–109] This seems to be a major mechanism by which pretreatment with low-dose cytoxan before vaccination can significantly enhance the capacity of vaccines to break tolerance. As new cell membrane molecules that define T_{reg} cells are identified, the capacity to block regulatory T-cell activity with antibodies to these molecules presents new opportunities for immunotherapeutic strategies to break tolerance to tumor antigens.

ONCOGENIC PATHWAYS ACTIVELY MEDIATE TUMOR–IMMUNE SYSTEM INTERACTIONS

The previous sections outline the complex interplay between tumor and host immune system and describe the experimental evidence that the immune system is in general tolerant to tumors and their antigens under circumstances in which a tumor has established and is expanding within the host. Is this tolerance to tumor antigens a passive default pathway, or does the tumor actively manipulate its immune microenvironment in a way to render the immune system tolerant to its antigens. Indeed, evidence is accumulating that activation of oncogenic pathways in the tumor as well as inactivation of tumor suppressor genes have immunologic consequences far beyond the more commonly studied roles in growth regulation and antiapoptosis. Critical signaling pathways whose role has been studied in this context include STAT3, NF-κB, BRAF, and PTEN. Although each of these pathways (either activation or inactivation) has been well studied for its role in "classic" tumor biology such as dysregulated growth, regulation of apoptosis, and resistance to DNA-damaging agents, additional roles in the organization of the immune microenvironment of the tumor have also been elucidated recently.

The best-studied oncogenic pathway to play a role in tumor immune evasion is the STAT3 pathway. STAT3 is one of two STATs (the other being STAT5A) to be constitutively activated in many diverse tumor types.[110–113] Activation of STAT3 involves tyrosine phosphorylation resulting in homodimerization in the cytosol that leads to nuclear transport where it participates in transcriptional activation (and in some cases repression) of diverse genes. Although synthetic mutations in STAT3 can confer upon it oncogenic activity, constitutive activation of STAT3 in tumors is not a consequence of mutation. Instead, STAT3 is downstream of several important oncogenic tyrosine kinases, both receptor tyrosine kinases and src family tyrosine kinases. Several receptor tyrosine kinases that play important roles in human cancer, including EGFR, HER2/Neu, and cMet, signal in part through STAT3.[114–116] In addition, src and potentially other src family tyrosine kinases can activate STAT3.[117] In fact, the original association of STAT3 with oncogenesis came from the demonstration that src-dependent transformation required STAT3.[118] Activated STAT3 in tumors participates in transcriptional activation of several genes associated with common cell-autonomous and non-cell-autonomous mechanisms of carcinogenesis and cancer promotion. These include cell cycle regulation (e.g., cyclin D1), antiapoptosis (e.g., BCL-Xl and survivin), and angiogenesis (e.g., vascular endothelial growth factor [VEGF]).[119,120]

In addition, STAT3 activation in tumors has been shown to repress the production of proinflammatory cytokines and chemokines that could enhance antitumor immune responses.[121] These include proinflammatory cytokines such as type 1 interferons and tumor necrosis factor as well as proinflammatory chemokines such as RANTES and IP-10. Thus, blockade of STAT3 signaling in tumor cells results in the release of multiple proinflammatory mediators and consequent infiltration with cells of both the innate and adaptive immune system that ultimately inhibit tumor growth.

Beyond simply repressing the production and release of molecules that could promote antitumor immune responses, STAT3 signaling also induces the release of factors that inhibit activation of multiple immune cell types in the tumor microenvironment. These include DCs, NK cells, and granulocytes, which, though present in significant numbers within tumors, are generally found in an unactivated state.

Some of the STAT3-regulated factors that induce this "quiescent microenvironment" include IL-10, VEGF, IL-6, and possibly IL-23. As will be described later, some of these cytokines promote distinct forms of immune responses that promote rather than inhibit tumor growth. The receptors for each of these factors are expressed on cells of the hematopoietic system and signal through STAT3. Thus, infiltrating hematopoietic cells within the tumor microenvironment are found to also express constitutively activated STAT3. Blockade of STAT3 in the hematopoietic system (for example, via hematopoietic-specific STAT3 knockout) results in dramatically enhanced activation of DCs and cells in the innate immune system (such as NK cells and granulocytes) and leads to antitumor immune responses. In fact, even aggressive tumors fail to grow when transplanted into animals with hematopoietic STAT3 knockout.[122] Thus, STAT3 seems to be an important global signaling pathway that restrains antitumor immunity.

Another immunologically relevant pathway that is commonly constituently activated in cancer is the NF-κB pathway.[123,124] Normally, NF-κB is activated in a highly stimulus-dependent fashion, but is constitutively activated in many types of tumors. Multiple NF-κB family members participate in either a canonical or noncanonical NF-κB activation pathway. Common to both pathways is the activation of IκB kinase (IKK), which phosphorylates IκB leading to ubiquitin-dependent degradation and release of NF-κB to traffic from the cytosol to the nucleus and activate gene transcription programs.[125] Alternatively, IKK phosphorylation can result in cleavage of a precursor protein for the activation of the noncanonical NF-κB pathway. The mechanism for constitutive NF-κB activation in tumors is not currently known. Normally, NF-κB plays a central role in the activation of virtually all cells in the immune system—both innate and adaptive. In the case of innate immunity, Toll-like receptors (TLRs) on the surface of cells or intracellular sensors of viral RNA or DNA (the RIGI or MDA5 pathway) result in a signaling cascade that activates NF-κB via TRAF6.[126,127] Paradoxically, constitutive activation of NF-κB in tumors is associated predominantly with activation of antiapoptotic genes, whereas many of the typical NF-κB-responsive proinflammatory/proimmunity genes are not activated in tumors. Recently, it was demonstrated that the selective NF-κB gene activation program in tumors is dependent on its association with STAT3. Indeed, coactivation of STAT3 and NF-κB is commonly observed in tumors. This coactivation seems in part to be due to a newly defined role for STAT3 in enhancing acetylation of NF-κB p50 subunit, resulting in enhanced retention of active NF-κB in the nucleus of tumor cells. This retention seems to be through the p300 acetyl transferase. The result is a shift in equilibrium toward nuclear retention of NF-κB. In addition, STAT3–NF-κB complexes fail to bind promoters of proinflammatory/proimmunity genes that are typically repressed in tumor cells, whereas STAT3–NF-κB dimers

are found associated with promoters driving antiapoptotic genes such as BCL-Xl and survivin. These findings highlight the interactivity between key signaling pathways of tumor cells as well as the interplay between gene expression programs mediating tumor immunity versus tumor survival.

An additional oncogenic pathway that seems to play a role in tumor immune evasion is the BRAF pathway.[128] BRAF is constitutively activated in the majority of human melanomas as a result of a single activating mutation. Kawakami and colleagues[128] have demonstrated that factors produced by melanoma cells that inhibit DC activation are in part driven by Braf. Knockdown of Braf with short interfering RNA abrogates the production by melanoma cells of factors that inhibit DC activation. This inhibition seems to be independent of but complementary to that provided by STAT3 activation in melanoma cells. Thus, it seems that multiple oncogenic pathways active in tumor cells may contribute to the release of factors that inhibit DCs and other components of innate immunity, shifting the balance of immune responses toward tolerance.

In addition to oncogenic pathways, inactivation of tumor suppressor pathways may also play a role in immune evasion by tumors. In one example, Parsa and colleauges demonstrated that expression of a T-cell-inhibitory molecule by tumors, B7-H1 (see later discussion), is linked to inactivation of PTEN. PTEN, an inhibitor of the oncogenic AKT pathway, is emerging as one of the most important tumor suppressor pathways in cancer.[129] More recently, Lowe and colleagues provided evidence that the p53 pathway may play a role in inhibiting innate immune responses to tumors. In a transgenic system in which inactivated p53 is conditionally reexpressed in tumors, they found that the inhibition of tumor growth induced by reactivation of p53 might be in part dependent on induction of innate immune responses mediated by NK cells.[130]

Taken together, these findings strongly suggest that oncogene and tumor suppressor gene pathways in tumors play important roles in orchestrating the interaction between the tumor cell and its immune microenvironment such that immune responses induced by the invasion and metastasis process do not eliminate the tumor cell itself. Whereas most of the focus on the function of oncogenic and tumor suppressor pathways has been on cell-autonomous functions within the tumor such as growth regulation, there is growing appreciation that these pathways additionally affect the tumor microenvironment via nontransformed cells. As an integral part of the tumor microenvironment, the immune system is clearly subject to regulation by these pathways. Understanding of the immunologic consequences of these pathways ultimately provides direct opportunities to develop therapeutic approaches that integrate inhibitors of oncogenic pathways, activators of tumor suppressor pathways, and other immunotherapeutic approaches to cancer.

IMMUNOLOGIC CHARACTERISTICS OF THE TUMOR MICROENVIRONMENT

Ultimate understanding of the relationship between the tumor and the host immune system requires elucidation of local cross-talk at the level of the tumor microenvironment. As mentioned at the outset, the hematopoietic/immune system is a major component of the tumor microenvironment. The systemic tolerance to tumor antigens begins with events that occur in this microenvironment. Beyond mechanisms that skew tumor-specific T cells toward immune tolerance, the tumor microenvironment is replete with mechanisms that dampen antitumor immune responses locally (Fig. 6-5). This represents an important barrier to successful immunotherapy even when activated effector responses can be generated with vaccines. As the specific cells and molecules within the tumor microenvironment that mediate this hostile immune environment are elucidated, inhibitors are being developed and tested to use as adjuncts to vaccination that will allow activated immune cells to function more effectively within the tumor microenvironment.

The previous section described how oncogenic pathways in the tumor cell directly affect the immune microenvironment of the tumor. In addition to its role in inhibiting the activation and effector function of DCs, granulocytes, and NK cells in the tumor microenvironment, STAT3 signaling has also been reported to play a role in guiding immature myeloid cells (iMCs) in the tumor microenvironment to differentiate into myeloid suppressor cells (MSCs) rather than DCs with APC activity. iMCs[131,132] and MSCs[133–136] represent a cadre of myeloid cell types, including tumor-associated

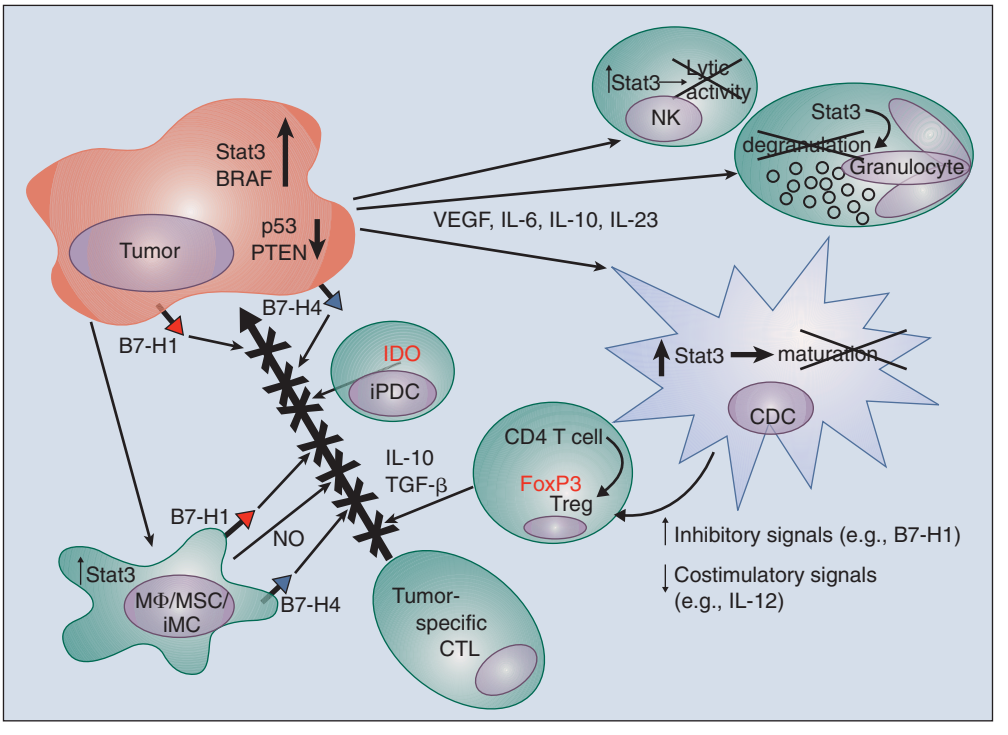

Figure 6-5 • The hostile immune microenvironment of the tumor. Activation of oncogenic pathways and inactivation of tumor suppressor pathways in the tumor lead to a cascade of molecular and cellular processes in the tumor microenviroment that block the killing function of innate immune effectors such as NK cells and granulocytes and block DC maturation (see Figs. 6-3 and 6-4). In addition, multiple cell membrane molecules such as IL-10, TGF-β, B7-H1, and B7-H4 are upregulated. These molecules bind to receptors that inhibit T-cell effector function. Immature myeloid cells (iMC) produce NO, which inhibits T cells, and immature plasmacytoid DCs (iPDC) produce indoleamine dioxygenase (IDO), which depletes tryptophan. Regulatory T cells also accumulate in the tumor microenvironment, further blunting antitumor T-cell responses.

macrophages, that share the common feature of inhibiting both the priming and effector function of tumor-reactive T cells. It is still not clear whether these myeloid cell types represent distinct lineages or different states of the same general immune-inhibitory cell subset.

In mice, iMCs and MSCs are characterized by coexpression of CD11b (considered a macrophage marker) and Gr1 (considered a granulocyte marker) while expressing low or no MHC class II or the CD86 costimulatory molecule. In humans, they are defined as $CD33^+$ but lack markers of mature macrophages, DCs, or granulocytes and are $HLA\text{-}DR^-$. Several molecular species produced by tumors tend to drive iMC/MSC accumulation. These include IL-6, CSF-1, IL-10, and gangliosides. IL-6 and IL-10 are potent inducers of STAT3 signaling. Another cytokine reported to induce iMC/MSC accumulation is GM-CSF.[137] This finding is somewhat paradoxical, in that GM-CSF is a critical inducer of DC differentiation and GM-CSF–transduced tumor vaccines enhance antitumor T-cell immunity via accumulation of DCs at the vaccine site followed by increased DC numbers in vaccine draining lymph nodes. It seems that the paradox is solved based on levels of GM-CSF. High local levels drive DC differentiation at the vaccine site, whereas chronic production of low levels of GM-CSF can promote iMC/MSC accumulation. GM-CSF–transduced vaccines that produce extremely high GM-CSF levels can induce iMC/MSC accumulation at distant sites (i.e., spleen and lymph nodes), because they release enough GM-CSF systemically to drive iMC/MSC accumulation.

Several mechanisms have been proposed to explain how iMC/MSC inhibit T-cell responses within the tumor microenvironment. Most include the production of reactive oxygen species (ROS) and/or reactive nitrogen species. Nitric oxide production by iMC/MSC as a result of arginase activity, which is high in these cells, has been well documented, and inhibition of this pathway with several drugs can mitigate the inhibitory effects of iMC/MSC. ROS, including hydrogen peroxide, have been reported to block T-cell function associated with the downmodulation of the ζ chain of the TCR signaling complex,[138] a phenomenon well recognized in T cells from cancer patients and associated with generalized T-cell unresponsiveness.

Another mediator of T-cell unresponsiveness associated with cancer is the production of indolamine-2,3 dioxygenase (IDO).[139] IDO seems to be produced by DCs either within tumors or in tumor-draining lymph nodes. Interestingly, IDO in DCs has been reported to be induced via backward signaling by B7-1/2 upon ligation with CTLA-4.[140,141] Apparently, the major IDO-producing DC subset is either a plasmacytoid DC (PDC) or a PDC-related cell that is $B220^+$.[142] IDO seems to inhibit T-cell responses through catabolism of tryptophan. Activated T cells are highly dependent on tryptophan and are therefore sensitive to tryptophan depletion. Thus, Munn and Mellor have proposed a bystander mechanism, whereby DCs in the local environment deplete tryptophan via IDO upregulation, thereby inducing metabolic apoptosis in locally activated T cells.[139]

Another inhibitory molecule produced by many cell types that has been implicated in blunting antitumor immune responses is TGF-β, which is produced by a variety of cell types, including tumor cells, and which has pleiotropic physiologic effects. For most normal epithelial cells, TGF-β is a potent inhibitor of cell proliferation, causing cell cycle arrest in the G1 stage.[143] In many cancer cells, however, mutations in the TGF-β pathway confer resistance to cell cycle inhibition, allowing uncontrolled proliferation. Additionally, in cancer cells the production of TGF-β is increased and may contribute to invasion by promoting the activity of matrix metalloproteinases. In vivo, TGF-β directly stimulates angiogenesis; this stimulation can be blocked by anti-TGF-β antibodies.[144] A bimodal role of TGF-β in cancer has been verified in a transgenic animal model using a keratinocyte-targeted overexpression.[145] Initially, these animals are resistant to the development of early-stage or benign skin tumors. However, once tumors form, they progress rapidly to a more aggressive spindle-cell phenotype. Although this clear bimodal pattern of activity is more difficult to identify in a clinical setting, it should be noted that elevated serum TGF-β levels are associated with poor prognosis in several malignancies, including prostate cancer,[146] lung cancer,[147] gastric cancer,[148] and bladder cancer.[149]

From an immunologic perspective, TGF-β possesses broadly immunosuppressive properties and TGF-β knockout mice develop widespread inflammatory pathology and corresponding accelerated mortality.[150] Interestingly, a majority of these effects seem to be T-cell mediated, in that targeted disruption of T-cell TGF-β signaling also results in a similar autoimmune phenotype.[151] Recent experiments by Chen and associates rather convincingly demonstrated a role for TGF-β in T_{reg}-mediated suppression of CD8 T-cell antitumor responses.[152] In these experiments adoptive transfer of $CD4^+$ $CD25^+$ regulatory T cells inhibited an antitumor CD8 T-cell effector response, and this inhibition was ameliorated when the CD8 T cells came from animals with a dominant negative TGF-β1 receptor.

One of the unresolved issues in the study of tumor immune evasion relates to the mechanisms by which tumors induce antigen-specific T-cell tolerance. Whereas the many mechanisms described previously, including STAT3 signaling-dependent mechanisms, IDO, ROS, reactive nitrogen species, TGF-β, and others, clearly inhibit priming of T-cell responses and/or tumor killing by activated effector T cells, it remains to be definitively determined which processes actively induce antigen-specific T-cell tolerance that has been documented in transgenic models. Self-tolerance induction for peripheral tissue antigens is now thought to involve specific presentation of tissue-specific antigens to mature T cells in the absence of appropriate costimulatory signals. Similar mechanisms are probably operative in the case of tumor-induced tolerance. Originally, the relevant costimulatory signals were envisioned to be provided by B7 family costimulatory molecules expressed by DCs.[153] It is now becoming clear that additional proinflammatory cytokines such as interferons, IL-12, tumor necrosis factor, and others are critical in the distinction between effector T-cell induction and tolerance induction.

An emerging concept is that immature or not fully matured DCs are critical in presenting self-antigens to induce T-cell tolerance in the absence of TLR-mediated danger signals associated with infection.[154,155] Unquestionably, DCs found within the tumor microenvironment have a relatively immature, unactivated phenotype characterized by low levels of proinflammatory cytokine production, and CD86 and surface MHC class II expression. As described previously, a major inhibitory signaling pathway induced in tumor-infiltrating DCs is the STAT3 pathway, which, when activated, strongly antagonizes TLR- and CD40-mediated DC activation. As mentioned, tumor-derived factors such as IL-10, IL-6, and VEGF (in part induced by STAT3 signaling in the tumor cell) can induce STAT3 activation in DCs. As described in the previous section, constitutive BRAF signaling in melanoma cells has additionally been shown to induce release of factors that inhibit DC activation.[128] These immature "activation-inhibited" DCs clearly represent a prime candidate for the induction of tumor-specific T-cell tolerance.

It remains an open question whether iMC/MSC represent a distinct intertumoral cell subset capable of presenting antigens to T cells in a toleragenic fashion.[156] A recent report indeed suggested that iMCs loaded with antigen and adoptively transferred into mice can induce antigen-specific T-cell tolerance. Finally, it has been suggested that IDO-expressing DCs can induce antigen-specific T-cell tolerance, because IDO-mediated tryptophan selectively kills or inhibits proliferation of activated T cells.[157] According to this model, IDO-expressing DCs would present antigen to T cells inducing activation followed by activation-associated cell death mediated by depletion of local tryptophan stores by the IDO in the presenting DCs. As described later, regulatory T cells play an additional important role in induction of or maintenance of tumor antigen-specific T-cell tolerance. Whether T_{reg} cells mediate T-cell tolerance independently from immature or toleragenic APCs, or whether the two mechanisms are completely interrelated (i.e., toleragenic DCs inducing a T_{reg}

phenotype among antigen-specific T cells and antigen-specific T_{reg} cells acting upon DCs to enhance their toleragenic capacity), remains to be definitely determined.

One of the most important classes of immune-inhibitory molecules shown to be expressed by both tumors and myeloid cells in the tumor microenvironment are members of the growing class of B7 molecules. Originally, B7.1 (also called CD80), and then B7.2 (CD86), were identified as critical costimulatory molecules expressed by APCs (first found on B cells, then macrophages, then DCs). Costimulation of T cells, defined as amplification of activation signals delivered through engagement of the TCR by antigen, was shown to be mediated by binding of B7.1 and B7.2 to CD28, expressed on all naive T cells. Subsequently, feedback inhibition of T-cell activation was shown to be mediated by inhibitory signals delivered by a second receptor for B7.1 and B7.2, termed CTLA-4. CTLA-4 is not expressed on the surface of naive T cells but is rapidly induced after T-cell activation, and, as is the case for TGF-β, CTLA-4 knockout mice develop lymphoproliferative autoimmunity, indicating a tonic role for CTLA-4–B7-1/B7-2 interactions in the prevention of autoimmunity.[158] According to these data, CTLA-4 blockade would be expected to function mostly during T-cell priming events, facilitating or enhancing an immune response. In several murine systems, CTLA-4 blockade exerts a pronounced antitumor effect,[159] generating enthusiasm for translating these observations to the clinic.[160]

A second coinhibitory molecule on T cells is PD1 (programmed death 1), a T-cell surface molecule originally discovered in a T-cell hybridoma undergoing apoptosis.[161] Further studies of PD1 identified expression on activated, but not naive T and B cells, in addition to potential overexpression in anergized CD4 T cells.[162] Recent data show that PD1 is also expressed on the surface of certain CD8 T cells, where it serves as a marker for T cells that have been "exhausted" by exposure to persistent viral antigen in vivo. As is the case for CTLA-4 and TGF-β, PD1 knockout mice develop strain-dependent autoimmune disease.[163] In murine models of experimental autoimmune encephalomyelitis and diabetes, anti-PD1 antagonist antibodies enhance disease progression.[164–166]

There are currently two known ligands for PD1: B7-H1 (also known as PD-L1) and B7-DC (also known as PD-L2). B7-H1 and B7-DC represent two of the five additional B7 family members identified over the past 10 years. These ligands have very different tissue distribution patterns, with B7-DC expression primarily confined to DCs and macrophages.[167] B7-H1 messenger RNA is widely expressed, but cell surface protein is not detectable in normal tissues other than a subset of macrophages.[168] Interestingly, B7-H1 expression can be detected in several tumor types,[169] and engagement of PD1 by tumor-associated B7-H1 promotes CD8 T-cell apoptosis.

In addition, B7-H1 has been reported to be upregulated on both DCs and macrophages within the tumor microenvironment. Clinically, it has been reported that B7-H1 expression is correlated with poor prognosis in renal cell carcinoma.[170] Interestingly, whereas B7-H1 expression on tumor cells was correlated with poor clinical prognosis, combined expression on tumor cells together with hematopoietic cells within the tumor sections was even more highly correlated with poor clinical outcome. Thus, it seems that PD1/B7-H1 interactions mediate a potent and specific immunoregulatory effect, preventing activated and trafficking CD8 T cells from lysing their targets in vivo. In recent data, this observation has been confirmed in murine tumor models, where blockade of either PD1 or of the PD1 ligand B7-H1 potentiates an antitumor immune response.[171] In contrast, the molecular role of B7-DC ligation in an immune response is complex,[172] and under some circumstances ligation of B7-DC on APCs seems to potentiate a costimulatory interaction with T cells.[173]

Another more recently identified inhibitory B7 family member, B7-H4, also seems to play an important role in the tumor microenvironment.[174] The receptor for B7-H4 has not yet been identified, but this molecule has been definitively shown to play an inhibitory role because treatment of mice with blocking antibodies and gene knockout resulted in increased immune responses. As with B7-H1, B7-H4 is expressed by several tumors and also by macrophages in the tumor microenvironment.[175] B7-H4 is regulated differently than B7-H1 and there seems to be a distinct pattern of tumor-selective expression for the two molecules, with some overlap. Recently, B7-H4 expression in human renal cancer has been shown to correlate with poor clinical prognosis, similarly to B7-H1. Patients whose tumors expressed high levels of both molecules displayed the worst clinical outcome, with almost all developing distant metastases.[176]

PROCARCINOGENIC VERSUS ANTICARCINOGENIC ROLES OF THE IMMUNE RESPONSE

Much to the chagrin of the immunotherapy community, skepticism among the oncology community regarding the capacity to induce therapeutically meaningful antitumor immune responses has been accompanied by increasing focus on the capacity of immune responses to induce cancer and potentially enhance cancer progression. Understanding the paradox between the potential procarcinogenic and anticarcinogenic immunity is arguably the most important frontier in cancer immunology (Fig. 6-6).

The capacity of inflammatory (i.e., innate) immune responses to enhance carcinogenesis has become well appreciated on the basis of clinical observations that chronic infections that induce chronic inflammation can lead to cancer. One of the best examples is hepatitis C virus (HCV) infection.[177] HCV infection leads to a chronic persistent state in the majority of infected individuals associated with chronic hepatitis. This chronic hepatitis is associated with development of hepatocellular carcinoma at the rate of roughly 1% per year. In contrast to other procarcinogenic chronic infections with viruses such as HPV that carry their own oncogenes, the HCV genome contains no oncogenes or genes encoding proteins that inactivate tumor suppressor genes. Thus, the evidence is quite strong that the chronic inflammatory response to HCV is responsible for the genesis of hepatocellular carcinoma. Similarly, the inflammatory responses associated with chronic *H. pylori* infection of the stomach are thought to be central to the genesis of stomach cancer.[178] Further evidence for the procarcinogenic effects of inflammation come from the findings that anti-inflammatory drugs, such as COX-2 inhibitors, can decrease the incidence of colon cancer.[179] Additional evidence includes the propensity of patients with certain forms of chronic colitis (e.g., ulcerative colitis) to develop colon cancer and the association of microinflammatory foci in the prostate with prostate intraepithelial neoplastic lesions.[180]

In animal models, experimental induction of inflammation in both the colon and the liver are associated with increased incidences of cancer. Recently, Karin and colleagues have used conditional knockouts of IKK to demonstrate an important role for NF-κB signaling in experimental models of colonic carcinogenesis.[181] Interestingly, they found that tissue-specific knockout of IKKβ in both colonic epithelial cells as well as in myloid cells resulted in a diminished incidence of dextran sulfate (DSS)-induced colon cancers. Epithelium-specific knockout of IKKβ resulted in a decreased incidence, whereas myeloid-specific knockout of IKKβ resulted in both decreased incidence and decreased progression rate. The effects of myeloid-specific IKK knockout were taken as evidence for an NF-κB-dependent proinflammatory role in carcinogenesis. More recently, carcinogen-induced liver cancer and colon tumor development in mice bearing heterozygous adenomatous polyposis coli gene mutations (Min mice) was shown to be dependent on MyD88, an adapter for TLR signaling that is necessary for TLR-dependent NF-κB activation.[182,183] In one case, IL-6 production was found to be an important downstream cytokine for liver carcinogenesis.

Although the majority of evidence linking immunity to cancer involves the innate immune system, Coussens and colleagues have

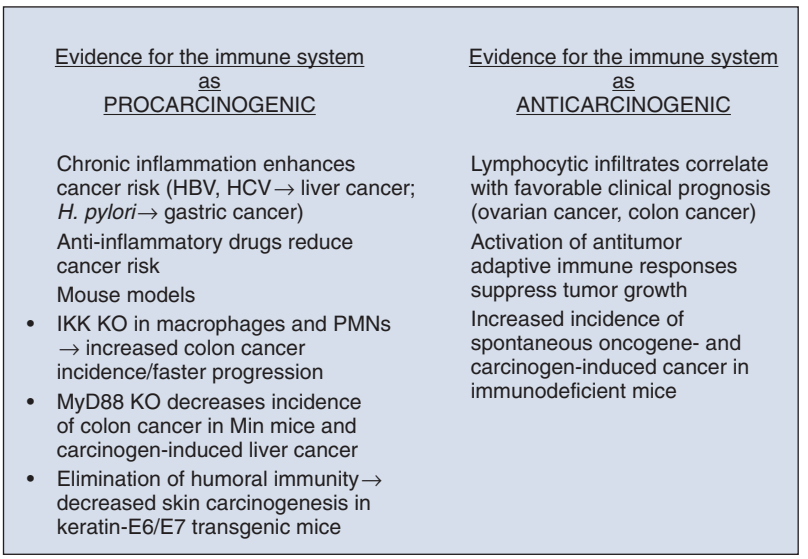

Figure 6-6 • Evidence for procarcinogenic and anticarcinogenic roles of the immune system. Ample evidence exists in both animal models and human disease settings that immune responses can promote or inhibit cancer development.

provided evidence that components of the adaptive immune response could contribute to carcinogenesis in a positive fashion. In a transgenic model of HPV E6/E7-induced skin carcinogenesis, they demonstrated that elimination of B cells resulted in a decreased incidence of tumorigenesis.[184] Surprisingly, T-cell knockout did not alter the incidence of tumorigenesis. The ultimate mechanism by which B cells contribute to carcinogenesis in this system is not fully defined, although antibody production seems to be involved.

Understanding the paradox between procarcinogenic versus anticarcinogenic effects of the immune response will be critical to ultimately defining successful immunotherapies. Recent studies suggest a solution to this paradox and provide insight into the notion that different forms of immune responsiveness can respectively be anticarcinogenic or procarcinogenic. Much evidence has been accumulated that a certain type of T-cell response, termed Th1, can be potently anticarcinogenic. Th1 responses are characterized by production of γ-interferon by CD4 T cells as well as induction of CTL responses by CD8 T cells. γ-interferon not only can enhance the activity of CD8 CTLs, it can also activate components of innate immunity such as macrophages that can kill tumors. Th1 responses are induced by STAT1 signaling and are significantly enhanced by IL-12 that can be produced by macrophages or DCs. Indeed, IL-12 activates not only Th1 responses but also innate immune responses by NK cells that can additionally kill tumor cells.[185,186]

Recently, a distinct IL-12 family cytokine, termed IL-23, has been discovered.[187,188] IL-23 shares the same β chain as IL-12 but has a distinct α chain, termed IL-23 p19. Likewise, the IL-23 receptor shares a common β chain with the IL-12 receptor but also has a distinct IL-23 receptor-specific α chain. Several immunopathologic states related to autoimmune disease that had been attributed to IL-12 and linked Th1 responses have now been shown to be instead attributable to IL-23.[189] Analogous to IL-12 driving both NK-dependent innate as well as Th1-type adaptive immune responses, IL-23 drives distinct innate immune responses from IL-12 that are just now being elucidated (characterized by granulocyte recruitment). In addition, IL-23 promotes the growth of a distinct type of helper T cell, termed Th17.[190–193] Th17 is applied to this helper T-cell pathway, because it is characterized by production of cytokine IL-17a rather than γ-interferon.

Recently Langowski and coworkers evaluated skin carcinogenesis and tumor growth in mice with either an IL-23 p19 gene knockout or an IL-12 specific p35 gene knockout.[194] As predicted from previous studies on the role of IL-12 in promoting both innate and Th1-dependent antitumor immunity, tumor formation in a carcinogen-induced skin cancer model as well as growth of transplanted tumors was increased in IL-12 p35 knockout mice. In striking contrast, carcinogenesis and tumor growth was decreased in the IL-23 p19 knockout mice. Carcinogenesis and tumor growth was also reduced in knockout mice for p40, the common subunit for IL-12 and IL-23. This result suggests that the procarcinogenic effects of IL-23 production dominate over the anticarcinogenic effects of IL-12 production. Although these initial findings will require extensive follow-up, they support the notion that qualitatively distinct types of immune responses, characterized by distinct cytokines that mediate distinct functions, can be procarcinogenic or anticarcinogenic.

Analysis of signaling pathways involved in the IL-12–Th1 axis and the IL-23–Th17 axis further suggest a model of "competition" between these two immune pathways. Th1 responses depend on signaling through STAT1, which is essential for commitment to the Th1 lineage, and STAT4, which is the major signal transducer for the IL-12 receptor. In contrast, both IL-23 transcription as well as IL-23 receptor transcription and signal transduction require STAT3 signaling. IL-17 production also requires STAT3 signaling, which is generated by IL-6, which, together with TGF-β, is a critical cytokine for Th17 development from naive T cells.[195,196] This may explain the role of IL-6 in the MyD88-dependent carcinogenesis described previously.[182] At several levels, STAT3 signaling and STAT1 signaling are mutually antagonistic such that increases in STAT3 signaling inhibit STAT1-induced gene expression programs whereas increases in STAT1 signaling inhibit STAT3-dependent gene expression programs.[197] This finding suggests that therapeutic manipulations of STAT signaling could potentially convert procarcinogenic to anticarcinogenic pathways of immune responsiveness. Ultimately it will be critical to evaluate the qualitative nature of immune responses in chronic infections that lead to carcinogenesis to determine whether this "yin-yang" paradigm of procarcinogenic IL-23–Th17 immunity versus anticarcinogenic IL-12–Th1 immunity represents a general principle translatable to human cancer initiation or promotion (Fig. 6-7).

CLINICAL IMPLICATIONS FOR MANIPULATION OF THE IMMUNE RESPONSE TO TUMOR CELLS

Fundamentally, we now have clear-cut evidence that antibodies and T cells can selectively recognize and kill cancer cells in patients. Cancer genetics, epigenetics, and genomics have provided us with a

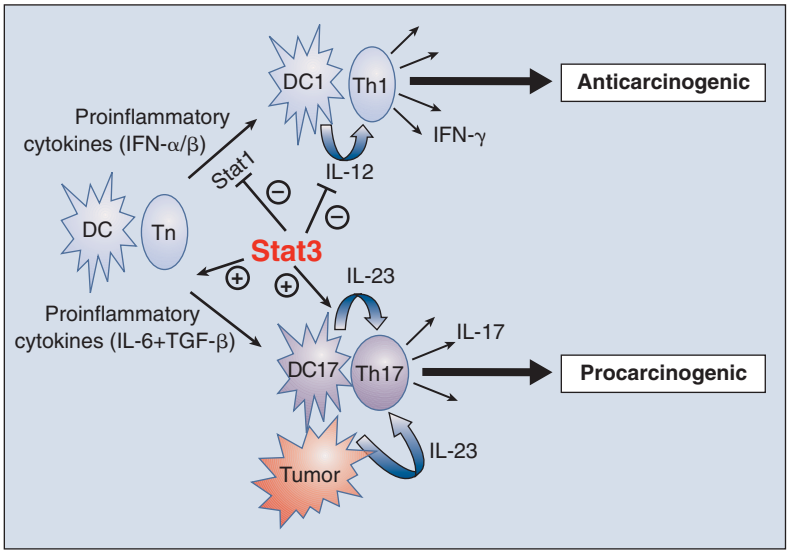

Figure 6-7 • Two mutually inhibitory pathways of immunity may inhibit or promote cancer. The Th1 pathway is promoted by STAT1 and STAT4 signaling, is initiated by type I interferons, and depends on IL-12. Th1 cells are characterized by production of γ-IFN but also produce many other cytokines. The IL-12/Th1 pathway is typically anticarcinogenic. The Th17 pathway is promoted by Stat3 signaling, is initiated by IL-6 and TGF-β, and depends on IL-23. Th1 cells are characterized by production of IL-17a but also produce many other cytokines. Evidence exists that the IL-23-Th17 pathway can promote carcinogenesis. These pathways are mutually inhibitory in a yin-yang fashion.

Box 6-2. CAN THE IMMUNE SYSTEM BE MANIPULATED TO OVERCOME TUMOR-INDUCED TOLERANCE AND IMMUNE EVASION?

One of the most consistent therapeutic failures thus far has come from attempts to treat cancer with tumor vaccines. Evidence has now mounted that a major reason for the lack of efficacy of tumor vaccines and other immunotherapeutic interventions is the barrier of immune tolerance to tumor antigens as well as the upregulation of molecules in the tumor microenvironment that inhibit effector immune responses. The bad news from these insights is that therapeutic efficacy of tumor vaccines used as single agents will probably always be limited, no matter how effective the vaccine is in inducing immunity in a naive host. It is likely that the only viable therapeutic application of cancer vaccines used as single agents will be in the setting of minimal residual disease. However, as the specific molecular pathways of immune tolerance and immune evasion are defined, antibodies as well as small molecule agonists and antagonists are being developed that can either enhance costimulatory pathways that amplify immune responses or specifically block receptors and pathways that inhibit immune effectors such as cytotoxic T cells. Preclinical experiments as well as very early-stage clinical experience suggest that combinations of vaccines that direct immune responses to particular tumor antigens together with agents that either enhance or costimulate immunity, as well as agents that block immune checkpoints, produce strong synergy in enhancing antitumor immune responses. It is likely that these combinatorial approaches will be the most fruitful for developing clinically relevant immune therapies of cancer.

far better understanding of the nature and specificity or selectivity of tumor antigens, providing new opportunities for targeted antigen-specific immunotherapy. We know much more about the details of antigen recognition by T cells allowing for the opportunity to modify antigens at critical residues to provide for enhanced immune-stimulatory capacity. Finally, we are learning much about the ligands, receptors, and signaling pathways that regulate immune responses and how they are expressed within the tumor microenvironment. Elucidation of these regulatory pathways has demonstrated that the outcome of antigen recognition is in large part determined by the balance between costimulatory signals and inhibitory signals.

These relatively recent insights into the molecular basis of immune regulation are demonstrating profound significance for the development of more potent combinatorial immunotherapy approaches to cancer (Box 6-2). Several consensus have emerged from both preclinical immunotherapy models as well as analysis of cancer patients. First and foremost, the natural state of endogenous tumor-reactive T cells is characterized by general hyporesponsiveness or anergy. This is probably due to several mechanisms that tumors utilize to induce tolerance as they develop. Whereas a number of the newer generation vaccines such as recombinant viral vaccines or GM-CSF gene-modified vaccines can effectively transfer antigen to and activate DCs, T-cell tolerance remains a major barrier that is difficult to overcome by vaccination alone. Preclinical models demonstrate that for poorly immunogenic tumors, once tolerance has been established, therapeutic vaccines alone are ineffective at curing animals with a significant established tumor burden. However, strategies combining vaccination with inhibitors of immunologic checkpoints and agonists for costimulatory pathways are proving capable of overcoming tolerance and generating significant antitumor responses even in cases of established metastatic cancer.

7 Stem Cells, Cell Differentiation, and Cancer

Michael F. Clarke and Irving L. Weissman

SUMMARY OF KEY POINTS

- Most cancers arise in tissues (e.g., the gut, breast, prostate, lungs, and bone marrow) that contain a stem cell population.
- Stem cells have three fundamental properties: the ability to divide and give rise to a new stem cell in a process called self-renewal, the ability to give rise to the differentiated cells of an organ, and genetic constraints on expansion.
- The fact that stem cells are the only long-lived cells in most tissues in which cancers arise suggests that early mutations that lead to cancer accumulate in stem cells.
- In addition to classes of oncogenes that affect cell survival and proliferation, there is a class of oncogenes that permits cells to self-renew. Thus, in some cancers, the target cells for neoplastic transformation may be progenitor cells that have acquired the ability to self-renew as a result of one or more mutations.
- New data suggest that in both leukemia and solid tumors, including tumors of the breast, colon, head and neck, pancreas, and prostate, a small, phenotypically distinct subset of cancer cells has the exclusive ability to form tumors.
- At present, therapeutic targets are selected on the basis of the proposition that all of the cancer cells within a particular tumor are capable of driving tumor formation and metastasis. However, because the bulk of the cancer cells in the tumor are unable to form tumors and most cancer agents are selected to reduce the bulk, these cells are the targets of many therapies.
- To be effective, therapies must target the critical tumorigenic cancer cell population.
- The ability to prospectively identify tumorigenic cancer cells should allow the identification of new diagnostic markers and therapeutic targets.

INTRODUCTION

Common cancers arise in tissues that contain a large subpopulation of proliferating cells that are responsible for replenishing the short-lived mature cells. In such organs, cell maturation is arranged in a hierarchy in which a rare population of stem cells, which perpetuate themselves through a process called *self-renewal,* gives rise to intermediate progenitors and then mature cells, neither of which self-renew.[1–11] Because of their rarity, stem cells must be isolated prospectively to study their biologic, molecular, and biochemical properties. Although it is likely that each tissue regenerates from tissue-specific stem cells, stem cells have been rigorously identified and purified in only a few. The stem cells that give rise to the lymphohematopoietic system, called *hematopoietic stem cells* (HSCs), have been isolated from mice and humans and are the best-characterized stem cells. The utility of tissue containing HSCs has been demonstrated in cancer therapy with its extensive use for bone marrow transplantation to regenerate the hematolymphoid system after myeloablative protocols.[12] The prospective isolation of HSCs from patients can result in a population of cancer-free cells for autologous transplantation.[13–17]

Understanding the cellular biology of the tissues in which cancers arise, and specifically that of the stem cells that reside in those tissues, could provide new insights into cancer biology. Several aspects of stem cell biology are relevant to cancer. First, both normal stem cells and cancer stem cells undergo self-renewal, and emerging evidence suggests that similar molecular mechanisms regulate self-renewal in normal stem cells and their malignant counterparts. Next, it is quite likely that mutations that lead to cancer accumulate in normal stem cells.[18] Finally, as was stated previously, it is likely that tumors contain a minority "cancer stem cell" population with indefinite proliferative potential that drives the growth and metastasis of tumors.[19–28]

PROPERTIES OF NORMAL STEM CELLS

HSCs are the most studied and best understood somatic stem cell population and serve as a model for stem cells from other tissues.[1,9,27,29,30] Hematopoiesis is a tightly regulated process in which a pool of HSCs eventually gives rise via oligo lineage intermediates[1,31–33] to the lymphohematopoietic system consisting of the formed blood elements (e.g., red blood cells, platelets, granulocytes, macrophages, and B and T lymphocytes). These cells are important for oxygenation, prevention of bleeding, immunity, and fighting infections. In the adult, HSCs have three fundamental properties. First, HSCs need to self-renew to maintain the stem cell pool. Self-renewal is not synonymous with proliferation. Self-renewal is a cell division in which one or both of the daughter cells remain undifferentiated and have the ability to give rise to another stem cell as well as to the spectrum of more differentiated progenitors. Second, HSCs must undergo differentiation to maintain a constant pool of mature cells in normal conditions and to produce increased numbers of a particular lineage in response to stresses such as bleeding or infection. Third, the total number of HSCs is under strict genetic regulation.[34]

In the mouse hematopoietic system, multipotent cells constitute 0.05% of bone marrow cells and are heterogeneous with respect to their ability to self-renew. There are three different populations of multipotent cells: long-term self-renewing HSCs, short-term

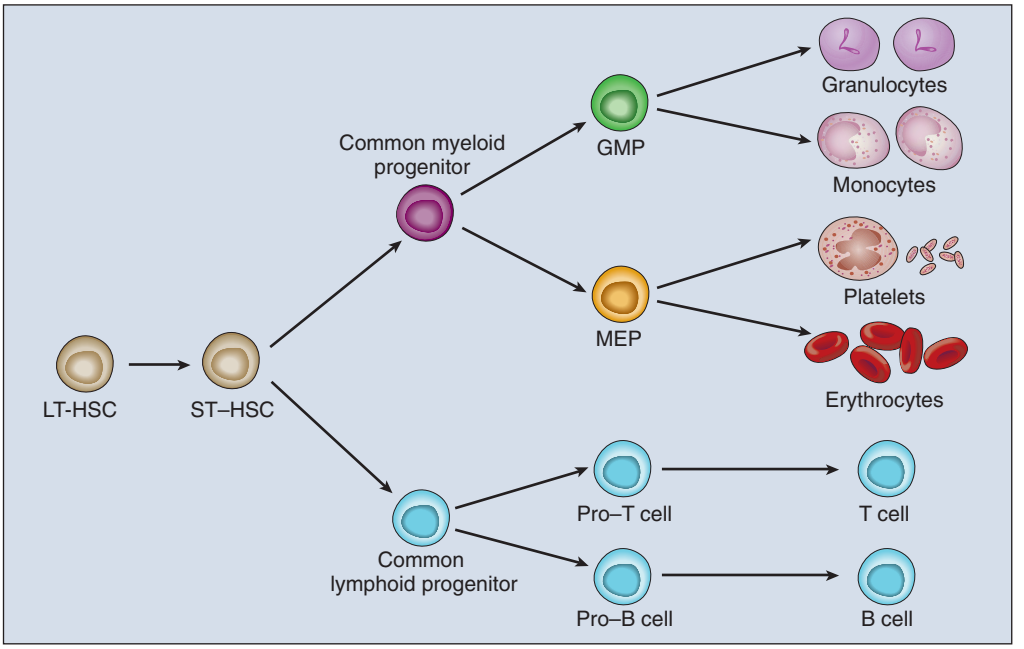

Figure 7-1 • Blood development hierarchy. All of the diverse mature blood cells arise from the hematopoietic stem cells (HSCs). The cells that are capable of multilineage reconstitution of a lethally irradiated mouse are contained within two identifiable and separate populations of cells: the long-term hematopoietic stem cells HSCs (LT-HSCs) and the short-term hematopoietic stem cells HSCs (ST-HSCs). Only the LT-HSCs are capable of self-renewal for the lifetime of the animal. In contrast, other cells, even the ST-HSCs that can give rise to large numbers of mature blood cells, have very limited life spans (measured in hours to 1 or 2 months). GMP, granulocyte-macrophage progenitors; MEP, myeloid-erythroid progenitors.

self-renewing HSCs, and multipotent progenitors without detectable self-renewal potential.[7,35] These populations form a hierarchy in which the long-term HSCs give rise to short-term HSCs, which in turn give rise to multipotent progenitors[7] (Fig. 7-1). As HSCs mature from the long-term self-renewing pool to multipotent progenitors, they become more mitotically active but lose the ability to self-renew. Only long-term HSCs can give rise to mature hematopoietic cells for the lifetime of the animal, whereas short-term HSCs and multipotent progenitors reconstitute in lethally irradiated mice for fewer than 8 weeks.[7]

Despite the fact that the phenotypic and functional properties of mouse and human HSCs have been extensively characterized,[2] understanding of the fundamental stem cell property, self-renewal, is minimal.[27,29,36] In most cases, HSCs differentiate when exposed to combinations of growth factors that can induce extensive proliferation in long-term cultures.[37] Although recent progress has been made in identifying culture conditions that maintain HSC activity in culture for a limited period,[38] it has proven to be exceedingly difficult to identify tissue culture conditions that promote a significant and prolonged expansion of progenitors with transplantable HSC activity.

GENETIC REGULATION OF SELF-RENEWAL IN NORMAL STEM CELLS AND CANCER CELLS

Maintenance of a tissue or a tumor is determined by a balance of cell proliferation and cell death.[39] As would be expected, many of the mutations that drive tumor expansion regulate either cell proliferation or survival. For example, the prevention of apoptosis by enforced expression of the oncogene Bcl-2 promotes the development of lymphoma and also results in increased numbers of HSCs in vivo, suggesting that cell death plays a role in regulating the homeostasis of HSCs; enforced expression of bcl2 does not endow short-term HSCs or multipotent progenitors with self-renewal properties.[40,41] In fact, the progression to experimental acute myelogenous leukemia (AML) in mice requires at least four independent events to block the several intrinsically triggered and extrinsically induced programmed cell death pathways of myeloid cells.[42] Proto-oncogenes such as c-myb and c-myc that drive proliferation of tumor cells are also essential for HSC development[43–46] as well as increased expression of the telomere regenerating enzyme and RNA.[47]

Self-renewal is critical for both normal stem cells and cancer stem cells. In a normal tissue, stem cell numbers are under tight genetic regulation, resulting in the maintenance of a constant number of stem cells in the organ.[34,48,49] In contrast, cancer stem cells have escaped this homeostatic regulation, and the number of cells within a tumor with the ability to self-renew is constantly expanding, resulting in the inevitable growth of the tumor. Because cancer cells and normal stem cells share the ability to self-renew, it is not surprising that a number of genes classically associated with cancer may also regulate normal stem cell development.[27,50] In combination with other growth factors, sonic hedgehog (Shh) signaling has also been implicated in the regulation of self-renewal by the finding that cells that are highly enriched for human HSCs ($CD34^{+}Lin^{-}CD38^{-}$) exhibit increased self-renewal in response to Shh stimulation in vitro.[51] Several other genes related to oncogenesis have been shown to be important for stem cell function. For example, mice that are deficient for *tal-1/SCL,* which is involved in some cases of human acute myeloid leukemia, lack embryonic hematopoiesis,[52] suggesting that *tal-1/SCL* is required for intrinsic or extrinsic events necessary to initiate hematopoiesis, for maintenance of the earliest definitive blood cells, or for the formation of blood cells downstream of embryonic HSCs.[52,53] Members of the Hox family have also been implicated in human leukemia, and enforced expression of *HoxB4* can affect stem cell functions.[54,55] One of the major targets of the p53 tumor suppressor gene is $p21^{cip1}$. Bone marrow from $p21^{cip1}$-deficient mice has a reduced ability to serially reconstitute lethally irradiated recipients. Failure at serial transfer could result from exhaustion of the stem cell pool, loss of telomeres, or loss of transplantability.[18,56,57] Thus, many genes that are involved in decisions about stem cell fate are also involved in malignant transformation.

The notion that the function of certain oncogenes is to regulate self-renewal is perhaps best illustrated by studies of the oncogene *bmi-1.* In mice, *bmi-1* cooperates with c-myc to induce lymphoma.[58,59] The number of HSCs is markedly reduced in postnatal $bmi\text{-}1^{-/-}$ mice, and transplanted $bmi\text{-}1^{-/-}$ fetal liver and bone marrow cells are able to contribute only transiently to hematopoiesis, indicating a cell autonomous defect of HSC self-renewal in $bmi\text{-}1^{-/-}$ mice.[60] The expression of stem cell-associated genes,[3] cell survival genes, transcription factors, and genes that modulate proliferation, including $p16^{Ink4a}$ and $p19^{Arf}$, is altered in bone marrow cells of $bmi\text{-}1^{-/-}$ mice. This suggests that the function of *bmi-1* is to regulate a cascade of genes

that modulate stem cell self-renewal. In a mouse model of leukemia, leukemic cells that lack expression of *bmi-1* eventually undergo proliferation arrest associated with signs of differentiation and apoptosis when they are transplanted in syngenic hosts. Infection of the cells with a *bmi-1* retrovirus completely rescues the proliferative defect of the *bmi-1*$^{-/-}$ leukemic stem cells.[61] Along a similar line, the regulated postnatal deletion of junB, an AP1 transcription factor, results in HSC expansion and then the development of a chronic myeloproliferative disorder that resembles human chronic myelogenous leukemia (CML) in its chronic phase.[62] Transduced overexpression of junB in HSCs inhibits or prevents their self-renewing proliferations. In the junB knockout HSCs, *p16*^{ink4a} and *p19*^{Arf} levels are lowered, and the antiapoptotic proteins bcl2 and bclx are increased, while the reverse is true in HSCs that have junB overexpression.[55] Only HSCs transplant this chronic phase of the disease, but later, in blast crisis, cells at a more differentiated stage emerge that transplant the blast crisis disease.[62,63] These studies conclusively demonstrate that malignant transformation requires not only activation of proliferation pathways, as well as inactivation of cell death and cell cycle arrest pathways, but also activation of self-renewal pathways.

Two other signaling pathways that are implicated in oncogenesis in both mice and humans, the Wnt/β-catenin and Notch pathways, may play central roles in the self-renewal of both normal and cancer stem cells. The Notch family of receptors was first identified in *Drosophila* species and has been implicated in development and differentiation.[64] In *Caenorhabditis elegans,* Notch plays a role in germ cell self-renewal.[65] In neural development, transient Notch activation initiates an irreversible switch from neurogenesis to gliogenesis by embryonic neural crest stem cells.[10] Notch activation of HSCs in culture with either of the Notch ligands Jagged-1 or Delta transiently increases the primitive progenitor activity both in vitro and in vivo, suggesting that Notch activation promotes either the maintenance of progenitor cell multipotentiality or HSC self-renewal.[66,67] Although the Notch pathway plays a central role in development and the mouse oncogene int-3 is a truncated Notch 4,[68] the role of Notch in de novo human cancer is complex and less well understood. Various members of the Notch signaling pathway are expressed in cancers of epithelial origin, and activation of the Notch pathway by chromosomal translocation is involved in some cases of leukemia.[69–73] Microarray analysis has shown that members of the Notch pathway are often overexpressed by tumor cells.[70,71] A truncated Notch 4 messenger RNA is expressed by some breast cancer cell lines.[74] Overexpression of Notch1 leads to growth arrest of a small cell lung cancer cell line, whereas inhibition of Notch1 signals can induce leukemia cell lines to undergo apoptosis.[64,66,75] Elegant work by Weizen and colleagues[76] showed that activation of Notch1 signaling maintains the neoplastic phenotype in Ras-transformed human cells. They also found that in de novo cancers, cells with an activating Ras mutation also demonstrate increased expression of Notch1 and Notch4.

Wnt/β-catenin signaling also plays a pivotal role in the self-renewal of normal stem cells and malignant transformation.[77–79] The Wnt pathway was first implicated in mouse mammary tumor virus-induced breast cancer in which deregulated expression of Wnt-1 caused by proviral insertion resulted in mammary tumors.[80,81] Subsequently, it has been shown that Wnt proteins play a central role in pattern formation. Wnt-1 belongs to a large family of highly hydrophobic secreted proteins that function by binding to their cognate receptors, members of the Frizzled and low-density lipoprotein receptor-related protein families, resulting in activation of β-catenin.[50,70,77,82,83] In the absence of receptor activation, β-catenin is marked for degradation by a complex consisting of the adenomatous polyposis coli, Axin, and glycogen synthase kinase-3β proteins.[78,79,84–87] Wnt proteins are expressed in the bone marrow, and activation of Wnt/β-catenin signaling by Wnt proteins in vitro or by expression of a constitutively active β-catenin expands the pool of early progenitor cells and enriched normal transplantable HSCs in tissue culture and in vivo.[27,79,84] Inhibition of Wnt/β-catenin by ectopic expression of Axin, an inhibitor of β-catenin signaling, leads to inhibition of stem cell proliferation both in vitro and in vivo. Addition of Wnt3a to purified HSC leads to their expansion, presumably self-limited usually by the expression of the β-catenin-induced transcription of axinII; transduction of purified HSC with axin prevents their expansion in vitro or in vivo.[88,89] Other studies suggest that the Wnt/β-catenin pathway mediates stem or progenitor cell self-renewal in other tissues.[85,86,90,91] The level of β-catenin in a particular keratinocyte directly correlates with its proliferative capacity.[85,86,91] As in their normal HSC counterparts, enforced expression of an activated β-catenin in epidermal stem cells increases their ability to self-renew and decreases their ability to differentiate. Mice that fail to express TCF-4, one of the transcription factors that is activated when bound to β-catenin, soon exhaust their undifferentiated crypt epithelial progenitor cells, further suggesting that Wnt signaling is involved in the self-renewal of epithelial stem cells.[50,90]

Activation of β-catenin in colon cancer by inactivation of the protein degradation pathway, most frequently by mutation of adenomatous polyposis coli, is common.[50,70,78,87] Expression of certain Wnt genes is increased in some other epithelial cancers, suggesting that activation of β-catenin might be secondary to ligand activation in such cancers.[77,92–97] There is evidence that constitutive activation of the Wnt/β-catenin pathway might confer a stem/progenitor cell phenotype to cancer cells. Inhibition of β-catenin/TCF-4 in a colon cancer cell line induced the expression of the cell cycle inhibitor p21^{cip-1} and induced the cells to stop proliferating and to acquire a more differentiated phenotype.[97] Enforced expression of the proto-oncogene c-*myc*, which is transcriptionally activated by β-catenin/TCF-4, inhibited the expression of p21^{cip-1} and allowed the colon cancer cells to proliferate when β-catenin/TCF-4 signaling was blocked, linking Wnt signaling to c-*myc* in the regulation of cell proliferation and differentiation.[97]

The implication of roles for genes such as Notch, Wnt, c-*myc*, and Shh in the regulation of self-renewal of HSCs, and perhaps of stem cells, from multiple tissues suggests that there might be at least some common self-renewal pathways in many types of normal somatic stem cells and cancer stem cells. It will be important to identify the molecular mechanisms by which these pathways work and to determine whether the pathways interact to regulate the self-renewal of normal stem cells and cancer stem cells.

TARGET CELLS FOR MALIGNANT TRANSFORMATION

If oncogenic mutations often target signaling pathways that regulate proliferation and self-renewal, then are stem cells, highly proliferative progenitor cells, or both the target of neoplastic transformation? Several lines of evidence suggest that stem cells might be involved in the evolution of a cancer. First, the fact that multiple mutations are necessary for a cell to become cancerous[98,99] suggests that in many cases, mutations accumulate in a stem cell. Progenitor cells have a very limited life span, making it less likely that all of the mutations occur during the life of these relatively short-lived cells.[1,7,8,27,29,31,32,100] Second, the regulation of stem cell expansion and self-renewal is under strict genetic regulation by multiple genes, and unregulated expansion of stem cells could, in essence, result in a cancer.[34,48,49] Third, most cancers arise in tissues that contain stem cells that have the intrinsic ability to self-renew. Because cancer cells must undergo self-renewal, this suggests that stem cells might more easily undergo steps in the progression to malignant transformation than will progenitor cells that lack this fundamental property and must therefore activate these self-renewal pathways to become malignant. In the hematopoietic system, the only cells that have the ability to self-renew are HSCs and mature lymphocytes. The common blood cancers, acute leukemias and lymphomas, may arise from the HSCs or lymphocytes, respectively, via constitutive activation of mitogenic pathways associated with the proliferation of normal cells.[27,39,101,102] Although stem cells

may undergo steps toward malignant transformation, it is possible, if not likely, that in many cases, their progenitor cells that inherit the changes in stem cells, and in addition add the ultimate transforming event, give rise to cancer. For example, the initial mutations that occur in the stem cell could permit a single mutation to transform a progenitor cell, or perhaps events that shut down self-renewal could occur in stem cells, but only progenitors outside of the stem cell regulatory niche expand as cancer stem cells.[18] It is also possible that certain oncogenic mutations such as *bmi-1* or its downstream targets could confer the property of self-renewal on a progenitor cell.

The target cells for transformation are best understood in hematopoietic malignancies because the developmental hierarchy of the blood is well established.[1,7,31,32] One of the most frequent mutations in AML in elderly patients is the t(8;21) translocation, which results in the expression of a chimeric AML-ETO transcript in the leukemic cells.[103–105] Marrow samples from patients with early onset 8;21 leukemia in Hiroshima Hospital had $CD34^{+}Thy1(CD90)^{+}CD38^{-}Lin^{-}$ HSCs, which, when isolated from patients in clinical remission, had up to 90% incidence of the chimeric AML-1-ETO transcript.[105] When these HSCs were analyzed by means of in vitro differentiation assays, the HSCs gave rise to normal myeloerythroid progeny, demonstrating that the mutation was present in the otherwise normal stem cells. In these patients, the CD90 neg subset of $CD34^{+}CD38^{-}Lin^{-}$ cells gave rise to leukemic colonies in vitro; this could represent HSCs that have lost Thy1 expression or downstream multipotent progenitors[106] that have gained self-renewal capacity.[105] Taken together, these observations support the notion that mutations accumulate in stem cells and that subsequent mutations in either the stem cells or their progeny result in overt leukemia.

Although stem cells are frequently the target of mutations that are on the path to malignant transformation, it is likely that their clonal progenitor cells may be transformed by subsequent genetic events that confer immortality, self-renewal potential, or both to these normally non-self-renewing cells (Fig. 7-2).[18] In patients with CML, the BCR-ABL mutation is present in both normal and leukemic stem cells. In otherwise normal hematopoietic cells, the BCR-ABL mRNA is expressed solely by the progenitor cells.[2,107,108] In a mouse model of CML, BCR-ABL expression targeted to myeloid progenitor cells by the hMRP-8 promoter resulted in CML-like disease in a subset of the mice. Furthermore, when $hMRP8p210^{BCR/ABL}$ mice were crossed with hMRP8bcl-2 mice, a proportion of the mutant mice developed a disease resembling AML or myeloid blast crisis.[109] Although the expression of transforming genes was targeted to early progenitor cells, the appearance of the leukemia cells and clinical course resembled human CML and AML in the $hMRP8p210^{BCR/ABL}$ mice and the $hMRP8p210^{BCR/ABL}$/hMRP8bcl-2 mice, respectively. In the chronic phase of human CML, the CML phenotype of the CML stem cell is identical to that of a normal HSC. β-Catenin signaling is active in both the normal HSCs and the CML stem cells but not in the progenitor cells. When CML progresses to "myeloid blast crisis," the patients develop an acute leukemia-like disease. The leukemic stem cell in CML blast crisis phenotypically is at the developmental stage of a granulocyte-macrophage progenitor cell that transplants the disease to immunodeficient mice and that self-renews replating potential in vitro.[110] Furthermore, the CML blast crisis stem cells appear to have activated the β-catenin signaling pathway and are inhibited in their in vitro self-renewal by transduced axin. Thus, disease progression in human CML appears to result from activation of self-renewal pathways in a progenitor cell population or, more likely, failure to shut down this pathway in the HSC to granulocyte-macrophage transition. These studies strongly suggest that the leukemia stem cell in CML blast crisis is derived from a progenitor cell, not from a normal stem cell, although the initial event and likely several progression events are in successive subclones of the initial bcr-abl HSC stage cells.

In a mouse model of high-grade glioblastoma, enforced expression of the epidermal growth factor receptor-enriched populations in either Ink4a/Arf null neuronal stem cells or Ink4a/Arf null astrocytes led to malignant glioblastomas when the cells were injected orthotopically into mice.[111] Notably, in the majority of the cases, the transformed astrocytes appeared to acquire an immature phenotype in the brains of the mice, suggesting to some researchers that there was "dedifferentiation,"[111] although we have never documented a case of dedifferentiation with purified normal hematopoietic progenitor cells. There are two other possible explanations for these results. First, the astrocyte tissue culture cells could have contained a rare population of neuronal stem cells that were transformed, and these stem cells were responsible for generating the tumors. Second, it is possible that the tissue culture conditions could have caused the dedifferentiation of the astrocytes and that unless the astrocytes are grown in tissue culture, they cannot give rise to glioblastomas in an animal. These observations in humans and mice support the notion that oncogenic mutations accumulate in the stem cells, but expression of the mutated gene by progenitors downstream of the stem cells can lead to their neoplastic transformation of progenitor cells. These observations have implications for targeted therapies.

It is possible that only a minority of the mice whose progenitors express BCR-ABL develop leukemia because the progenitors must acquire an additional mutation or epigenetic change that causes deregulated self-renewal. Two lines of evidence support this notion. First, expression of *bmi-1* is necessary for the self-renewal of adult HSCs, and the blast cells of patients with AML express large amounts of this protein.[101] Although expression of *HoxA9* and *Meis1* induces transplantable AML in normal mice, expression of these genes in the absence of *bmi-1* does not.[60,61] This suggests that both normal HSCs and leukemic stem cells require *bmi-1* to self-renew. Second, deregulated β-catenin signaling occurs in many de novo human cancers and causes cancer in transgenic mouse models. Because expression of a constitutively active β-catenin can promote the self-renewal of normal HSCs, as well as stem cells from other tissues, it is quite plausible that activation of this pathway promotes self-renewal of the cancer cells.[2,27,90,91,97,102,107,109,112,113] From these results, it is evident that

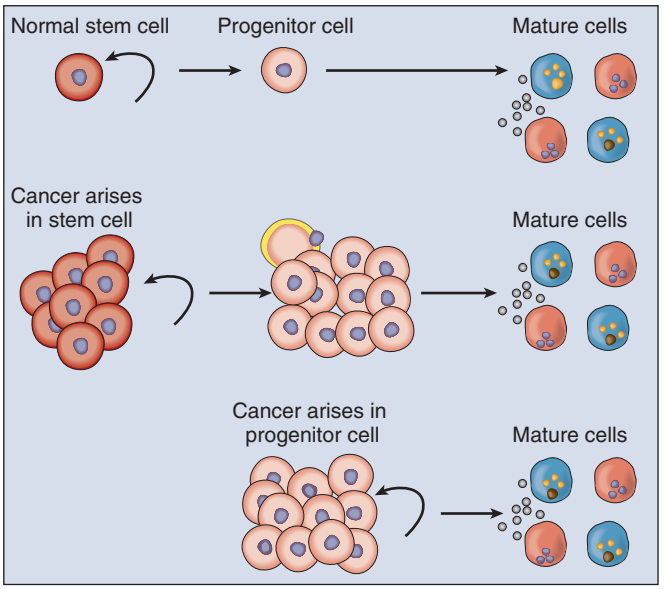

Figure 7-2 • Target cells for neoplastic transformation. In many tissues in which cancers arise, the stem cells are the only long-lived cells and are the only cells capable of self-renewal. Because they are already capable of extensive self-renewal, they are good targets for neoplastic transformation. Dysregulation of the self-renewal process may be simpler in these cells than in progenitor cells that lack this ability. For progenitor cells to undergo malignant transformation, they must acquire the ability to undergo extensive self-renewal as a result of oncogenic mutations.

future studies focusing on the molecular regulation of the self-renewal of normal stem cells and cancer cells will likely lead to more effective therapies for cancer.

EVIDENCE FOR CANCER STEM CELLS

It has long been known that cancers consist of phenotypically heterogeneous populations of cancer cells.[23–26,114–117] These phenotypically distinct cell populations could arise in part from sequential mutations caused by genetic instability, environmental factors, or both (Fig. 7-3A). Alternatively, a tumor can be viewed as an aberrant organ containing a tumorigenic (stem cell) population that drives tumor growth. These tumorigenic cells would have acquired oncogenic mutations and epigenetic changes that result in unregulated self-renewal, extended cell survival, and avoidance of innate and adaptive immune surveillance and would also give rise to phenotypically diverse populations of tumor cells that lack the ability to self-renew (Fig. 7-3B). Several lines of evidence suggest that the latter model accounts for some of the cellular heterogeneity that is seen in tumors, although genetic instability and environmental factors could also contribute to the variability in phenotypes.[118,119] It is well documented that many types of cancer contain heterogeneous populations of cells that variably express differentiation markers that reflect the tissues from which the tumors originate, as well as cancer cells that have an immature appearance.[115,120,121] Examples of this include the variable expression of milk proteins by some breast cancers and the variable expression of myeloid markers, lymphoid markers, or both in CML and AML. Perhaps the most striking example of abnormal differentiation in cancer is the variable expression of diverse tissues in some germ cell tumors. Mature tissues such as teeth, skin, and hair are present in some cases of teratocarcinomas (Fig. 7-4). In contrast, in some tumors, only a minority of the cancer cells express immature cell markers such as α-fetoprotein (see Fig. 7-4). Because the terminally differentiated cells that form the teeth and hair in the tumors are unlikely to be able to proliferate and form new tumors, these data suggest that the minority population of α-fetoprotein-expressing cancer cells has the exclusive ability to form new tumors consisting of more tumorigenic cells, as well as the phenotypically diverse populations of non-self-renewing abnormally differentiated cells. If this is true, these cells can thus be considered cancer stem cells.

If a tumor is viewed as an abnormal organ, then the principles of stem cell biology can be applied to better understand the biology of these diseases.[1,8,9] It was first shown in hematopoietic malignancies and subsequently in solid cancers that only a subset of cancer cells were clonogenic when placed in tissue culture or injected into immunodeficient mice.[21,23–25,115,117,122,123] For example, only 1 in 100 to 1 in 10,000 mouse myeloma cells obtained from ascites fluid formed in in vitro colony-forming assays. Similarly, only 1% to 4% of leukemic cells formed spleen colonies when transplanted into mice. In solid cancers, only 1 in 1000 to 1 in 5000 ovarian cancer or lung cancer cells formed colonies in soft agar. Because only a minority of normal bone marrow cells was also clonogenic, the clonogenic cancer cells were described as *cancer stem cells,* implying that only a distinct population of cancer cells was able to proliferate extensively in these assays. However, an alternative explanation is that all the cancer cells had an intrinsic ability to proliferate extensively but only a minority of cells did so in a particular assay.[117] Variable plating efficiency in a variety of in vitro cells and cell lines could have accounted for the poor performance of such cells, and in none of the assays did the investigators prospectively purify the plating cell to show that it was, or was not, a cancer stem cell.

To prove that a phenotypically distinct population of cancer cells is solely responsible for perpetuating the disease, it is necessary to isolate different populations of cancer cells and demonstrate that one or more groups are enriched for the ability to initiate disease and other populations lack this ability. This was done in the case of AML, when it was shown that in most cases of human AML, a leukemic tumor initiating subpopulations of cells could be identified prospectively and enriched from the bone marrow of multiple patients. In most cases of AML, the minority population of $CD34^{+}CD38^{-}$ cells was the only group of cells that was capable of establishing human AML in the bone marrow of nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice.[124,125] Remarkably, within the $CD34^{+}CD38^{-}$ population are $Thy1^{+}CD34^{+}CD38^{-}$ $Lineage^{-}$ normal HSCs[2,100,105,124–127] as well as $Thy1^{-}CD34^{+}38^{-}Lineage^{-}$ progenitors.[106] Because normal HSCs, but not their leukemic initiating cell counterparts, express Thy1, it is likely that the early mutations occurred in the HSCs and the final transforming mutations occurred either in early downstream progenitors or in HSCs if, as a consequence of neoplastic transformation, Thy1 expression was lost.[105]

Recently, tumorigenic and nontumorigenic subsets of cancer cells have been isolated from human breast cancer tumors. When a similar model for human breast cancer was used in which isolated

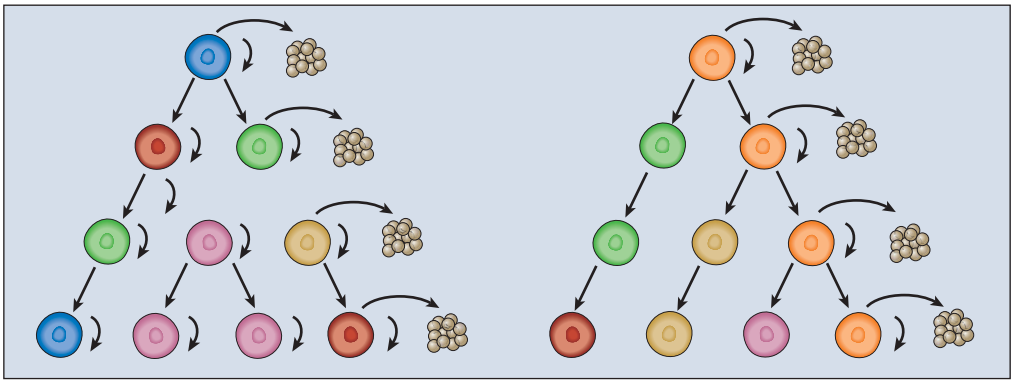

Figure 7-3 • The two most likely models of heterogeneity of the cancer cells, shown as different colored cells within a tumor. **A,** Heterogeneity is due to environmental factors (*gold, red, green,* and *blue* cells) or due to ongoing mutations in the cancer cells (*magenta* cells). In this model, all of the cancer cells have the intrinsic ability to form tumors. **B,** Cancer stem cells (*yellow* cells) have the exclusive ability to self-renew. As in normal tissues, the stem cells would give rise to more stem cells with the capacity to form new tumors, as well as the other heterogeneous populations of cancer cells that lack the ability to form new tumors. To date, therapeutic and diagnostic strategies have been based on model A, but these strategies might be limited because they might not target the rare population of cancer stem cells depicted in model B.

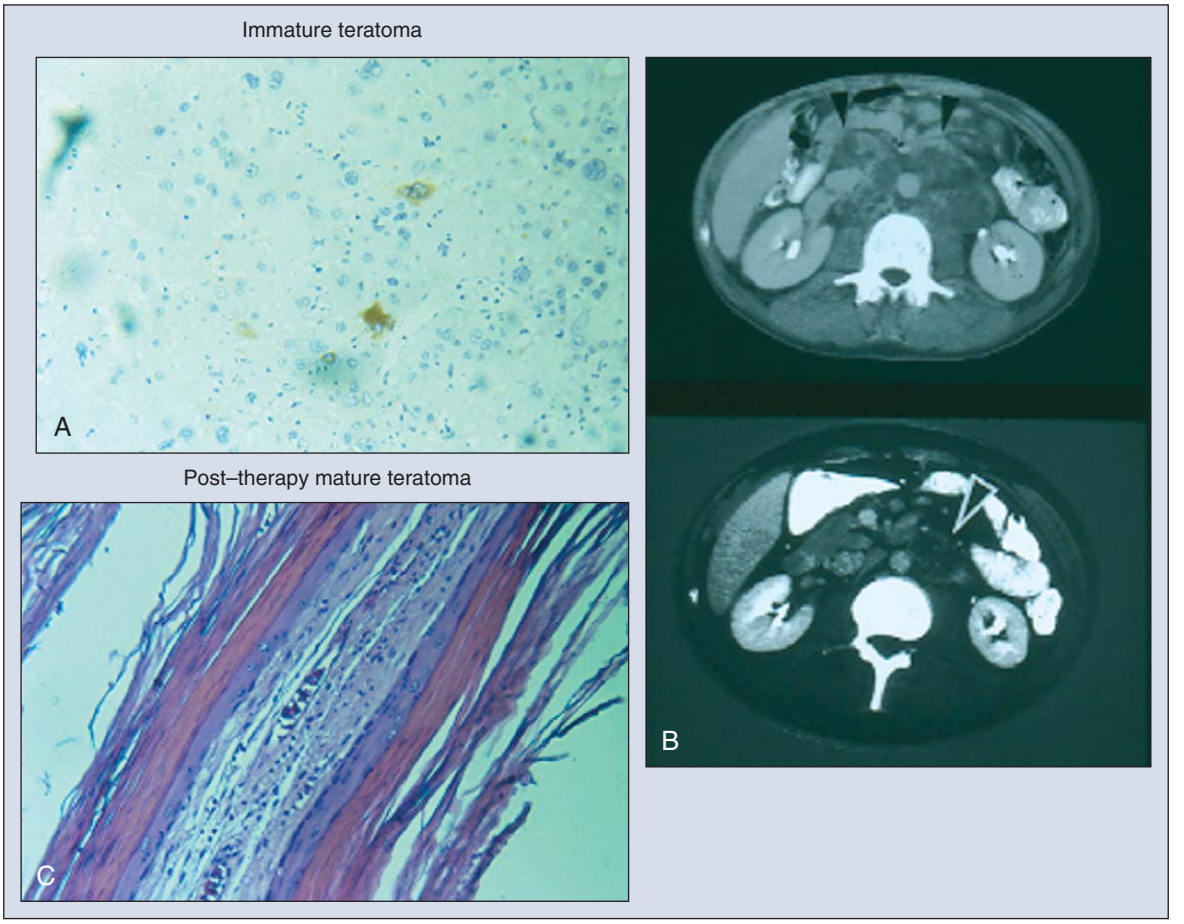

Figure 7-4 • Clinical evidence for the stem cell model. The clinical and radiographic information for a patient with metastatic teratocarcinoma of the testis is shown. **A,** In the original testicular biopsy specimen, expression of α-fetoprotein by only rare cancer cells (*brown* cells) was detected by immunohistochemistry of the original testicular tumor. The original histologic finding in this patient was believed to represent a teratoma. **B,** Computed tomographic scans before treatment (*upper panel*) demonstrated large retroperitoneal masses that were still present after four courses of platinum-based chemotherapy (*lower panel*). **C,** Biopsy specimen of the residual mass revealed only mature teratoma. No cells expressed the immature marker α-fetoprotein. The patient has survived for more than 10 years without recurrence of his germ cell cancer. This suggests that in some patients, therapies that selectively eliminate the rare stem cell population while sparing the "nontumorigenic" cancer cells could be curative.

cells were grown in immunocompromised mice, a minority population of breast cancer cells that had the ability to form new tumors was identified.[19] Tumorigenic cells could be distinguished from nontumorigenic cancer cells on the basis of surface marker expression. In eight of nine patients, tumorigenic cells could be prospectively identified and isolated as $CD44^+CD24^{-/low}Lineage^-$ cells.[19] As few as 100 $CD44^+CD24^{-/low}Lineage^-$ cells were able to form tumors, whereas tens of thousands of cells from other populations of cells within the tumor failed to form tumors in NOD/SCID mice. These tumorigenic cells could be serially passaged in mice, and each time, cells within this population generated new tumors containing additional $CD44^+CD24^{-/low}Lineage^-$ tumorigenic cells, as well as phenotypically mixed populations of other nontumorigenic cancer cells. These data demonstrate the presence of a hierarchy of cells within a breast cancer tumor in which only a fraction of the cells have the ability to proliferate extensively and other cells have only a limited proliferative potential, suggesting that the tumorigenic cells can both self-renew and differentiate. The phenotype of the tumorigenic breast cancer cells may be similar to that of normal breast epithelial stem or progenitor cells, because early multipotent epithelial progenitor cells have been reported to express epithelial cell antigen and CD44.[128–130]

The $CD44^+CD24^{-/low}Lineage^-$ tumorigenic breast cancer cell and the $CD34^+CD38^-CD90^-$ leukemia-initiating cells share with normal stem cells the abilities to proliferate extensively and to give rise to diverse cell types with reduced developmental or proliferative potential.[5,19] The extensive proliferative potential of the tumorigenic breast cancer cell population was demonstrated by the ability of as few as 200 tumorigenic breast cancer cells or several thousand leukemia-initiating cells to give rise to tumors that could be serially transplanted in NOD/SCID mice. This extensive proliferative potential contrasts with the bulk of the breast cancer cells that lack the ability to form detectable tumors. Not only was the $CD44^+CD24^{-/low}Lineage^-$ population of cells able to give rise to additional tumorigenic $CD44^+CD24^{-/low}Lineage^-$ cells, it was also able to give rise to phenotypically diverse nontumorigenic cells that made up the bulk of the tumors. Thus, both tumorigenic breast cancer cells and leukemia-initiating cells from most tumors appear to exhibit properties of cancer stem cells. However, before these cells can definitively be called cancer stem cells, new assays are needed to demonstrate that a single transplanted cell gives rise to all of the diverse populations of cancer cells within a tumor.

Cancer stem cells have since been identified in multiple tumors, including cancers arising in the brain, head and neck, pancreas, colon, and prostate.[131–135] Interestingly, CD44 seems to be useful as a marker for isolation of cancer stem cells from multiple types of tumors of epithelial origin, including head and neck cancer. Importantly, in histology sections, the cancer stem cells in well-differentiated or mod-

erately differentiated tumors showed that the cancer stem cells, but not the nontumorigenic cancer cells, expressed CD44 and *bmi-1,* which had previously been shown to be involved in self-renewal in some types of stem cells.[133] However, the nontumorigenic cells expressed mature cell markers, while the cancer stem cells did not.[133] These studies demonstrate that the differential expression of the stem cell markers was not an artifact of flow cytometry.

IMPLICATIONS OF CANCER STEM CELLS FOR THE DIAGNOSIS AND TREATMENT OF CANCER

Although the immunocompromised mouse model provides compelling evidence in support of the stem cell model of cancer, the ultimate confirmation of the hypothesis requires proof in humans. If the growth of solid cancers is driven by cancer stem cells, this would have profound implications for the diagnosis and treatment of cancer. At present, all of the phenotypically diverse cancer cells are treated as if they possess the ability to form tumors and the ability to metastasize. However, if in most tumors, only a small population of cancer cells has the ability to self-renew and other populations of cancer cells have only limited ability to proliferate, then this would explain several conundrums of cancer biology. For example, for many years, it has been recognized that disseminated cytokeratin-positive breast cancer cells can be detected in the bone marrow of patients who never experience relapse, even without adjuvant therapy.[136–143] One possibility is that the cancer cells lie dormant until some unknown event triggers them to proliferate. Another explanation is that the cancer cells in the bone marrow in this group of patients arose from the spread of nontumorigenic cancer cells, and only when the cancer stem cells metastasize and subsequently self-renew will frank tumors form. Thus, the development of diagnostic reagents that allow cancer stem cells to be identified may have prognostic significance for patients with breast cancer.

The ability to prospectively isolate cancer stem cells and nontumorigenic cancer cells makes it possible to do molecular analyses of each population of cancer cells in a tumor. A 186-gene signature, called the invasiveness gene signature (IGS), was derived by identifying genes that are differentially expressed by breast cancer stem cells and normal breast epithelial cells.[144] The IGS was used to stratify patients with early stage breast cancer on the basis of the similarity of the gene expression of the whole tumor to the cancer stem cell-derived signature. Remarkably, the IGS was associated with both survival and the risk of developing metastasis. The prognostic power of the IGS was greater than gene signatures derived from the nontumorigenic cancer cells, indicating that the IGS contained both cancer-specific and cancer stem cell-specific elements. The prognostic power of the IGS was even greater when combined with a wound repair signature[145] derived from serum-stimulated fibroblasts. This suggests that cancer stem cells interact with normal tumor stromal elements. Such an interaction is further supported by the observation that the cancer stem cells are adjacent to normal stromal elements in well-differentiated and moderately differentiated head and neck tumors.[133]

Another example of the implications of cancer stem cells is the observation that in most solid cancers, such as breast cancers, chemotherapy can frequently shrink tumors, but in most patients, the tumors rapidly recur, and there is only a small impact on patient survival.[13,146,147] Most of the cancer therapeutic agents that are in current use have been developed largely for their ability to shrink a tumor. If only a minority of the cancer cells are tumorigenic and are responsible for driving tumor growth and metastasis, then tumor shrinkage must reflect primarily the elimination of the bulk population of nontumorigenic cells. If a substantial number of tumor stem cells were spared, then the tumors would regenerate from these cells. In support of this model, many patients who are treated with chemotherapy experience an initial shrinkage of their tumors, but tumors recur in sites of prior disease.

The similarities of the AML tumor-initiating cells and normal HSCs suggest that the AML tumor-initiating cells may be more resistant to chemotherapy than the bulk population of leukemic blasts. Compared with their differentiated progeny, normal HSCs express high levels of genes that make them more resistant to cytotoxic agents including antiapoptotic members of the bcl-2 family, as well as members of the ABC transporters that pump many drugs out of the cell.[30,41,148–151] If the same is true for their cancer stem cell counterparts, then these cells may be significantly more resistant to cytotoxic agents than their nontumorigenic progeny. In support of this possibility, although the chemotherapeutic agent cytosine arabinoside very efficiently killed leukemic blast cells isolated from many patients, the leukemia-initiating cells were selectively spared.[152] In glioblastoma, the cancer stem cells are more resistant to radiation than are their nontumorigenic cancer cell counterparts.[153] These observations suggests that the effect of a particular therapeutic agent on the cancer stem cell population must be taken into account when its curative potential is evaluated.[154]

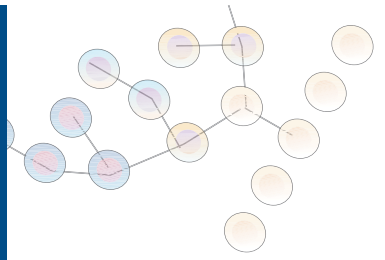
Because therapeutic agents are selected on the basis of their ability to shrink tumors rapidly, agents that selectively target the cancer stem cells could be overlooked in screens to identify potential therapeutic agents. Initially, such agents would be expected to slow the growth of a tumor only modestly. However, the elimination of the cancer stem cells would eventually halt the spread of the tumor. Perhaps the best clinical evidence of this model occurs in patients with teratocarcinoma. Platinum-based chemotherapy is curative in the majority of these patients;[155] however, many patients are left with residual masses (see Fig. 7-4). After surgical resection, the immature cancer cells have been eliminated, leaving only differentiated cancer cells in a mature teratoma (see Fig. 7-4). Patients with mature teratomas only occasionally have metastases, and most are cured, demonstrating that the elimination of the presumed stem cell population by the chemotherapy is sufficient for curing this solid cancer. Box 7-1 discusses alternative models for cancer cell heterogeneity.

Box 7-1. ALTERNATIVE CANCER CELL HETEROGENEITY MODELS

An alternative explanation for the ability of a single, phenotypically unique population of AML cells or breast cancer cells to engraft in NOD/SCID mice is that all cancer cells are tumorigenic in humans but that only the $CD34^+CD38^-Thy1^-Lineage^-$ AML cells or the $CD44^+CD24^{-/low}Lineage^-$ breast cancer cells are able to proliferate in mice. However, there are several reasons that this appears unlikely. First, NOD/SCID mice have previously been validated as in vivo models for the growth of normal human HSCs and human neural stem cells.[2,9,126,156–158] Second, tumors that are passaged in mice contain heterogeneous cancer cells that are phenotypically similar to the cancer cells that were present in the original tumors from patients, including both tumorigenic and nontumorigenic fractions.[19,20,125,126] This demonstrates that the mouse environment is not incompatible with the survival of the nontumorigenic cell fractions. Third, in the case of breast cancers, the tumorigenic and nontumorigenic fractions of cancer cells exhibit a similar cell cycle distribution in mouse tumors, demonstrating that the nontumorigenic cells are able to divide in mice.[19] Thus, on the basis of these data and the data obtained for other types of normal and malignant human stem cells, the NOD/SCID mouse model reliably supports the engraftment of clonogenic human progenitors. However, human data are required to completely exclude the possibility that different populations of cancer cells are clonogenic in mice than are clonogenic in humans. Because ethical issues preclude the injection of cancer cells into humans, unequivocal proof of the stem cell model will require clinical studies that confirm that therapeutic agents that effectively target cancer stem cells in the immunodeficient mice also eliminate cancer stem cells in patients and result in clinical cures.

FUTURE IMPLICATIONS OF CANCER STEM CELLS

The ability to prospectively identify cancer stem cells should have a major impact on the development of new diagnostic and therapeutic agents. At present, all of the cancer cells within a tumor are treated as if they had the ability to drive tumor growth, invasion, and metastasis. The ability to identify these crucial cells will allow efforts to develop new diagnostic markers and therapies to be focused on the cells that are responsible for the maintenance of the malignancy—the cancer stem cells. For example, in efforts to identify the genes and proteins expressed by cancer cells, either whole tumors or all of the phenotypically diverse cancer cells within a tumor are currently used. Because the cancer stem cells represent only a minority of the cancer cells in most tumors, it is nearly impossible to identify diagnostic markers or therapies that target these cells. However, directing expression analyses to enriched populations of cancer stem cells should allow the identification of novel diagnostic markers and novel therapeutic targets that can be exploited to more effectively diagnose and treat cancer. This principle is illustrated by the observation that BCR/ABL oncogene mRNA is not expressed by HSCs that carry the mutation in their DNA;[159,160] such an approach may have implications even when oncogenic mutations are targeted.



The ability to prospectively identify the cancer stem cells should also improve the ability to evaluate the curative potential of new therapeutic agents. Although cancer cell lines are useful for evaluating particular biologic pathways, they have proven to be somewhat unreliable when used in attempts to predict the clinical efficacy of a particular therapeutic agent in patients.[159,160] Because the tumors that arise in immunodeficient mouse models of human cancer appear to more closely recapitulate the phenotypic diversity of patients' original tumors, including the generation of tumorigenic and nontumorigenic cells, these models might more effectively predict the potential usefulness of a particular drug. New agents could be tested for their ability to eliminate the tumorigenic (cancer stem cell) component of tumors from multiple patients, allowing the agents that have the greatest curative potential to proceed to human clinical trials.

8 Vascular and Interstitial Biology of Tumors

Rakesh K. Jain and Dan G. Duda

SUMMARY OF KEY POINTS

- A solid tumor is an organ composed of neoplastic cells and host stromal cells nourished by the vasculature made of endothelial cells—all embedded in an extracellular matrix. The interactions among these cells and between these cells, their surrounding matrix, and their local microenvironment control the expression of various genes. The products encoded by these genes, in turn, control the pathophysiologic characteristics of the tumor. The tumor pathophysiology governs not only tumor growth, invasion, and metastasis but also the response to various therapies.
- Tumor vasculature is made of host vessels co-opted by tumor cells and by new vessels formed by the processes of vasculogenesis and angiogenesis. A constellation of positive and negative regulators of angiogenesis governs the process of neovascularization.
- Tumor vessels are abnormal in terms of their organization, structure, and function. These abnormalities contribute to heterogeneous vascular permeability, blood flow, and microenvironment.
- Tumor interstitial matrix is formed by proteins secreted by host and tumor cells and by those leaked from the nascent blood vessels.
- Tumor interstitium is heterogeneous, with some regions fairly permeable and others difficult to penetrate. Modification of the collagen matrix can improve penetration of large-molecular-weight therapeutics.
- Interstitial hypertension is a hallmark of solid tumors and results from vessel leakiness, lack of functional lymphatics, and compression of vessels by proliferating cancer cells.
- Judicious application of angiogenic therapy can normalize the tumor vessels and make them more effcient for delivery of oxygen (a known radiosensitizer) and drugs. Antiangiogenic agents can prune tumor vessels, induce cancer cell apoptosis, reduce the number of blood circulating endothelial cells and progenitor cells, and lower interstitial hypertension in tumors.
- Thus far, three antiangiogenic agents have been approved for patients with certain types of cancer. Based on these successes, antiangiogenic therapy is expected to make a difference in many other tumor types. Two main hurdles to further development of antiangiogenic agents are the better understanding of the mechanisms of action of these agents and developing biomarkers to monitor their effects.

INTRODUCTION

A solid tumor is an organ composed of neoplastic cells and host stromal cells nourished by the vasculature made of endothelial cells—all embedded in an extracellular matrix (Fig. 8-1). The interactions among these cells and between these cells, their surrounding matrix, and their local microenvironment, control the expression of various genes. The products encoded by these genes, in turn, control the pathophysiologic characteristics of the tumor. The tumor pathophysiology governs not only the tumor growth, invasion, and metastasis but also the response to various therapies. In this chapter we will discuss various pathophysiologic parameters that characterize the vascular and extravascular compartments of a tumor and the mechanisms governing the formation and function of these compartments.

VASCULAR COMPARTMENT

Neoplastic cells, like normal cells, need oxygen and other nutrients for their survival and growth. Every normal cell in our body is located within 100 to 200 μm from a blood capillary so that it can receive oxygen and other nutrients by the process of diffusion. Likewise, cells undergoing neoplastic transformation depend on nearby capillaries for growth. These preneoplastic (i.e., hyperplastic or dysplastic) cells can grow as a spherical or ellipsoidal cellular aggregate. Once the size of the cellular aggregate reaches the diffusion limit for critical nutrients and oxygen, however, the aggregate as a whole can become dormant. Indeed, human tumors can remain dormant for many years because of a balance between neoplastic cell proliferation and apoptosis. However, once they have access to new blood vessels they may grow and metastasize. What triggers the growth of new vessels? What molecular and cellular mechanisms are involved? How do these vessels compare with normal vessels with respect to structure and function? Can we prevent or delay tumor progression only by interfering with the neovascularization process?

New Vessel Formation

It has been known for nearly a century that the vascular system is associated with tumor growth in animals and humans.[1] Powerful insights into the neovascularization of transplanted tumors using the transparent window techniques were developed in the 1940s.[2–5] The possibility that tumors produce an "angiogenic" substance was suggested in 1968.[6,7] The hypothesis that blocking angiogenesis should

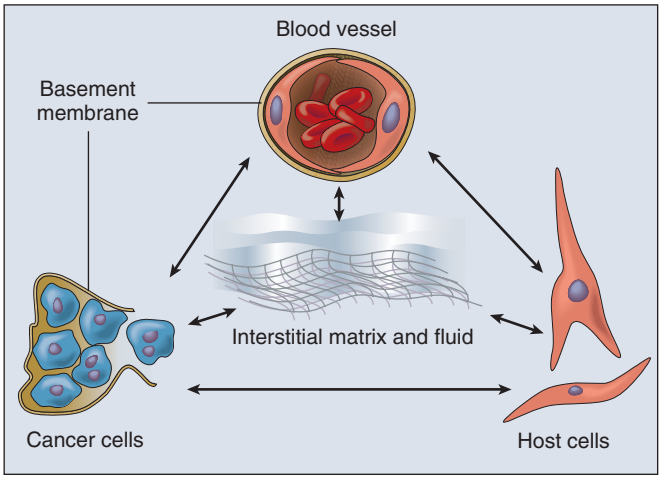

Figure 8-1 • Schematic representation of a solid tumor. The key components include cancer cells, host cells, and vasculature made of endothelial cells—all embedded in a matrix bathed in interstitial fluid. Arrows indicate interactions between the components. (Adapted from Jain RK: Angiogenesis and lymphangiogenesis in tumor: insights from intravital microscopy. Cold Spring Harbor Symp Quant Biol [The Cardiovascular System] 2002;67:239–248.)

block tumor growth and metastasis was proposed shortly thereafter in 1971.[8] The concept that a tissue acquires angiogenic capacity during neoplastic transformation—and, by extension, that antiangiogenesis could be used to prevent cancer—was put forward in 1976.[9] The first antiangiogenic agent approved for cancer patients was bevacizumab, an antibody specific to vascular endothelial growth factor (VEGF), on the basis of the increased survival seen in metastatic colorectal cancer patients with the combination of bevacizumab with standard chemotherapy in a pivotal randomized placebo-controlled phase III trial.[10] At present, various anti- and proangiogenesis strategies are being evaluated clinically to prevent or treat a large number of diseases, including cancer.[11–13] Both normal and pathologic angiogenic processes are governed by the net balance between pro- and antiangiogenic factors.[14,15] This balance is spatially and temporally regulated under physiologic conditions, so that the "angiogenic switch" is "on" when needed (e.g., during embryonic development, wound healing, formation of the corpus luteum) and "off" at other times. During neoplastic transformation and tumor progression, this regulation is deranged, and blood vessels form ectopically to support a growing tumor mass.

Cellular Mechanisms

At least four cellular mechanisms are involved in the vascularization of tumors: co-option, intussusception, sprouting (angiogenesis), and vasculogenesis (Fig. 8-2).[11] Tumor cells can co-opt and grow around existing vessels to form "perivascular" cuffs. However, as stated earlier, these cuffs cannot grow beyond the diffusion limit of critical nutrients and may actually cause the collapse of the vessels due to the growth pressure (referred to as "solid stress"). Alternatively, an existing vessel may enlarge in response to the growth factors released by tumors, and an interstitial tissue column may grow in the enlarged lumen and partition the lumen to form an expanded vascular network. This mode of intussusceptive microvascular growth has been observed during tumor growth, wound healing, and gene therapy.[16–19] "Sprouting" angiogenesis is perhaps the most widely studied mechanism of vessel formation. During sprouting angiogenesis, the existing vessels become leaky in response to growth factors released by normal cells or cancer cells; the basement membrane and the interstitial matrix dissolve; pericytes dissociate from the vessel; endothelial cells (ECs) migrate and proliferate to form an array/sprout; a lumen is formed in the sprout (a process referred to as canalization); branches and loops are formed by confluence and anastomoses of sprouts to permit blood flow; and finally, these immature vessels are invested in basement membrane and pericytes. During physiologic angiogenesis, these vessels differentiate into mature arterioles, capillaries, and venules, whereas in tumors they remain largely immature.[5,11,12,20] During embryonic development, a primitive vascular plexus is formed from endothelial precursor cells (EPCs, also known as angioblasts) by a process referred to as vasculogenesis. In adults, EPCs—mobilized from bone marrow niches into the peripheral blood circulation—can also contribute to neovascularization (process referred to as "postnatal" vasculogenesis) in tumors and other tissues.[21–23] The current challenge is to discern the relative contribution of each of the four

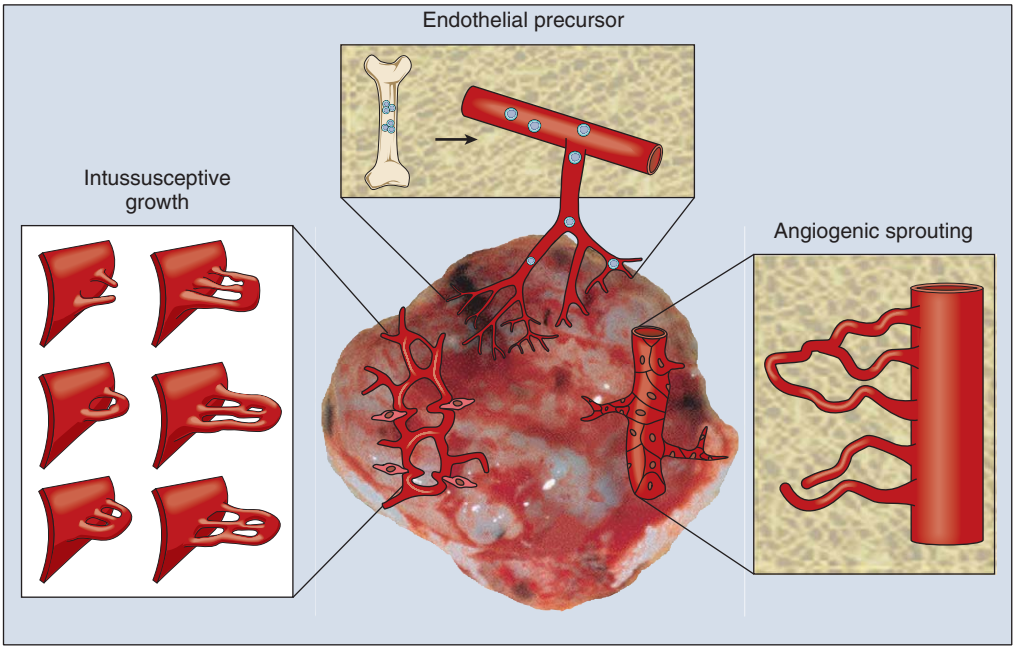

Figure 8-2 • Cellular mechanisms of vascularization in tumors. At least four mechanisms are involved: (1) intussusception, where tumor vessels enlarge and an interstitial tissue column grows in the enlarged lumen, expanding the network; (2) vasculogenesis, where endothelial precursor cells mobilized from the bone marrow or peripheral blood contribute to the endothelial lining of tumor vessels; (3) "sprouting" angiogenesis, where the existing vascular network expands by forming sprouts or bridges; and (4) co-option (not shown), where tumor cells grow around existing vessels to form "perivascular" cuffs. (Adapted from Jain RK, Carmeliet PF: Angiogenesis in cancer and other diseases. Nature 2000;407:249–257.)

mechanisms of neovascularization during the growth and/or during treatment of tumors.[24]

Molecular Mechanisms

Various pro- and antiangiogenic molecules that orchestrate different steps in vessel formation, along with their functions, are listed in Table 8-1. VEGF is currently considered the most critical proangiogenic molecule. Originally discovered in 1983 as the vascular permeability factor and cloned in 1989, VEGF increases vascular permeability, promotes migration and proliferation of ECs, serves as an EC survival factor, can mobilize EPC populations from the bone marrow, and is known to upregulate leukocyte adhesion molecules on ECs.[16,22,25–27] During tumor progression, or with treatment, the number of distinct angiogenic molecules produced by a tumor can increase.[28–30] Thus, after VEGF signaling is blocked, a tumor might rely on other, alternative angiogenic molecules (e.g., basic fibroblast growth factor [bFGF], stromal-derived factor 1α [SDF1α], placental-derived growth factor [PlGF], or interleukin-8 [IL-8]).[31] Other positive regulators of angiogenesis include the angiopoietins that are involved in stabilizing vessels and controlling vascular permeability; various proteases involved in dissolving/remodeling matrix and releasing growth factors; and recently discovered organ-specific angiogenic stimulators (e.g., endocrine gland VEGF).[20,32,33] Angiogenesis inhibitors include endogenous soluble receptors of various proangiogenic ligands (e.g., sVEGFR1) and molecules that downregulate the expression of stimulators (e.g., interferons) or that interfere with the release of the stimulators or binding with their receptors (e.g., platelet factor 4). Thrombospondins are among the first and most well-characterized endogenous inhibitors that interfere with the growth, adhesion, migration, and survival of ECs.[14] Other endogenous inhibitors include fragments of various plasma or matrix proteins (e.g., angiostatin, a fragment of plasminogen; endostatin, a fragment of collagen XVIII; tumstatin, a fragment of collagen IV).[34–36] Neither the mechanisms of action of the matrix-derived inhibitors nor their physiologic role are well understood.[37] The generation of pro- and antiangiogenic molecules can be triggered by metabolic stress

Table 8-1 Angiogenesis Activators and Inhibitors*

Activators	Function	Inhibitors	Function
VEGF family members†‡	Stimulate angio/vasculogenesis, permeability, leukocyte adhesion	VEGFR-1; soluble VEGFR-1; soluble neuropilin-1 (NRP-1)	Sink for VEGF, VEGF-B, PlGF
VEGFR‡, NRP-1, NRP-2	Integrate angiogenic and survival signals	Ang 2†‡	Antagonist of Ang 1
EG-VEGF	Stimulate growth of endothelial cells derived from endocrine glands	TSP-1,2	Inhibit endothelial migration, growth, adhesion, and survival
Ang 1 and Tie 2†‡	Stabilize vessels	Angiostatin and related plasminogen kringles	Inhibit endothelial migration and survival
PDGF-BB and receptors	Recruit smooth muscle cells	Endostatin (collagen XVIII fragment)	Inhibit endothelial survival and migration
TGF-β1§, endoglin, TGF-β receptors	Stimulate extracellular matrix production	Tumstatin (collagen IV fragment)	Inhibit endothelial protein synthesis
FGF, HGF, MCP-1	Stimulate angio/arteriogenesis	Vasostatin; calreticulin	Inhibit endothelial growth
Integrins $\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_5\beta_1$	Receptors for matrix macromolecules and proteinases	Platelet factor-4	Inhibit binding of bFGF and VEGF
VE-cadherin; PECAM (CD31)	Endothelial junctional molecules	Tissue-inhibitors of MMP (TIMPs); MMP-inhibitors; PEX	Suppress pathologic angiogenesis
Ephrins‡	Regulate arterial/venous specification	Meth-1; Meth-2	Inhibitors containing MMP-, TSP-, and disintegrin domains
Plasminogen activators, MMPs	Remodel matrix, release growth factor	IFN-α, -β, -γ; IP-10, IL-4, IL-12, IL-18	Inhibit endothelial migration; downregulate bFGF
PAI-1	Stabilize nascent vessels	Prothrombin kringle-2; antithrombin III fragment	Suppress endothelial growth
NOS; COX-2	Stimulate angiogenesis and vasodilation	16 kD-prolactin	Inhibit bFGF/VEGF
AC133	Regulate angioblast differentiation	VEGI	Modulate cell growth
Chemokines§	Pleiotropic role in angiogenesis	Fragment of SPARC	Inhibit endothelial binding and activity of VEGF
Id1/Id3	Inhibit differentiation	Osteopontin fragment	Interfere with integrin signaling
		Maspin	Protease inhibitor
		Canstatin, proliferin-related protein, restin	Mechanisms unknown

(e.g., low pO_2, low pH, or hypoglycemia), mechanical stress (e.g., shear stress, solid stress), immune/inflammatory cells that have infiltrated the tissue, and genetic mutations (e.g., activation of oncogenes or deletion of suppressor genes that control the production of angiogenesis regulators).[14,15,38–41] These molecules can emanate from cancer cells, endothelial cells, stromal cells, blood, and extracellular matrix (Fig. 8-3).[42–45] Because the normal host cells differ among organs, the detailed mechanisms of angiogenesis might depend on the specific host-tumor interactions operating within a given tissue.[46–53] Furthermore, because the tumor microenvironment is likely to change during tumor growth, regression, and relapse, profiles of pro- and antiangiogenic molecules are likely to change with time and space.[54,55] The challenge currently is to develop a unified conceptual framework to describe the temporal and spatial profiles of this increasingly diverse array of angiogenesis regulators with the aim of developing effective therapeutic strategies.[56,57]

Vascular Architecture

In a normal tissue, blood flows from an artery to arterioles to capillaries to venules to a vein. Although the tumor vasculature originates from these host vessels and the mechanisms of angiogenesis are similar, its organization may differ dramatically, depending on the tumor type, its location, and whether it is growing, regressing, or relapsing.[16,58–61] In general, tumor vessels are dilated, saccular, tortuous, and chaotic in their patterns of interconnection.[62] For example, whereas normal vasculature is characterized by dichotomous branching, tumor vasculature has many trifurcations and branches with uneven diameters.[63,64] The fractal dimensions and minimum path lengths of tumor vasculature are different from those of normal host vasculature.[58–60] The molecular mechanisms of this abnormal vascular architecture are not understood, but it seems reasonable to hypothesize that the imbalance of VEGF and angiopoietins is a key contributor.[20,65] In mice, "normalization" of the tumor vasculature observed during therapies that reduce VEGF (e.g., hormone withdrawal from a hormone-dependent tumor), interfere with VEGF signaling (e.g., treatment with anti-VEGF or anti-VEGFR2 antibody; Fig. 8-4), or mimic an antiangiogenic cocktail (e.g., trastuzumab [Herceptin] treatment of a HER2-overexpressing tumor) is in concert with this molecular hypothesis.[12,54–56,66] Mechanical stress generated by proliferating tumor cells also can lead to the partially compressed or totally collapsed vessels often found in tumors.[67,68] The decompression of blood vessels observed after induction of apoptosis in perivascular cells supports this mechanical hypothesis.[69,70] Perhaps the combination of both molecular and mechanical factors renders the tumor vasculature abnormal, and, thus, both types of factors must be taken into account when designing novel strategies for cancer treatment.

Blood Flow and Microcirculation

Blood flow in a vascular network, whether normal or abnormal, is governed by the arterio-venous pressure difference and flow resistance. Flow resistance is a function of the vascular architecture (referred to as geometric resistance) and of the blood viscosity (rheology, referred to as viscous resistance).[62] Abnormalities in both vasculature and viscosity increase the resistance to blood flow in tumors.[64,71–73] As a result, overall perfusion rates (blood flow rate per unit volume) in tumors are lower than in many normal tissues.[74–76] Both macroscopically and microscopically, tumor blood flow is temporally and spatially chaotic. Macroscopically, four spatial regions can be recognized in a tumor (Fig. 8-5):

1. An avascular necrotic region
2. A semi-necrotic region
3. A stabilized microcirculation region
4. An advancing front[77,78]

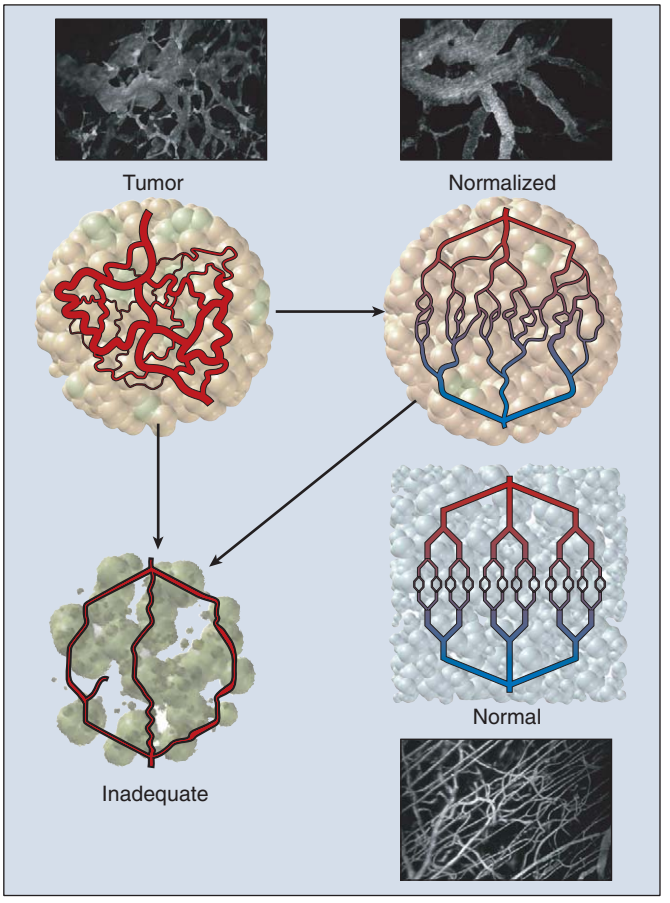

Figure 8-4 • Normalization of tumor vasculature. Normal vessels are well organized with even diameters. In contrast, tumor vessels are tortuous, with increased vessel diameter, length, density, and permeability. Antiangiogenic therapies "normalize" the tumor vascular network and could ultimately reduce the vasculature to the point at which it provides inadequate support for tumor growth. (Adapted from Jain RK: Normalizing tumor vasculature with anti-angiogenic therapy: a new paradigm for combination therapy. Nat Med 2001;7:987–989; Jain RK: Angiogenesis and lymphangiogenesis in tumor: insights from intravital microscopy. Cold Spring Harbor Symp Quant Biol [The Cardiovascular System] 2002;67:239–248; Jain RK, Carmeliet PF: Vessels of death or life. Sci Am 2001;285:38.)

At the microscopic level, in normal tissues, erythrocyte velocity is dependent on vessel diameter, but there is no such dependence in most tumors.[47,52,79] Furthermore, the average erythrocyte velocity can be an order of magnitude lower in some tumors as compared with that of normal host tissue (Fig. 8-6).[52] In a given vessel within a tumor, blood flow fluctuates with time and can reverse its direction.[77,79,80] In addition to the elevated geometric and viscous (rheologic) resistance, other molecular and mechanical factors contribute to this spatial and temporal heterogeneity. These include imbalance between pro- and antiangiogenic molecules, "solid stress" generated by proliferating cancer cells, vascular remodeling by intussusception, and coupling between luminal and interstitial fluid pressure via hyperpermeability of tumor vessels.[17,57,58,67–69,81–83] As we will learn later, this heterogeneity contributes to both acute and chronic hypoxia in tumors—a major cause of resistance to radiation and other therapies. Considerable effort has gone into increasing tumor blood flow for improving radiation therapy, or decreasing tumor perfusion in the case of hyperthermia. This has been difficult to achieve reproducibly, because tumor vasculature consists of both vessels co-opted from the pre-existing host vasculature and vessels resulting from the angiogenic response of host vessels to cancer cells. The former are invested in normal contractile perivascular cells, whereas the latter lack these perivascular cells or these cells are abnormal.[42,62,84] Presumably as a result, efforts to increase the tumor blood flow by pharmacologic or physical agents have not always been reproducible or successful.[62,75] On the other hand, the strategy of decreasing or shutting down the tumor blood flow—by "stealing" blood away from the "passive component" of the tumor vasculature by vasodilators, by vascular targeting, or by intravascular coagulation—has shown promise in experimental systems.[75,76,85–87] It also appears that judiciously applied antiangiogenic therapy could "normalize" the abnormal tumor microcirculation by pruning the immature vessels (see Fig. 8-4), thus rendering the remaining vasculature more responsive to vasoactive agents.[88]

VASCULAR PERMEABILITY

Once a blood-borne molecule has reached an exchange vessel, its extravasation occurs by diffusion, convection, and, to some extent, presumably by transcytosis.[88] The diffusive permeability, *P*, of a molecule depends on the size, shape, charge, and flexibility of the molecule, and on the size, shape, charge, and dynamics of the transvascular transport pathway. In normal vessels, these pathways include diffusion along the EC membrane (for lipophilic solutes), trans-EC diffusion, interendothelial junctions (<7 nm), open or closed fenestrations (<10 nm), and transendothelial channels (including vesicles or vesicovacuolar channels).[16,89] Some of these anatomical pathways may be lined with glycocalyx on EC, thus effectively reducing the size of the pathway. A basement membrane may further retard the movement of molecules. Ultrastructure studies show widened interendothelial junctions, increased numbers of fenestrations, vesicles, and vesicovacuolar channels in tumor vessels, and a lack of normal basement membrane and pericytes.[16,49,84,89,90] In concert with these ultrastructural findings, both vascular permeability and hydraulic conductivity (a measure of water movement by pressure gradient) of

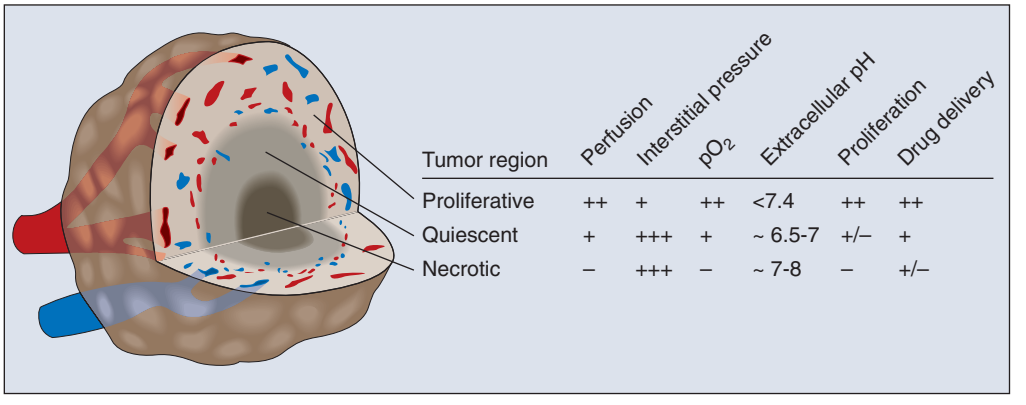

Figure 8-5 • The tumor microenvironment is heterogeneous with proliferative, quiescent, and necrotic regions. These regions can be characterized in terms of various physiologic parameters. Decreasing magnitude of these parameters is indicated as +++, ++, +, +/–. and –. (From Jain RK, Forbes NS: Can engineered bacteria help control cancer? Proc Natl Acad Sci USA 2001;98:14748–14750.)

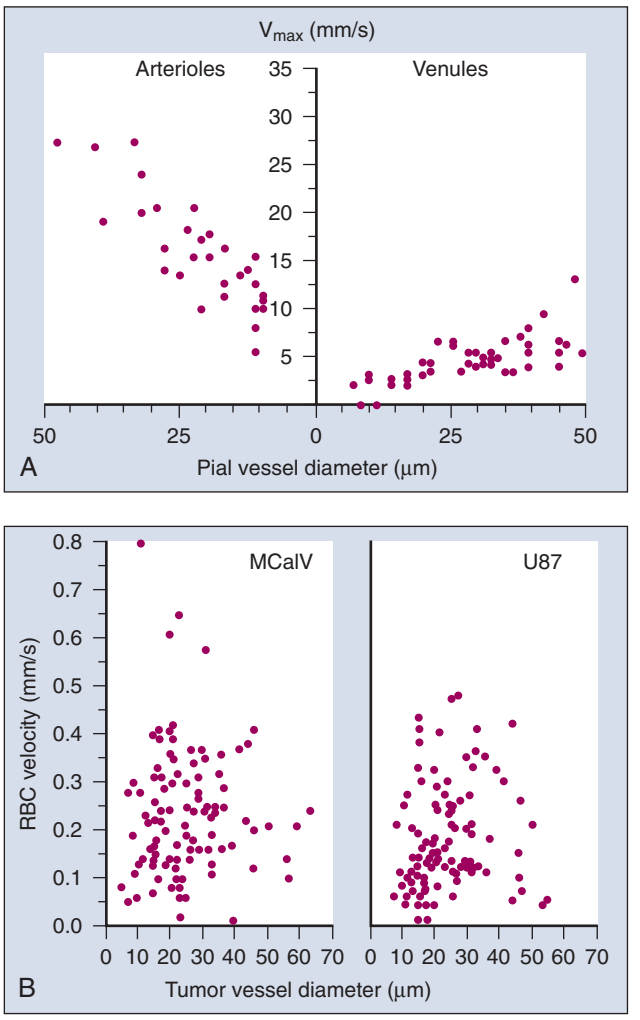

Figure 8-6 • Blood velocity as a function of vessel diameter. **A,** Normal pial vessels. **B,** MCaIV (mammary carcinoma) and U87 (glioma) tumors xenografted on the pial surface. The measured tumor blood velocities are an order of magnitude lower than the velocities in the normal host tissue and are not related to the vessel density. (From Yuan F, Salehi HA, Boucher Y, et al: Vascular permeability and microcirculation of gliomas and mammary carcinomas transplanted in rat and mouse cranial windows. Cancer Res 1994;54:4564–4568.)

tumors, in general, are significantly higher than those for various normal tissues.[52,91–95] Furthermore, unlike normal vessels, tumor vessels lack selectivity in permeability to different molecules.[96] Positively charged molecules have a higher affinity for the negatively charged angiogenic tumor vessels.[97–99] Despite increased overall permeability, not all blood vessels of a tumor are leaky (Fig. 8-7A). Even the leaky vessels have a finite pore size that is tumor dependent (Fig. 8-7B), and ultrastructural studies show that the larger pore size in tumors represents wide interendothelial junctions.[49,90] Not only do the vascular permeability and pore size vary from one tumor to the next (see Fig. 8-7A–C), but within the same tumor they vary spatially and temporally, as they do during tumor growth, regression, and relapse.[49,54,55] The local microenvironment plays an important role in controlling vascular permeability (Fig. 8-7D). For example, a human glioma (HGL21) has fairly leaky vessels when grown subcutaneously in immunodeficient mice, but it exhibits blood-brain barrier properties in the brain.[52,65] Such site-dependent differences for other tumors have been observed in other orthotopic sites.[47,50,51] One possible explanation is that the host-tumor interactions control the production and secretion of cytokines associated with permeability increase (e.g., VEGF) and decrease (e.g., angiopoietin 1).[20,33,65,100,101] A better understanding of the molecular mechanisms of permeability regulation in tumors is likely to yield strategies for improved delivery of molecular medicine to tumors.

Movement of Cells across Vessel Walls

Both cancer cells and immune cells frequently move across the walls of blood vessels—the former in the process of metastasis and the latter during immune response or cell-based immunotherapy. Both transendothelial (through ECs) and periendothelial (between ECs) pathways have been proposed as a route for intravasation and extravasation of cells. Very little is known about intravasation except that tumors might shed more than a million cells per gram per day and most of these are not clonogenic.[102–105] More is known about the molecular and cellular mechanisms of extravasation.[106] When a cell enters a blood vessel, it can continue to move with the flowing blood, collide with the vessel wall, adhere transiently or stably, and finally extravasate. These interactions are governed both by local hydrodynamic forces and adhesive forces. The former are determined by the vessel diameter and fluid velocity and the latter by the expression, strength, and kinetics of bond formation between adhesion molecules and by the surface area of contact.[107–111] Deformability of cells affects both types of forces.[112] In addition, cancer cells may grow intravascularly at the distant site (e.g., in the lungs).[113]

Rolling of endogenous leukocytes is generally low in tumor vessels, whereas stable adhesion (≥30 sec) is comparable between normal vessels and tumor vessels.[114] On the other hand, both rolling and stable adhesion are nearly zero in angiogenic vessels induced in collagen gels by bFGF or VEGF, two of the most potent angiogenic factors.[46] Whether this observation is due to a low flux of leukocytes into angiogenic vessels and/or to downregulation of adhesion molecules in these immature vessels is currently not known. The age of the animal also plays an important role in leukocyte-endothelial interactions.[115] Further insight into the types of cells that adhere to tumor vessels comes from studies on the localization of IL-2–activated natural killer (A-NK) cells in normal and tumor tissues in mice using positron emission tomography.[116,117] After systemic injection, these cells localized primarily in the lungs immediately after injection and could not be detected in the tumor.[116] Increased rigidity caused by IL-2 activation might contribute to the mechanical entrapment of these cells in the lung microcirculation.[118,119] Constitutive expression of certain adhesion molecules in the lung vasculature might also facilitate their retention in the lungs.[106] One approach to reducing lung entrapment is to reduce the rigidity of these cells.[112,117] Alternatively, the lung can be circumvented by injecting A-NK cells directly into the blood supply of tumors. In this case, A-NK cells, both xenogenic and syngeneic, adhered to some blood vessels in three different tumor models via CD18 and very large antigen-4 (VLA-4) on the A-NK cells and intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selectin on the activated endothelium of angiogenic vessels.[27,117,120–123] These molecules can be upregulated by tumor necrosis factor-α (TNF-α) and a protein of 90 kd molecular weight (p90) that is secreted by some neoplastic cells and downregulated by transforming growth factor-β (TGF-β)—also, presumably, secreted by cancer cells.[48,107,124–128] Surprisingly, the proangiogenic VEGF also can upregulate these molecules, presumably via VEGFR1, whereas another proangiogenic molecule, bFGF, can downregulate these molecules.[27,45,55,66,129] On the other hand, inflammatory cells such as monocyte/macrophages or neutrophils are also recruited by VEGF and may play important roles in promoting matrix remodeling and angiogenesis.[130] The challenge currently is to decrease nonspecific entrapment of immune cells in normal vessels and to increase their delivery to tumor vessels to improve various cell-based therapies, including gene therapy.

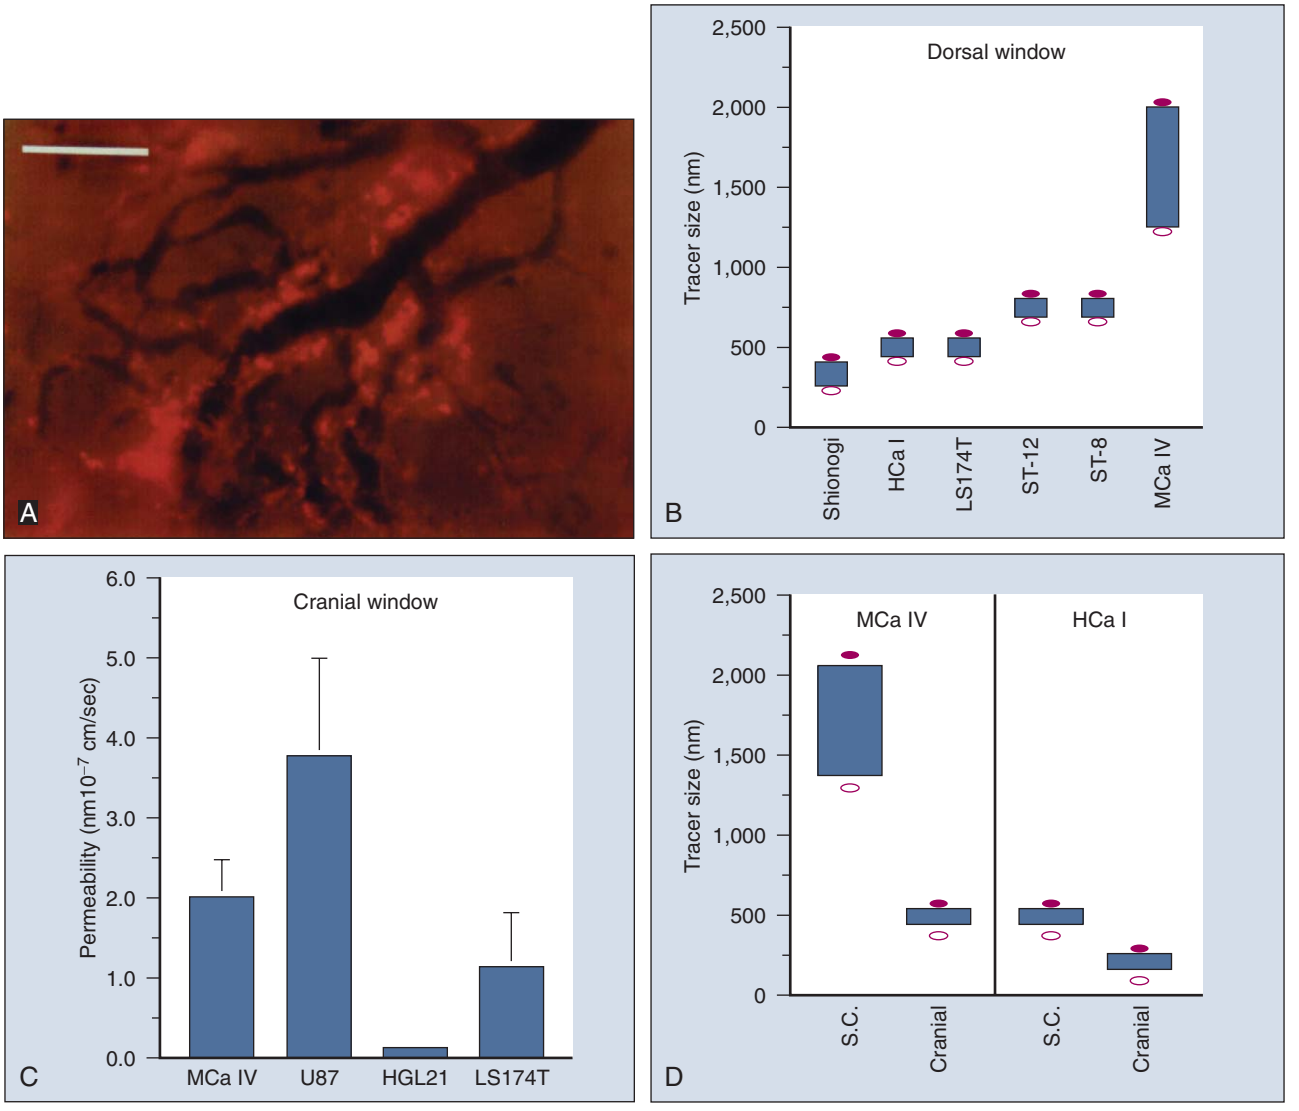

Figure 8-7 • Heterogeneous permeability of tumor vessels. Vessel permeability varies spatially within a given tumor, between tumors of identical type implanted in different host organ environments, and between different tumor types in the same organ environment. **A,** Vessels within a given tumor are leaky in some areas and relatively impermeable in others. **B** and **C,** Tumors of different types grown in the same environment show variations in both vessel pore size and permeability. Pore sizes are measured by the largest tracer particle able to permeate the vessel wall. **D,** MCaIV and HCaI tumors implanted in two different sites (subcutaneous and cranial) have vessels with different pore sizes. For both tumor types, larger pore sizes are observed in the subcutaneous (S.C.) tumors compared with the cranial tumors. (**A** and **C,** From Yuan F, Leunig M, Huang SK, et al: Microvascular permeability and interstitial penetration of sterically stabilized [stealth] liposomes in a human tumor xenograft. Cancer Res 1994;54:3352–3356. **B** and **D,** From Hobbs SK, Monsky WL, Yuan F, et al: Regulation of transport pathways in tumor vessels: role of tumor type and microenvironment. Proc Natl Acad Sci USA 1998;95:4607–4612.)

EXTRAVASCULAR COMPARTMENT

Composition and Origin

The extravascular compartment of a solid tumor consists of neoplastic cells (parenchyma) and host cells (e.g., inflammatory cells, fibroblasts) residing in an interstitial matrix bathed by the interstitial fluid (see Fig. 8-1). Depending on the tumor type and its stage of differentiation, neoplastic cells might be dispersed in the matrix as individual cells (e.g., lymphomas, melanomas) or as clumps, sheets, or nests (e.g., carcinomas). More than 80% of tumors are carcinomas arising from epithelial cells. The remaining include sarcomas arising from mesenchymal cells (e.g., bone or muscle cells), lymphomas arising from lymphoid tissue, leukemias arising from hematopoietic cells, and hemangiomas arising from ECs. In a poorly differentiated carcinoma, the cancer cells might be packed loosely in clumps, whereas in a well-differentiated carcinoma, the cells might be connected with intercellular junctions and tightly packed in a nest enveloped by a basement membrane. With tumor progression, cancer cells can invade the basement membrane and spread to other regions.[16] These various types of normal host cells must migrate into the tumor from normal tissue. Inflammatory cells might enter the tumor via blood vessels or might infiltrate from the adjacent tissue or lymphatics.[106] Other host cells, such as fibroblasts, might proliferate and migrate from the adjacent connective tissue.[20,42,43] The interstitial subcompartment of a tumor is bounded by the walls of the blood vessels on one side and by the membranes of cancer and stromal cells on the other. In normal tissues, the blood vessels are surrounded by a basement membrane, which, as discussed before, is defective in tumors.[20] In addition, functional lymphatics might be confined to

the tumor margin.[131,132] The interstitial space of tumors, like that of normal tissues, is composed of a collagen and elastin fiber network that provides structural support to the tissue. Interdispersed in this cross-linked structure are the interstitial fluid and macromolecular constituents (polysaccharides, hyaluronan, and proteoglycans), which form a hydrophilic gel. Compared with our understanding of blood vessel formation, our understanding of stroma generation is minimal. Dvorak and coworkers have proposed that the extravasated plasma protein fibrinogen, a key component of the tumor interstitial fluid, clots to form fibrin, which serves as a major component of the provisional stroma. This provisional stroma eventually is replaced by more mature connective tissue stroma. The tumor interstitial fluid also contains several other Arg-Gly-Asp (RGD)-containing proteins, including fibronectin, vitronectin, osteopontin, thrombospondin, decorin, and tenacin.[16] These proteins are present in both free and bound forms. Their Arg-Gly-Asp sequence provides a binding site for adhesion that assists in the migration of various cells, including stromal cells. In addition to extravasating from the leaky tumor vessels, these proteins, along with collagen and various proteoglycans, are also synthesized by the stromal cells, albeit in a form that differs from that in the plasma or normal tissues.[16] Tumor interstitial fluid also can contain various growth factors that facilitate stroma formation. For example, in vitro studies suggest that platelet-derived growth factor-ββ (PDGF-ββ) is involved in the recruitment of fibroblasts to tumors, and TGF-β induces the production of collagen and other matrix molecules in tumors.[20,133] With the increasing interest in using the fragments of matrix constituents for controlling angiogenesis, our understanding of the molecular and cellular mechanisms of stroma generation in tumors will increase.[37]

Interstitial Transport

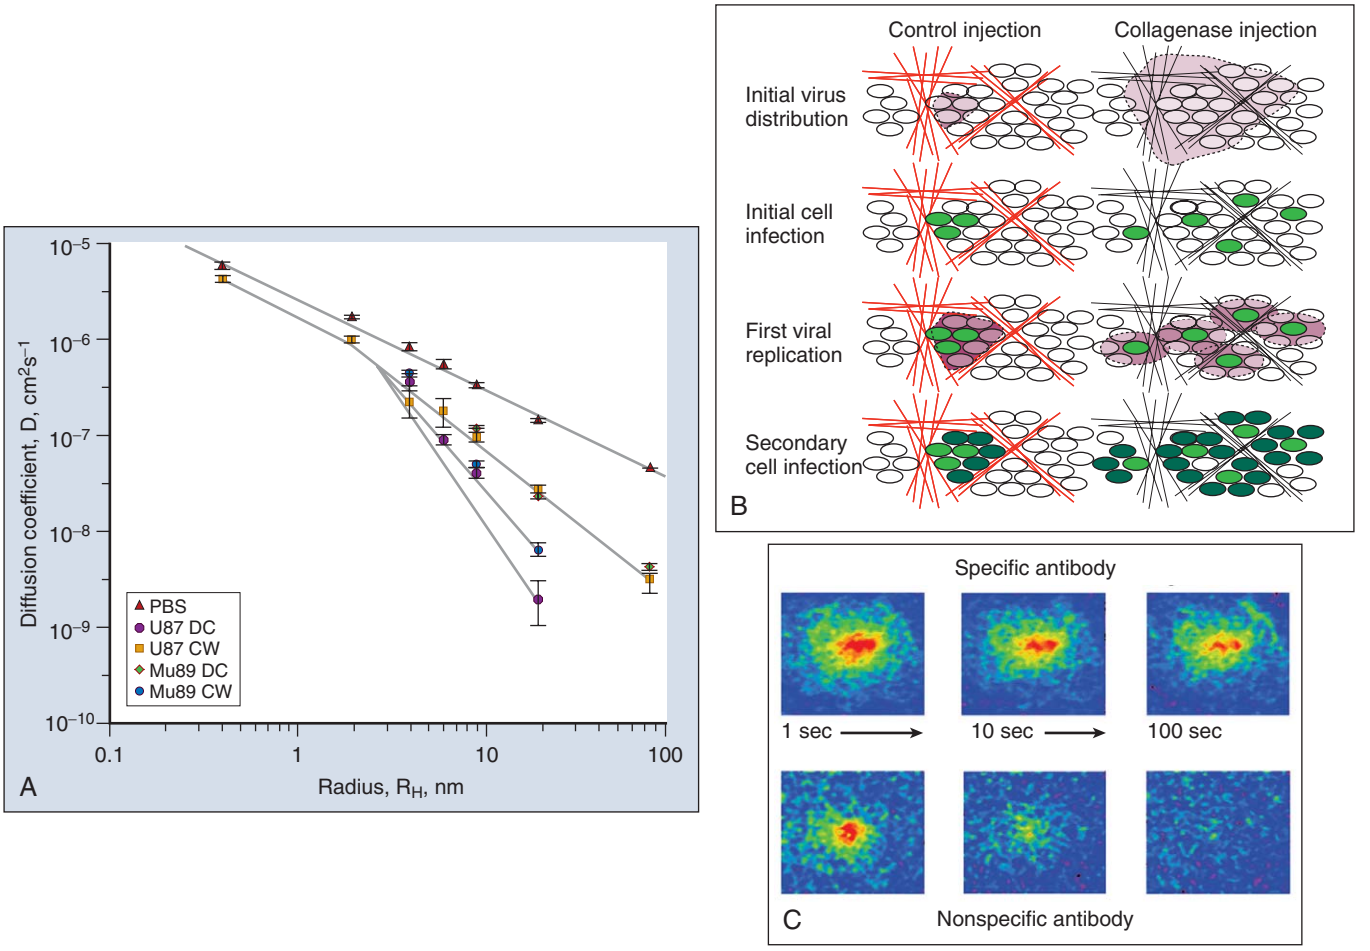
Once a molecule has extravasated, its movement through the interstitial space occurs by diffusion and convection.[134] Diffusion is proportional to the concentration gradient in the interstitium, and convection is proportional to the interstitial fluid velocity, which, in turn, is proportional to the pressure gradient in the interstitium. Just as the interstitial diffusion coefficient D (cm^2/s) relates the diffusive flux to the concentration gradient, the interstitial hydraulic conductivity K ($cm^2/mmHg/sec$) relates the interstitial velocity to the pressure gradient.[134] Values of these transport coefficients are governed by the structure and composition of the interstitial compartment and by the physicochemical properties of the solute molecule.[135–144] The value of K for a human colon carcinoma xenograft (LS174T), measured using two different methods, was found to be higher than that of a hepatoma, which, in turn, was higher than that of the normal liver.[140,145,146] Using fluorescence recovery after photobleaching, D of various molecules in tumors was found to be about one-third that in water and higher than the values in the host tissue (Fig. 8-8A).[136,147] Collagen content and structure have a significant effect on D in tumors.[142,143,145,148–150] This is surprising because hyaluronan and proteoglycans, not collagen, account for most of the resistance to transport in normal tissues. Because collagen is produced by host cells (e.g., fibroblasts), the penetrability into a tumor depends on the host-tumor interaction (see Fig. 8-8A). Thus, agents that interfere with collagen synthesis and/or organization (e.g., relaxin, bacterial collagenase) might increase interstitial transport in tumors[144,150] (Fig. 8-8B). The time constant for a molecule with diffusion coefficient D to diffuse across a distance L is approximately $L^2/4D$. For diffusion of immunoglobulin G (IgG) in tumors, this time constant is on the order of 1 hour for a 100-μm distance, days for a 1-mm distance, and months for a 1-cm distance. So for a 1-mm distance in tumor, diffusional transport would take days, and for a 1-cm distance in tumor, it would take months. If the central vessels have collapsed completely due to cellular proliferation and interstitial matrix rearrangement, the reduced delivery of macromolecules by blood flow would make diffusion the primary mechanism of delivery to this necrotic center.[67,69] Binding of a low- or high-molecular-weight drug to plasma proteins and various tissue components could further retard their transport in tumors.[147,151–157] The role of binding is clearly illustrated in Figure 8-8C, which compares the rate of fluorescence recovery of a photobleached spot in tumor tissue injected with a nonspecific vs. a specific IgG. In addition to the heterogeneity of D in tumors, the most unexpected result of these photobleaching studies was the large extent (30% to 40%) of nonspecific binding.[147] These results collectively suggest that the interstitial compartment of a tumor can be a formidable barrier to the uniform delivery of therapeutic macromolecules (e.g., antibodies, genes) in tumors, and strategies are needed to modify this barrier.

Lymphangiogenesis and Lymphatic Transport

In most normal tissues, extravasated plasma and macromolecules are taken up by the lymphatics and returned to the blood circulation. It is widely accepted that lymphatic vessels are present in the tumor margin and the peritumoral tissue (Fig. 8-9A). Indeed, invasion of peritumoral lymphatics is considered to be a poor prognostic factor for several tumors (e.g., breast, colorectal, and endometrial cancers), and lymphatic metastasis is a major cause of morbidity and mortality for others (e.g., melanoma, head and neck cancer, lung cancer, and cervical cancer). The hotly debated issue for nearly a century has been whether anatomically defined lymphatic vessels are present within solid tumors and, if so, whether they function (see Fig. 8-9A).[74,158] Currently available immunohistochemical markers stain for structures in some tumors that resemble lymphatic vessels. Because many of these markers lack specificity, however, it is not clear whether they stain functional lymphatic vessels, ECs from remnant lymphatic vessels, or some other structures (e.g., preferential fluid channels).[132,145,159,160] It is likely that the "mechanical" stress induced by proliferating cancer cells compress and impair lymphatic vessels that are co-opted or formed within a tumor.[67,70] The impaired lymphatic vessels, in turn, contribute to the interstitial hypertension characteristic of animal and human tumors (to be discussed shortly). Embryonic lymphatic vessels originate primarily from blood vessels according to the following process (Fig. 8-9B).[161–163]

1. In the early embryo, endothelial cells of the cardinal vein express lymphatic vascular endothelial receptor-1 (LYVE-1) and VEGFR3, molecules observed primarily (but not exclusively) on lymphatic vessels in normal adult tissues.
2. A yet unknown signal triggers the expression of the homeobox gene *Prox-1* so that the protein is displayed in a polarized fashion in the endothelial cells of the cardinal vein. This marks the first stage of commitment to the lymphatic lineage.
3. These $LYVE\text{-}1^+VEGFR3^+Prox\text{-}1^+$ cells then start to bud, again in a polarized fashion.
4. At this stage, these early lymphatic endothelial cells start expressing secondary lymphoid chemokine and increased levels of VEGFR3, markers of mature lymphatic ECs.
5. They then begin to form the lymphatic system.

Members of the angiopoietin family (Ang-2) and its receptor (Tie-2), as well as podoplanin are presumably involved in the maturation and patterning of these nascent lymphatic vessels.[164] The hematopoietic signaling pathway, Syk/SLP-76, contributes to the separation of lymphatics from blood vessels. The molecules involved in angiogenesis are also involved in lymphangiogenesis. For example, VEGF-C and -D can induce both angiogenesis and lymphangiogenesis and are associated with lymphogenic metastasis in a variety of tumors.[131] Their receptor VEGFR3 is present in both lymphatic and selected vascular endothelium. As is the case with vascular angiogenesis, other positive and negative regulators (e.g., angiopoietins) and other receptors (e.g., chemokine receptors and neuropilins) could be involved in lymphangiogenesis, and as discussed already, mechanisms analogous to co-option, intussusception, sprouting, and vasculogen-



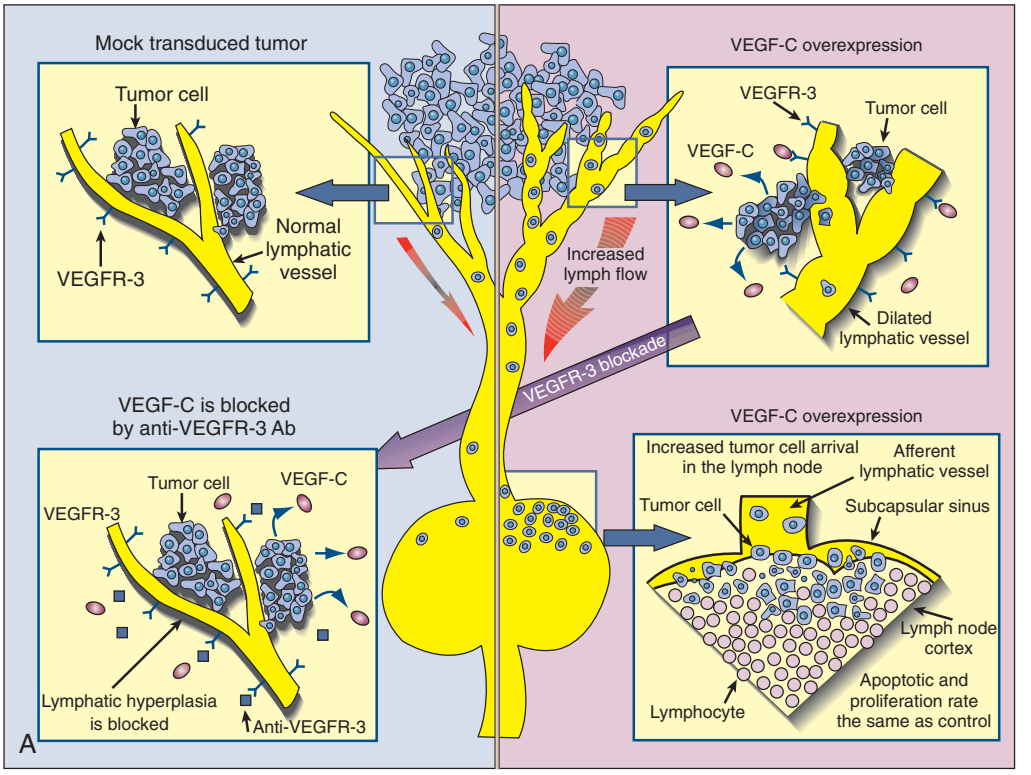


Figure 8-8 • Interstitial transport in tumors. Transport of molecules through a tumor is affected by several factors. **A,** Diffusivity of a molecule in a tumor decreases with increasing molecular weight and is dependent on the host-tumor interaction. The diffusivity of macromolecules is lower in subcutaneous (sc) tumors in dorsal chamber (DC, octagons-U87 glioblastoma and diamonds-Mu89 melanoma) than in the same tumors grown in cranial windows (CW, squares-U87 and triangles-Mu89), and both are less than in phosphate-buffered saline (PBS). **B,** A representative model of improvement in oncolytic viral distribution and tumor cell infection by collagenase treatment. Following direct intratumor injection, viral spread (red area) is limited by fibrillar collagen (red lines) and results in a cluster of infected cells (*light green*). The collagen network also restricts the distribution of subsequent viral progeny, and tumor cell infection beyond the initial injection site is not achieved. In contrast, injection of virus together with collagenase results in a more diffuse distribution of viral particles and a greater number of initially infected cells (*light green*). Viral particles released by these cells have greater access to neighboring uninfected cells. This process results in more widespread secondary infection (*dark green*) and ultimately greater therapeutic efficacy. **C,** Interstitial transport is also reduced by binding. The fluorescence of a photobleached spot recovers much more slowly with a specific antibody than with a nonspecific antibody. The binding of the specific antibody hinders the transport of the molecule into the photobleached spot, slowing the fluorescence recovery. (**A,** From Pluen A, Boucher Y, Ramanujan S, et al: Role of tumor-host interactions in interstitial diffusion of macromolecules: cranial vs. subcutaneous tumors. esis might operate in lymphatic growth.[11,164] Similar to the recently discovered organ-specific angiogenic molecule (EG-VEGF) and endothelial precursor cells, there could be organ-specific lymphangiogenic molecules and lymphatic EPCs that contribute to tumor-associated lymphangiogenesis.[22,32,163] Moreover, the proteolytic processing of lymphangiogenic molecules and the phenotype and function of the resulting lymphatics might depend not only on the tumor type but also on the host organ in which the tumor is growing.[66,159,161,163]

The mechanical and/or molecular signals that could trigger the lymphangiogenic switch are unknown. Because lymphatic vessels help maintain the balance of fluid in tissues, hydrostatic pressure is a probable trigger. Whether the hyperplasia and the increased density of lymphatic vessels seen in the tumor margins are a response to elevated hydrostatic pressure in tumors and whether the newly formed lymphatics are able to remain open and carry cancer cells are open questions. Techniques such as microlymphangiography, reagents that block signaling of VEGF-C and -D, and lymphangiogenic factors yet to be discovered will allow us to answer these important questions.[4,159,163,165–170]

Interstitial Hypertension

Unlike normal tissues, in which the interstitial fluid pressure (IFP) is around 0 mmHg, both animal and human tumors exhibit interstitial hypertension (Table 8-2).[132,134,146,171–182] The tumor IFP begins to increase as soon as the host vessels become leaky in response to permeability factors such as VEGF, and, thus, IFP can be lowered by antibodies against VEGF or VEGFR2.[183–185] The IFP increases with tumor size in some tumors and remains independent of tumor size

Figure 8-9 • **A,** Schematic of lymphatics in tumors. It is widely accepted that peritumoral lymphatics exist and that metastasis can occur via these lymphatic vessels. Recent evidence shows that structures within tumors that stain for lymphatic markers are not functional. The lower-left insert shows the molecular players in lymphangiogenesis. **B,** Mechanisms of lymphatic vessel formation and separation from blood vessels. **C,** The tumor is modeled as a sphere of radius *R,* embedded in a body fluid (e.g, peritoneal cavity, pleural cavity) or host tissue. The interstitial fluid oozing from the tumor periphery carries therapeutics (e.g, monoclonal antibodies), growth factors (e.g, VEGF-A, -B, -C, and -D), and cells (e.g., metastatic cells) into the surrounding fluid/tissue. The result may be higher fluxes of cancer cells and growth factors from the tumor into the surrounding tissue or body fluid. The growth factors (including VEGF-A, B, C, and D) can induce angiogenesis and lymphangiogenesis, and the cancer cells can contribute to metastatic dissemination via the lymphatic or blood vessels. Fluid seeping from the tumor surface can also cause edema (e.g., around brain tumors) and ascites formation (e.g., ovarian cancer). Antiangiogenic therapy can "normalize" the tumor vasculature, leading to lower interstitial fluid pressure (IFP) at the center, less steep IFP gradients and lower fluid flow rates at the tumor margin, thus potentially reducing peritumor edema, ascites formation, and lymphatic metastasis. Furthermore, the normalized vessels may be more resistant to cancer cell intravasation, a prerequisite for hematogenous metastasis. in others.[171,172,175,176] Three mechanisms contribute to interstitial hypertension in tumors. In normal tissues, the lymphatics maintain the fluid homeostasis; thus, the lack of functional lymphatics in tumors is a key contributor. Indeed, DiResta and colleagues have been able to lower the IFP by placing "artificial lymphatics" in tumors.[186] The second contributor is the high permeability of tumor vessels. As a result, the hydrostatic and oncotic (colloid osmotic) pressures become almost equal between the intravascular and extravascular spaces.[174,187] At least two pieces of evidence support this hypothesis. First, reducing permeability by blocking VEGF signaling lowers IFP.[184,185,188,189] Second, IFP increases and decreases with the microvascular pressure within seconds.[190–192] The two mechanisms described thus far can only explain interstitial hypertension up to 20–30 mmHg, the microvascular pressure of most exchange vessels (the hydrostatic pressure within the lumina of capillaries) in our bodies, but IFPs as high as 94 mmHg have been measured in human tumors.[173] Because microvascular pressure (MVP) is the driving force for IFP in tumors, these tumors must have a high MVP. Indeed, this is the case.[174] There are two possible explanations for elevated MVP in tumors: the tumor vessels have reduced arterial resistance so that the MVP becomes closer to arterial pressure, and/or the tumor vessels have increased venous resistance due to compression and tortuousity so that the whole intratumor vascular network is under hypertension. Indirect evidence for the latter comes from the decrease in IFP after decompression of tumor vessels by taxol-induced apoptosis of perivascular cells.[69]

The elevated pressure can compromise the tumor microcirculation and delivery of therapeutics in three ways:

1. Reduced transmural pressure gradients due to equilibrium between MVP and IFP reduce convection across tumor vessel walls and thus compromise the transport of macromolecules.[174,192]
2. Because IFP is nearly uniform throughout a tumor and drops precipitously in the tumor margin, the interstitial fluid oozes out of the tumor into the surrounding normal tissue, carrying macromolecules with it (Fig. 8-10).[171,193]
3. Finally, transmural coupling between IFP and MVP due to high permeability of tumor vessels can lead to blood flow stasis in tumors without physically occluding the vessels.[81–83]

The enhanced permeability can also facilitate lymphatic metastasis (Fig. 8-9C). Thus, decreasing vascular permeability might restore the transmural pressure gradients and potentially resume/reestablish blood flow in the nonperfused regions of tumors. Some direct and indirect antiangiogenic therapies might "normalize" the tumor vasculature through this mechanism (see Fig. 8-4).[88] This normalization can also reduce the number of cells shed into peritumor lymphatics and alleviate peritumor edema (see Fig. 8-9C).[194]

METABOLIC ENVIRONMENT

Hypoxia

A key function of the vasculature is to provide adequate levels of nutrients and oxygen to the parenchymal cells and to remove waste products. Based on the anatomy of the capillary bed and a mathematical model of oxygen diffusion and consumption, the Nobel laureate August Krogh introduced the concept of a diffusion limit for oxygen of 100–200 μm nearly a century ago.[195] This unit of tissue—a single capillary surrounded by a 100- to 200-μm-radius cylinder—is referred to as a "Krogh cylinder" in physiology. Nearly 50 years later, Thomlinson and Gray identified similar "cords" in human lung cancer and found necrotic cells beyond 180 mm away from blood vessels, presumably as a result of lack of oxygen.[196] This is referred to as "chronic hypoxia" or "diffusion-limited" hypoxia. Although various hypoxia markers and microelectrodes have suggested these gradients, the first direct measurements of these perivascular gradients, along with pO_2 and blood flow rate of the same vessels, became possible only recently with the development of phosphorescence quenching microscopy (Fig. 8-11A).[197,198] As discussed previously, blood flow in tumor vessels is intermittent, and, thus, some regions of a tumor are starved for oxygen periodically. The resulting hypoxia is referred to as "acute hypoxia" or "perfusion-limited hypoxia."[199,200] A necessary consequence of intermittent blood flow is the resumption of blood flow after shutdown, and the resulting production of free radicals can lead to "reperfusion injury" or "reoxygenation injury," applying additional selection pressure on cancer cells.

Low pH

Another consequence of the abnormal microcirculation of the tumor is low extracellular pH. There are at least two sources of H^+ ions in tumors—lactic acid and carbonic acid.[201] The former results from glycolysis and the latter from conversion of CO_2 and H_2O via carbonic anhydrase. The intracellular pH of cancer cells remains neutral or alkaline (pH 7.4), however, despite the acidic extracellular pH. Because carbonic anhydrase-9, various glucose transporters (GLUT1, GLUT3), and enzymes in the glycolytic pathway are upregulated by hypoxia, one would expect low extracellular pH and hypoxia to track each other and to colocalize with regions of low blood flow.[202] Surprisingly, there is a lack of spatial correlation among these parameters (Fig. 8-11B), a discovery made possible by recent developments in optical techniques that permit the simultaneous high-resolution mapping of multiple physiologic parameters.[198] A potential explanation for this lack of concordance is that some perfused tumor vessels carry hypoxic blood.[198] Thus, although they might not be able to deliver adequate oxygen to the surrounding cells, they may be able to carry away the waste products (e.g., lactic acid).

Molecular, Cellular, and Therapeutic Consequences

The presence of oxygen during irradiation makes the damage to DNA produced by radiation-induced free radicals permanent, whereas such damage can be repaired under hypoxic conditions.[203] Therefore, hypoxia in solid tumors significantly reduces their radiation sensitivity. Tumor hypoxia is also associated with resistance to some chemotherapeutics.[203] Similarly, low extracellular pH can affect the cellular uptake and cytotoxicity of some therapeutics adversely or favorably.[204–206] As a result, for nearly half a century, considerable preclinical and clinical efforts have been focused on alleviating hypoxia by improving tumor perfusion with various therapies, including the following:

- Mild hyperthermia or drugs
- Increasing oxygen content of the blood (via hyperbaric oxygenation, for example)
- Increasing hemoglobin/hematocrit (via erythropoietin, for example)
- Developing radiation sensitizers

Unfortunately, the clinical outcome has not met expectations for multiple reasons. These include the inability to increase pO_2 in all regions of tumors to optimal levels and/or to deliver radiation sensitizers or chemotherapeutic drugs to all regions of a tumor at therapeutically effective levels. As a result, three broad strategies are emerging:

1. Use hypoxia and/or low pH to activate drugs or to attract anaerobic bacteria.
2. Dissect hypoxia-induced pathways to identify novel targets for drug development.
3. Normalize tumor vasculature.[207]

The first strategy has led to the development of drugs such as tirapazamine and to the rejuvenation of interest in bacteriolytic therapy; both approaches are in clinical trials.[78,203] The second strategy has revealed several molecular determinants of the physiologic

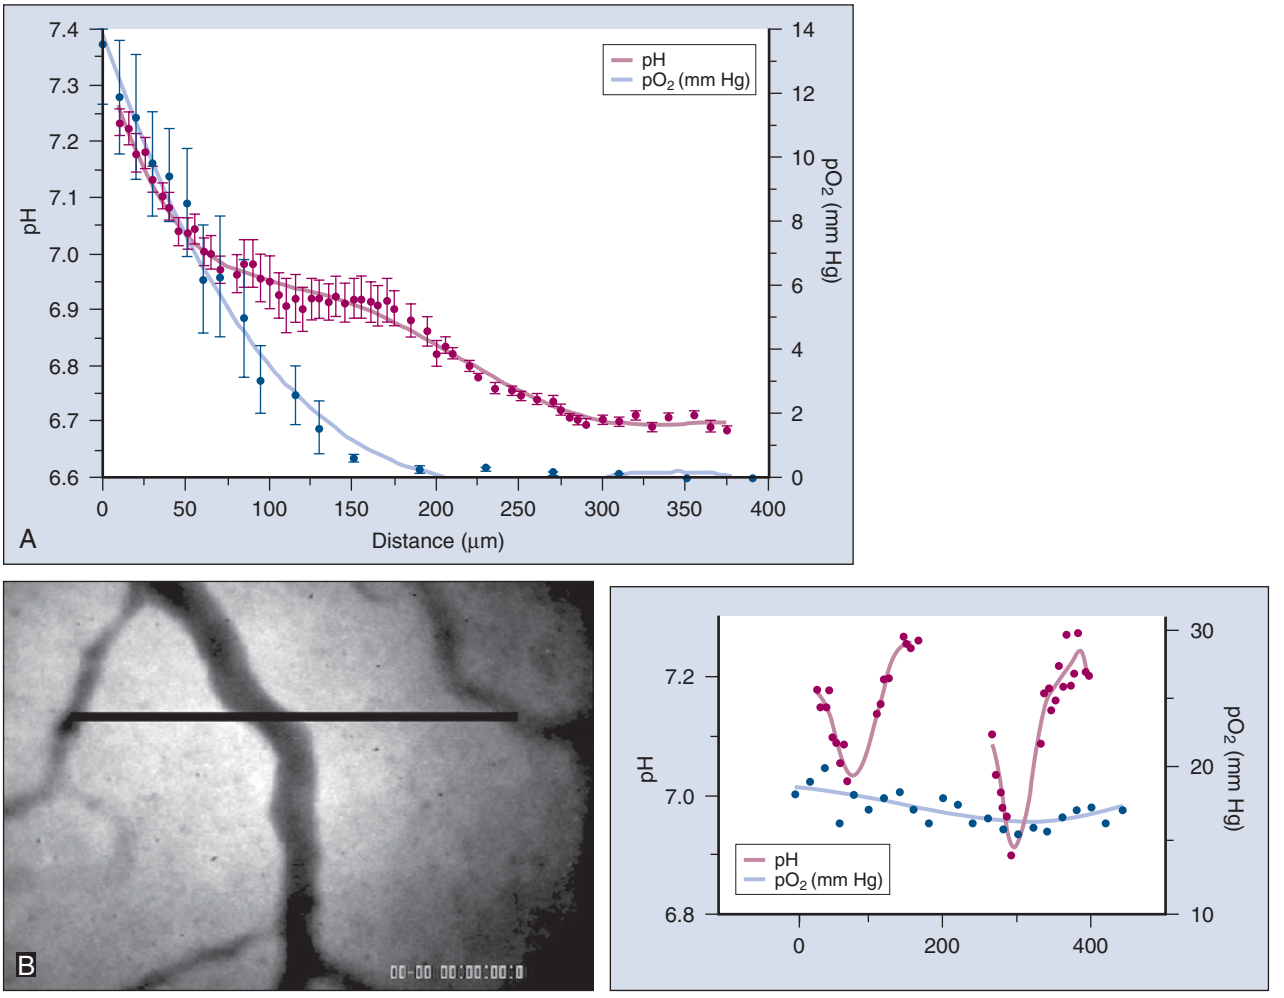

Figure 8-11 • **A,** pH and pO_2 as a function of distance from a blood vessel in a tumor. The tumor environment becomes progressively more hypoxic and acidic farther away from a blood vessel. **B,** Lack of correlation between pH and pO_2 in tumors. (From Helmlinger G, Yuan F, Dellian M, et al: Interstitial pH and pO_2 gradients in solid tumors in vivo: high-resolution measurements reveal a lack of correlation. Nat Med 1997;3:177.)

and pathophysiologic responses to hypoxia.[202] The balance between hypoxia-induced apoptosis/necrosis on one hand, and the increased resistance to cell death mediated by various hypoxia-induced pathways on the other, determines whether a tumor can survive and even grow under hypoxic conditions. Ultimately, hypoxia might select for tumor cells that are more malignant, more invasive and genetically unstable, and less susceptible to apoptosis, thus rendering them resistant to various therapies. Therefore, several molecules in the hypoxia-induced pathways are now being targeted in the development of diagnostic and therapeutic agents. Finally, normalization of tumor vessels by antiangiogenic agents may reduce hypoxia within tumor environment and synergize with radiation therapy.[207]

Hypoxia-induced pathways include genes involved in the following processes:

- Oxygen delivery (e.g., heme oxygenase 1, erythropoietin)
- Glycolysis and glucose uptake (e.g., GLUT1 and GLUT3, hexokinase-1 and -2)
- pH control (e.g., carbonic anhydrase-9 and -12)
- Stress-response pathways (e.g., growth arrest- and DNA damage-induced gene *GADD153*)
- Growth factor signaling (e.g., IL-6, IL-8, insulin-like growth factor-2 [IGF-2])
- PDGF-β
- Angiogenesis (e.g., VEGF-A, VEGFR1, Ang-2, Tie-2, FGF-3, TGF-β, nitric oxide synthase [NOS], cyclooxygenase-2 [COX-2], hepatocyte growth factor [HGF])
- Transcription (e.g., HIF1α and HIF2α, JUN, FOS, nuclear factor κB [NF-κB])
- Apoptosis (e.g., BCL-interacting killer [BIK], annexin V, 19-kd interacting protein-3 [NIP3], NIP3-like protein X [NIX])
- Growth inhibition signaling factors (e.g., p21, p27, GADD153)
- Invasion and metastasis (e.g., metalloproteinases [MMPs], MMP-13, plasminogen activator inhibitor-1 [PAI-1])[202]

Of the various molecules involved in sensing and responding to hypoxia, HIF1α has received the most attention. This transcription factor is upregulated in several human tumors.[202] Regulated by a proline hydroxylase, HIF1α can activate the genes for angiogenesis, vasodilation, glycolysis, and erythrocyte production by binding to the hypoxia-response element. Surprisingly, teratomas arising from $HIF1\alpha^{-/-}$ embryonic stem cells grow more rapidly despite lower levels of VEGF and angiogenesis.[45,208] This counterintuitive finding could be a result of the ability of $HIF1\alpha^{-/-}$ cells to survive under hypoxic conditions instead of undergoing apoptosis.[42] Interestingly, other $HIF1\alpha^{-/-}$ cancer cells lead to slowly growing tumors. As a result, molecular therapies that target HIF1α or hypoxia-response element are under intensive investigation for cancer detection and treatment.[202]

ANTIANGIOGENIC AGENTS IN THE CLINIC

Two major problems currently plague the nonsurgical treatment of malignant solid tumors. First, physiologic barriers within tumors impede the delivery of therapeutics and oxygen (a key sensitizer to ionizing radiation) at effective concentrations to all cancer cells.[209,210] Second, inherent or acquired resistance resulting from genetic and epigenetic mechanisms reduces the effectiveness of both conventional and novel therapies.[211] Can we take advantage of the unique pathophysiology of tumors to overcome these problems for better management of cancer?

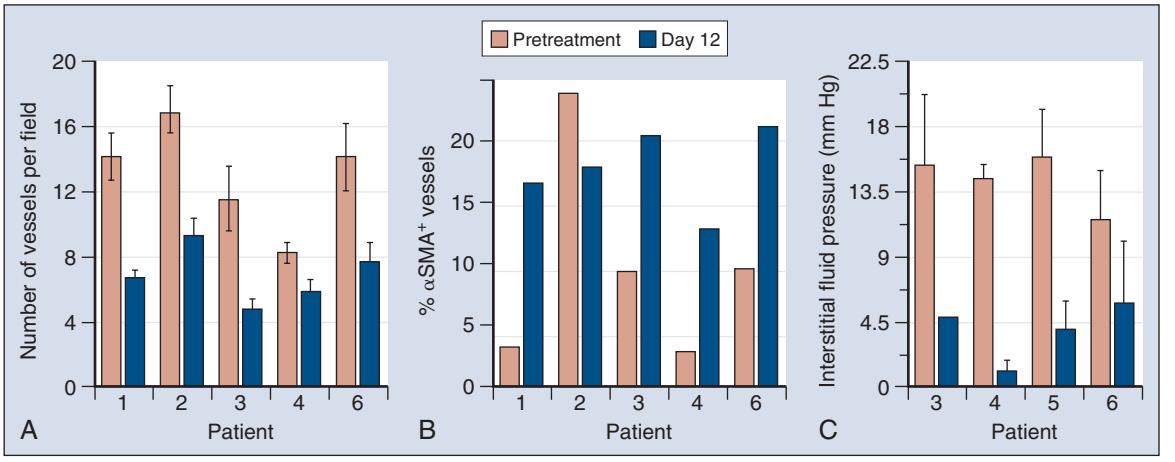
Mechanisms of Action

As discussed next, recent clinical data offer great hope, with three VEGF-blocking antiangiogenic agents (bevacizumab, sorafenib, and sunitinib) already in clinical use.[212] Our studies in rectal cancer and glioblastoma patients have largely confirmed the hypotheses that anti-VEGF therapy has antivascular effects and can induce vascular normalization in cancer patients.[31,188,189,212] In brief, bevacizumab alone reduced the tumor tissue vascular density by approximately half at day 12 after first infusion, reduced significantly the tumor blood flow evaluated on computed tomography scans and the number of viable circulating endothelial cells and progenitor cells. Clinically, both the low-dose-bevacizumab and the high-dose-bevacizumab infusion showed a less hyperemic/hemorrhagic appearance, but no significant tumor regression after bevacizumab treatment at flexible sigmoidoscopy.[188,189] Although the significant pruning of tumor vasculature led to a significant increase in cancer cell apoptosis, it also led to a more mature (pericyte-covered) tumor vasculature, and a stable or increased cancer cell proliferation (Fig. 8-12A–D).[188,189] Whether the increase in tumor cell apoptosis was due to a direct or indirect effect of bevacizumab is currently unclear. Similarly, the role of VEGF blockade on immune or stromal cells in patients is not yet understood. After bevacizumab therapy alone, the tumor IFP was consistently decreased, particularly in the patients with high baseline values.[188,189] This suggested that in human tumors, similar to mouse models, the tumor microenvironment was normalized by the reduction of the excessive vascularization and potentially sensitized the tumor to the subsequent cytotoxic therapy within the "normalization window."[185,207] Imaging studies landed more supportive data for the normalization hypothesis: despite the significant reduction in vessel density and blood flow, the fluorodeoxyglucose uptake measured on positron emission tomography scans (a measure of tumor metabolic activity) and the $P \cdot S$ product (proportional to the penetration of tracer in tumor) evaluated on computed tomography scans did not significantly change at day 12.[188,189] A recent study of antiangiogenic therapy in recurrent glioblastoma demonstrated the existence of a window of vascular normalization in cancer patients (Fig. 8-12E and F).[31]

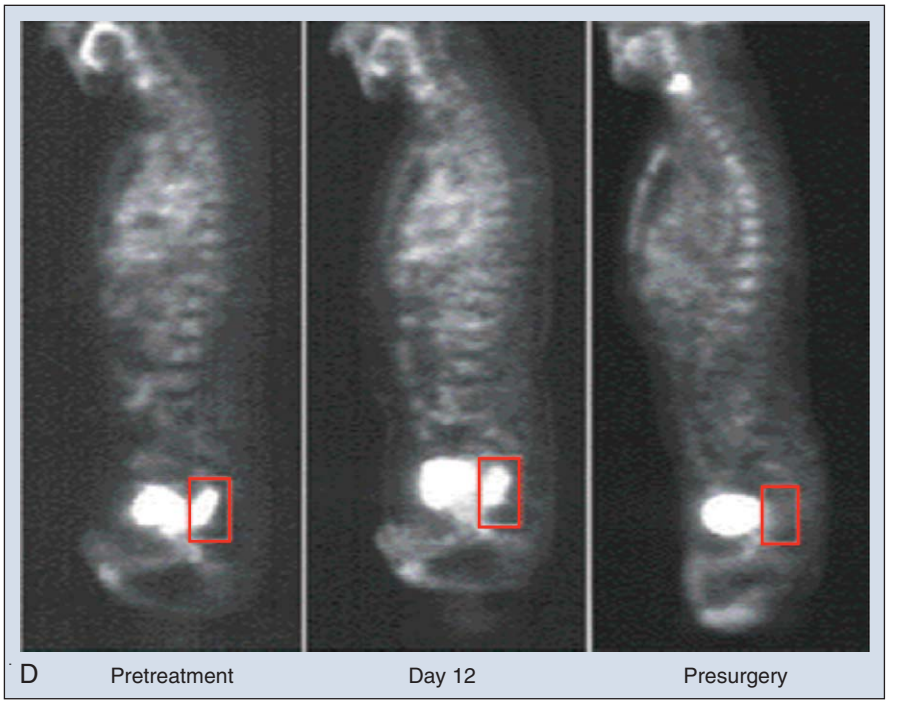
Biomarkers

Biomarker identification and validation for this novel type of therapy are also facing important hurdles. Unlike preclinical models, the phase III bevacizumab experience in metastatic colorectal cancer patients did not identify p53, k-ras, or b-raf status, VEGF or thrombospondin-2 (TSP2) expression, or microvascular density at baseline as predictive markers of response.[213,214]

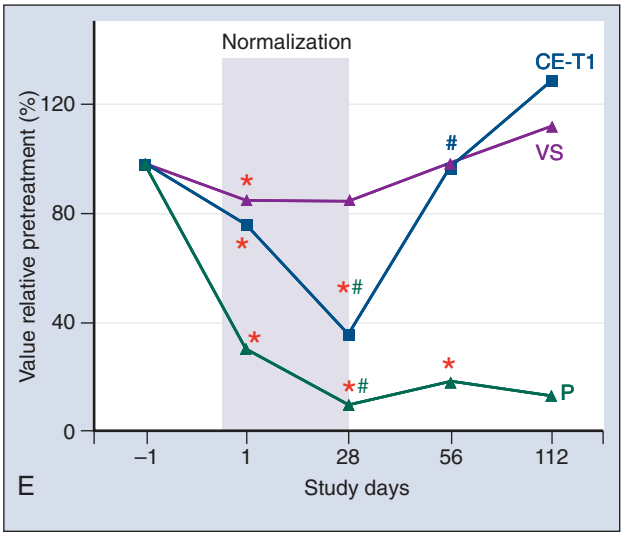
Our results in rectal cancer patients demonstrated that bevacizumab decreased tumor microvascular density and the number of viable circulating ECs, consistent with an antivascular effect.[188,189,215] Whether these changes have predictive value is currently being investigated in an ongoing phase II trial. Plasma angiogenic proteins have also been investigated in multiple phase I–II and in some phase III trials. We reported that the plasma levels of VEGF and PlGF are significantly increased in cancer patients receiving bevacizumab.[189] Other groups have reported similar observations with a variety of anti-VEGF agents, and have also found a decrease in soluble VEGFR2 levels in plasma.[216,217] These data strongly suggest a potential "pharmacodynamic biomarker" value for these three plasma markers. Of great interest for the field would be to identify biomarkers that predict disease progression through anti-VEGF therapy. Although in the rectal cancer patients we were unable to identify significant changes in bFGF, our data from a recently completed phase II trial of AZD2171 in recurrent glioblastoma patients showed a highly significant correlation between bFGF and SDF1α and tumor progression.[31] These differences may be due to the excellent clinical response in rectal cancer patients, or to disease or agent specificity. In addition, we discovered that viable circulating ECs correlate with progression of glioblastoma during antiangiogenic therapy, whereas circulating progenitor cells predicted relapse after drug interruptions.[31] With the development and improved flow cytometry and protein array analysis techniques and subsequent standardization, circulating cell and plasma protein measurements hold great promise for biomarker validation for antiangiogenic therapy.



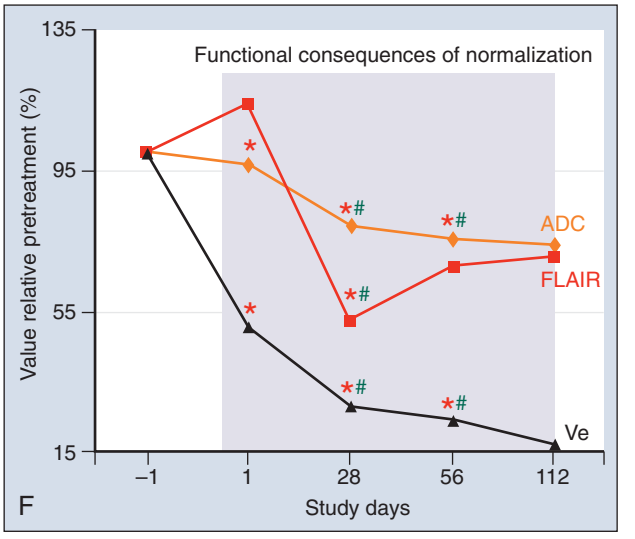
Toxicity



Experimental studies have shown that, in 11 of the 17 healthy organs studied, VEGF blockade can significantly decrease the number of normal capillaries.[218] In cancer patients, most anti-VEGF agents often induce proteinuria, hypertension, thyroid-stimulating hormone elevation, and gastrointestinal toxicity, but agent-specific toxicities have also been reported.[13] In addition, the long-term effects of antiangiogenic therapies in patients with less advanced lesions remain to be established.



Perspective



The major directions for the immediate future are further understanding of the mechanisms of action and identification of the first biomarkers for anti-VEGF therapy.[212] Achieving these goals would allow optimization of treatment protocols and reduction of the adverse effects.

Figure 8-12 • Vascular "normalization" in cancer patients. In rectal cancer patients, tumor vessel "normalization" following a single injection of bevacizumab is suggested by the **(A)** reduced tumor microvessel density, **(B)** increased fraction of tumor vessels with pericyte coverage, and **(C)** reduced interstitial fluid pressure. **(D)** Positron emission tomography reveals no change in 18-fluorodeoxyglucose (FDG) uptake after a single dose of bevacizumab and complete resolution of FDG uptake following neoadjuvant chemoradiation (bevacizumab, 5-fluorouracil, pelvic external beam radiation therapy). The stability of FDG uptake following bevacizumab monotherapy, despite marked reductions in microvessel density, suggests the efficiency of persistent tumor blood vessels after bevacizumab treatment is improved. **E** and **F,** Changes in magnetic resonance imaging parameters in glioblastoma patients receiving AZD2171 over time. **E,** Median values for contrast-enhancement T1-weighted tumor volume (CE-T1), vessel size (VS), and permeability (P) of the tumor over time as measured by an independent expert. Day –1 was set as 100% in all lesions, and changes during AZD2171 treatment were plotted for all 16 patients. Note the rebound of volume and vessel size after day 28, which indicates a partial closure of the normalization window. **F,** Median values of T2-weighted abnormality volume measured in fluid-attenuated inversion recovery images (FLAIR), apparent diffusion coefficient (ADC), and extracellular-extravascular volume fraction (Ve) before and during treatment showing a sustained decrease of edema while taking AZD2171. First, identifying the vascular "normalization window" in patients would allow synergistic combinations with chemotherapeutics or radiotherapy. Second, understanding the mechanisms of vessel pruning and cancer cell apoptosis induced by anti-VEGF therapy, and tumor escape from it, may allow further sensitization of tumor cells to cytotoxic therapies. Third, characterization of the effect of anti-VEGF therapy on bone marrow-derived cells' contribution to tumor growth and relapse would allow judicious and more effective approaches to therapy involving these cells. Finally, clarification of other mechanisms involving the immune system or the stromal and interstitial matrix compartments would contribute to establishing more efficacious combinatorial strategies.

In this respect, new biomarkers and improved imaging techniques will play a major role in monitoring the effects and stratifying the patients with the ultimate goal of individualized therapy.

CONCLUSION

The recent successes of the anti-VEGF agents have raised great hope and have taught us important lessons about the significance of the target, timing, and dosage of each agent[212]:

- According to the results of the phase III trials completed to date, bevacizumab can increase median survival when combined with standard chemotherapy, but not when used as monotherapy.
- Anti-VEGF therapy with bevacizumab can increase overall survival and/or progression-free survival in colorectal, breast, and lung cancer patients when combined with cytotoxic agents.
- Improved survival has been observed with broad-spectrum multitargeted tyrosine kinase inhibitors (e.g. sorafenib, sunitinib) when used in monotherapy.
- In colorectal cancer patients, vatalanib, a VEGF receptor–selective tyrosine kinase inhibitor, does not confer the same survival advantage as bevacizumab when combined with chemotherapy.
- Anti-VEGF therapy can prune and "normalize" tumor vasculature, and decrease the number of circulating endothelial cells and progenitor cells.
- There is an urgent need to identify biomarkers to guide anti-VEGF therapy and combination therapies using anti-VEGF agents.

Antiangiogenic agents are now expected to make a difference in cancer patients with a wide variety of tumor types. With the advent of specific and potent new agents—approved or in the process of being approved—oncologists have a variety of direct and indirect antiangiogenic agents to choose from when designing therapy protocols. Determining whether the regimens used in the successful trials are optimal, however, and whether antiangiogenic agents will work in patients outside the rigorous inclusion criteria used for those trials, will be critical for deciding the standard of care for different malignancies. Establishing the most advantageous combinations will require a better understanding of the mechanisms of action of each anti-VEGF agent and the sensitivity of each tumor type, as well as development of robust biomarkers and imaging techniques to guide patient selection and protocol design. A deeper understanding of the mechanisms of antitumor activity of specific and multitargeted antiangiogenic agents in patients, how they can best be combined with other treatment approaches such as chemotherapy and radiation therapy, and how optimization of these effects can be monitored clinically, should contribute to significantly improved cancer treatment and extend survival of cancer patients in the near future, as well as enhance the prospects of developing curative treatment for different cancers in the more-distant future.

ACKNOWLEDGMENTS

We would like to thank Kevin Kozak for his input on updating this chapter. This chapter is an updated and expanded version of a chapter by R.K. Jain entitled "Molecular Pathophysiology of Tumors (In Perez CA, Brady LW, Halperin EC, Schmidt-Ullrich R [eds]: Principles and Practice of Radiation Therapy. New York, Lippincott, Williams & Wilkins, 2003, pp 163–179). The work summarized here has been supported continuously by the National Cancer Institute since 1980 with funding to R.K. Jain.

B. GENESIS OF CANCER

9 Environmental Factors

Paul T. Strickland and Thomas W. Kensler

SUMMARY OF KEY POINTS

History of Identification of Human Carcinogens

- The carcinogenic effects of many environmental and occupational agents were first described in humans.
- Beginning in the 20th century with the advent of animal bioassay programs, evidence of carcinogenicity in experimental animals has preceded evidence from epidemiologic or case studies in humans.
- The majority of human cancers probably result from the interaction of several or more carcinogenic influences (often unidentified) along with intrinsic factors (inherited genes, hormones, immune status).

Role of Environmental Agents in the Etiology of Human Cancer

- Although the causes of most human cancers remain unidentified, cumulative data support the opinion that environmental agents are the principal causes of human cancers.
- Cigarette smoking could be responsible for 25% of all cancers in the United States.
- Chemical carcinogens include aromatic amines, benzene, aflatoxins, tobacco chemicals, and chemotherapeutic agents.
- Radiation carcinogens include ultraviolet radiation, ionizing radiation, and radon.
- A number of metal carcinogens have been identified, including arsenic, nickel, cadmium, and chromates. These have been associated largely with occupational exposures.
- Fibers (asbestos, silica) and dusts are well established as etiologic agents in lung cancers.
- Many components in the diet can influence the development of cancer through carcinogenic or anticarcinogenic mechanisms.

Exposure Biomarkers and Susceptibility Factors and Chemoprevention

- The identification of molecular biologic markers of exposure, effect, and susceptibility (reflecting events before clinical disease) will help to further our understanding of human carcinogenesis.
- The characterization of the human genome has permitted study of the roles of common polymorphisms in carcinogen metabolism or of DNA repair genes in susceptibility to cancer.
- Primary and secondary approaches to the prevention of cancer will be greatly facilitated by the development of noninvasive biomarkers that identify high-risk individuals.
- Tertiary prevention might also be enhanced by characterizing cancers with respect to etiology, genetic profile, or metabolic capacity.

INTRODUCTION

The carcinogenic effects of a sizable number of environmental or industrial chemicals have first been described in humans. The influences of occupation and lifestyle in cancer occurrence were observed at least as early as the 16th century. Ramazzini in 1700 noted that nuns showed a higher frequency of breast cancer than was observed among other women. Also in that century, Paracelsus and Agricola described Bergkrankheiten in miners in the Schneeberg and Joachimstal regions of Europe. Bergkrankheiten was later recognized as lung cancer, probably caused by uranium and its decay product radon.[1] Subsequently, in 1761 Hill associated the use of tobacco snuff with cancer in the nasal passage, and in 1775 Pott noted the occurrence of soot-related scrotal cancer among chimney sweeps. In 1895 Rehn published evidence that occupational exposure to aromatic amines was associated with bladder cancer, whereas Unna in 1894 associated sunlight exposure with skin cancer. It was not until the early 20th century that animal models for chemical carcinogenesis were developed. For example, Yamagiwa and Ichikawa reported in 1915 on the production of skin tumors following topical application of crude coal tar to the ears of rabbits, and Sasaki and Yoshida reported in 1935 that feeding of azo dyes to rats led to the development of liver tumors. In the intervening decades, there has been substantial growth in our understanding of the roles of chemicals (both manufactured and naturally occurring), radiation, and viruses in the cancer process. Of particular importance has been the recognition that these extrinsic factors interact with intrinsic factors (e.g., inherited genes, hormones, immune status) to determine overall susceptibility and risk. A central role of diet in these interactions is featured by observations that diet can both enhance and inhibit tumor formation.

Contrary to experiences in earlier centuries, with the advent of animal bioassay programs, evidence of carcinogenicity in experimental animals has preceded evidence obtained from epidemiologic studies or case reports in many instances. Although the term carcinogen means "giving rise to carcinomas" (e.g., epithelial malignancies) in general, broader operational definitions are used for carcinogens in animal bioassays. A carcinogen may be defined as an agent whose administration to previously untreated animals leads to a statistically significant increased incidence of malignant neoplasms, compared with the incidence in appropriate untreated control animals, whether the control animals have a low or high spontaneous incidence of the neoplasms in question. Chemicals, radiation, and

Table 9-1 Agents and Processes Considered Carcinogenic in Humans by the International Agency for Cancer Research

Agent or Process	Common Organ or Tissue Sites of Cancer
AMBIENT AND DIETARY EXPOSURE	
Aflatoxins	Liver
Arsenic and arsenic compounds	Lung, skin
Erionite	Pleura, peritoneum
CULTURAL HABITS	
Alcoholic beverages	Oral cavity, pharynx, larynx, esophagus, liver
Betel quid with tobacco	Oral cavity
Tobacco products, smokeless	Oral cavity
Tobacco smoke	Respiratory tract, urinary bladder, renal pelvis, pancreas
Salted fish, Chinese style	Nasopharynx
Solar radiation	Skin
OCCUPATIONAL	
Aluminum production	Lung, urinary bladder
4-Aminobiphenyl	Urinary bladder
Asbestos	Lung, pleura, peritoneum, larynx, gastrointestinal tract
Auramine O, manufacture of	Urinary bladder
Benzene	Leukemia
Benzidine	Urinary bladder
Beryllium	Lung
Bis(chloromethyl)ether and chloromethyl methyl ether	Lung
Boot and shoe manufacture and repair	Nasal sinus
Cadmium	Lung
Chromium (VI) compounds	Lung
Coal gasification	Lung, urinary bladder, scrotum
Coal-tar pitches	Skin, scrotum, lung
Coal tars	Skin, lung
Coke production	Skin, scrotum, lung, urinary bladder
Dioxin	All cancers combined
Ethylene oxide	Lymphatic, hematopoietic
Formaldehyde	Liver
Furniture and cabinet making	Nasal sinus
Iron and steel founding	Lung
Isopropyl alcohol manufacture (strong acid process)	Nasal sinus
Magenta, manufacture of	Urinary bladder
Mineral oils (untreated and mildly treated)	Skin, scrotum
Mustard gas	Lung, larynx/pharynx
2-Naphthylamine	Urinary bladder
Nickel and nickel compounds	Lung, nasal sinus
Painting	Lung
Benzo[*a*]pyrene	Lung
Rubber industry	Urinary bladder, leukemia
Shale oils	Skin, scrotum
Silica, crystalline	Lung
Soots	Skin, scrotum, lung
Strong inorganic acid mists containing sulfuric acid	Larynx
Talc containing asbestiform fibers	Lung
Underground mining with exposure to radon	Lung
Vinyl chloride	Liver, lung, gastrointestinal tract, brain
Wood dust	Nasal cavities, paranasal sinuses
THERAPEUTIC USE	
Analgesics mixtures containing phenacetin	Renal, urinary bladder
Azathioprine	Leukemia
N,*N*-Bis(2-chloroethyl)-2-naphthylamine	Urinary bladder
1,4-Butanediol dimethanesulfonate	Leukemia
Chlorambucil	Leukemia
Cyclosporin	Lymphoma
Cyclophosphamide	Urinary bladder, leukemia
Estrogen replacement therapy	Endometrium, breast
Estrogen, nonsteroidal	Cervix/vagina, breast, endometrium, testes
Estrogens, steroidal	Endometrium, breast
Melphalan	Leukemia
8-Methoxypsoralen plus UV radiation	Skin
Methyl-CCNU	Leukemia
MOPP	Leukemia
Oral contraceptives (combined)	Liver
Oral contraceptives (sequential)	Endometrium
Tamoxifen	Endometrium
Thiotepa	Leukemia
Treosulfan	Leukemia
INFECTIOUS AGENTS	
Epstein-Barr virus	Lymphoma
Helicobacter pylori	Stomach
Hepatitis B virus	Liver
Hepatitis C virus	Liver
Human immunodeficiency virus type 1	Kaposi's sarcoma
Human papilloma viruses types 16, 18, others	Cervix
Human T-cell lymphotropic virus type I	Adult T-cell leukemia/lymphoma
Opisthorchis viverrini	Cholangiocarcinoma
Schistosoma haematobium	Urinary bladder

methyl-CCNU, semustine; MOPP, mechlorethamine, vincristine, procarbazine, and prednisone (combination therapy).

Data from International Agency for Research on Cancer: IARC monographs on the evaluation of carcinogenic risk to humans, Vol. 1–88, Lyon, IARC, 1970–2006. An updated listing of the overall evaluation of carcinogenicity to humans can be accessed on the Internet at http://monographs.iarc.fr under the heading "classifications". (Note: for examples of carcinogenic ionizing radiations, see Table 9-3).

viruses are the primary agents identified. Synthetic and naturally occurring chemicals compose the largest group of known human carcinogens. More than 100 chemicals, chemical mixtures, biologic agents, physical agents, or industrial processes have been classified as human carcinogens (Table 9-1) and more than 300 chemicals have been identified as animal carcinogens so far. These figures evolve from an environmental milieu of perhaps 10^7 chemicals, although the vast majority of these agents have not been evaluated for carcinogenicity.

Chemical carcinogens comprise a diverse array of chemical structures, including both organic and inorganic compounds. Relatively few carcinogens are direct acting, because the innate reactivity of such compounds also tends to make them unstable. Instead, most carcinogens require metabolic activation to reactive species, often in the target cells. Once formed, the reactive intermediates can interact with DNA to produce genetic lesions that can result in mutation of critical cellular genes, including oncogenes and tumor suppressor genes. Metabolic pathways can be influenced strongly by a variety of extrinsic and intrinsic factors and are important determinants of both interindividual and target organ susceptibilities to carcinogens. Carcinogenesis is a dynamic, multistage process through which a normal cell is converted into a malignant one. Although our understanding of the neoplastic process is incomplete, current knowledge provides considerable insight into the critical actions of carcinogens. The goal of this chapter is to highlight the roles of discrete chemical and physical agents in the etiology of human cancers. In turn, fuller understanding of the mechanistic basis for the actions of these carcinogenic agents will allow for more effective means to identify other carcinogens in our environment and to develop preventive strategies to interrupt, block, or reverse the neoplastic process.

ROLE OF ENVIRONMENTAL AGENTS IN THE ETIOLOGY OF HUMAN CANCERS

The causes of most human cancers remain unidentified; however, considerable evidence suggests that "extraconstitutional" or environmental and lifestyle issues are important contributors. For example, cigarette smoking could be responsible for 25% of all cancers in the United States. The opinion that environmental agents are the principal causes of human cancers is derived largely from the following series of epidemiologic observations:

- Although the overall incidence of all cancers is reasonably constant among countries, incidences of specific cancer types can vary up to several hundred fold.
- There are large differences in tumor incidence within populations of a single country.
- Migrant populations assume the cancer incidence of their new environment within one to two generations.
- Cancer rates within a population can change rapidly.

Although the extent to which environmental agents contribute to human carcinogenesis remains to be defined precisely, a considerable number of epidemiologic studies indicate important roles for the various naturally occurring and manufactured chemicals, radiations, metals, and fibers found in our individual environments.

Chemicals

Polycyclic Aromatic Hydrocarbons

The English surgeon Percival Pott[2] was among the first to document the association of an environmental agent with cancer. During the late 18th century, he determined that the unusually high incidence of scrotal cancer among chimney sweeps was due to their occupational exposure to soot and tar. As a consequence, recommendations for bathing and use of protective clothing were promulgated by chimney sweepers' guilds in parts of Europe, but not in England. Subsequent decreases in the incidence of scrotal cancer were observed in continental Europe, demonstrating the efficacy of simple prevention efforts. It was not until the present century that the active carcinogens in soot and coal tar were shown to be polycyclic aromatic hydrocarbons (PAHs).[3] This result was accomplished through the application of coal tar and fractions thereof to the skins of test animals that subsequently developed malignant skin tumors. Although many PAHs were identified in coal tar, most of the carcinogenic activity was attributed to the PAH benzo[*a*]pyrene.

Humans are exposed to PAHs from a variety of sources that include occupation, smoking, diet, and air.[4] PAHs are readily absorbed into the body through the skin, lungs, and gastrointestinal tract. Occupational and medicinal exposures constitute the highest levels of human PAH exposure (albeit in small groups within the population), whereas diet and smoking are the major sources of exposure to PAHs in the general population. Air concentrations of greater than 10 μg benzo[*a*]pyrene/m^3 are characteristic of topside gas and coke work environments. Broiled, barbecued, or smoked meats and fish contain relatively high concentrations of benzo[*a*]pyrene (1–20 μg/kg).

Cutaneous occupational exposure to PAHs has been associated with increased risk of skin and scrotal cancers in chimney sweeps and in individuals exposed to unrefined lubricating oils in the textile and machining industries.[1] Scrotal cancer among mule spinners in the Manchester (UK) cotton industry was attributed to the saturation of the workers' trousers with lubricating oil. A review of all admissions for scrotal cancer to the Royal Manchester Infirmary from 1902 to 1922 indicated that 49% had worked as mule spinners, while 16% had worked with tar or paraffin. As the textile industry declined in the middle 20th century, an increasing proportion of scrotal cancer was associated with cutting oils used in metal machining.

An excess of lung cancer has been demonstrated among individuals with substantial inhalation exposure to PAHs, including roofers and pavers, coke oven workers, certain steel and iron manufacturing workers, and aluminum production workers.[5] In addition, several studies suggest that workers highly exposed through inhalation might also be at increased risk of cancer at sites other than skin and lung. The strongest evidence for such an association is for bladder cancer, where a dose-response relationship has been demonstrated between PAH exposure and bladder cancer risk in aluminum workers after adjustment for smoking. Other sites with suggestive increases in risk include the pancreas and upper gastrointestinal tract.

Several biochemical pathways are involved in the metabolism of PAHs and of benzo[*a*]pyrene in particular (Fig. 9-1).[3] The initial step in benzo[*a*]pyrene metabolism involves the epoxidation of an aromatic double bond by one of the cytochrome P-450 monooxygenases (CYP1A1). The epoxide-benzo[*a*]pyrene intermediates might form phenols or glutathione conjugates or be further oxidized by epoxide hydrolase to form dihydrodiol-benzo[*a*]pyrene. This latter metabolite can undergo a second oxidation step, resulting in the highly reactive 7,8-dihydrodiol-9,10-epoxide benzo[*a*]pyrene. Experimental studies demonstrate that cultured human lung or colon tissue metabolizes benzo[*a*]pyrene to the proximate carcinogen 7,8-dihydro-7,8-dihydroxybenzo[*a*]pyrene and that benzo[*a*]pyrene metabolites bind to DNA in cultured tissue. Oral administration of benzo[*a*]pyrene to rodents produces benzo[*a*]pyrene-DNA adducts in liver, stomach, colon, and intestine, and cancers of the esophagus, forestomach, intestine, lungs, and mammary gland.

Aromatic Amines

The occurrence of bladder cancer among dye industry workers was reported in 1895 by the German physician Ludwig Rehn, who suggested a causal relationship. With the rapid expansion of the chemical industry during and after World War I, increased risk of bladder cancer was observed among workers employed in chemical manufacturing and textile dyeing.[6] An industry-wide study of workers exposed to dyes in England and Wales demonstrated increased risks of bladder cancer among men exposed to 1-naphthylamine (observed

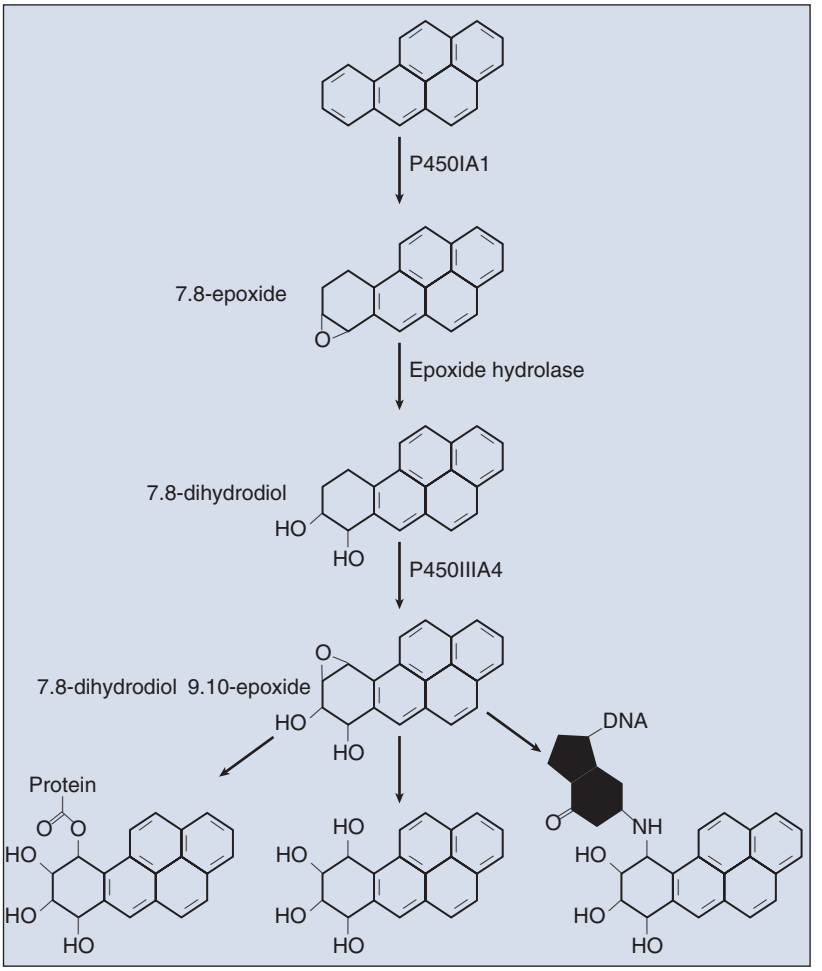

Figure 9-1 • Metabolic activation of benzo[*a*]pyrene and formation of DNA and protein adducts.

[O]/expected *[E]* = 8.6), benzidine (*O*/*E* = 13.9), 2-naphthylamine (*O*/*E* = 86.7), or mixed dyes (*O*/*E* = 54.7). The International Agency for Research on Cancer subsequently considered that the cancer hazard associated with exposure to 1-naphthylamine was due to the probable contamination of commercial-grade 1-naphthylamine with 4% to 10% 2-naphthylamine.[7] Additional studies in the dye industry identified auramine O and magenta as human bladder carcinogens. Increased risk of bladder cancer among rubber workers and in the electric cable industry has been attributed to the naphthylamine added to rubber as an antioxidant.

Excess risk of bladder cancer has been observed in the silk-dyeing industry, in which benzidine-based dyes are used extensively. Elevated incidence of bladder cancer associated with benzidine manufacturing and production in the United States and Japan is complicated by probable coexposure to 2-naphthylamine and *o*-toluidine. The production of these aromatic amines has declined in recent years; the result has been a considerable reduction in bladder cancer among workers in these industries.

Aromatic amines are metabolized and excreted through a process involving acetylation by *N*-acetyltransferase.[8] Genetic variation in one of the genes, *NAT2,* encoding this enzyme produces either rapid or slow metabolic phenotypes in humans. Analysis of the NAT2 phenotypes of patients with bladder cancer from the dye industry indicates that individuals showing the slow phenotype could be more susceptible to bladder cancer caused by aromatic amines. This is consistent with a recent meta-analysis indicating that NAT2 slow acetylation status is associated with an increased risk of bladder cancer in the general population.[9]

Benzene

Exposure to benzene was suspected to be the cause of leukemia in a number of individual cases and case series reported worldwide between 1928 and 1976.[1] Case-control studies indicated increased risks of nonlymphocytic leukemia among workers in Sweden exposed to benzene-containing petroleum products and for lymphomas among workers in New York State exposed to benzene. Prospective studies conducted in the rubber industry provide the most convincing evidence for an association between benzene exposure and leukemia. Most of the excess leukemia in this industry is found among rubber workers exposed to solvents, including benzene. Excess mortality from leukemia has been observed among former employees of a rubber film production plant (*O*/*E* = 4.7) and a rubber coating plant (*O*/*E* = 3.7).

Aflatoxins

The hepatotoxic effect of aflatoxins was first recognized when aflatoxin-contaminated feed was inadvertently fed to poultry. Subsequent animal studies demonstrated the carcinogenic potential of the aflatoxins, particularly aflatoxin B_1. The aflatoxins are produced by the fungal strains *Aspergillus flavus* and *A. parasiticus.* Grains and foodstuffs for human consumption such as corn, peanuts, and rice can become contaminated with aflatoxin during growth or storage. The considerable variation in levels of human exposure to aflatoxin worldwide is determined by climate and by the preventive measures used to protect susceptible foods from mold contamination and growth.[10]

Dietary aflatoxin is correlated with high liver cancer rates in sub-Saharan Africa and Asia. Case-control studies in the Philippines and Mozambique show an increased risk of liver cancer with estimated levels of aflatoxin consumption. The co-carcinogenic role of hepatitis B virus (HBV) infection and dietary aflatoxin in liver cancer has been the focus of several studies. The incidence of liver cancer in different regions of Swaziland correlated more closely with aflatoxin intake than with HBV infection. A prospective study conducted in Guangxi Province, China, compared the incidence of liver cancer in regions of high and low aflatoxin contamination and determined HBV infection status.[10] A strong interaction between aflatoxin exposure and HBV-positive status was observed for relative risk of liver cancer. Among HBV-positive individuals, the incidence of liver cancer was 649 per 100,000 in the high-aflatoxin region and 66 per 100,000 in the low-aflatoxin region, whereas among HBV-negative individuals, the incidence of liver cancer was 99 per 100,000 and <1 per 100,000 in high- or low-aflatoxin regions, respectively.

The new techniques of molecular dosimetry for human carcinogen exposure have been applied in populations exposed to aflatoxin. With individual exposures often in excess of 10 to 100 µg/day, the presence of aflatoxin metabolites and DNA adducts can be quantified in the urine after exposure. The association of urinary aflatoxin-DNA adducts with risk of liver cancer has also been demonstrated in a prospective epidemiologic study.[11]

Tobacco Chemicals

Tobacco use causes more cancer deaths worldwide than any other human activity. Cigarette smoking is associated with cancers of the lung, oral cavity, pharynx, larynx, esophagus, bladder, renal pelvis, and pancreas. The use of smokeless tobacco (chewing tobacco or snuff) leads to cancer of the oral cavity. Thus, although combustion enhances the carcinogenic properties of tobacco, it is not required for cancer induction.

Although the carcinogenic properties of tobacco tar were first demonstrated experimentally during the 1920s, evidence of a human cancer risk from the use of tobacco did not appear until 1939, when Muller and colleagues[12] reported an association between tobacco use and lung carcinoma in Germany. Subsequent epidemiologic studies conducted in the United States and the United Kingdom during the next decade confirmed this causal relationship. These findings met with considerable resistance in both the scientific community and the general public, however. Unlike occupational exposure to carcinogens, which was subject to regulation in many countries, tobacco exposure was a personal habit considered by many users to be more pleasurable than dangerous. Unfortunately, the addictive characteristics of nicotine, a major constituent of tobacco, made it more difficult for tobacco users to reduce their consumption. Societal acceptance of a causal association with lung cancer was advanced by the first reports from the Royal College of Physicians in the United Kingdom (1962) and from the Surgeon General in the United States (1964) regarding the risks of tobacco use. By contrast, the tobacco industry has steadfastly resisted attempts to educate the public to the health hazards of tobacco use and has continued to market cigarettes aggressively, particularly in developing countries. Explosive increases in the incidence of lung cancer, probably even outranking those already occurring in the United States, can be anticipated in these countries over the next few decades. Based on tobacco usage trends, it is estimated that more than one million new cases per year of lung cancer will occur in China in the 21st century.[12]

More than 3000 chemicals have been identified in cigarette smoke, of which at least 30 are known to be carcinogenic in animals (Table 9-2). The gas phase of tobacco smoke contains several carcinogenic or tumor-promoting compounds, including dimethylnitrosamine, dialkylnitrosamines, vinyl chloride, acrolein, and benzene. The particulate phase contains carcinogenic and co-carcinogenic PAHs, methylated PAHs, heterocyclic hydrocarbons, chlorinated hydrocarbons, phenols, catechols, and metals. Organ-specific

Table 9-2 Tumorigenic Agents in Tobacco Smoke

Compounds	Mainstream Smoke Compounds (per Cigarette)
PAHS	
Benzo[*a*]anthracene	20–70 ng
Benzo[*b*]fluoranthene	4–22 ng
Benzo[*f*]fluoranthene	6–21 ng
Benzo[*k*]fluoranthene	6–12 ng
Benzo[*a*]pyrene	20–40 ng
Chrysene	40–60 ng
Dibenz[*a,h*]anthracene	4 ng
Dibenzo[*a,i*]pyrene	1.7–3.2 ng
Dibenzo[*a*-1]pyrene	Detectable
Indenol[1,2,3-*c,d*]pyrene	4–20 ng
5-Methylchrysene	0.6 ng
AZA-ARENES	
Quinoline	1–2 µg
Dibenz[*a,h*]acridine	0.1 ng
Dibenz[*a,j*]acridine	3–10 ng
7H-Dibenzo[*c,g*]carbazole	0.7 ng
N-NITROSAMINES	
N-Nitrosodimethylamine	0.1–180 ng
N-Nitrosethylmethylamine	3–13 ng
N-Nitrosodiethylamine	0–25 ng
N-Nitrosopyrrolidine	1.5–110 ng
N-Nitrosodiethanolamine	0–36 ng
N-Nitrosonornicotine	0.12–2.7 µg
4-(Methylnitrosamine)-1-(3-pyridyl)-1-butanone	0.08–0.77 µg
N-Nitrosoanabasine	0.14–4.6 µg
AROMATIC AMINES	
2-Toluidine	30–200 ng
2-Naphthylamine	1–22 ng
4-Aminobiphenyl	2–5 ng
ALDEHYDES	
Formaldehyde	70–100 µg
Acetaldehyde	18–1400 ng
Crotonaldehyde	10–20 µg
MISCELLANEOUS ORGANIC COMPOUNDS	
Benzene	12–48 µg
Acrylonitrile	3.2–15 µg
2-Nitropropane	0.73–1.21 µg
Ethylcarbamate	20–38 ng
Vinyl chloride	1–16 ng
INORGANIC COMPOUNDS	
Hydrazine	24–43 ng
Arsenic	40–120 ng
Nickel	0–600 ng
Chromium	4–70 ng
Cadmium	41–62 ng
Polonium-210	0.03–1.0 pCi

From Reducing the Health Consequences of Smoking: 25 Years of Progress. Washington, DC, U.S. Department of Health and Human Services, 1989.

carcinogens in the particulate phase include N-nitrosamines (and precursors), which have been associated with esophageal and pancreatic cancers, and aromatic amines, which are associated with kidney and bladder cancers. An important finding from experimental studies is the strong interactive effect observed when certain mixtures of these compounds are assayed for carcinogenic potential.

Chemotherapeutic Agents

The systemic toxicity of sulfur mustard gas among soldiers exposed during World War I led to investigations of the mechanism of action of nitrogen mustard compounds. The cytotoxic effect observed in lymphatic tissues was subsequently replicated and studied in experimental animal models. This property of nitrogen mustards and other alkylating compounds prompted their use as antineoplastic drugs during the 1940s. Several other types of drugs were developed at that time for use in the treatment of cancer, including the antibiotic actinomycin A and the antimetabolite methotrexate. Later decades saw the introduction of a variety of alkylating agents (e.g., chlorambucil, cyclophosphamide, bis-chloroethylnitrosourea, busulfan, cisplatin), antimetabolites (5-fluorouracil, 6-mercaptopurine), antibiotics (adriamycin, bleomycin, daunomycin), and mitotic inhibitors (vincristine, vinblastine) as antineoplastics.

As early as 1948, the carcinogenic properties of the anticancer drug 4-aminostilbene and its metabolites were reported. This and subsequent findings led to the institution of carcinogenesis bioassays for new anticancer drugs under development by the National Cancer Institute. Preneoplastic dysplasias were frequently observed in the epithelial tissues of patients with cancer undergoing chemotherapy. The appearance of frank second malignancies among patients treated by chemotherapy was reported during the 1970s. In addition, renal transplant patients receiving anticancer drugs for immunosuppression showed excess risks of mesenchymal and epithelial cancers.

The successful treatment of Hodgkin's disease with multiagent chemotherapy is associated with the long-term complication of acute myeloid leukemia (AML) and non-Hodgkin's lymphoma. Increased risk of acute myeloid leukemia among patients treated for non-Hodgkin's lymphoma, ovarian cancer, multiple myeloma, or small-cell carcinoma of the lung has also been attributed to antineoplastic therapy. The risk of acute myeloid leukemia is most strongly associated with the alkylating antineoplastics—particularly cyclophosphamide, melphalan, busulfan, treosulfan, and semustine (methyl-CCNU)—or with combination chemotherapies that include alkylating agents.

A large case-control study conducted in collaboration with 11 population-based cancer registries and two large oncology hospitals in Europe and Canada identified 114 cases of leukemia among 99,113 ovarian cancer survivors.[13] Patients receiving chemotherapy alone had a relative risk for leukemia of 12 as compared with patients treated by surgery alone. By contrast, patients receiving radiation therapy alone (as compared with surgery alone) had no significant increase in the risk of leukemia. In order of decreasing leukemogenic potency, the drugs melphalan, thiotepa, chlorambucil, cyclophosphamide, and treosulfan were independently associated with significantly increased risk of leukemia. Combination treatment with adriamycin and cisplatinum also increased the risk of leukemia, indicating that one or both of these drugs is leukemogenic in humans.

Radiation

Ultraviolet

Solar ultraviolet (UV) radiation is the major physical carcinogen in our environment and the primary cause of skin cancer in humans. More than 800,000 individuals will develop new basal cell carcinoma or squamous cell carcinoma of the skin each year in the United States, making nonmelanoma skin cancer the most common cancer.[7] The incidence of both nonmelanoma and melanoma skin cancer among light-skinned individuals is increasing at a rate of 3% to 5% per year in the United States. This increase has been attributed to changing lifestyle and leisure habits over the past five decades, resulting in an increase in the number of people receiving greater exposure to sunlight. Although basal cell carcinoma occurs more frequently than squamous cell carcinoma (the ratio of basal cell to squamous cell carcinoma is approximately 3:1), the incidence of squamous cell carcinoma seems to be increasing more rapidly than that of basal cell carcinoma. In addition, squamous cell carcinoma metastasizes more frequently and is responsible for more deaths than are caused by basal cell carcinoma.

The relationship between solar UV exposure and skin cancer in humans has been demonstrated from incidence data in human populations residing at different latitudes. The incidence of nonmelanoma skin cancer shows a generally increasing trend with decreasing latitude among individuals with similar skin types.[7] Nonmelanoma skin cancers and the premalignant skin neoplasm, actinic keratosis, are also associated with cumulative lifetime UV exposure estimated from outdoor activities. This is particularly apparent among those with outdoor occupations such as farmers and sailors. The anatomic distribution of these skin neoplasms, primarily on sun-exposed areas, including the face, ears, neck, and hands, is consistent with a solar etiology. The phenotypic characteristics of light skin complexion, ease of sunburning (skin type), and light hair color are known to enhance the risk of nonmelanoma skin cancer. Pigmentation of the skin, either constitutive or induced (as in tanning), clearly plays an important role in protecting skin from the carcinogenic effects of UV radiation. Individuals with moderately to heavily pigmented skin (Latin, Hispanic, Negroid) show much lower rates of skin cancer than do those with poorly or nonpigmented skin (Celtic, albino). The importance of pigmentation is also demonstrated by the finding that susceptibility to sunburn is a strong indicator of risk of both basal and squamous cell carcinoma.

Molecular evidence also supports an etiologic role of solar UV in human skin cancer. Increased levels of DNA photodamage are detected in the normal epidermis of individuals following exposure to solar UV radiation. In addition, analysis of mutational spectra in human nonmelanoma skin cancer DNA shows that mutations specific for UV radiation (dipyrimidine mutations) are frequently present.

Animal studies confirm the carcinogenic effects of UV radiation and indicate that the UV-B portion (280–320 nm) of the solar spectrum is primarily responsible for the carcinogenic properties of sunlight. This wave band encompasses the long-wavelength end of the absorbance spectrum of DNA and has been shown to cause mutations in mammalian cells. Stratospheric ozone efficiently absorbs UV-B wavelengths below 300 nm, thereby determining the short-wavelength end of the solar spectrum reaching the earth's surface. Concern over the destruction of stratospheric ozone due to environmental pollution with chlorofluorocarbons, resulting in increased intensity of UV-B radiation at the earth's surface, has encouraged the refinement of risk estimates for human skin cancer under conditions of reduced atmospheric ozone.

Ionizing

The discovery and manipulation of ionizing radiation in the early 20th century led to detrimental health effects among many researchers. Toxicity, radiation burns, and cancer were observed among handlers of radioactive materials. The deaths of Marie Curie and Thomas Edison's assistant from cancer have been attributed to severe radiation exposure. The use of radium in luminous paint during the 1930s led to a high incidence of osteosarcoma among dial painters who inadvertently ingested radium when shaping their brush tips with the tongue.[1] By the 1940s, an elevated incidence of leukemia was observed among radiologists. After World War II, excess leukemia was observed among atomic bomb survivors and among patients treated with x-rays.

Epidemiologic studies of populations exposed to high doses of radiation indicate increased risks for a variety of cancers, depending on the type of radiation and route of exposure (Table 9-3). Among atomic bomb blast survivors, excess leukemias appeared within several years of exposure, whereas excess cancers of the breast, lung, esophagus, thyroid, colon, bladder, and ovary, as well as multiple myeloma appeared only 20 to 25 years later. In contrast, populations exposed to nuclear weapons fallout show only excess risk of thyroid cancer due to radioactive iodine. Heavy exposure to x-rays for diagnostic or therapeutic procedures has been associated with increased risk of the following types of cancers: leukemia after in utero exposure; breast cancer after repeated chest exposure; leukemia, lung, stomach, and esophagus after spinal exposure; and thyroid, skin, and neck after scalp or thymus exposure.[5]

The use of cobalt-60 x-ray treatment for cervical cancer is associated with leukemia and cancers of the stomach, rectum, bladder, vagina, buccal cavity, nasopharynx, and lung. Because most radiation exposure in ambient or occupational environments occurs as protracted low-dose exposure, an important public health concern is the cancer risk from low-level exposure. However, most risk estimates are extrapolated from high to low doses and from acute to chronic exposures and are therefore subject to several assumptions that profoundly influence the resulting low-level risk estimates. Populations with potential (or known) low-level radiation exposures include employees in the nuclear industry, individuals living near nuclear production or storage facilities, military personnel participating in atmospheric nuclear weapons tests or living near test sites, patients receiving diagnostic radiation, and residents of buildings with radon contamination. In addition, nuclear accidents such as the Chernobyl incident in the former Soviet Union produce both acute and chronic exposure to local and distant populations.

Radon

Radon gas is encountered in hard rock mining for iron, tin, fluorspar, and uranium.[7] The radioactive decay of radon and its products produces alpha particles. The earliest reports defining an association between lung cancer and mining described the high rate of lung cancers among uranium miners in the Schneeberg region of Czechoslovakia in the late 19th century. Many potential causes were proposed, including radon inhalation. Studies of lung cancer mortality among Colorado uranium miners demonstrated dose-related increases in lung cancer risk in miners with protracted exposure to radon.[1] In addition, small-cell undifferentiated carcinomas predominated in highly exposed miners, in contrast to the typical distribution of pulmonary cancer pathology in the general U.S. population. Elevated risk of lung cancer has also been reported for iron ore miners in England, France, and Sweden; however, the proportion of risk attributable to radon in these populations is more difficult to assess.

Analysis of lung cancer mortality and smoking in Colorado uranium miners suggests a greater than additive mortality rate for cumulative radon exposure and cumulative cigarette smoking.[7] In other words, the increased risk of lung cancer among miners as compared with nonminers is larger when comparing smokers than when comparing nonsmokers. Interestingly, among atomic bomb survivors, cigarette smoking and radiation exposure have only an additive effect for lung cancer risk. This anomaly has been attributed to the different exposure patterns experienced by atomic bomb survivors (acute) and uranium miners (protracted).

Table 9-3 Examples of Radiation-Induced Cancers

Sources of Exposure	Exposure Circumstances	Cancer Types
EXPLOSIONS OF NUCLEAR WEAPONS		
Blast	Atomic bombing survivors in Hiroshima and Nagasaki	Leukemia, breast, lung, thyroid, stomach, colon, multiple myeloma, esophagus, ovary
Fallout	Populations exposed through atmospheric testing, including Marshall Islanders, veterans in the Pacific, general population in Nevada, Utah	Thyroid
DIAGNOSTIC PROCEDURES		
X-rays	Children exposed in utero	Leukemia
Thorotrast	Cerebral and limb angiography; of biliary passages	Liver
Fluoroscopic x-ray	Monitoring of lung infections in patients with tuberculosis	Breast
THERAPEUTIC PROCEDURES		
X-ray	Postpartum mastitis	Breast
X-ray	Ankylosing spondylitis	Leukemia, lung, stomach, esophagus
Cobalt-60	Treatment for cancer of the cervix	Leukemia, stomach, rectum, bladder, vagina, female genital, lung, buccal cavity, nasopharynx, esophagus
X-ray	Treatment of benign head and neck conditions	Thyroid, skin, central nervous system
Radium-224	Ankylosing spondylitis, bone tuberculosis	Bone sarcoma
PROFESSIONAL EXPOSURES		
X-ray	Early radiologists	Skin, leukemia
Radon	Uranium, hard-rock miners	Lung cancer
X-ray, γ-rays, neutrons	Nuclear industry	Multiple myeloma
Radium isotopes	Radium dial painters	Bone, head sarcoma

Metals

Arsenic

Medicinal use of inorganic arsenic was associated with skin cancers in the early 20th century. More recently, excess skin cancer has been observed in populations exposed to arsenic-contaminated drinking water, whereas excess lung cancer has been found in populations with occupational exposure to inorganic arsenic compounds.[1] An increased risk of lung cancer of 6- to 14-fold was reported for gold miners in Rhodesia, where the ore contains arsenic. Chronic arsenism was also prevalent among these miners. Several studies in Japan, Sweden, and the United States have documented excess lung cancers among workers involved in copper smelting. Inorganic arsenic is a byproduct of the smelting process and is also used as a hardener. Two large retrospective studies of copper smelters have shown that lung cancer mortality is related to estimated arsenic exposure.

Another source of occupational exposure is the manufacture and use of arsenical pesticides.[1] An early study of mortality among workers at a factory manufacturing arsenical sheep dip in Wales found an excess of skin and lung cancers, particularly among those directly involved in the chemical processes. Case-control studies in two U.S. plants manufacturing arsenical pesticides found arsenic dose-related increases in risk of lung cancer. Reports of skin and lung cancers among vineyard workers with exposure to arsenic fungicides and pesticides appeared during the late 1950s. An autopsy series of 82 vineyard workers exposed in Germany found 61 deaths from cancer, including 44 respiratory tract cancers; many skin cancers and Bowen's disease were also reported.

Nickel

The nickel refining industry was established in South Wales around 1900. During the subsequent 40 years, evidence accumulated for increased rates of nasal cancer, and later, lung cancer among workers in nickel refineries.[7] Several prospective studies in England and Wales found elevated risks of nasal cancer (O/E = 12) and lung cancer (O/E = 16), particularly among process workers in the refinery. The highest cancer risk was associated with the calcination of impure nickel copper sulfate. Further studies indicated that the cancer risk began to decline when environmental controls were introduced in the industry during the 1930s. Evidence of excess cancer risk associated with nickel exposure as late as the 1950s was reported in a refinery in Norway, however. Excess nasal, laryngeal, and lung cancers were observed; smoking and nickel exposure seemed to contribute to lung cancer risk in an additive manner.

Cadmium

Elevated risk of prostate and lung cancer among workers exposed to cadmium has been reported. Cadmium exposure has a stronger association with lung cancer than with prostate cancer.[7] Several small historical prospective studies of cadmium smelters and battery workers show increased risks of prostate cancer (O/E = 1.2 to 3.5) and lung cancer (O/E = 1.35); however, a larger study of 7000 workers exposed to cadmium for at least 1 year showed no increased risk of prostate cancer. A major nonoccupational source of cadmium exposure is from cigarette smoke, which contains 1 to 2 μg cadmium per pack of cigarettes.

Chromates

Several reports of lung cancer in chromate industry workers appeared in Germany during the 1930s. Subsequent epidemiologic investigations examined this association in workers involved in chromate production, chromate pigment manufacture, and chrome plating.[7] Excess lung cancer was found among workers in three chromate production plants in England (threefold excess) and in a production plant in Baltimore (twofold excess). Exposure to lead and zinc chromate pigments, but not to lead pigment alone, was related to excess lung cancer in a British study. Confirmatory results have been reported for workers exposed to lead and zinc chromates in the Netherlands, West Germany, and Norway. Experimental investigations indicate that the hexavalent salts of chromium are highly carcinogenic, whereas trivalent chromium is not carcinogenic.

Fibers and Dusts

Asbestos

The appearance of lung cancer in asbestosis patients was first reported in the 1930s. Over the next 50 years, many different study complications were recognized and overcome in the process of determining the lung cancer risk associated with the naturally occurring silicate fiber, asbestos.[5] A major problem was exposure assessment, in that many workers were mobile, having variable levels of exposure in a variety of industries or worksites. Furthermore, measurement techniques for asbestos fibers were also variable, making the use of historical measurements suspect. Some studies did not report asbestos type; that is, chrysotile, amosite, anthophyllite, or crocidolite. The long latency period between first exposure and lung cancer also complicates risk estimates. Misdiagnosis of the cancer pathologies specific to asbestos (mesothelioma) is a potential problem, especially in studies that depend on death certificates.

More than 30 epidemiologic studies have been mounted to examine lung cancer risk in workers with potential exposure to asbestos during mining, milling, manufacturing, insulating, and shipbuilding.[1] In general, these studies demonstrate enhanced risk of lung cancer, and possibly enhanced risk of laryngeal cancer. The association between asbestos exposure and mesothelioma of the lung, a relatively rare cancer, was reported in the early 1960s. This finding was confirmed among insulation workers, asbestos manufacturing workers, and other occupationally exposed populations.

Cases of pleural malignancies in Denmark and Germany in the 1930s were reported to be concentrated in seaport towns rather than in other urban areas. Later studies of the geographic distribution of mesothelioma deaths in England and Wales demonstrated a correlation between mesothelioma and areas of high asbestos use related to shipbuilding, gas mask manufacture, or asbestos manufacturing. Further studies led to the conclusion that risk of mesothelioma was not limited to the workers but extended to members of their household and to residents living in the vicinity of asbestos-related industries.

Evidence of a synergistic effect of asbestos and smoking for lung cancer risk was found among insulation workers in New York.[7] The age-standardized mortality ratio for lung cancer was 5.2 for nonsmoking asbestos-exposed workers (compared with nonexposed nonsmokers), 10.8 for nonexposed smokers, and 53.2 for asbestos-exposed smokers. Thus, the risk of lung cancer from both smoking and exposure to asbestos is much greater than the sum of the risks associated with either exposure. A similar result was reported for female workers at a British asbestos factory, but the results for male workers at the same factory could not distinguish between additive or multiplicative effects.

Silica

Exposure to silica dusts occurs in several occupational groups, including foundry workers, pottery workers, miners, and quarry workers. Examination of occupational mortality statistics in high-exposure segments of these industries consistently show an increased risk for lung cancer among silica-exposed workers.[1] Two studies using silicosis registries have shown an association between silicosis and lung cancer. Excess mortality from lung cancer (O/E = 2.8) was found among 3600 men recorded in the Swedish silicosis registry from 1931 to 1969. An excess of lung cancer deaths (O/E = 2.0) was also found among 1910 miners registered with silicosis in Ontario, Canada, from 1940 to 1975. Pottery workers in the United States showed a significant excess of lung cancer among men whose work entailed making ceramic plumbing fixtures.

Wood Dust

The cancer risk associated with wood dust has been investigated in furniture workers, carpenters, woodworkers, lumberjacks, sawmill workers, and paper or pulp mill workers.[7] Excess nasal adenocarcinoma is found consistently among furniture workers in several countries, primarily with exposure in the 1920s and 1930s. The highest risk is seen among those with exposure to hardwood dusts, and after a latent period of 30 years. Small increases in risk of larynx cancer, lung cancer, and Hodgkin's disease have also been reported among persons with these occupations.

DIETARY MODIFIERS OF CARCINOGENESIS: NATURALLY OCCURRING CARCINOGENS AND ANTICARCINOGENS

Most of the known human carcinogens discussed in the foregoing sections have been identified from occupational and iatrogenic exposures; however, with the exception of tobacco, such agents are rather minor contributors to the current overall cancer burden. Exposures to many of these agents have been typically at high doses in small, well-defined cohorts. Most human cancers probably result from interactions of several or more carcinogenic influences, none of which singly is readily detectable. The carcinogenic process is subject to influence by many modifying variables, which in the aggregate probably represent the largest determinant of human cancer. These variables can be constitutive, including age, gender, immunologic status, and genetic composition. Extraconstitutional variables are also very important, particularly diet and lifestyle habits such as smoking and alcohol consumption. Many epidemiologic studies indicate that general increases in consumption of fiber-rich cereals, fruits, and vegetables and decreased consumption of fat-rich foods and excessive alcohol will serve as prudent approaches to reducing overall cancer risk.

Many components in the diet can contribute to carcinogenesis. Two major influences are fat and calorie consumption. Fat consumption is most strongly associated with the hormone-dependent cancers (breast, ovary, and endometrium in females and prostate in males) and the gastrointestinal cancers (gallbladder, colon, and rectum in both sexes). It is not known whether these relationships are causal and, if so, whether they relate to the type of fat (saturated, unsaturated, polyunsaturated) or to the overall caloric content of the diet. Dietary fat intervention studies such as the Women's Health Trial might provide direct information on the effects of reducing dietary fat consumption on the incidences of cancer and other diseases. Decreased fat consumption could exert protective effects through both direct and indirect means. Fats can promote tumor development directly and are also a major source of calories (Box 9-1). Animals fed high-fat diets consistently demonstrated enhanced tumorigenic outcomes. Conversely, it has been recognized for decades that caloric restriction has a very powerful, general inhibitory effect on carcinogenesis in many induced and spontaneous laboratory animal tumor models. The behavioral changes required to effect comparable population-wide reductions in fat and/or calorie consumption, however, pose formidable challenges.

Many minor dietary components act as carcinogens or anticarcinogens.[14] Dozens of natural mutagens and carcinogens derived from plant, fungal, and bacterial sources have been described, which present a significant carcinogenic challenge to humans. These natural carcinogens, however, are opposed by an equally expansive array of food-derived anticarcinogens. These anticarcinogens consist of both nutrient (e.g., vitamins, minerals) and non-nutrient components,

Box 9-1. DO CARCINOGENS IN FRIED AND BROILED MEATS CONTRIBUTE TO RISK OF COLON CANCER?

The risk of colon cancer is strongly associated with consumption of red meat and animal fat. This association has been observed in several international correlative studies and case-control studies. Prospective studies of colon cancer risk demonstrate an association with consumption of red meat and animal fat (but not with vegetable fat), independent of total energy intake.[26] The increased risk associated with animal fat is due primarily to meat intake as opposed to dairy product intake. Other studies have addressed cooking practices, finding that consumption of fried foods and barbecued, broiled, or smoked meats is associated with increased risk of colorectal cancer.

Despite these observations, and despite rapid advances in the molecular genetics of susceptibility and predisposition, the specific chemical etiologies of colon and other diet-associated cancers remain unclear. Several hypotheses have been proposed to explain the strong association of colon cancer risk with red meat and animal fat. Diets high in fat increase the incidence of chemically induced colon cancers in rats and also increase the excretion of primary bile acids, which are converted to secondary bile acids by bacterial metabolism. Some secondary bile acids (e.g., deoxycholic and lithocholic acid) are colon tumor promoters in animal models. Thus, it has been hypothesized that increased animal fat in the human diet leads to promotion of colon tumors by secondary bile acids. An alternative (or complementary) hypothesis is that carcinogens in cooked meats contribute to colon carcinogenesis. The cooking of meat produces at least two major classes of carcinogens—polycyclic aromatic hydrocarbons (PAHs) and heterocyclic aromatic amines—which induce genotoxic damage or cancer in the gastrointestinal tracts of animals receiving these compounds orally.[27] Because cooked meats are a major source of animal fat in Western diets; it has been suggested that cooking-induced carcinogens in meat, rather than animal fat, play a causative role in colon cancer. Estimates of average daily ingestion of PAHs and heterocyclic amines from diet are comparable (0.1–10 μg/day).

Recent studies have explored the role of cooking-induced carcinogens as risk factors for colorectal carcinogenesis by administering food frequency questionnaires with detailed sections on cooking methods and doneness levels. This information is then linked to PAH and heterocyclic amine databases of food items cooked or prepared under a variety of conditions. One such study reported increasing risk for colorectal adenoma with quintile of daily intake of benzo[*a*]pyrene.[28]

In addition to PAHs, highly mutagenic heterocyclic amine compounds are formed during the broiling or frying of meat and fish as a result of pyrolysis of amino acids and proteins. More than a dozen heterocyclic amines have been identified; the most common forms are quinolines, quinoxalines, pyridines, and carbolines.[27] These compounds are highly mutagenic in bacteria and carcinogenic in animals, causing colon cancer, mammary cancer, liver cancer, prostate cancer, and lymphoma. PhIP (2-amino-1-methyl-6-phenylimidazo(4,5-β)pyridine) is one of the most common heterocyclic amines formed in broiled and fried meats, occurring at levels comparable to or greater than those of benzo[*a*]pyrene. Male rats fed PhIP develop colon adenocarcinomas, whereas female rats develop mammary adenocarcinomas. A recent study assessing heterocyclic amine intake in colon cancer cases and controls found an increased risk for colon cancer among those who had the highest quintile of heterocyclic amine intake.[29] The precise role of heterocyclic amine compounds and PAHs in the etiology of human colon cancer, however, requires further confirmation.

many of which function as antioxidants. In addition to scavenging oxidants, many of the non-nutrient anticarcinogens in plants alter the balance between the metabolic activation and inactivation of chemical carcinogens. Inverse epidemiologic associations between risk of cancer at several sites and ingestion of fruits and vegetables have been observed.[15] These associations might be linked to β-carotene, other carotenoids, folate, fiber, vitamin C, and other antioxidants, and to other components of the fruits and vegetables. Although a protective role of specific nutrients has been difficult to establish in many instances, inverse relationships between intake of foods rich in vitamin C and oral, esophageal, and gastric cancer incidence and between β-carotene intake and lung cancer incidence have been described. A fuller understanding of the role of dietary factors in human carcinogenesis is destined to have a significant impact on disease incidence.

EXPOSURE BIOMARKERS AND SUSCEPTIBILITY FACTORS

Assessing Human Exposure: Role for Intermediate Biomarkers

Increased understanding of the mechanistic basis of carcinogenesis provides opportunities for the identification of molecular biologic markers reflecting events occurring between exposure and clinical disease. These molecular biologic markers can be classified into three major categories:

1. Markers of exposure reflecting either an internal or a biologically effective dose of carcinogen
2. Markers of effect indicating a biologic response to an exposure
3. Markers of susceptibility that characterize the inherent susceptibility of an individual to a carcinogenic agent[16]

It is anticipated that the use of biologic markers will help define the roles of environmental agents (particularly in complex mixtures) in the etiology of human cancer.

The interaction of a carcinogen with macromolecules was demonstrated by Miller and Miller in 1947, when they showed that azo dye bound to the liver protein of treated rats. Later studies indicated the importance of carcinogen modification of DNA (either directly or after metabolic activation) in the cancer process. The measurement of carcinogen metabolites, carcinogen-DNA adducts, or carcinogen-protein adducts in human tissues or fluids provide the basis for molecular dosimetry research and the rapidly expanding field of "molecular" cancer epidemiology. The potential advantage of this approach is that more accurate assessments of individual or group dose may be achieved than through estimates of carcinogen exposure in the environment or workplace.

Carcinogen-DNA and carcinogen-protein adducts have been detected in tissues from a variety of human populations with known or suspected carcinogen exposure.[16,17] PAH-DNA adducts are elevated in white blood cells from individuals occupationally exposed to airborne PAHs, including coke oven workers, foundry workers, and aluminum plant workers. Increased levels of PAH-DNA adducts have also been reported in lung tissue from heavy smokers. DNA isolated from exfoliated bladder epithelial cells of cigarette smokers has been shown to contain 4-aminobiphenyl adducts. Alkylation damage has been detected in DNA from esophageal tissue of persons living in regions with documented dietary exposure to nitrosamines. Aflatoxin adducts are found in hepatic DNA following dietary exposure to this mycotoxin. Cisplatin-DNA intrastrand adducts have been measured in white blood cells of patients undergoing cancer chemotherapy.

Carcinogen-DNA adducts excreted in urine provide a noninvasive means for quantifying DNA damage. Urinary concentration of aflatoxin-guanine adducts is strongly correlated with dietary aflatoxin intake. In addition to their use as indicators of previous carcinogen exposure, DNA adducts have the potential for use as direct indicators of future cancer risk. The first prospective test of this application appeared in 1992, when detectable levels of aflatoxin-guanine adducts, as well as several other aflatoxin metabolites, in urine were shown to be predictive of liver cancer development.[11] Furthermore, an interactive effect for liver cancer risk was seen between urinary aflatoxin biomarkers and HBV infection history.

Carcinogen-protein adducts have also proved useful as biomarkers of human exposure. Alkylation damage in hemoglobin has been used as an exposure index in risk assessment analyses of individuals occupationally exposed to ethylene oxide. 4-aminobiphenyl adducts in hemoglobin are highly specific (and sensitive) markers of exposure to cigarette smoke.[16] The level of 4-aminobiphenyl hemoglobin adducts is related to the number of cigarettes smoked, the type of tobacco, and the metabolic phenotype of the smoker. The levels of these adducts drop markedly after smoking cessation.

Unreacted carcinogen metabolites excreted in urine are also used to monitor human exposure to and uptake of carcinogens and related compounds. Concentrations of hydroxylated PAHs (e.g., 1-hydroxypyrene) in urine are elevated in smokers, in patients after topical treatment with coal tar, in road pavers, in coke oven workers, in aluminum plant workers, and in individuals ingesting PAHs from food.[18] In occupational settings, the concentration of urinary 1-hydroxypyrene is highly correlated with estimated or measured concentrations of airborne PAHs. This noninvasive approach to exposure assessment has potential application as a routine biomonitoring tool. In all these studies, significant differences in adduct or metabolite levels are often observed between individuals with similar carcinogen exposure. These differences have been attributed to several factors, including individual biologic variability, exposure misclassification, and confounding variables such as diet, physical activity, smoking, or personal environment. An understanding of the true basis for these differences will be useful in elucidating the determinants of individual susceptibility to cancer. By identifying specific modulators that enhance or inhibit carcinogen metabolism and the formation of adducts, it will be possible to examine their effects on human cancer risk.

Metabolic Polymorphisms and Human Susceptibility

Another major area of research in molecular cancer epidemiology is the study of individual metabolic phenotypes and their roles in determining biomarker levels and human susceptibility to carcinogens.[19] Certain cytochrome P-450 metabolic enzymes are known to be involved in the activation of specific human carcinogens, and some have been linked to increased cancer risk. For example, inducible CYP1A1 activity is higher in cultured lymphocytes from lung cancer cases than in controls. Genetic polymorphisms in the *CYP1A1* structural gene have also been associated with lung cancer risk in Asian populations.

Hepatic arylamine *N*-acetyltransferase correlates with individual differences in susceptibility to human bladder cancer.[19] A series of genetic polymorphisms of this enzyme exist in humans, resulting in slow- and rapid-acetylator phenotypes. The rapid-acetylator phenotype seems to protect aromatic amine-exposed individuals from bladder cancer These results are attributed to the competition of N-acetylation of arylamines against the formation of reactive arylamine metabolites that reach the bladder.

A recent meta-analysis of 22 case-control studies in the general population examined the effect of slow acetylation on risk of bladder cancer.[9] Overall, the slow-acetylation phenotype/genotype was found to increase risk of bladder cancer by about 40% as compared with rapid acetylators (odds ratio of 1.4, with 95% confidence interval of 1.2–1.6). This is the clearest example of a common metabolically modified cancer risk in the general population. The carcinogenic exposure in this case is, presumably, due to aryl amine compounds from various sources, including cigarette smoke.

DNA Repair and Human Susceptibility

An important mechanism that protects the genome from mutagenic effects of carcinogens is the repair of cellular DNA. The importance of this protection is perhaps best illustrated by the unusually severe effects of sunlight on individuals who are deficient in DNA repair.[20] The rare inherited disorder xeroderma pigmentosum (XP) is characterized by various levels of DNA-repair deficiencies. Individuals with XP show an unusually high incidence of multiple skin cancers and rarely live beyond early adulthood in the absence of protective measures against sunlight. The median age of onset for nonmelanoma skin cancers among XP patients is approximately 8 years of age, as compared with about 60 years of age in the general population. In addition, the prevalence of melanoma of the skin is unusually high among XP patients.

Several other inherited diseases show altered cellular response to DNA damage.[21] Ataxia telangiectasia, Bloom syndrome, and Fanconi's anemia are autosomal recessive genetic disorders characterized by chromosomal instability, with patients developing malignancies more frequently and at younger age than occurs in the general population. Approximately 10% of individuals with ataxia telangiectasia develop malignancies, primarily of the lymphoreticular system, before the age of 20. Heterozygous relatives of individuals with ataxia telangiectasia and those with Fanconi's anemia are also at moderately increased risk of cancer as compared with unrelated persons.

Although these diseases clearly represent unusual cases, some forms of these diseases (e.g., complementation group XP-E) show only moderate deficiencies in DNA repair—approximately 60% to 90% of normal—yet remain unusually susceptible to cancer. This finding suggests that small reductions in DNA repair efficiency can lead to considerable increases in cancer susceptibility. Interestingly, significant variability in DNA repair proficiency has been demonstrated among disease-free "normal" individuals. This variability in the general population could contribute to differences in susceptibility not only to skin cancer but also to cancers of other organs.

PUBLIC HEALTH APPROACHES TO CANCER PREVENTION

An aging population and a decline in mortality from cardiovascular disease could soon herald the emergence of cancer as the major cause of death in the United States. Moreover, the curative treatment of many established (and especially disseminated) malignancies remains an enigmatic problem for which progress is measured in small steps. Clearly, the optimal way for dealing with virtually all diseases, including cancer, is prevention. As a consequence, the challenge to public health professionals is to devise and implement preventive measures against cancer.

As presented in Figure 9-2, the prevention of cancer can take several forms. Primary prevention targets healthy individuals and can be achieved by avoiding exposure to risk factors. Another approach is to stimulate the defense mechanisms of the host to interfere with the carcinogenic process. Secondary prevention measures use early detection and intervention before pathologic conditions are clinically apparent. The success of these strategies will be greatly facilitated by the development of noninvasive biomarkers that identify high-risk individuals. Finally, tertiary prevention is aimed at minimizing the effect of existing disease and consequent disability by avoiding development of new cancers and complications or relapses after therapy for initial malignancies.

Identifying Human Carcinogens

The major current strategy for cancer prevention is the avoidance of exposure to environmental, industrial, and social hazards (Box 9-2). Identification of human carcinogens takes two forms. In several instances (e.g., soot and coal tars, aromatic amines, vinyl chloride, and benzene), carcinogenic compounds were discovered after they were suspected of being involved in the development of cancers in humans. However, currently most carcinogenic substances are identified in the course of long-term toxicologic studies in animals. The value of this approach is buttressed by the fact that for those chemicals identified as being causally associated with human cancer, and for which there has been adequate experimental evaluation, all have been shown to cause cancer in laboratory animals.[22] However, animal bioassays for carcinogenicity are very costly (several million dollars per compound) and time consuming (5 years). Therefore, much attention is being directed toward the development and validation of short-term tests for carcinogens. Many assays for genotoxicity using mutagenesis, chromosome damage, or DNA repair as endpoints are used to screen chemicals for carcinogenic potential. Short-term assays for modifying factors such as co-carcinogens, tumor promoters, and anticarcinogens are being developed as well. A major difficulty in the use of animal bioassays is estimation of risk to humans. The assumptions contained in interspecies comparisons and high- to low-dose extrapolations render a straightforward assessment difficult. Bioassays are typically conducted with high doses of carcinogens to provide adequate tumor yields and statistical strength; however, there are strong concerns on mechanistic grounds as to the relevance of these types of exposures to chronic low-dose exposures in human populations. Protective host defense systems could be overwhelmed in these aberrant exposure settings. Another controversial issue in dose-response relationships is whether no-effect or threshold levels exist for chemical carcinogens. Based on considerations of metabolism, the barriers to electrophiles reaching critical targets in DNA, multiple alleles for transforming and/or suppressor genes, DNA repair, and other factors, it seems likely that for every carcinogen there must be a threshold. It could be very low for powerful carcinogens and correspondingly higher for weak carcinogens. Faced with the inability in practice to define human thresholds, however, prudent policy dictates avoidance of carcinogens wherever possible. The current regulatory posture in the United States assumes that all animal carcinogens are potential human carcinogens.

Cancer Chemoprevention

The use of chemical or dietary interventions to alter the susceptibility of humans to the actions of carcinogens and to retard, block, or reverse carcinogenesis can be applied to all levels of prevention and has been termed chemoprevention.[23] There are many indications that these strategies are extremely effective in laboratory animals. Moreover, chemoprevention against cancer also works in humans.[24] Recent investigations have established significant site- and agent-specific effects in the prevention of invasive skin, upper aerodigestive tract, and breast cancers in high-risk groups.

It was first observed in the early part of the 20th century that carcinogenesis could be modified by discrete chemical agents. These initial experiments demonstrated that the formation of skin tumors in rodents could be blocked by local application of chemopreventive agents. The protective agents used in these early studies, however, were typically carcinogens or toxins themselves. Consequently, their application to humans did not appear to be practical. Thus, the field of cancer chemoprevention did not receive significant attention until the early 1970s, when Wattenberg demonstrated that dietary antioxidants could protect against tumor formation.[25] The experimental observations that seemingly innocuous preservatives found in the Western diet could dramatically protect against diverse carcinogens at distal sites sparked the development of chemoprevention as a viable strategy for the reduction of human cancers. Thus far, more than 20 classes of discrete chemicals have been shown to be effective inhibitors of experimental carcinogenesis.[25]

The expectation that effective chemoprotection against cancer can be achieved is supported by the view that cancer is unlikely to be the exception to the history of other major (infectious and noninfectious)

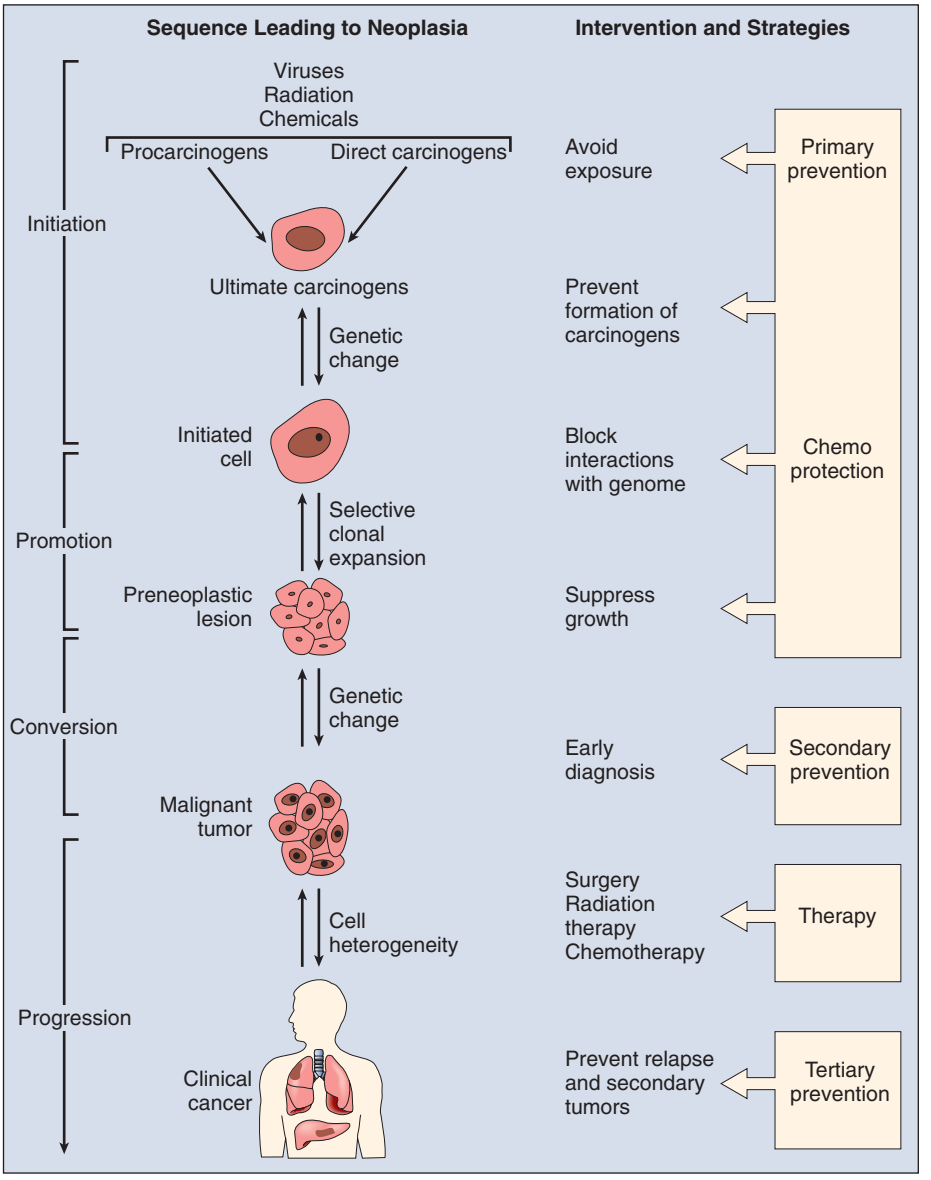

Figure 9-2 • Strategies for prevention of multistage carcinogenesis.

diseases of humans, in which the mortality began to decline as a result of protective and preventive measures far in advance of specific treatments. Cancer chemoprevention could be especially valuable in populations at high risk of certain neoplasms, particularly as improved molecular techniques allow for the identification of these high-risk individuals. Preventive strategies can involve both prescriptive interventions with specific nutrients, non-nutrients, and drugs in selected populations at high risk of cancer, and lifestyle changes that include altered nutrition and social habits. These latter approaches might ultimately play an even greater role in the overall reduction of cancer in the general population.

SUMMARY

The carcinogenic effects of many environmental and occupational agents were first described in humans. These observations were replicated in animal models beginning in the early 20th century. Whereas carcinogenic agents come in many forms, including naturally occurring and manufactured chemicals, radiations, metals, fibers, and viruses, tobacco use is probably the single most important cause of cancer. Nonetheless, the majority of human cancers probably result from interactions of several or more carcinogenic influences, none of which singly is readily detectable. Elucidation of the carcinogenic process has led to the recognition that both extrinsic and intrinsic factors interact to determine overall susceptibility and risk.

The identification of molecular biologic markers of exposure, effect, and susceptibility, reflecting events occurring before clinical disease, will help to further our understanding of human carcinogenesis. It is anticipated that the use of biologic markers will help define the roles of environmental agents (particularly in complex mixtures) in the etiology of human cancers. With the recent characterization of the human genome, much attention has focused on the role of common polymorphisms in carcinogen metabolism or of DNA repair genes and susceptibility to cancer. By identifying specific factors that enhance or inhibit carcinogen metabolism and biomarker formation, it will be possible to examine their effects on human cancer risk.

Primary and secondary approaches to the prevention of cancer will be greatly facilitated by the development of noninvasive biomarkers that identify high-risk individuals. Tertiary prevention might also be enhanced by characterizing cancers with respect to etiology, genetic profile, or metabolic capacity. The use of chemical or dietary

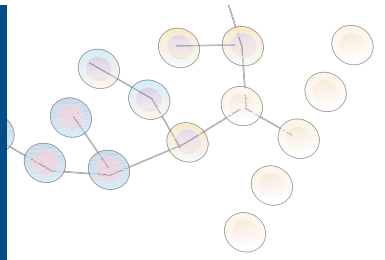
Box 9-2. HEALTH EFFECTS AND CONTROL OF SMOKING

A series of reports from the U.S. Surgeon General since 1964 have argued that cigarette smoking is the most significant source of preventable morbidity and premature mortality in developed countries. An estimated annual excess mortality of 350,000 is attributed to cigarette smoking in the United States. These deaths are the result of coronary heart disease, cancer, and various respiratory diseases.[30] Cancers associated with smoking or smokeless tobacco use include those of the lung, oral cavity, esophagus, pharynx, larynx, and bladder. Weaker associations have been reported for cancers of the pancreas, kidney, stomach, nasopharynx, and cervix.[12] The overall increase in risk of disease among smokers compared with nonsmokers is about tenfold for lung cancer, sixfold for chronic obstructive pulmonary disease, and twofold for myocardial infarction. The combined effect of smoking-related diseases on the average life expectancy of smokers is a reduction of 5 to 8 years.

On a worldwide basis the data are equally disturbing. An estimated 4 to 5 million deaths per year are attributed to tobacco use—the majority of these in developed countries. If current usage trends continue unabated, estimates as high as 10 million deaths due to tobacco use annually could be expected by the year 2030.[30] Most of these deaths (approximately 7 million) are expected to occur in developing countries, where tobacco use is increasing rapidly. Whereas percentage of world tobacco consumption in developing countries was 49% in 1974 through 1976, this figure increased to 61% in 1984 through 1986 and to 70% in the year 2000. Per capita consumption of cigarettes is increasing most rapidly in developing Asian countries. Although the majority of tobacco is produced in developing countries, the declining market in developed countries has refocused the efforts of producers in these countries toward developing countries for continued growth.

The addictive properties of tobacco smoking, due primarily to nicotine, cause both physiologic and psychologic dependence. Withdrawal symptoms can be severe and include irritability, aggressiveness, hostility, depression, difficulty concentrating, and a craving for tobacco. These pharmacologic factors are reinforced by social factors such as peer pressure, emulation of family role models, and cultural influences. Because most smokers begin smoking, and often form lifelong smoking habits, in their teenage years, preventive educational measures should be focused on this age group.

Smoking control measures use various strategies: cessation programs, clinical or community interventions, governmental or private-sector regulations, taxation of tobacco products, and smoking prevention programs. Although the majority of ex-smokers have achieved abstinence without extensive personal assistance from organized cessation programs, other control measures (national health education programs, physician counseling, indoor smoking regulations) and family pressure are important influences contributing to smoking cessation. Smoking prevention programs, particularly in schools, and government taxation have been somewhat effective in reducing the initiation of smoking among children and adolescents in developed countries. These approaches will need to be applied in developing countries to stem the expansion of smoking worldwide.



interventions to alter the susceptibility of humans to the actions of carcinogens and to retard, block, or reverse carcinogenesis can be applied to all levels of prevention and has been termed chemoprevention. Preventive strategies can involve both prescriptive interventions with specific nutrients, non-nutrients and drugs in selected populations at high risk of cancer, and lifestyle changes that include altered nutrition and social habits.

The major current strategy for cancer prevention is the avoidance of exposure to environmental, industrial, and social hazards that increase the risk of cancer. Currently, most carcinogenic substances are identified in the course of long-term toxicologic studies in animals. Much attention is also directed toward the development and validation of short-term tests for carcinogens, such as mutagenicity, chromosome damage, or DNA repair.

10 DNA Damage Response Pathways and Cancer

James M. Ford and Michael B. Kastan

SUMMARY OF KEY POINTS

- DNA repair and the cellular response to DNA damage are critical for maintaining genomic stability.
- Defects in DNA repair or the response to DNA damage encountered from endogenous or external sources results in an increased rate of genetic mutations, often leading to the development of cancer.
- Inherited mutations in DNA damage response pathway genes often result in cancer susceptibility.
- The major active pathways for DNA repair in humans are nucleotide excision repair, base excision repair, mismatch DNA repair, translesional DNA synthesis, and homologous recombination or nonhomologous end joining processes for double-strand break repair.
- Defects in nucleotide excision repair lead to the skin cancer-prone syndrome xeroderma pigmentosum, as well as Cockayne syndrome and trichothiodystrophy.
- Defects in base excision repair can result in enhanced colon adenomas and cancers.
- Defects in mismatch repair result in hereditary nonpolyposis colorectal cancer syndrome.
- Defects in DNA double-strand break repair and response pathways underlie a number of cancer-prone disorders, including ataxia-telangiectasia, Nijmegen breakage syndrome, Bloom syndrome, Werner syndrome, Rothmund-Thompson syndrome, and Fanconi anemia.
- The highly cancer-prone Li-Fraumeni syndrome, due to inherited p53 mutations, and breast-ovarian cancer syndrome, due to inherited mutations of the BRCA1 and BRCA2 genes, exhibit defects in multiple DNA repair and DNA damage response pathways.

INTRODUCTION

Cancer is a genetic disease that is caused by the accumulation over time of changes to the normal DNA sequence resulting in alterations, loss, or amplification of genes that are important for normal cellular functions and growth properties, including many proto-oncogenes and tumor suppressor genes. Nearly all cancers are clonal in origin; that is, they originate from a single progenitor cell rather than a group of cells. The development of cancer in a particular cell type or tissue is caused by a series of specific mutations, each of which could be caused by DNA replication errors or unrepaired endogenous or exogenous DNA damage or be the result of inherited mutations. For the most common cancers, multiple genetic events occur in many different genes during the process of carcinogenesis, suggesting that an early and perhaps necessary event in the cancer process is an underlying defect in mechanisms to maintain genomic stability.[1] In fact, alterations in the specific genes that are required for recognizing, processing, and responding to DNA damage may result in an enhanced rate of accumulation of additional mutations, recombinational events, chromosomal abnormalities, and gene amplification.[2]

In addition, cancer cells must be able to tolerate increased amounts of unrepaired DNA damage associated with genomic instability and therefore frequently inactivate DNA damage-inducible signaling and checkpoint pathways. Therefore, DNA repair and the DNA damage response are essential not only for the basic processes of transcription and replication required for cellular survival, but also for maintaining genomic stability and avoiding the development of malignancies. Numerous links have been identified between oncogenesis and acquired or inherited defects in genomic stability that cause a "mutator" phenotype, highlighting the key role of DNA protection systems in tumor prevention. This chapter reviews the major DNA repair mechanisms that are active in mammalian cells and our emerging understanding of DNA damage-signaling pathways that integrate with other cellular processes that regulate transcription, replication, cell division, and apoptosis in response to DNA damage. The relevance of these mechanisms to cancer is explored by focusing on several human cancer predisposition syndromes that are caused by underlying defects in DNA damage processing.

Advances in cancer genetics have defined three general groups of genes that are involved in the development of human cancers: oncogenes, tumor suppressor genes, and DNA damage repair and response genes. The latter set of genes is particularly important to hereditary cancer susceptibility, owing to their direct involvement in maintaining genomic stability. Much of what we know about cancer genes in sporadic tumors comes from the study of relatively rare inherited cancer syndromes caused by mutations passed along in the germline DNA of families and predisposing to the development of cancers, often at a very young age and at a high incidence, in affected carriers. Individuals who inherit a germline mutation in genes that are involved in or required for DNA repair usually are at increased risk for the development of cancer, owing to the enhanced frequency of mutations and increased genomic instability. Susceptibility to cancer may also be affected by environmental factors and multiple low-penetrance modifier genes.

Many converging lines of experimental evidence reveal the complexity of the cellular responses to DNA damage and their role in malignant transformation.[3] A number of interrelated biochemical pathways exist that influence the following actions: (1) the

Table 10-1 Human DNA Repair Pathways

DNA Repair Pathway	Type of DNA Damage	Approximate No. of Genes
Nucleotide excision repair	Bulky or helix-distorting DNA adducts, e.g., ultraviolet photoproducts, carcinogen adducts	37
Base excision repair	Oxidative DNA damage	40
	Spontaneous depurination	
Mismatch repair	Mispaired nucleotides	26
	1–15 nucleotide insertion-deletion loops	
Homologous recombination	Double-strand DNA breaks, DNA cross-links	20
Nonhomologous end joining	Double-strand DNA breaks	10

metabolism of potentially mutagenic or carcinogenic agents, (2) the efficiency and manner by which damaged DNA is recognized and repaired, (3) cell cycle progression and the coordination of DNA replication and cell division relative to the repair of lesions, and (4) the decision point determining survival or the active induction of programmed death of cells that carry different types and amounts of DNA damage. Many cellular pathways have evolved that require hundreds of gene products for the direct repair of DNA damage and involve excision of damaged DNA bases and joining of broken DNA strands (Table 10-1). The central role of DNA damage responses in neoplastic transformation has been highlighted by the discovery that mutations in several classes of genes that are required for DNA repair and the maintenance of genomic integrity result in a predisposition to the development of certain malignancies.[4] In fact, a number of rare inherited disorders have been described that appear to be caused by defects in the repair of DNA lesions (Table 10-2), and many of these are associated with an increased risk of developing certain cancers.[5]

TYPES OF DNA DAMAGE

DNA undergoes several types of spontaneous modifications, and it also can react with many physical and chemical agents, some of which are endogenous products of normal cellular metabolism (e.g., reactive oxygen species) whereas others, including ionizing radiation and ultraviolet light, are threats from the external environment (Fig. 10-1). One pronounced example is exposure to genotoxic compounds in cigarette smoke, which contributes to the development of some of the most common cancers seen in Western countries. Most active chemotherapeutic agents function by damaging DNA through alkylation, cross-linking, and other means, and mechanisms to repair these lesions determine the sensitivity of a tumor to such treatments. Damage to DNA can cause genetic mutations, and these mutations can lead to the development of cancer. DNA damage also may result in cell death, which can have serious consequences for the organism of which the cell is a part, for example, loss of irreplaceable neurons in the brain. Accumulation of damaged DNA is thought to contribute to some of the features of aging. Therefore, it is not surprising that a complex set of cellular surveillance and repair mechanisms has evolved to reverse or limit potentially deleterious DNA damage. Some of these DNA repair systems are so important that life cannot be sustained without them. An increasing number of human hereditary diseases that are characterized by severe developmental problems or a predisposition to cancer have been found to be linked to deficiencies in DNA repair (see Table 10-2).

CONSEQUENCES OF DNA DAMAGE

The results of DNA damage are diverse and frequently adverse. Acute effects arise from disturbed DNA metabolism, triggering cell cycle arrest or cell death. Long-term effects result from irreversible mutations contributing to oncogenesis and inherited genetic disorders. Many lesions block transcription, and this has elicited the development of a dedicated repair system, transcription-coupled repair (TCR), which displaces or removes the stalled RNA polymerase and assures preferential repair of lesions within the transcribed strand of expressed genes.[6–8] Transcriptional stress due to DNA lesions that block RNA polymerase and DNA strand breaks caused by DNA damage or stalled replication forks constitute two major signals for DNA damage-inducible responses, including apoptosis,[9–11] through both p53-dependent and independent mechanisms.[12]

Lesions also may interfere with DNA replication. Recently, a class of at least 10 specialized DNA polymerases was discovered that appear devoted to overcoming damage-induced replication stress.[13–15] These special polymerases take over temporarily from the stalled replicative DNA polymerases. Though translesion polymerases protect the genome, this solution to replication blocks comes at the expense of a higher replicative error rate, and mutations in some of these polymerases cause cancer susceptibility.[5] Therefore, detection of DNA lesions may occur by blocked transcription, replication, or specialized sensors. Although the precise molecular mechanisms by which the cell senses altered DNA remains obscure, such signals result in a complex cellular response that includes cell cycle checkpoints, DNA repair, and apoptosis.

DNA DAMAGE RESPONSE PATHWAYS

DNA damage checkpoints initially were defined as regulatory pathways that control the ability of cells to arrest the cell cycle in response to DNA damage, allowing time for repair.[16] However, in addition to controlling cell cycle arrest, proteins that are involved in these pathways have been shown to control the activation of DNA repair pathways,[3,17–21] the movement of DNA repair proteins to sites of DNA damage,[22–27] and activation of transcriptional responses.[28–30] When damage is too significant or it benefits the tissue or organism as a whole, a cell may opt for the ultimate mode of rescue by initiating its own death via apoptosis.[31–33] As the DNA damage response pathway has been better defined at a molecular level, it has been seen as a network of interacting pathways that together execute the response.[34] Initial recognition of DNA damage occurs by a variety of damage-specific DNA binding proteins that either by themselves or together with complexes of associated proteins that are not directly involved in DNA repair may signal the DNA damage response.[35] Transduction and amplification of the DNA damage signal often is carried out by an overlapping set of conserved protein kinases, including the phosphoinositide-3-kinase-related proteins, which include ataxia-telangiectasia mutated (ATM) and ATM-Rad3-related (ATR) proteins, the checkpoint kinases Chk1 and Chk2, and others.[3,36–41] Many of these protein kinases are themselves targets for phosphorylation and activation; they then further target downstream genes that

Table 10-2 Human Genetic Diseases Involving Defects in DNA Damage Response Pathways

Syndrome	Gene(s)	Biologic Functions	Clinical Features	Hypersensitivities
Xeroderma pigmentosum	XPA–XPG XPV	Nucleotide excision repair Translesional DNA synthesis	Sunlight hypersensitivity Neurologic defects Skin cancers	UV, chemical carcinogens
Cockayne syndrome	CSA, CSB XPB, XPD, XPG	Transcription-coupled repair	Growth retardation Mental retardation Premature aging Sunlight hypersensitivity	UV, chemical carcinogens Reactive oxygen species
Trichothiodystrophy	XPB, XPD, TTDA	Nucleotide excision repair Transcription	Sulfur-deficient brittle hair Dry, scaly skin Mental and physical retardation Sunlight sensitivity	UV
Hereditary nonpolyposis Colorectal cancer (Lynch syndrome)	MLH1, MSH2, MSH6, PMS1, PMS2	Mismatch repair	Colorectal, endometrial, gastric, bile duct cancers	6-Thioguanine and cisplatin resistance
Ataxia telangiectasia	ATM	DNA damage-responsive kinase	Cerebellar ataxia Telangiectasia Immunodeficiency Lymphomas	Ionizing radiation
Ataxia telangiectasia–like disease	MRE11	Double-strand break repair	Similar to AT	
Nijmegen breakage syndrome	NBS1	Double-strand break repair	Microcephaly Immunodeficiency Lymphomas, neuroblastoma Rhabdomyosarcoma	Ionizing radiation
Bloom syndrome	BLM	DNA helicase Homologous recombination at stalled replication forks?	Sunlight hypersensitivity Growth retardation Leukemias, lymphomas Breast and intestinal cancers	UV, hydroxyurea
Werner syndrome	WRN	DNA helicase Homologous recombination? Translesional synthesis?	Premature aging Atherosclerosis Soft tissue sarcomas Melanoma, thyroid cancer	4-NQO, camptothetin Hydroxyurea
Rothmund-Thompson syndrome	RECQL4	DNA helicase	Growth deficiency Sunlight sensitivity Osteogenic sarcomas Squamous cell carcinomas	UV
Fanconi anemia	FANCA—G BRCA2	Interstrand crosslink repair Homologous recombination	Growth retardation Anatomic defects Bone marrow failure Myeloid leukemia Squamous cell cancers	Bifunctional alkylating agents Ionizing radiation
Li-Fraumeni syndrome	p53	Apoptosis Cell cycle checkpoints Nucleotide excision repair	Breast cancer Brain cancers Adrenocortical carcinoma Leukemia Bone and soft tissue sarcomas	?
Li-Fraumeni–like syndrome	Chk2	DNA damage responsive kinase	Similar to Li-Fraumeni syndrome	
Breast-ovarian cancer syndrome	BRCA1 BRCA2	Double-strand break repair Nucleotide excision repair	Breast cancer Ovarian cancer	Ionizing radiation? UV, cisplatin

UV, ultraviolet.

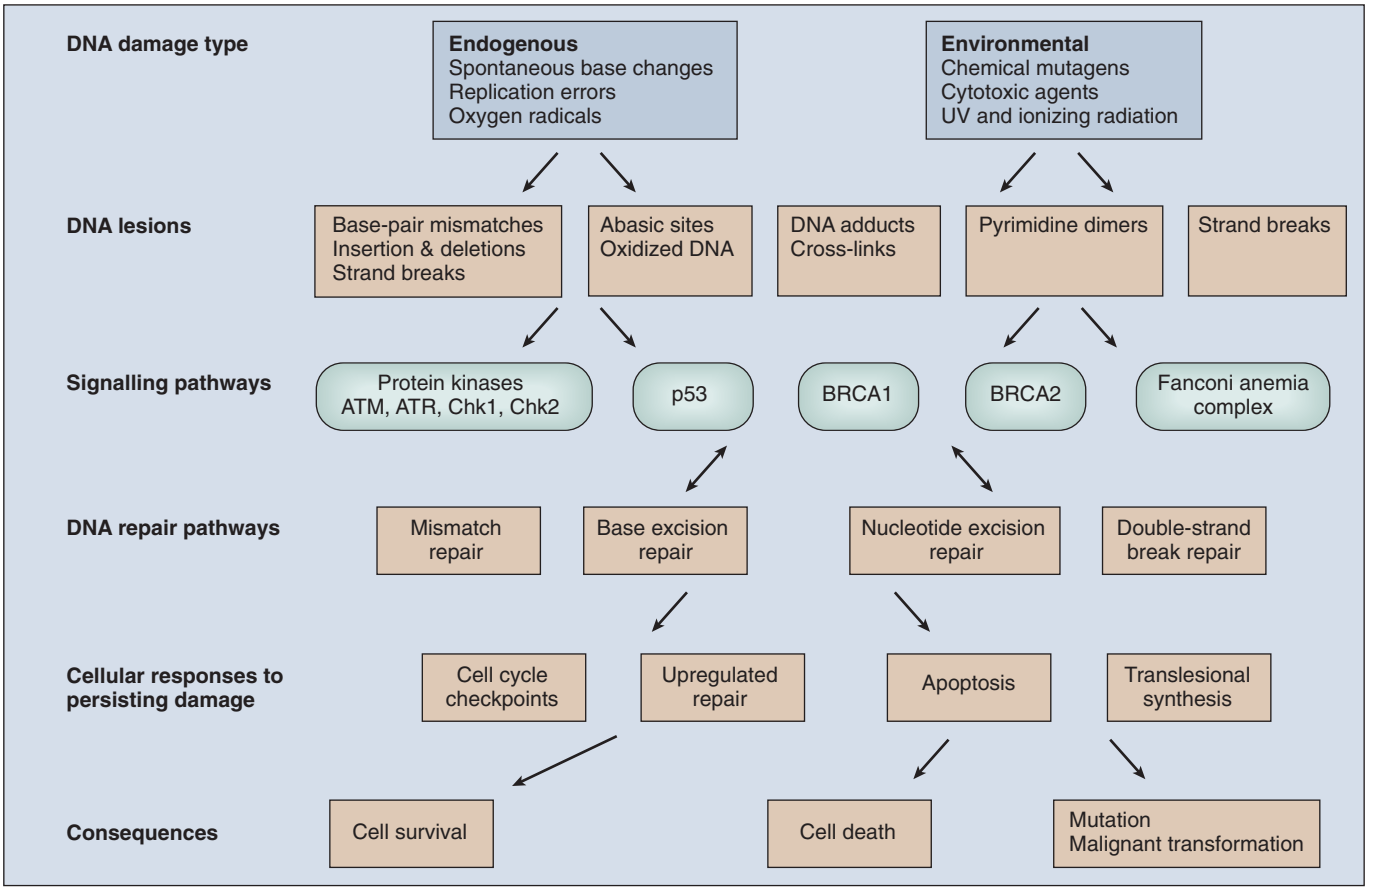

Figure 10-1 • Cellular responses to DNA damage. Different types of DNA damage cause a variety of different types of lesions, and these, in turn, are dealt with by a variety of DNA repair mechanisms and signal various cellular response pathways. The outcome of DNA damage may be cell survival of a normal cell, cell death, or mutagenesis, possibly leading toward malignant transformation.

are critical to oncogenesis such as p53 and BRCA1.[34,36,42–44] The ultimate targets of this highly regulated DNA damage response include mechanisms for DNA repair, and although much of DNA repair is constitutive, a number of regulatory connections between the DNA damage response pathway and DNA repair have emerged.[3] In mammals, a large number of genes that are involved in DNA repair are transcriptionally induced in response to DNA damage, suggesting that many facets of repair are inducible, similar to the RecA-dependent SOS response in bacteria that enhances DNA repair and mutagenesis following DNA damage.[3,21,45] In fact, the p53 tumor suppressor gene is a central mediator of the DNA damage-inducible transcriptional response in humans, and p53 mutant mammalian cells are deficient in several aspects of DNA repair.[17–21,46] Therefore, the mammalian DNA damage-inducible response pathway is highly regulated and fine-tuned to determine whether a particular cell type proceeds to a cell cycle checkpoint and DNA repair or to cell death following a significant damage insult. Defects at any level of these pathways can alter repair and result in carcinogenesis (see Fig. 10-1).

TYPES OF DNA REPAIR AND THEIR CONTRIBUTION TO CANCER

DNA repair may be defined as the cellular responses that are associated with the restoration of the normal nucleotide sequence following events that damage or alter the genome.[47] Given the wide variety of DNA damage that a cell encounters, it is not surprising that a large number of repair systems are available to handle these insults. Indeed, many of the repair systems are broadly overlapping and interacting, several sharing certain strategies and even specific gene products. Much of what is known about the basic mechanisms of many types of DNA repair comes from the study of lower organisms, such as bacteria and yeast, since many aspects of these pathways have been conserved through evolution. Inherited defects in any of the major DNA repair pathways in humans, in general, predisposes to malignancy, and several of these syndromes will be discussed in detail. In humans, a great deal has been learned about DNA repair from the often rare, autosomal recessive hereditary syndromes associated with defects in DNA repair genes.[5]

Nucleotide Excision Repair

The most versatile and ubiquitous mechanisms for DNA repair are those in which the damaged or incorrect part of a DNA strand is excised and then the resulting gap is filled by repair replication using the complementary strand as template. The redundancy of genetic information provided by the duplex DNA structure is essential to the maintenance of the genome by this "cut and patch" mode known as *excision repair*. Each DNA strand can serve as a template for replication-based repair of the other strand. Excision repair was discovered in the early 1960s through basic studies on the effects of ultraviolet (UV) irradiation on DNA synthesis and repair replication in bacteria.[48–50] Nucleotide excision repair (NER) functions to remove many types of lesions, including bulky base adducts of chemical carcinogens, intrastrand cross-links, and UV-induced cyclobutane primidine dimers (CPDs) and 6-4 photoproducts. Such lesions may serve as structural blocks to transcription and replication owing to distortion of the helical conformation of DNA, and they also may result in

mutations if translesional replication occurs or if they are not repaired correctly. The sequential steps for NER are (1) recognition of the damaged site, (2) incision of the damaged DNA strand near the site of the defect, (3) removal of a stretch of the affected strand containing the lesion, (4) repair replication to replace the excised region with a corresponding stretch of normal nucleotides using the complementary strand as a template, and (5) ligation to join the repair patch at its 3′ end to the contiguous parental DNA strand (Fig. 10-2).[51,52] This excision repair pathway can remove DNA damage from sites throughout the genome and is termed *global genomic repair* (GGR). The majority of human NER genes have been identified and cloned, and many have been shown to be mutated in hereditary NER-deficient, cancer-prone diseases.[21,46,53]

A unique problem arises if a bulky lesion is encountered by a translocating RNA polymerase making messenger RNA, before repair enzymes have removed the damage and restored intact DNA. The polymerase may be arrested at the site of the lesion and prevent access to the damage by repair enzymes. Furthermore, the arrest of transcription in human cells is a strong signal for p53 activation and can trigger apoptosis.[12] In this situation, a dedicated excision repair pathway known as *transcription-coupled repair* (TCR) comes to the rescue to displace the RNA polymerase and then efficiently repairs the blocking lesion so that transcription may resume—and so that the cell may survive.[45] The existence of a mechanism to facilitate the preferential repair of the transcribed strand of active genes in both eukaryotes and prokaryotes raises a number of questions as to its evolutionary role. Certainly, strand-specific repair of active genes should be important for maintaining genomic stability in multicellular organisms by helping to avoid transforming mutations in expressed proto-oncogenes and tumor suppressor genes. However, the lack of an increased incidence of malignancy in individuals with Cockayne syndrome (CS), a disease in which TCR has been selectively lost but GGR has been retained, argues against the idea that this NER pathway is critical in the process of transformation. The existence of TCR in unicellular and prokaryotic organisms suggests that its function might be more important to the basic processes of transcription and replication required for cellular survival than for avoidance of transforming mutations. Recent evidence suggests that cells from patients with CS, trichothiodystrophy (TTD), and xeroderma pigmentosum/CS share a defect in repair of oxidative DNA damage that might explain the overlapping progeroid features of these syndromes.[54]

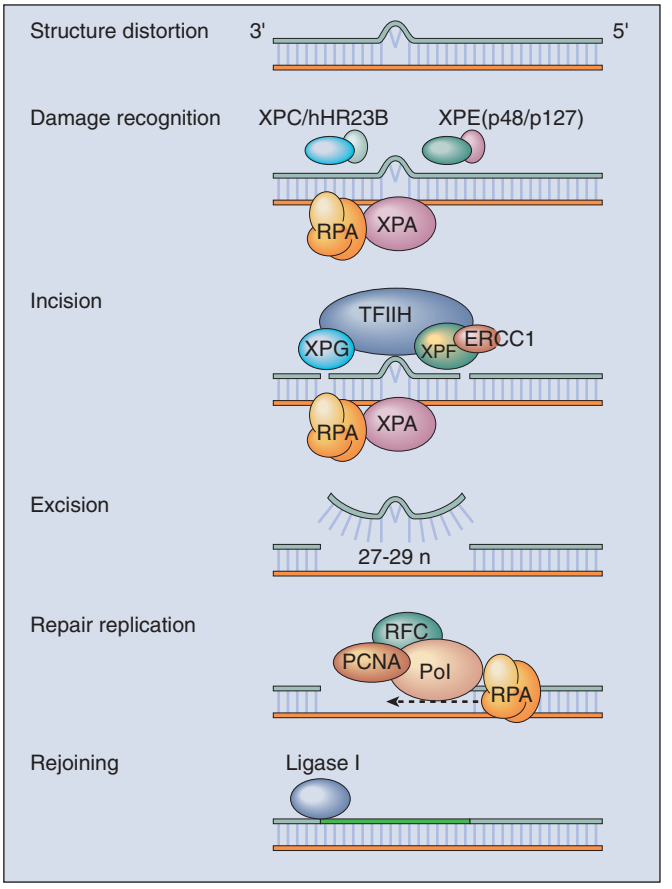

Figure 10-2 • Mechanism for human nucleotide excision repair. Ultraviolet irradiation-induced adducts in genomic DNA are recognized by the XPE and XPC/hHR23B protein heteroduplexes that recruit the XPA/RPA complex and the larger TFIIH protein complex. Dimers that occur in the transcribed strand of an expressed gene result in a blocked RNA polymerase II molecule, which together with the CSA and CSB gene products serves to recruit the downstream repair machinery. The TFIIH complex contains helicases, including XPB and XPD, that unwind the DNA and allow the other repair proteins access for incision and excision of the damaged DNA oligonucleotide. After excision, repair replication based on the normal DNA template and ligation of the newly synthesized DNA sequence occurs. In total, more than 25 proteins participate in NER.

Recently, it has become apparent that the GGR subpathway of NER is damage inducible and highly regulated by both transcriptional and post-translational mechanisms following DNA damage, in concert with damage inducible cell cycle checkpoints and apoptosis.[3,46] In fact, the p53 gene, which is central to maintaining genomic stability in human cells, is required for efficient GGR of UV-light- and carcinogen-induced DNA damage and functions as a DNA damage-activated transcription factor that directly regulates the expression of several NER damage recognition genes.[19–21] Similarly, several other important cancer-related genes have been shown to transcriptionally regulate the DNA damage recognition NER genes XPC and DDB2, including BRCA1 and E2F1.[55,56] Therefore, the GGR pathway of NER appears relevant to suppressing DNA damage-induced malignancy and highly regulated by genes involved in tumor suppression.

Further evidence for the importance of exquisite regulation of DNA damage recognition and repair activity to carcinogenesis come from a new appreciation for the role of the ubiquitin-proteasome system in maintenance of genomic stability.[57] Many complex intracellular signaling processes, including DNA repair, are controlled not only by the regulated expression of proteins, but also by their assembly and targeted degradation through post-translational ubiquitination. With regard to NER, the same DNA damage recognition proteins that are found to be transcriptionally induced following DNA damage (XPC and DDB2) are also rapidly ubiquitinated following DNA damage by an E3 ubiquitin ligase activity that contains the DDB2 binding partner DDB1, resulting in a higher order of regulation.[46] The ubiquitin-proteasome system has been found to regulate other repair pathways as well, including translesional synthesis, and the Fanconi anemia–associated homologous recombination.[57] Therefore, mammalian cells have evolved a proteolytic pathway to limit their repair capability through restricting certain types of DNA repair activities. Considering that most DNA damage recognition complexes identify a variety of DNA damages or metabolic conditions rather than binding to specific DNA sequences, it is plausible that a "checkpoint" mechanism is required to limit DNA damage binding from interfering with other cellular processes involving unconventional DNA structures and that following inducible expression of DNA repair genes, levels are actively reduced to avoid gratuitous DNA repair and associated mutagenesis mediated by error-prone polymerases.

Recently, a class of specialized error-prone DNA polymerases, termed ζ (zeta) to σ (sigma), were discovered that seem to be devoted specifically to overcoming damage-induced replicational stress.[13–15,58] These special polymerases take over temporarily from the stalled

replicative DNA polymerases (δ [delta] and ε [epsilon]). They have more flexible base-pairing properties permitting translesion DNA synthesis, with each polymerase probably designed for a specific category of injury. Though translesion polymerases protect the genome, this solution to replication blocks comes at the expense of a higher error rate. For instance, inherited defects in pol η (eta), encoded for by the XPV/POLH/RAD30 gene, which specializes in relatively error-free bypassing of UV-induced cyclobutane pyrimidine dimers, causes a variant form of the skin cancer–prone disorder xeroderma pigmentosum.[59,60]

Human Nucleotide Excision Repair–Deficient Syndromes and Cancer

A direct correlation between unrepaired DNA damage and carcinogenesis in humans was first established when James Cleaver found that the cancer-prone hereditary disease xeroderma pigmentosum (XP) involved a defect in the repair of DNA lesions produced by UV light.[61] Since then, at least three syndromes have been attributed to inborn errors in NER: XP, CS, and TTD, all characterized by exquisite sun sensitivity.

XP is a rare, autosomal recessive disease in which homozygous individuals display several characteristics: (1) extreme sensitivity of the skin to sun exposure that is evident by 1 year of age, (2) pigmentation abnormalities and premalignant lesions in sun-exposed skin, (3) increases up to 4000-fold in the incidence of skin cancers (predominantly squamous and basal cell carcinomas but also melanomas) and ocular neoplasms, occurring three to five decades earlier than in the general population, and (4) a 10- to 20-fold increased incidence of internal cancers in non-sun-exposed sites.[5,62,63] Overall, the life span is reduced by approximately 30 years among patients with XP, and many die due to malignancies.[64] Approximately 20% of patients with XP also display progressive neurologic degeneration, characterized by peripheral neuropathy, sensorineural deafness, progressive mental retardation, and cerebellar and pyramidal tract involvement.[65] XP occurs worldwide, in all ethnic groups and with a frequency varying from one to ten patients per million.

The biochemical defect in cells from most XP individuals is in NER,[61] though in a small number of cases (termed XP-variants), excision repair appears normal, and a defect exists in bypass replication at unrepaired lesions due to a mutation in the pol η (eta) translesional synthesis gene (XPV).[66] Complementation analysis via fusion of cells from different patients has demonstrated genetic heterogeneity within XP and has provided evidence for the existence of at least seven excision-deficient complementation groups, termed XP-A to XP-G, in addition to XP-variant.[5]

CS is another autosomal recessive disease that is associated with defective TCR of UV-damaged and oxidative-damaged DNA.[67–69] It is characterized by cutaneous photosensitivity, cachectic dwarfism, skeletal abnormalities, retinal degeneration, cataracts, severe mental retardation, and neurologic degeneration characterized by primary demyelination.[65,70] In contrast to patients with XP, those with CS are not at increased risk for developing skin cancers. The average life span of individuals with CS is only 12 years, most patients succumbing to infectious or renal complications rather than cancer.[71] CS is characterized by the existence of at least three complementation groups. Several patients have been described in XP groups B, D, and G who share the DNA repair defects and clinical features of CS together with the cutaneous manifestations of XP.[72,73]

TTD is an autosomal recessive condition that shares many of the signs and symptoms of CS, with the additional hallmark of brittle hair and nails, due to reduced sulfur content in the component proteins. As with CS, XPB and XPD are among the responsible genes that are implicated, but there is a third complementation group, TTD-A, for which no gene has been identified. The favored model for TTD is that of a transcription deficiency with respect to the genes relevant to the phenotype, including sulfur-containing proteins.[74] It is also conceivable that TTD and CS could be diseases of "premature cell death" in which the transcription deficiency and deficiency in TCR could cause the apoptosis of certain classes of metabolically active cells that sustain significant endogenous oxidative damage (e.g., neurons).

Analysis of the specific abnormalities in NER displayed by the various genetic complementation groups of XP, CS, and TTD allow correlations to be drawn with their heterogeneous clinical features. Specifically, only those subgroups of patients who display a defect in GGR are at significantly increased risk for developing UV-induced malignancies. In contrast, the neurologic symptoms and developmental abnormalities that are associated with other complementation groups of XP and CS are found only in the groups that are defective in TCR. The fact that the TFIIH complex, containing the XPB and XPD proteins, is common to both core NER and transcriptional initiation, supports the suggestion that the clinical phenotype of patients with defects in TCR might actually be due to abnormalities in transcription rather than in repair itself.[74]

Although these observations might explain the molecular basis for many of the clinical characteristics of XP and CS, they present an apparent paradox with regard to these patients' cancer risk. Many currently recognized oncogenes and tumor suppressor genes are known to possess important cellular functions and to be actively expressed in normal cells. Because CS cells are defective in the repair of actively expressed genes, it would be reasonable to expect that these patients would acquire mutations in genes leading to transformation more readily than normal patients. However, this is not supported by the clinical picture. It has been demonstrated that defects in TCR specifically activate DNA damage induced apoptosis,[9,10] which may eliminate potentially mutagenic, premalignant cells.

Another puzzling aspect of the clinical phenotype of XP is why these patients do not appear to be at a greater risk for developing neoplasms other than skin cancers. Although a disproportionate number of relatively rare tumors such as brain sarcomas and extraglossal carcinomas of the oral cavity have been described in XP patients under 40 years of age,[62] individuals with XP do not appear to be at significantly increased risk for more common solid or hematologic malignancies. It might be that the early mortality that XP patients experience or a decreased exposure to non-UV environmental carcinogens during early life may partially explain these observations. However, modest alterations in NER activity caused by functional polymorphisms in XP genes may contribute to the risk of solid tumors.[75,76]

Base Excision Repair

A major source of DNA damage to cellular genomes arises from normal metabolism in the cytoplasmic environment through hydrolysis and exposure to reactive metabolites that cause oxidation and alkylation of DNA. The repair system that is primarily involved in identifying and removing such lesions, as well as for dealing with the spontaneous loss of purines from DNA, is the base excision repair (BER) pathway.[77,78] The essential nature of BER for viability is highlighted by the fact that although a number of BER proteins have been discovered, only recently has a single human hereditary disease been identified that appears to result from a mutation in a gene that is unique to this pathway.[79–82] The enormous task that is required for BER is exemplified by the fact that a human being spontaneously loses on the order of a trillion guanines from the DNA in his or her body every hour and each of these must be replaced. Similarly, a large number of cytosines become deaminated spontaneously, and the resulting product, uracil, must be removed and replaced with cytosine to restore the correct nucleotide sequence. In most cases, BER is initiated by one of a set of lesion-specific glycosylases that recognize the altered or inappropriate base and cleaves it from its sugar moiety in the DNA (Fig. 10-3). Different DNA glycosylases remove different kinds of damage, conferring specificity to the process. Once the

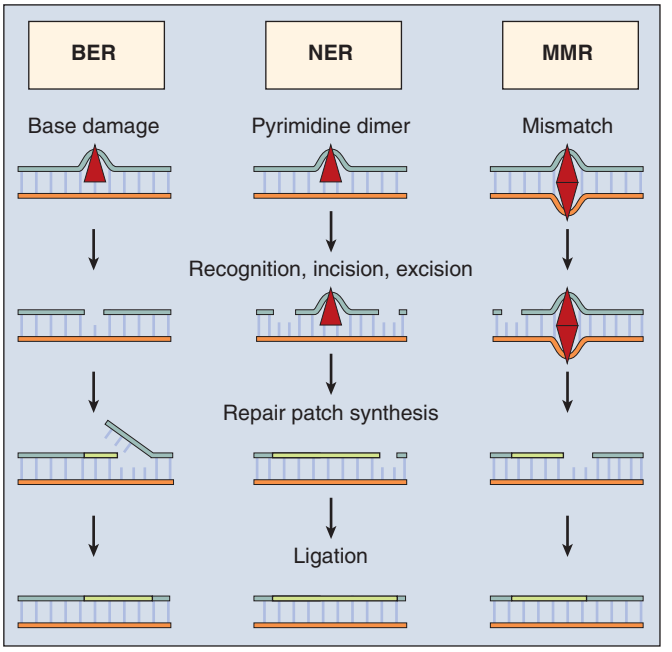

Figure 10-3 • Excision repair pathways for DNA damage. The three main excision repair pathways in human cells—base excision repair (BER), nucleotide excision repair (NER), and mismatch repair (MMR)—proceed through similar steps to restore the normal DNA sequence. Following recognition of altered DNA bases, employing lesion-specific glycosylases for BER, XP proteins for NER, and MutS homologs for MMR, incision of DNA is achieved by endonucleases and displacement or degradation of single-stranded sections of DNA that contain the damage by enzymes with helicase and exonuclease activity. Repair replication of the resulting DNA gap and strand ligation results in the repaired double-stranded DNA molecule. The many repair enzymes that are involved in each specific step are tightly coupled and may be regulated or inducible by DNA damage response pathways.

base is removed, the apurinic/apyrimidinic (AP)-site is removed by an AP-endonuclease or an AP-lyase, which cleave the DNA strand 5′ or 3′ to the AP-site, respectively. The remaining deoxyribose phosphate residue is excised by a phosphodiesterase with the resulting gap filled by a DNA polymerase and the strand sealed by DNA ligase. The major oxidized purine lesion is 8-oxo-7,8-dihydroguanine (8-oxoG), which is abundant and has strong mutagenic properties. Oxidized pyrimidines include thymine glycol, 5-hydroxycytosine, and formamidopyrimidines. Oxidized bases, including both 8-oxoG and thymine glycol, share the property of blocking DNA replication and transcription and must be repaired efficiently to maintain genomic stability.[83,84]

In mammalian cells, the gene functions that are responsible for the strand incision steps of BER include the glycosylases hNTH1, which removes oxidized pyrimidines; hOGG1, which targets oxidized purines; and MYH, which removes adenines mispaired with an 8-oxoG, together with AP endonuclease 1 (APE1).[85] Attempts to engineer mice that are deficient in the core enzymes that are required for BER have typically resulted in early embryonic death, whereas knockout of individual glycosylases produce mice with no overt phenotype at all.[86] This attests to the importance of the repair of DNA lesions from endogenous causes during embryonic development as well as the likely redundancy between individual glycosylases. It is also consistent with the near absence of known human hereditary diseases characterized by defects in BER genes.

However, given the mutagenic and cytotoxic potential of the classes of DNA damage that are BER substrates, it seems likely that altered activity in these pathways would result in enhanced cancer risk. The most direct evidence for a role for BER in cancer comes from the discovery that germline mutations in the MYH gene, involved in processing 8-oxoG lesions, is associated with recessive inheritance of a predisposition to develop multiple colorectal adenomas (polyposis) and colon cancers.[79–81] Tumors from affected individuals exhibit excess transversions of a guanine-cytosine pair to a thymine-adenine pair in the APC gene, itself associated with colon carcinogenesis and causative of familial adenomatous polyposis. Therefore, biallelic inherited mutations in MYH result in a polyposis-like syndrome termed MYH-associated polyposis (MAP). Patients with MAP tend to develop tens to hundreds of polyps by the age of 40, and nearly 50% present with colon cancer.[82] Box 10-1 discusses the affect of genetic variations in other DNA repair genes.

Mismatch Repair

Mismatch repair (MMR) is another example of an excision repair mechanism that utilizes a similar strategy for genomic maintenance (see Fig. 10-3). MMR is a process that corrects mismatched nucleotides in the otherwise complementary paired DNA strands, arising from DNA replication errors and recombination, as well as from some types of base modifications.[94–96] This repair mode also can deal with small loops of single-stranded DNA at sites of insertions or deletions in the duplex DNA structure. The importance of this repair mechanism in maintaining genetic stability is illustrated by the observation that its absence results in a large increase in the frequency of spontaneously occurring mutations, particularly in microsatellite sequences of highly repetitive DNA.[97] Some of these spontaneous mutations arise from mistakes that are introduced during DNA replication, in spite of the operation of a "proofreading" system that also helps to ensure the high fidelity of replication. In humans, genetic defects in several mismatch repair genes have been linked to hereditary nonpolyposis colon cancer (HNPCC) as well as to sporadic cancers that exhibit instability in regions of DNA containing short repetitive sequences of nucleotides, a feature that is known as microsatellite instability (MSI).

As with other modes of excision repair, four principal steps are required for MMR: (1) mismatch recognition, (2) recruitment of additional MMR factors, (3) identification of the newly synthesized DNA strand containing the mismatched nucleotides, followed by their excision, and (4) resynthesis of the excised tract and ligation. The biochemical workings of this pathway are best understood in bacteria, but a similar set of events occurs in human cells. On the basis of functional homologies to their bacterial counterparts and sequence homology to corresponding yeast genes, a number of human genes have been cloned that participate in MMR, including those that are homologous to the bacterial MutS mismatch recognition protein (hMSH2, hMSH3, and hMSH6) and to the bacterial MutL gene (hMLH1 and hPMS2).[98–100] In humans, heterodimers of the MSH2/6 proteins recognize single-base-pair mismatches and short insertion-deletion loops, whereas MSH2/3 dimers recognize longer loops. Heterodimeric complexes of MLH1/PMS2 and MLH1/PMS1 interact with the MSH complexes and replication factors for strand discrimination and DNA excision. Similar to NER and BER, additional proteins are then recruited for repair replication on the basis of the original DNA template.

The MMR system also might interact with DNA damage due to certain alkylators and intercalating agents that assume structural alterations in DNA similar to those of mismatches and might actually result in erroneous or futile MMR cycles, resulting ultimately in apoptosis. Thus, intact MMR might confer chemosensitivity to these chemotherapeutic agents, and MMR-defective tumors may exhibit resistance to certain drugs.[101]

Human Mismatch Repair Deficiency and Cancer

HNPCC, also known as Lynch syndrome, is the most common hereditary colorectal cancer predisposition syndrome.[102,103] HNPCC is an autosomal dominant inherited condition with an incidence of

Box 10-1. GENETIC VARIATION IN DNA REPAIR GENES: IMPLICATIONS FOR CANCER RISK AND PREVENTION

Despite many decades of investigation, the exact cause of most cancers remains unknown, with a few important exceptions (e.g., certain cancers of the lung, skin, and cervix). Rather, cancer is associated with a broad and heterogeneous group of genetic and environmental influences, making the development of schemes for risk assessment and targeted prevention difficult. However, 30 years ago, prior to much of our current understanding of the specific molecular and genetic changes associated with cancer, Dr. Larry Loeb proposed that a common early event in the development of many cancers is the expression of a "mutator phenotype" resulting from functional mutations in genes that normally function to maintain genetic stability.[87] On the basis of calculations of the estimated fidelity of DNA replication and repair in normal human cells and the rarity of spontaneous mutations that occur in normal cells, Loeb noted the statistical unlikelihood that the large number of chromosomal aberrations and genetic mutations that are observed in human malignancies would occur by chance in a single cell. However, he speculated that if a cell exhibited unusual levels of genetic instability due to inherited or acquired mutations in the genes that regulate the processes of DNA replication and repair, the rate of additional mutations occurring in other genes important for carcinogenesis will be dramatically elevated. As is obvious from the many specific examples that are discussed in this chapter, Loeb's prediction has been borne out by many subsequent studies of multistep carcinogenesis and the identification of cancer susceptibility syndromes caused by inherited mutations in DNA repair genes.[88] However, these highly penetrant hereditary cancer syndromes (e.g., HNPCC) caused by inactivating mutations in tumor suppressor or DNA repair genes account for only a fraction of most common types of cancers (usually fewer than 10%). Therefore, an emerging hypothesis is that more common polymorphic genetic variation in DNA repair genes may result in variability in DNA repair capacity between individuals and result in altered cancer susceptibility.[76] Rapid advances in DNA sequencing technologies have allowed for large-scale genetic epidemiology studies to be performed to address this possibility. To date, the results have been rather inconsistent. A meta-analysis of associations between single-nucleotide polymorphisms (SNPs) in base excision repair genes and cancer risk found SNPs in the 8-oxoguanine DNA glycosylase (OGG1), apurinic/apyrimidinic endonuclease (APE1/APEX1) and XRCC genes affected lung cancer risk.[89,90] Several other studies show similar results, though many do not find significant increased relative risk of cancer associated with DNA repair SNPs. This may be due to methodologic limitations, such as study size, false positives, and population heterogeneity, but an important possibility is that a single common sequence variant might not be detectable in population association studies. Rather, a combination of multiple variants in the same gene or genes in common pathways might be more important in carcinogenesis. Sir Walter Bodmer proposed just this by suggesting that multiple rare low-penetrance SNPs might together account for a substantial proportion of inherited cancer susceptibility, and recent results from his work in colon polyps and colon cancer support these ideas.[91,92]

The mutator phenotype theory and individual genetic variation in DNA repair capacity also have major implications for the prevention of cancers. Whole-genome approaches to mapping genetic variation in DNA repair genes, potentially in combination with functional assays for individual DNA repair capacity,[93] might allow for targeted approaches for cancer prevention. Reducing the amount of DNA damage to which normal or premalignant cells are particularly vulnerable could slow the accumulation of additional mutations. Certainly, reducing exposure to known environmental carcinogens is important in this goal, but the majority of DNA damage likely occurs as the result of endogenous reactants of normal cellular metabolism, such as oxygen-reactive species, activated lipids, and metal cations. In fact, it has been estimated that oxidative radicals generate up to 10,000 DNA damage events per cell per day. Therefore, means to reduce the amount of oxidative DNA damage or enhance its repair, might slow the carcinogenic process sufficiently to prevent the clinical occurrence of some cancers. Indeed, evidence from several fields suggests that antioxidants might have chemopreventative properties. For example, epidemiologic evidence suggests that diets that are rich in the common trace element selenium might be associated with reduced cancer risk. However, clinical trials of antioxidant approaches to cancer prevention have not generally been successful. Given the complex genetic pathways that are involved, it is hoped that individualized risk assessment by using genetic approaches will allow for the identification of specific pharmacologic agents for cancer prevention. Certainly, our rapidly increasing understanding of processes for the prevention and repair of DNA damage provides many new targets for rational drug development.

one in 1000 in the general population. It accounts for approximately 5% of all colorectal cancers patients with HNPCC, who are also at elevated risk for cancers of the endometrium, ovary, stomach, small bowel, and other sites. Patients with HNPCC have an 80% lifetime risk for colorectal cancer and a 50% lifetime risk for endometrial cancer. The discovery of MSI, that is, the frequent alteration in the tract lengths of certain short repetitive nucleotide sequences, in some hereditary colorectal cancers provided the first indication that the etiology of these cancers might involve a problem in the MMR system.[104] The finding of germline MMR gene defects in patients with HNPCC established that these defects are the cause of the enhanced incidence of cancer.[98–100] Germline mutations in MLH1 and MSH2 together account for more than half of all cases of HNPCC. Defects in MSH6 cause a late-onset HNPCC phenotype. No strong genotype-phenotype correlations have been observed to date, but mutations in the MSH2 gene do appear to be associated with more extracolonic manifestations than are seen with mutations in the MLH1 gene.

MSI has been identified as a source of the genomic instability driving tumorigenesis in a number of sporadic tumor types in addition to those that arise in the context of inherited germline mutations of MMR genes.[104,105] For example, up to 20% of sporadic colon cancers exhibit MSI, particularly when presenting in the ascending colon and in individuals younger than 50 years old, the majority due to epigenetic silencing of MLH1 gene expression by promoter hypermethylation.[106,107] Whether through genetic or epigenetic inactivation, loss of MMR results in an elevated rate of mutations, particularly at microsatellite sequences, several of which occur in the coding sequences of other genes that are often found mutated in cancers, including TGF beta type II receptor, BAX, and the mismatch repair genes MSH3 and MSH6, themselves. Therefore, clear genetic evidence demonstrates that the phenotype of genetic instability associated with defects in MMR results in the genotype of tumors that arise owing to these defects.[108] Intriguingly, the survival of patients with MSI-associated colorectal cancer is better than those with more typical tumors exhibiting chromosomal instability.[109–111] These tumors also demonstrate different sources of genomic instability, resulting in distinct biologic and pathological characteristics.[112] Whether their more favorable outcome reflects differences in clinical behavior, responsiveness to therapy, or both remains to be fully determined.

Double-Strand Break Repair

Double-strand breaks (DSBs) in DNA that are induced by ionizing radiation, endogenously produced reactive oxygen radicals, chemicals, replication across single-strand breaks, and during repair of interstrand DNA cross-links are dealt with through either the recombination machinery or the relatively error-prone nonhomologous end-joining pathway (Fig. 10-4). An unrepaired DSB is a highly lethal event, and even a single occurrence in the entire genome is thought to be sufficient to signal cell cycle checkpoints that prevent attempted DNA synthesis or cell division until repair has been completed or apoptosis if improperly repaired. DSBs also pose problems during mitosis, because intact chromosomes are a prerequisite for proper chromosome segregation during cell division. Thus, these lesions often induce various sorts of chromosomal aberrations, including aneuploidy, deletions (loss of heterozygosity), and chromosomal translocations, all of which are associated with carcinogenesis. Genetic recombination is the principal mechanism in cycling cells for dealing with DSBs that involve homologous stretches of nucleotides at the ends to be joined. If no such homology is present or if the cell is not cycling, then there is a system for nonhomologous end joining, which is more error-prone.

Recent studies have identified a cascade of protein kinases that are involved in signaling cellular processes in response to DSBs. Many of these have been found to be defective in cancer-prone disorders that exhibit genomic instability, such as the ATM protein,[41] and the Chk2 protein kinase associated with a Li-Fraumeni–like cancer susceptibility syndrome.[113–115] A major target for these kinase activities is the p53 tumor suppressor gene. When activated, this protein is involved in inducing G1 arrest or apoptosis following ionizing radiation and other cellular stresses.[36,37,116–120] Germline mutation of p53 results in the Li-Fraumeni cancer susceptibility syndrome. Many other enzymes that are involved in processes required for effective DSB repair have been found in cancer-prone disorders, including MRE11 (AT-like disorder), NBS1 (Nijmegen breakage syndrome), BRCA1 and BRCA2 (breast-ovarian cancer syndrome), and the RecQ-like helicases (Werner, Bloom and Rothmund Thomson syndromes).[121]

Ataxia Telangiectasia

Ataxia telangiectasia (AT) was first identified as a disorder characterized by progressive neurodegeneration, immune deficiency, and cancer predisposition. A link to DNA damage responses arose when AT patients with lymphomas exhibited severe reactions to radiation therapy that was used to treat their tumors. A single gene, ATM, is responsible for the multiple and surprisingly diverse symptoms of this disease, including the predisposition to lymphoma and leukemia. It has been estimated that over 10% of AT patients develop cancer at an early age. AT is an autosomal recessive disease with an incidence of nearly one in 100,000 live births. Persons who are heterozygous for AT mutations, about 1% of the general population, may have an increased predisposition to cancer, in particular breast cancers, especially in individuals who express an ATM with missense mutations resulting in a dominant-negative effect on their wild-type ATM gene.[122–124] The ATM gene product is a central signaling protein in the DNA damage response, and cells lacking ATM fail to execute many critical cellular responses to DNA damage. For example, one hallmark of AT is what has been termed X-ray resistant DNA synthesis. It is now know that the ATM gene product is a key element in delaying the initiation of DNA replication following DNA damage resulting in strand breaks.

ATM is a protein kinase that is activated by introduction of DSBs into the genome and phosphorylates numerous substrates involved

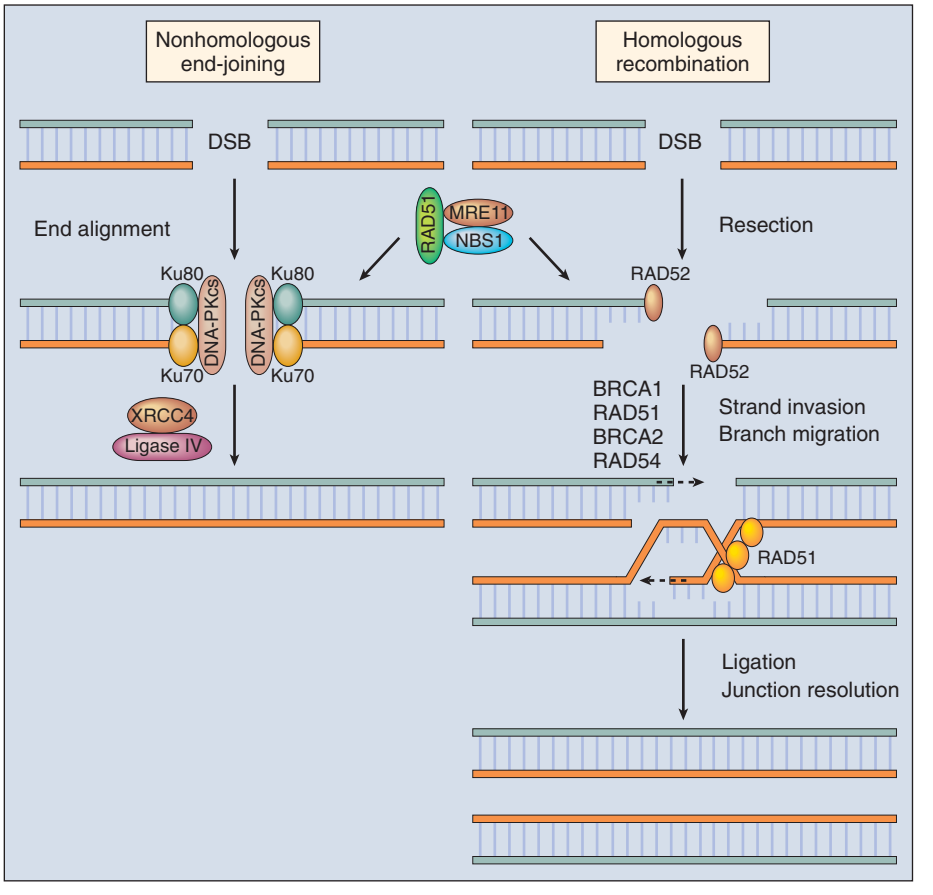

Figure 10-4 • Mechanisms for DNA double-strand break repair. The repair of DNA DSBs is carried out by two mechanisms. *Left,* The rapid, but error-prone, nonhomologous end-joining that directly seals breaks but may result in the gain or loss of several nucleotides due to short areas of microhomologies used for annealing prior to ligation. Exposed DNA ends are recognized by the Ku70/80 heterodimer that recruits the DNA-dependent protein kinase catalytic subunit and other proteins assisting in strand alignment. The XRCC4-ligase IV heteroduplex joins the breaks. *Right,* The high-fidelity, homologous recombination of sister chromatids at sites of DSBs is the less prominent mode in mammalian cells. This DNA repair pathway is mediated by RAD51-associated proteins, including RAD52 that recognizes single-strand DNA ends and together with other proteins results in short nuclease-mediated resection. RAD51 then forms a nucleoprotein filament on the exposed strand and, probably with BRCA2 and other proteins, promotes strand invasion and displacement at homologous sequences. Thus, the undamaged sister molecule acts as a template for the resynthesis of the missing nucleotides.

in controlling cellular responses to DNA damage, including p53, BRCA1, and CHK2.[34] In addition, ATM directly phosphorylates the NBS1 protein, which exists in a complex with the MRE11 and RAD50 proteins, a complex that is required both for nonhomologous end-joining and homologous recombination of DSBs.[125] Inherited germline mutations of the NBS1 and MRE11 genes, themselves, result in clinical variants of AT, termed *Nijmegen breakage syndrome* and *AT-like disorder,* respectively.[126,127] In fact, it has recently been shown that cells from patients with NBS have defective ATR-dependent signaling and appear phenotypically similar to ATR-defective Seckel syndrome.[127] Therefore, ATM is central to a DNA damage response pathway that is critical for regulating cellular responses to stress, including recombination and repair following DSBs. Defects in many of the component proteins in the pathway result in genomic instability and a predisposition to cancer.

OTHER CANCER-PRONE DISORDERS ASSOCIATED WITH GENOMIC INSTABILITY

Diseases Involving Homologs of *recQ*

There are at least three cancer-prone diseases in humans in which the defect is in a homolog of the *recQ* gene that was originally discovered in bacteria.[128] The product of *recQ* is a helicase, which in *E. coli* is involved in processing the nascent DNA at arrested replication forks. Helicases are enzymes that separate the complementary strands of nuclei-acid duplexes using energy that is derived from ATP hydrolysis. In humans, recQ helicases are thought to function at the interface between DNA replication and recombination in dealing with damaged replication forks and interact with many other nuclear proteins that are required for DNA metabolism.[129] The biologic and clinical effects of the homozygous deficiency of these genes can be quite dramatic and profound. Bloom syndrome, a disorder that is caused by homozygous loss of the BLM helicase, is characterized by an extremely high frequency of genetic exchanges (so-called sister chromatid exchanges) that cause genomic instability and lymphoma, leukemias, and solid tumors of the GI tract and breast.[130,131] Of interest, recent studies have identified an increased risk that individuals who are heterozygous for a BLM mutation will develop colorectal cancer, potentially due to haploinsufficiency.[132,133] Werner syndrome results from a deficiency in another *recQ* homolog, WRN, and has features of profound premature aging as well as predisposition to sarcomas, melanoma, and cancer of the thyroid.[134–136] Yet another *recQ* homolog defect, Rothmund-Thompson syndrome, is characterized by growth deficiency and cancer predisposition, in particular to osteogenic sarcomas.[137,138]

p53 Gene and Li-Fraumeni Syndrome

The discovery of the p53 tumor suppressor gene over 25 years ago inspired widespread investigations with the aim of understanding the basic biology behind its role in maintaining genomic stability and the cellular response to DNA damage. p53 is one of the most commonly mutated genes in human cancers[139] and its product is a multifunctional protein that regulates many physiologic processes, including cell cycle checkpoints, apoptosis, and DNA repair.[21,116,117,140,141] The primary role of p53 in tumor suppression has been attributed to its function as a transcription factor, regulating expression of several hundred different cellular genes,[142] although it appears to exhibit transcription-independent activities as well. Indeed, p53 appears to act as a central "node" that lies at the intersection of upstream signaling cascades induced by DNA damage and cellular stress responses and downstream DNA repair and DNA damage response pathways. In response to a variety of genotoxic stimuli, p53 protein is induced and stabilized.[34,143] This activated p53 protein binds to DNA in a sequence-specific manner and regulates the transcription of downstream target genes that contain a consensus p53 response element in their promoter or intronic segments. These p53 target genes include those that are important for cell cycle checkpoints, such as p21;[144] apoptosis, such as BAX and PERP;[145] and DNA repair, such as the DDB2 and XPC genes that are required for NER.[19–21,46] In addition, some evidence suggests that p53 protein might act in a transcription-independent manner to modulate BER through interactions with DNA polymerase beta and OGG1, and homologous recombination in conjunction with *recQ* proteins.[141]

Patients with the rare autosomal dominant Li-Fraumeni syndrome (LFS) are at increased risk for developing a number of common tumors at an early age due to an inherited germline defect in one allele of the p53 gene, including soft-tissue and osteosarcomas, breast cancer, brain tumors, lymphomas, leukemia, and adrenocortical carcinomas. Mutations in the p53 tumor suppressor gene account for 70% to 85% of classic LFS cases.[146–148] Although the heterozygote carriers of a defective p53 allele do not appear to have clinical problems or DNA repair defects, when the second allele has been mutated or lost, the absence of functional p53 results in severe problems for the cell. First of all, the p53-controlled pathway of apoptosis is disengaged, so severely damaged cells will survive and be at risk for carcinogenic transformation because of their genomic instability. That genomic instability derives from the fact that p53 is also an important regulator of cell cycle checkpoints. Thus, as with the situation in AT, the cells continue to progress through their growth cycle rather than pausing to allow time for DNA lesions to be repaired. Loss of p53 also leads to increased aneuploidy of cells, further contributing to genetic instability and the progression to malignancy or metastasis. Finally, p53 serves an important regulatory function in NER and perhaps in BER and recombination, and in its absence, some important mutagenic lesions are simply not repaired. That, of course, is a major contributor to the genomic instability and the consequent development of tumors. See Box 10-2 for a discussion of DNA repair and cancer treatment.

BRCA1, BRCA2, and Breast-Ovarian Cancer Susceptibility

Hereditary breast cancer includes a broad group of hereditary predisposition conditions in which breast cancer is a component tumor; these account for approximately 5% to 10% of all breast cancer cases. Hereditary syndromes of breast and ovarian cancer susceptibility have been particularly associated with germline mutations of two genes, BRCA1 and BRCA2, as well as rare cases due to mutations in the p53 gene in LFS, the PTEN gene in Cowden disease, and perhaps the ATR gene, Chk2 gene, and others. Recent experimental data suggest that both the BRCA genes might be involved in multiple DNA repair activities.[21,55,149,150,157–159]

The BRCA1 and BRCA2 genes are large and complex. Many hundreds of different germline mutations have been detected in each, but only rare sporadic breast or ovarian cancers have been found to harbor BRCA1 mutations. The exact biochemical functions of these proteins remain unknown, but increasing evidence suggests that they might be involved in various aspects of DNA repair and DNA damage response pathways. For example, BRCA1 is phosphorylated after exposure to DNA-damaging agents by ATM, ATR, and Chk2 and associates with a number of DNA repair proteins including MSH2, MSH6, ATM, RAD51; and the RAD50-MRE11-NBS1 protein complex following DNA damage and localizes to nuclear foci with these proteins after treatment with ionizing radiation and UV radiation.[24,160,161] The association of BRCA1 with RAD51, an enzyme that is involved in the coordination of recombination, suggests its involvement in DSB repair, and strong data exist that implicate BRCA1 in homologous recombination.[149,162] Other studies suggest that BRCA1 might regulate cellular processes through transcriptional coactivation. BRCA1 has been shown to transcriptionally regulate the NER genes XPC and DDB2 and affect GGR of UV and cisplatin-induced DNA damage.[55,150,163] Chromosomal instability also is

Box 10-2. DNA REPAIR AND CANCER TREATMENT

As was discussed in this chapter, many genes that are implicated in the development of cancer play roles in DNA repair. The mechanism of action for most cancer chemotherapeutic drugs, as well as radiation therapy, is thought to be through DNA damage. Therefore, it seems logical that cancers that acquired defects in DNA repair during the tumorigenic process would also be particularly susceptible to the cytotoxic effects of DNA-damaging therapeutic agents. However, for most common cancers, the clinical experience suggests otherwise. It is likely that the frequently concurrent inactivation of cell cycle checkpoints and apoptotic processes during tumorigenesis obscures the effect of DNA repair defects; therefore, the response of clinical tumors to various treatments remains very difficult to predict, even with genetic information. Nevertheless, several examples have emerged in which a detailed understanding of the DNA repair defects that are present in a particular tumor type might allow for the rational selection of certain treatment approaches that are likely to be more effective.

One example relates to the function of the BRCA1 gene, which is involved in several types of DNA repair, including double-strand break repair, nucleotide excision repair, and DNA cross-link repair.[46,149,150] Germline mutations in the BRCA1 gene predispose individuals to a very high risk for developing breast and ovarian cancers, and somatic inactivation of BRCA1 activity has also been observed in sporadic breast and ovarian cancers due to promoter methylation. Clinical and experimental data suggest that breast and ovarian tumors that are deficient in BRCA1 function are particularly sensitive to the chemotherapeutic drug cisplatin, which causes DNA damage to be repaired through the nucleotide excision and cross-link repair pathways, and ionizing radiation, which causes double-strand DNA breaks.[150] Another very exciting recent finding relates to the selective activity of PARP-1 inhibitors in tumors that are deficient for BRCA1/2.[151,152] PARP-1 is the first described member of a large family of enzymes that can detect and bind to DNA nicks and strand breaks and is thought to play a key role in base excision repair.[153] Chemical inhibitors of PARP activity are thought to enhance killing of cells defective in double-strand break repair through synthetic lethality. The success of this approach in preclinical models has led to the rapid development of clinical trials of PARP inhibitors in breast cancers in women with known BRCA1/2 mutations, as well as in "triple-negative" breast cancers (ER/PR/Her-2 negative) that share phenotypic activity with BRCA1/2 mutant tumors.[154,155]

A quite different example relates to the 15% to 20% of colorectal cancers that have inactivated the mismatch repair pathway and exhibit microsatellite instability (MSI). It has been appreciated for some time that individuals with colorectal cancer who express high levels of MSI have longer survival than do stage-matched patients with colorectal cancer without MSI.[109] However, whether these prognostic differences related to differences in tumor biology or sensitivity to chemotherapy was unclear. Recently, though, clinical studies suggest that patients with surgically resected stage II or III MSI-positive colorectal cancer do not benefit from 5-fluorouracil based adjuvant chemotherapy, as do patients with mismatch repair–intact colorectal cancers but nevertheless have better outcomes even without additional therapy. Experiments with mismatch repair–defective colon cancer cell lines suggest that they are also resistant to the cytotoxic effects of oxaliplatin (in fact, an intact mismatch repair pathway may be necessary to confer the apoptotic effects of platinum-induced DNA damage) but susceptible to the topoisomerase I inhibitor, CPT-11.[156] Since both these drugs are now being used for the treatment of colorectal cancer, concurrent diagnostic testing of tumors for MSI and mismatch repair activity may help guide their selection and use in individual patients. These examples and others suggest that our rapidly improving knowledge of the role of specific cancer genes in DNA repair pathways may significantly impact the treatment of human cancers. Efforts to obtain genotypic and phenotypic information from individual tumors will hopefully allow for tailored, rational selection of therapies for cancer treatment, an approach that is central to the emerging field of pharmacogenomics.

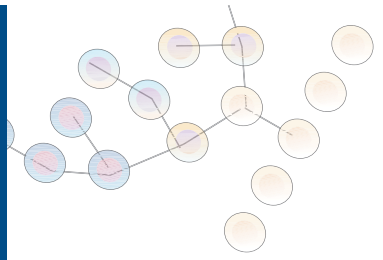
characteristic of breast tumors that harbor BRCA2 mutations, probably owing to defective recombination-mediated DSB repair. BRCA2 has been shown to bind to the RAD51 protein, an enzyme that is involved in the coordination of recombination, and together they colocalize to nuclear sites that contain DNA strand breaks caused by ionizing radiation. Structural studies of BRCA2 DNA-binding domains suggest that it might facilitate interactions of RAD51 with single-stranded DNA during recombination.[164,165] The genomic instability that is associated with mutations of BRCA1 and 2 therefore might be due in part to the intact but error-prone nonhomologous end-joining repair pathway.[158]

MDC1 is another important regulator of ATM-dependent phosphorylation of BRCA1 and is required to activate Chk2 as part of the response of mammalian cells to DNA damage.[149] Therefore, a hypothesis is that BRCA1 lies at a critical intersection of the DSB response pathways. Post-translational regulation of BRCA1 by phosphorylation has established a link between BRCA1 and Chk2, BRCA2, ATR, and ATM and suggests mechanisms that promote genomic instability and increased susceptibility to cancer when mutant.

Fanconi Anemia, Cancer, and Interstrand Cross-Link Repair

The centrality and interwoven nature of DNA repair pathways for genomic stability have been highlighted by findings regarding Fanconi anemia, a rare, autosomal recessive disease that confers an increased risk of acute myeloid leukemia, squamous cell carcinomas of the head and neck and esophagus, gynecologic carcinomas, and liver tumors at a young age.[166,167] At least 13 subtypes of Fanconi anemia have been determined by complementation analyses, and germline mutations in genes have been identified for most of them.[168,169] The proteins that are encoded by these Fanconi anemia genes all cooperate in a common DNA repair pathway that is involved in interstrand cross-link repair. Germline homozygous inactivating mutations of the BRCA2 gene result in the D1 group.[170] Eight of these proteins are subunits of a nuclear E3 ligase, required for the monoubiquitination of the downstream D2 protein, which itself links Fanconi anemia proteins to BRCA1 in the response to DNA damage by colocalizing to nuclear sites occupied by RAD51 and BRCA2.[171] This process also is regulated by the ATM protein kinase, which phosphorylates FANCD2 in response to DNA damage.[172] It has long been appreciated that cells from Fanconi anemia patients are hypersensitive to DNA cross-linking agents, such as mitomycin C and cisplatin, in addition to being modestly sensitive to ionizing radiation. Although DNA cross-link repair in mammalian cells is poorly understood, it has been proposed that it utilizes components of both the excision repair and DSB repair systems to sequentially incise DNA near the site of a cross-link followed by homologous recombination or nonhomologous end-joining.[167] Therefore, the Fanconi anemia proteins appear to function at an interface between several DNA repair and DNA damage response pathways.

CONCLUSIONS AND FUTURE DIRECTIONS



Recent molecular biology and genetic research has provided ample evidence to support the long-standing prediction that genomic instability is a major factor driving the onset and progression of carcinogenesis.[88] Overlapping and interacting mechanisms for DNA repair and the cellular response to DNA damage are critical components for the maintenance of genomic stability. Alterations in these pathways often are early events in the multistep acquisition of genetic mutations that lead to cancer development. Continued exploration of the DNA damage response will prove important for our improved understanding of cancer etiology, prevention, genetic susceptibility, diagnosis, and treatment.

11 Viruses and Human Cancer

Paul F. Lambert and Bill Sugden

SUMMARY OF KEY POINTS

- The last 35 years have revealed the existence of human tumor viruses.
- Human tumor viruses contribute to at least 15% of all human cancers.
- The study of tumor viruses led to the discovery of cellular oncogenes and tumor suppressor genes, which are key contributors to cancers regardless of the etiology.
- Virally induced tumors can be eradicated by the development of prophylactic viral vaccines, or other public health measures for preventing transmission.

INTRODUCTION

Viruses cause cancers in people. Today, approximately 15% of all human cancers are thought to have a viral etiology,[1] and this fraction is likely to grow as we investigate additional cancers for a potential viral cause and identify new human viruses. Identifying a human cancer as having a viral etiology has substantive consequences both for its treatment and for its prevention. The known virally caused human cancers often express virally encoded products in the tumor cells. These viral products are potential targets for antiviral, tumor-specific therapies. Viral infections can be prevented by vaccines; therefore, it might be possible to eliminate those human cancers that require viral contributions for their development.

HUMAN TUMOR VIRUSES

The search for human tumor viruses has been propelled by a long appreciation that viruses can cause cancers in birds and rodents. Viruses were isolated as filterable extracts from avian tumors in the first decade of the twentieth century and were shown to induce tumors in susceptible animals.[2,3] Parallel findings were made in mice in the 1940s.[4] These animal tumor viruses were in the retrovirus family and led researchers to look for retroviruses as human tumor viruses in the 1960s and 1970s. However, most of the human tumor viruses that were subsequently identified are in different virus families and do not conform to some of the expectations that have been derived from the study of highly oncogenic animal retroviruses. For example, highly oncogenic tumor viruses induce tumors in animals rapidly. The inoculation of Rous sarcoma virus into the wing web of newborn chicks can induce fatal sarcomas within 2 weeks in 100% of susceptible animals.[5] In addition, highly oncogenic tumor viruses are oncogenic because they have acquired and express potent derivatives of cellular proto-oncogenes. In fact, many of the known human proto-oncogenes were first identified as homologs of the oncogenes that are transduced by the highly oncogenic animal retroviruses.[6] Known human tumor viruses, however, usually do not induce cancers rapidly; often, 15 to 50 years will elapse between the primary infection and tumor development. Nor do human tumor viruses express cellularly derived oncogenes; rather, some of them have evolved to inhibit cellular tumor suppressor genes. These differences between highly oncogenic animal viruses and human tumor viruses probably have contributed to the reticence in our recognizing that viruses do cause cancers in people.

A second obstacle in our recognizing that viruses can be tumorigenic in their human host is that we lack convincing animal models in which to test these viruses directly. For all practical purposes, all known human tumor viruses infect only people. In addition, we now know that human viruses that are found not to be tumorigenic in people are tumorigenic when experimentally introduced into test animals. For example, human adenovirus 12, which causes only respiratory infections in people, is highly oncogenic when inoculated into newborn hamsters.[7] The lack of an experimentally tractable animal host for human tumor viruses has required multiple lines of evidence to affirm that a given virus can contribute to a given human cancer. In particular, epidemiologic findings have been combined with genetic and molecular analyses in cell culture to identify human tumor viruses. Experiments with mice that are transgenic for viral genes have also supported these identifications.

Here, we shall introduce the six known human tumor viruses, the tumors with which they are associated, data that support these associations, and models to explain the viral contributions to these tumors. These viruses will be presented in the order of their discovery; early findings have often provided insights for analyses of subsequently identified viruses. Finally, we shall outline the kinds of virus-specific therapies that it might be possible to develop and the likelihood of developing vaccines to human tumor viruses in order to limit or eliminate specific human cancers.

Epstein-Barr Virus

Epstein-Barr Virus (EBV) was identified through the insight and advocacy of Dennis Burkitt, who, as a young surgeon, having identified Burkitt's lymphoma as a new disease entity, analyzed the geographic and climatic distribution of this childhood lymphoma, determined that it overlapped with that of malaria, and posited it to have an infectious etiology.[8] At his urging and with his proffered biopsy samples, Tony Epstein and his colleagues identified EBV in Burkitt's lymphoma–derived cells.[9] To do so, they developed the expertise to propagate these cells in culture.[10] Cell lines derived from EBV-positive Burkitt's lymphomas proved to be powerful tools to

associate EBV with different human diseases. Different EBV-positive cell lines express different viral antigens and thereby have served as test samples for patients' expressing antibodies to EBV-encoded antigens.

The analyses of these antibodies by serology led the Henles in Philadelphia to propose EBV as the cause of infectious mononucleosis.[11,12] A colleague in their laboratory who had lacked antibodies to EBV-encoded antigens developed those antibodies on presenting with infectious mononucleosis. The etiologic role for EBV in this "self-limiting lymphoproliferation" was subsequently established by careful, prospective epidemiologic studies in which serology was used to demonstrate that only immunologically naive people were at risk of developing infectious mononucleosis; on doing so, they would express antibodies first to EBV-encoded antigens of the IgM class and only later to those of the IgG class.[13] Thus, about 85% of infectious mononucleosis cases were shown to arise from a primary infection with EBV. Serologic studies also allowed the Henles to propose that nasopharyngeal carcinoma (NPC) might be caused by EBV because NPC patients were characterized by having atypically high titers to EBV-associated antigens.[14] However, the data that linked EBV causally to Burkitt's' lymphoma and NPC by the early 1970s was only "guilt by association." While EBV caused most infectious mononucleosis on primary infection, serology had also demonstrated that children in the parts of Africa in which Burkitt's lymphoma is endemic and adults in the parts of China in which NPC is prevalent had all been infected with EBV, that is, were "EBV-seropositive," long before they developed these cancers.

The serologic analyses of EBV in the 1960s and 1970s illustrate a conundrum for viruses and human cancers: "How can many people be infected with a given virus, and yet how can that virus contribute to tumor development in only a few infected subjects after long periods of time?" This apparent paradox applies, in fact, to most cancers associated with human tumor viruses and explains a major reluctance to consider viruses as etiologic agents for human cancers. The World Health Organization, without resolving this conundrum, sponsored a prospective epidemiologic survey in Uganda to assay 42,000 youngsters serologically for evidence for or against EBV's contributing causally to Burkitt's lymphoma. The region that was studied had a high incidence of this cancer. Children were bled, their serum was stored, and those who were later identified as developing Burkitt's lymphoma were bled again, and their titers to EBV-antigens were determined. This prospective survey found 14 youngsters who developed Burkitt's lymphoma over the 5 years they were followed, and those who did develop the lymphoma had, prior to tumor development, on average a 3.4-fold higher titer of antibodies to one class of EBV-antigens than did the children who did not develop the lymphoma.[15] That is, for children in the portions of the world in which EBV-associated Burkitt's lymphoma is endemic, a high titer of antibodies to a given set of EBV-encoded antigens represents a 30-fold risk factor for developing Burkitt's lymphoma.[15]

Do these findings prove that EBV causes Burkitt's lymphoma? No, they do not; proof in such cases for which direct experiments are not feasible ultimately comes from the accretion of supporting findings in the absence of confounding data. The World Health Organization study did, however, make it unlikely that EBV is a passenger virus that merely replicates well in tumor cells, because the antibody titers were elevated 7 to 54 months before tumor detection.[15] Similar prospective surveys were carried out in China and identified antibodies of the IgA class to the same set of EBV antigens as a risk factor for developing NPC.[16]

The association of EBV with Burkitt's lymphoma and NPC and the demonstration that EBV causes the bulk of infectious mononucleosis have led researchers to consider other diseases with which EBV might be associated. During the last 20 years, EBV has also been linked to post-transplant lymphoproliferation disease (PTLD),[17] oral hairy leukoplakia,[18] approximately one third to one half of Hodgkin's disease,[19,20] and one tenth of gastric carcinomas.[21] These linkages have been made not only through serology, but also by molecular genetic analyses that render the linkages more robust. The latter analyses have been made possible by the elucidation of the molecular virology of EBV in cell culture.[22]

EBV is a herpesvirus; it has a double-stranded DNA of 165,000 to 170,000 base pairs[23] and encodes approximately 80 genes[24] (Fig. 11-1). Like other herpesviruses, EBV has two distinct phases to its life cycle. It can infect cells, express a small subset of its genes (see Fig. 11-1), and cohabit with the cell without killing it. This is its "latent" phase. EBV can also emerge from its latency, express all or most of its genes, amplify its DNA, assemble progeny virions, and kill its host cell by lysis. This is its "lytic" phase. Unlike neurotropic herpesviruses such as herpes simplex virus type 1 and varicella zoster virus, EBV in its latent phase need not be maintained in a nonproliferating host cell. Rather, it has the capacity to both initiate and maintain proliferation in at least the B-lymphocytes that it infects in cell culture and at early stages of primary infection in vivo.[25,26] It is EBV's ability to affect proliferation and survival of its infected host cell that likely renders it oncogenic.

EBV induces and maintains infected B-lymphocytes to proliferate by maintaining its DNA extrachromosomally and expressing at least five viral genes that regulate expression of both viral and cellular genes and control viral DNA replication.[27] EBV-infected cells that contain intact viral DNA and express two or more viral genes are hallmarks of all EBV-associated diseases. The identification of viral DNA and of viral gene products, our gradual appreciation of the functions of these viral gene products, and the immune responses to them now constitute much of the persuasive evidence linking EBV causally to its associated cancers.

EBV clearly can induce and maintain proliferation of infected B cells. Genetic experiments in which two viral genes, *EBNA2* and *LMP1* (see Fig. 11-1), within the context of the virus are expressed conditionally demonstrate that each gene product when assayed alone needs to function for infected B cells to continue to proliferate.[28,29] These observations are particularly telling because they help to explain the multistep evolution of Burkitt's lymphoma. Many other genetic analyses have shown that three additional viral genes—*EBNA1, EBNA3a,* and *EBNA3c* (see Fig. 11-1)—contribute to some facet of cell proliferation.[27] *EBNA1* has recently been found to be required for survival of infected cells and, at least indirectly, to be required to maintain cell proliferation as well.[30] *EBNA3a* acts at the stage of initiation of proliferation.[31] All of these viral "transforming" genes except for *EBNA1* are recognized by the host's cytotoxic T-cell response.[32] *EBNA1* encodes a stretch of gly-gly-ala residues that inhibits its proteolytic degradation and subsequent presentation by class I HLA molecules.[33] The host's cytotoxic response is sufficiently robust that patients recovering from infectious mononucleosis lack B cells that express RNAs encoding these transforming genes. The surviving EBV-infected B cells are in distinct, differentiated states in which they no longer proliferate and detectably express only another viral protein, *LMP2* (see Fig. 11-1), a viral gene product that is not required for cellular proliferation.[34,35]

The failure of this robust immune response to EBV's transforming proteins contributes to PTLD. The infected proliferating B cells in these immunosuppressed patients express all five of EBV's transforming proteins.[6] Two kinds of successful treatments for PTLD demonstrate the critical role of the patient's immune response in failing to limit this "iatrogenic" tumor. First, if immunosuppression can be reduced for the patient such that the transplant is still tolerated, PTLD may regress. Second, several groups have amplified the donor's T cells that are cytotoxic for EBV's transforming proteins prior to bone marrow transplantation. Treatment of PTLD patients with these syngenic, specific T-killer cells has cured the disease.[36] These encouraging findings underscore the important role of the immune response in limiting the survival of EBV-infected cells.

Two startling features of tumor cells that have been freshly isolated from Burkitt's lymphoma biopsies help to explain the evolution

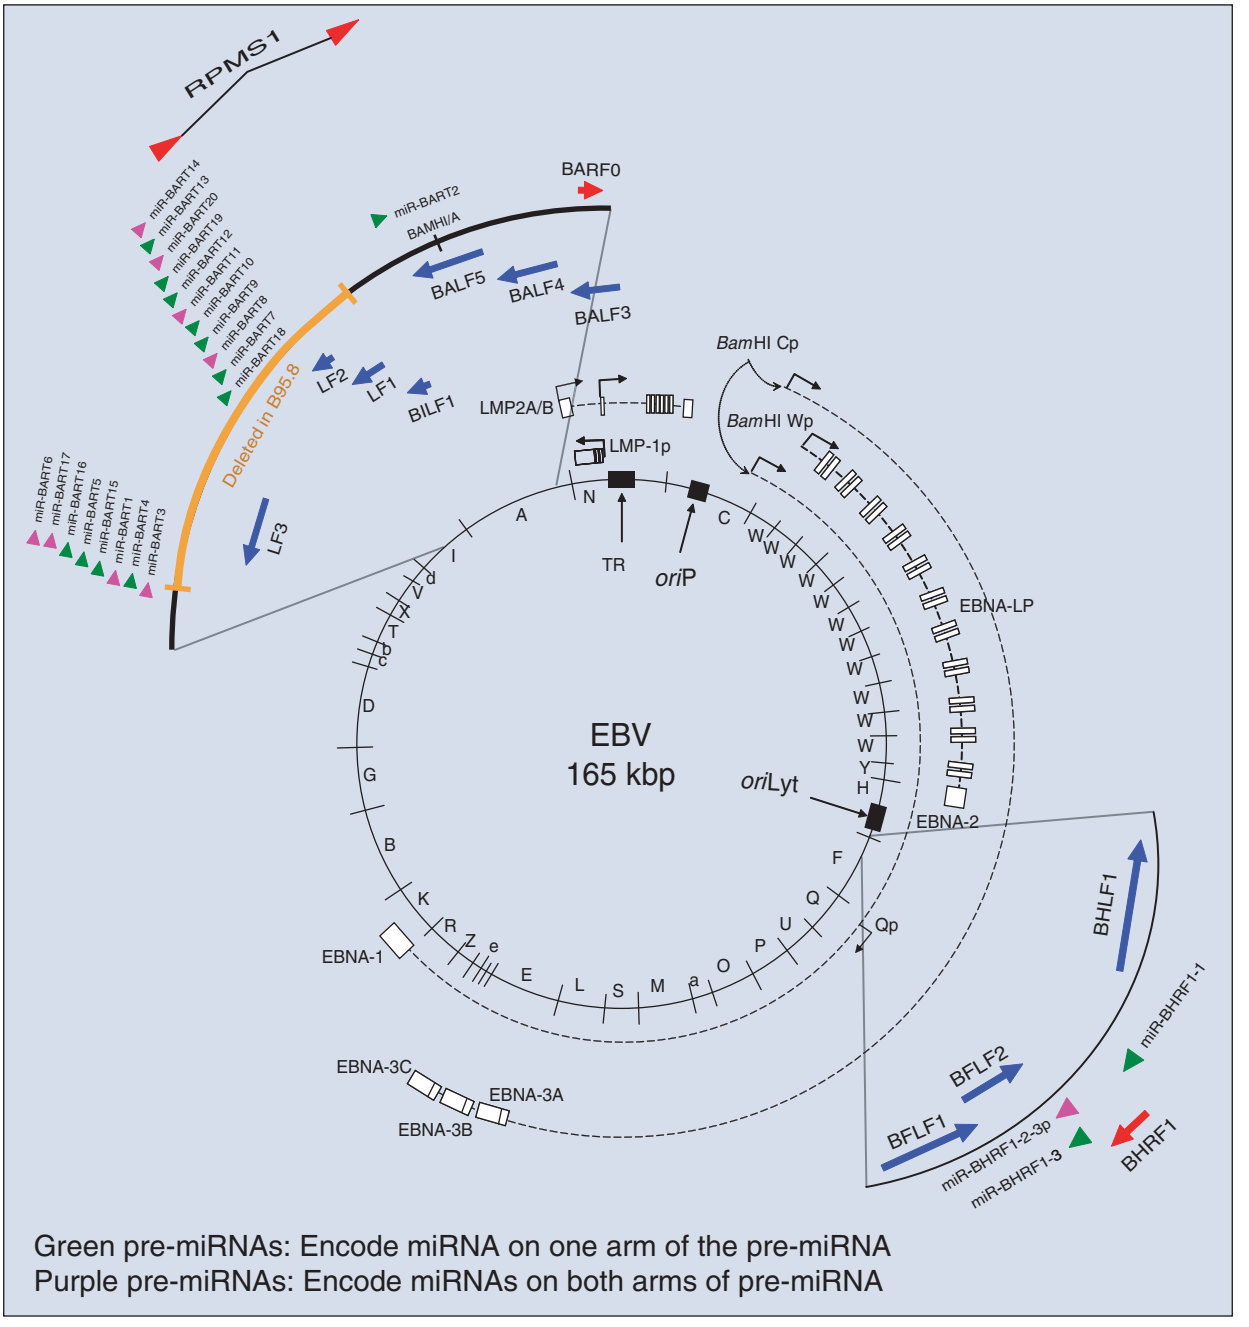

Figure 11-1 • Map of the EBV genome. The genome of the B95-8 strain of EBV in its circular double-stranded DNA form of 165 kbp is depicted as it is found in latently infected B cells. The genome is a linear DNA within the viral particle and is circularized on infection at its terminal repeat (TR) elements found at the ends of the linear molecule. The segments of the circle denoted with *letters* represent the fragments of the DNA generated by cleavage with the BamHI enzyme and used to map EBV's open reading frames. The EBV genome encodes approximately 100 genes. Shown as *boxes* are the exons for coding segments of those viral genes that are expressed in B cells infected in vitro, including *EBNA1, EBNA2, EBNA3A/B/C, EBNA-LP, LMP1,* and *LMP2A/B.* The boxes denoted EBERS are the two small RNAs that are encoded by EBV. *Dashed lines* represent primary transcripts originating from viral promoters denoted with a lowercase p. Also shown are the positions of the origins of replication, OriP and OriLyt, that support the latent and lytic replication of the viral genome, respectively. The *expanded arcs* represent the two regions of EBV DNA found recently to encode miRNAs (miRNAs derived from the BHRF1 and the BART transcripts). Many of these miRNA genes are deleted in the B95-8 strain.

of this tumor when considered in the context of EBV's transforming genes and the immune response to them. These tumor cells express only *EBNA1* among the required viral transforming proteins, yet they proliferate.[37] They also display a chromosomal translocation between one of three human immunoglobulin loci and the c-myc proto-oncogene.[38,39] The juxtaposition of an immunoglobulin locus to c-myc drives expression of the proto-oncogene in these B cells, as it does in murine plasmacytomas that display similar translocations.[40] These observations can be arranged to provide a satisfying, though necessarily speculative, model for the genesis of Burkitt's lymphoma. First, EBV infects young children living in regions of central Africa in which malaria is endemic.[41] The malaria is a T-cell

immunosuppressive that decreases the children's ability to limit proliferation of infected cells.[42] Youngsters with severe infections do have increased antibody titers to viral antigens but have more proliferating B cells and are at increased risk for the chromosomal translocations, fostered by the recombination mechanism, that occur in B cells and use signals at immunoglobulin loci.[43] A rare immunoglobulin/c-myc translocation provides the cell constitutive proliferative signals that can substitute for those provided by EBV's *LMP1, EBNA2, EBNA3a,* and *EBNA3c.* A developmental switch occurs in a cell such that these four viral transforming genes are not transcribed, *EBNA1* is transcribed from a different promoter, and the cell continues to proliferate but can no longer be recognized by the host's residual cytotoxic T-cell response. The cell proliferates, acquires additional mutations (often mutations inactivating *p53*), and evolves rapidly into a Burkitt's lymphoma.[44] This model fits well with what we know today. However, each of the cancers with which EBV is causally associated is sufficiently idiosyncratic to make it impractical to extend this model beyond Burkitt's lymphoma.

All of EBV-associated cancers do contain EBV DNA and express *EBNA1* and EBERs (see Fig. 11-1), which are small viral RNAs, and some also express *LMP1.*[45] We know less about the genesis of these other tumors, but recent findings with NPC provide evidence for an unexpected contribution of EBV to its etiology. Huang and colleagues have shown that EBV infects cells that already can be distinguished as being "preneoplastic" in the evolution of NPC.[46] This finding might lead one to think that EBV is merely a passenger in this tumor. However, 100% of NPC tumors are infected with EBV, making it likely that the virus contributes some selective advantage to infected, preneoplastic cells such that they are the ones that evolve into tumors. It is not known what this selective advantage is, but it is reasonable to hypothesize that EBV could provide these cells proliferative or survival signals, as it does to Burkitt's lymphoma cells during their evolution.

Two additional cancers associated with EBV differ dramatically from Burkitt's lymphoma, NPC, and PTLD in their viral association. Whereas effectively all cases of Burkitt's lymphoma in Africa, all of NPC, and all of PTLD are EBV-positive, only approximately 30% to 50% of cases of Hodgkin's disease and 10% of cases of gastric carcinoma are EBV-positive.[20,47] This lack of a general association makes it difficult to demonstrate a causal role for EBV in the fraction of tumors that are virus-positive. However, in the cases that are EBV-positive, it has been claimed that all of the tumor cells have been infected. This finding depends on single-cell assays to detect viral gene products such as the EBERs and the *LMP1* protein in the tumor cells. Such assays are not 100% efficient, nor is the identification of tumor cells perfect, so it is accurate to conclude only that the bulk of the tumor cells are infected. Were we to know that all of the tumor cells in a given patient are EBV-positive, then we could conclude that viral infection was an early event in the evolution of that tumor. The retention of this extrachromosomal genome would favor the virus's contributing a selective advantage to the evolving tumor cell such that the rare infected cell outgrew any uninfected, precancerous siblings. Any contributions of EBV to virus-positive Hodgkin's disease and gastric carcinoma are therefore uncertain. The strongest evidence for there being some viral contribution is the recognition that EBV does contribute to the other cancers for which most or all cases are EBV-positive.

The many clinical and basic scientific studies of EBV and its associated cancers can be extracted to yield some lessons for tumor viruses in general. First, the viral genomic nucleic acid remains in tumor cells and expresses one or more viral genes. Second, the virus contributes information to infected cells, which provides them a selective advantage in evolving towards tumor cells. However, this information is not sufficient for tumor formation. Additional, multiple rare events must occur in the infected cells for them to evolve into tumors. These additional essential events explain both why only a fraction of the people who become infected with a given tumor virus develop the associated tumors and why they usually do so only after long delays.

Hepatitis B Virus

Hepatitis B virus (HBV) was identified by virtue of its being recognized as an antigen in sera of donors by antibodies in sera of other infected donors.[48] Thoughtful analyses by Blumberg and his colleagues correlated the presence of the antigen with hepatitis, a correlation that was strengthened by the seroconversion of a lab member who contracted hepatitis.[48] By the late 1960s, blood that was donated to blood banks was screened for the antigen, positive samples were removed, and only negative samples were used for transfusions. This early insightful intervention led to a significant reduction in transfusion-associated hepatitis.[49] Blumberg and his colleagues also demonstrated a striking association between HBV, antibodies to its antigens, and hepatocellular carcinoma (HCC).[48] These early findings have been built on to demonstrate that HBV does cause HCC, which is either the fifth or sixth most common cancer in people today. HBV is estimated to cause between 50% and 70% of the approximately 500,000 new cases of HCC in the world each year.[50,51] Most of the rest of these cases are attributable to hepatitis C virus (HCV), a member of the flavivirus family.

Two kinds of data have established HBV's causal role in HCC. A prospective survey of 22,707 male civil servants in Taiwan was initiated at the end of 1975.[52] Of these subjects, 3454 were found to be positive for HBV's surface antigen (HBsAg), indicating that they were chronically infected with HBV. The whole group of 22,707 members was observed on average for 8.9 years. By the end of 1986, 152 of the 3454 HBsAg-positive men had developed HCC, while only 9 of the 19,253 HBsAg-negative men had developed it. The relative risk of the HBsAg-positive cohort for developing HCC was therefore 100 times greater than that for the negative group.[53] This prospective epidemiologic study provides robust data that the presence of HBV is strongly associated with the development of HCC.

The second kind of data demonstrating that HBV can cause HCC has been derived by removing HBV from a population and determining whether the incidence of HCC declines in the population. Taiwan began vaccinating children in 1984, first with a plasma-derived antigen and eventually with a recombinant antigen. Between 1984 and 1994, the incidence of infection as monitored by the presence of HBsAg dropped from 9.8% to 1.3% among children 12 years or younger.[54]

Similar findings have been made in the Gambia, where children who are vaccinated during their first year develop into only 10% as many chronically infected 9-year-olds as do unvaccinated children.[55] HCC is a cancer that peaks in people between 50 and 60 years of age but does occur rarely in children from 6 to 14 years of age. The incidence of HCC in this latter population in Taiwan dropped from 0.64 per 100,000 per year when averaged from 1981 to 1990 to 0.36 per 100,000 per year when averaged between 1990 and 1994 and is statistically significant ($P < 0.01$).[56] This decline presumably reflects the eightfold reduction of chronic HBV infection in children who are at risk for developing HCC. The finding that removing a virus from a population decreases an associated cancer in that population is compelling evidence that the virus contributes causally to the cancer. We can expect that a decline of HCC in the vaccinated adult population will be more striking in decades to come.

Although it is clear that HBV causes HCC in people, it is not clear how it does so. Researchers now invoke two distinct contributions, direct or indirect, to explain HBV's oncogenesis. HBV encodes one gene, pX (Fig. 11-2), that can affect viral and cellular transcription and has been proposed to contribute directly to oncogenesis. HCC in general evolves in patients who have marked liver cirrhosis. HBV can contribute to that cirrhosis by providing targets for T-cell killing and thereby could contribute indirectly to oncogenesis. The

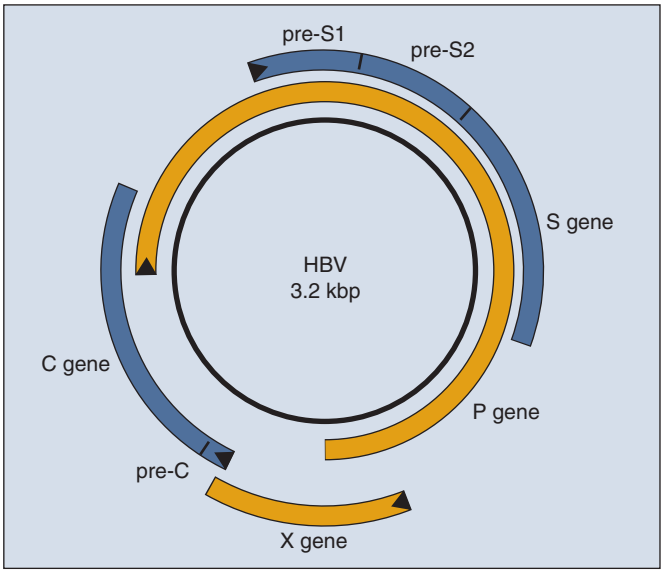

Figure 11-2 • Map of the HBV genome. The 3200-bp genome of HBV is a circular double-stranded DNA in infected cells *(black)*. The genome in the viral particle is partially double-stranded DNA because of an incomplete extension of the plus-strand by the viral DNA polymerase, P. Shown as *colored boxes* are the coding segments for the structural *(blue)* and nonstructural *(yellow)* viral genes. The arrowheads represent the sites at which translation of the viral proteins initiates. These viral proteins are translated from multiple mRNAs: one for Pre-S1, Pre-S2, and S; one for Pre-S2 and S; one for core and P; and one for x. See Ganem and Schneider[280] for details of HBV's genome and life cycle.

molecular virology of HBV has illuminated the viral life cycle but has yet to identify its mode of oncogenesis.[57] HBV is a small, enveloped virus with a double-stranded DNA genome, one strand of which is incomplete. The complete viral duplex DNA is 3.2 kbp in length (see Fig. 11-2), serves as a template for transcription by RNA polymerase II, and is replicated via reverse transcription of a greater than full-length RNA transcript of approximately 3.4 kbp. All members of the hepadnavirus family preferentially infect hepatocytes. This tropism is apparently mediated by a cellular receptor that is expressed in hepatocytes and by viral transcription being controlled in part by cellular transcription factors principally expressed in hepatocytes. Unlike most DNA viruses, HBV undergoes its complete life cycle to yield progeny virions, which exit from hepatocytes via secretory pathways, without killing the host cell. This anomalous behavior of hepadnaviruses means that in the absence of an exogenous function of the host, an infected hepatocyte could survive, carry out its normal functions, and release large amounts of infectious HBV for long periods of time. Accordingly, some chronically infected people do have large amounts of HBV in their sera.

Mammalian hepadnaviruses encode pX, which is not found in the avian species; only the mammalian members are known to cause HCC in their hosts. This correlation has focused interest on pX as being likely to contribute to the oncogenesis of mammalian hepadnaviruses. It is difficult to gauge pX's potential role in HBV's oncogenesis; however, much information about it is in the literature, yet no ready synthesis of this information explains such a role. Most HCC tumor biopsies retain viral sequences encoding pX,[58] but few express the protein detectably.[59] It has been proposed that pX associates with *p53* and inhibits its activation of apoptosis[60]; however, pX is not detected in HCC biopsies,[59] and between 30% and 90% of such biopsies have mutations in *p53*.[58,59] The viral protein pX in studies in cell culture can bind one subunit of RNA polymerase II as well as TFIIB.[61,62] It also associates with Smad4, an integral member of the TGF-β signaling pathway, to foster this pathway's signaling.[63] How these different transcriptional activities of pX might contribute to the evolution of HCC is unclear.

HBV is often integrated in HCC tumors,[64] and it has been proposed that integration of the viral DNA could affect transcription of nearby cellular genes. This suggestion has been strengthened by the recognition that the woodchuck member of the hepadnavirus family does contribute to HCC via insertional mutagenesis.[65] However, HBV has not been found to integrate at sites that can be interpreted to affect its oncogenesis. In addition, HBV DNAs cloned from HCC biopsies have been tested and found not to score as enhancer sequences in hepatoma cells in culture.[66]

The hypothesis that HBV contributes to the development of HCC indirectly by inducing rounds of cirrhosis and subsequent liver regeneration is appealing. HBV infection can be acute or chronic; it appears that acute infection correlates with a robust cytotoxic T-cell response to all viral antigens, while chronic infection correlates with a weak T-cell response.[67] These cytotoxic responses do lead to death of hepatocytes; however, experiments in mice that are transgenic for HBV genes and in infected chimpanzees indicate that there is also a potent noncytotoxic mechanism for limiting viral expression in infected hepatocytes.[68,69] In these experiments, immune cells release γ-interferon, which by some means inhibits viral gene expression and promotes loss of viral DNA from infected cells.[68,69] The administration of IL-18 limits viral replication efficiently in a transgenic mouse model by inducing production of both type 1 and type 2 interferons.[70] Chronic, not acute, infection correlates with the eventual development of HCC. How these two modes of eliminating infected cells would be balanced to yield long-term or chronic infection, the resulting cirrhosis, and the concomitant hepatocellular regeneration required for the accumulation of mutations predisposing to HCC is not known.

A role for cytotoxic T cells in the evolution of HCC has been modeled in mice that are transgenic for HBV surface proteins (see Fig. 11-2). These mice are tolerant to these viral antigens, but when the mice are reconstituted with syngeneic, nontransgenic bone marrow and subsequently challenged with syngeneic, immune, nontransgenic splenocytes, they develop cirrhosis and maintain cytotoxic T cells that are specific for HBsAg.[71] These animals have long-term liver damage and develop HCC by 18 to 20 months of age.

There are two consequences of the model in which HBV contributes to HCC indirectly. The first is that HBV's oncogenesis should be limited to the liver because it depends on the liver's capacity to regenerate to provide the proliferation required to accumulate mutations that predispose to cancer. HBV does cause only HCC. Second, no function of HBV would be required to maintain proliferation of tumor cells. This latter consequence would mean that therapies targeting functions such as pX's enhancement of transcription would be ineffective.

Human Papillomaviruses

Cervical cancer is caused by human papillomaviruses (HPVs). Over 100 genotypes of HPVs have been identified to date. Most HPV genotypes infect squamous epithelia lining the skin; a subset are mucosotropic and infect stratified, squamous epithelia lining the anogenital tract and oral cavity. A subset of these mucosotropic HPVs, the so-called high-risk HPVs, are associated with more than 99% of human cervical cancers, other anogenital cancers, and a subset of squamous carcinomas of the head and neck, particularly those of the oropharynx. HPV16 and HPV18, the high-risk HPVs that are most common in cancers, are present in over 85% of human cervical carcinomas. The mucosotropic HPVs are thought to be transmitted sexually. The association of specific mucosotropic HPVs with human cancers was first recognized in the 1980s when Harald zur Hausen and associates at the German Cancer Research Institute in Heidelberg detected the presence of then novel HPV genotypes in human cervical cancers and in cell lines derived from such cancers.[72,73]

In these cell lines, which include HeLa cells, the HPV DNA is often integrated into the host genome, and only a subset of viral genes, *E6* and *E7,* is expressed.[74,75] This discovery led to the hypothesis that HPV *E6* and *E7* genes contribute to cervical cancer, a premise that is now well supported by experimental research.

An association of papillomaviruses with cancer was first demonstrated in the early 1930s with the recognition that a subcellular, transmittable (i.e., infectious) agent causes squamous carcinomas in cottontail rabbits.[76] The agent was later identified to be a virus, cottontail rabbit papillomavirus, that induces warts in the rabbits. A subset of these infected rabbits develops cancers at the original site of cottontail rabbit papillomavirus infection. Other animal papillomaviruses induce frank cancer. Bovine papillomaviruses (BPV), which represent a class of papillomaviruses that induce fibropapillomas, characterized by hyperplasia of both the dermal fibroblasts and epidermal epithelial cells, can induce epithelial tumors of the alimentary canal in cows.[77] Such tumors are thought to arise when animals ingest bracken fern, which contains quercetin, a potent chemical carcinogen.[78–80] Thus, papillomaviruses and chemical carcinogens act together to induce tumors in cattle.

The study of papillomaviruses in the laboratory began in earnest in the late 1970s when Doug Lowy, Peter Howley, and their colleagues at the National Institutes of Health in Bethesda discovered that BPV-1 infects and transforms a mouse fibroblast cell line, C127, in cell culture.[81–83] The parental C127 cells, while immortalized, are contact inhibited. Infection by BPV-1 or transfection of C127 cells with a bacterial recombinant plasmid containing the entire BPV-1 genome yields foci of cells that are no longer contact inhibited. Transformed C127 cells harbor the viral genome as a nuclear plasmid and express viral early genes. The viral gene products *E5* (E referring to "early," 5 referring to the fifth largest translational open reading frame), *E6,* and *E7*[84–89] contribute to this transformation (Fig. 11-3). Thus, by the time HPVs were recognized as potential etiologic agents in human cervical cancers in the mid-1980s, a wealth of information pointing to the transforming potential of animal papillomaviruses in tissue culture had been established.

The seminal studies of zur Hausen and colleagues in the early to mid-1980s, identifying HPV DNA in cell lines derived from cervical cancers, checkmated a long-argued role for herpes simplex virus type II (HSV-II) in human cervical cancer. The posited role for HSV-II in cervical cancer arose from findings that cervical cancer patients often had antibodies to HSV-II, a sexually transmitted agent. However, their tumor cells lack HSV-II DNA, and today it is accepted that HSV-II does not contribute causally to cervical cancer. This early error provides an important lesson to researchers and epidemiologists who are trying to identify biologic agents that contribute to cancer. Proof by today's standards requires a smoking gun (in this case, the gun includes the viral genome and expression of viral genes in cancer cells).

In 1985, both the zur Hausen and Howley laboratories reported that HPV DNAs (see Fig. 11-3) were integrated in chromosomal DNAs in cell lines derived from cervical cancers.[74,75] This finding initially led to speculation that HPVs contribute to cervical cancer by integrating in or nearby to cellular genes that protect against cancer (i.e., inactivating tumor suppressor genes) or activate those cellular genes that can promote cancers (i.e., promoter/enhancer insertion at proto-oncogenes), akin to the mechanism of oncogenesis by certain oncogenic avian and rodent retroviruses. However, a role for HPV as an insertional mutagen in cancer is not consistent with its different sites of integration in different cancers, which have not been found to be near known or suspected tumor suppressor genes or proto-oncogenes. Rather, it is likely that the integration of the HPV genome leads to the selective upregulation of expression of two viral genes, *E6* and *E7* (see Fig. 11-3), which encode gene products that directly contribute to cancer. The mechanism for this upregulation remains poorly understood but might reflect (1) derepression of *E6* and *E7* expression from the viral promoter resulting from the disruption of a viral transcription factor, *E2,* that can repress their transcription[90]; (2) an increase in the stability of the *E6* and *E7* mRNAs resulting from the disruption on integration of an mRNA instability element present in the 3′ end of the *E6* and *E7* mRNAs[91]; or (3) increased transcriptional initiation from the viral promoter directing expression of *E6* and *E7* following integration of the viral DNA. The recognition of the increased expression of *E6* and *E7* in cervical carcinomas, coupled with the knowledge that *E6* and *E7* contribute to the transforming potential of BPV-1 in mouse fibroblasts, has provided the impetus to examine the tumorigenic activities of these two viral genes.

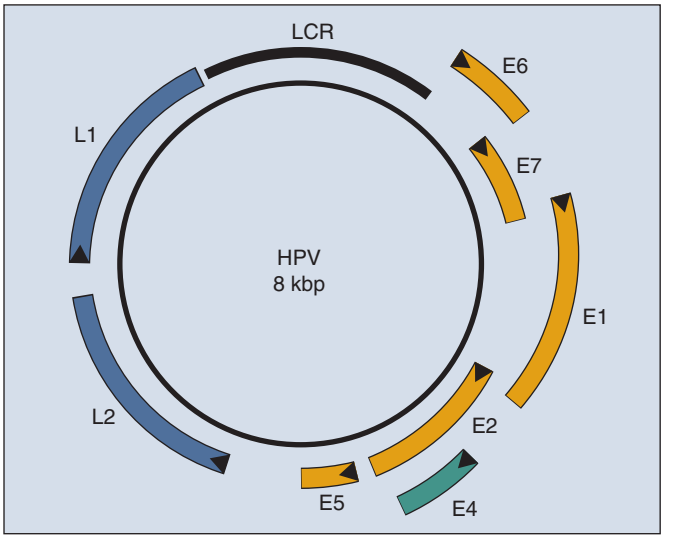

Figure 11-3 • Map of the HPV genome. Indicated by the circle is the approximately 7900-bp circular double-stranded DNA genome of HPV16 as found in viral particles and infected cells. Shown by the *boxes outside the circle* are the various translational open reading frames (ORFs) that encode the viral proteins. These include the early (E) and late (L) ORFs. Most early ORFs (those highlighted in *yellow*) are found expressed throughout the viral life cycle within stratified squamous epithelia, whereas the late ORFs, which encode the capsid proteins (highlighted in *blue*), and *E4* (highlighted in *green*), are selectively expressed in the productively infected, terminally differentiated epithelial cells. Note, among the early ORFs are *E6* and *E7,* the two ORFs encoding like-named oncoproteins that are commonly found expressed in HPV-associated anogenital and oral cancers. RNA synthesis of papillomaviruses is complex, yielding many potential mRNAs, all of which terminate at polyadenylation sites located at the end of the *E5* and *L1* open reading frames. The LCR or long control region encodes multiple *cis*-acting elements that regulate viral transcription and synthesis of viral DNA. See Howley and Lowy[281] for details of the HPV genome and life cycle.

Evidence for a critical role of increased expression of HPV *E6* and *E7* in the genesis of cervical cancers comes from multiple studies: (1) Cervical epithelial cells harboring integrated HPV16 DNA have a selective growth advantage over cells harboring normal extrachromosomal viral genomes, and this growth advantage correlates with the increased expression of *E6* and *E7.*[92] (2) *E6* and *E7* bind and inactivate the tumor suppressor gene products, *p53* and *pRB,* respectively.[93,94] (3) *p53* and *pRB* are wild-type in cell lines derived from HPV-positive cervical cancers, whereas they are mutated in HPV-negative, cervical cancer-derived cell lines.[95] (4) The expression of the *E6* and *E7* viral genes is required for survival of cervical cancer-derived cell lines.[96–101] Together, these observations strongly support the hypothesis that *E6* and *E7* contribute causally to human cervical cancers at least by blocking the functions of cellular tumor suppressors.

The *E6* and *E7* genes from the high-risk HPVs are transforming in tissue culture. They act independently or synergistically to immortalize multiple cell types, including human foreskin keratinocytes,

cervical epithelial, or mammary epithelial cells.[102–107] In addition, *E7* cooperates with an activated *ras* to transform baby rat kidney or human cervical epithelial cells.[108–110] The oncogenic properties of high-risk HPV *E6* and *E7* in vivo have been validated through the characterization of HPV transgenic mice.[111–118]

E6 and *E7* are best known for their ability to associate with the cellular tumor suppressors, *p53* and *pRB*, respectively.[93,94] The discovery of these interactions represents a major advance in our understanding of the mechanisms of oncogenesis: The inhibition of tumor suppressors predisposes cells to evolve into tumors. *E6* induces degradation of *p53*, at least in part via recruitment of a ubiquitin ligase, E6-AP.[119–121] *E6* inhibits *p53* protein's transcriptional regulatory activities in tissue culture cells.[122,123] Association of *E7* with *pRB* also promotes the degradation of *pRB*[124,125] and disrupts *pRB*'s capacity to bind and functionally inactivate the cellular E2F transcription factors.[110,126] While these abilities of *E6* and *E7* to inactivate *p53* and *pRB,* respectively, likely play an important role in their oncogenic potentials, it is important to recognize that *E6* and *E7* both can bind additional cellular factors, and certain of these interactions likely contribute to HPV-associated carcinogenesis.[127,128] Which of these many interactions contribute to oncogenic potential largely remains to be determined. In the case of *E6*, one group of cellular interacting partners implicated in *E6*-mediated carcinogenesis are the PDZ domain proteins such as Dlg and Scribble, proteins that were originally identified in *Drosophila* to be tumor suppressors.[128,129]

E6 proteins from multiple papillomaviruses bind to cellular proteins other than *p53* and *E6AP.* These other interacting partners include p300,[130,131] paxillin,[132,133] E6 target protein-1 *(E6TP1),*[134] interferon regulatory factor-3 (IRF3),[135] *E6* binding protein-1 (*E6BP1*),[136] Bak,[137] protein kinase PKN,[138] myc,[139] the mammalian homolog of *Drosophila* disk-large tumor suppressor gene product (DLG),[140,141] Scribble,[142] MAGI-1,[143] and MUPP1[144] In addition, *E6* can induce expression of telomerase activity by a yet-to-be-defined activity,[145–148] a property that correlates with *E6*'s immortalizing potential.

In addition to binding *pRB, E7* can bind to other cellular proteins, including p107 and p130, which are related to *pRB* protein,[149] and can interact with different members of the E2F family of transcription factors.[150,151] *E7* also is argued to complex with cyclins[149,152–154] and to inactivate cyclin-associated kinase inhibitors, p21 and p27.[125,155] Thus, *E7* can associate with and/or alter the activities of multiple cellular factors that themselves interact normally and thereby contribute to the normal regulation of the cell cycle. Still other interactions have been identified between *E7* and cellular factors, including S4 subunit of the 26 S proteasome;[156] Mi2-beta, a component of the NURD histone deacetylase complex;[157] the fork-head domain transcription factor MPP2;[158] the transcription factor AP-1;[159] insulin-like growth factor-binding protein 3;[160] TATA box-binding protein (TBP);[161,162] TBP-associated factor-110;[163] and a novel human DnaJ protein, hTid-1.[164] It remains unclear whether any of these additional interactions contribute to *E7*'s oncogenic potential.

There is a growing appreciation of HPV's role not only in anogenital cancers such as cervical cancer, but also in head and neck cancers of the oral cavity and in skin cancers.[165–168] The multiple interactions of *E6* and *E7* with cellular proteins that have regulatory functions is consistent with *E6* and *E7* contributing to cancers through multiple mechanisms. Studies in tissue culture strongly support the hypothesis that continued expression of *E6* and *E7* is required for the continued growth of cervical cancer cells[96–100] and, perhaps, with other cancers to which HPVs contribute causally.

Cervical cancers take decades to arise in most patients after initial infection with high-risk HPVs. During this time, the HPV must persist in the patient. Strategies that can interfere with viral persistence could prove effective in preventing the development of cancer. *E6* and *E7* are important to the replicative phase of the HPV life cycle and therefore for viral persistence, indicating that they are also appropriate targets for antiviral and antitumor drug development. Recent studies have used organotypic tissue culturing to recapitulate the life cycle of HPVs in fully differentiating, stratified squamous epithelial cells. These studies have implicated *E7* in reprogramming cells within the terminally differentiating compartment of the epithelia to support the amplification of the viral DNA genome, likely through its inactivation of *pRB.*[169] *E6*'s inactivation of *p53* might be necessary for viral replication by inhibiting cellular stress responses elicited by *E7*'s inactivation of *pRB.*[170] At least two more HPV proteins, *E1* and *E2* (see Fig. 11-3), contribute to the replication of the viral genome.[171] *E1* and *E2* bind to an origin-of-DNA replication on the viral genome.[172] *E1* is a DNA helicase that unwinds the viral double-stranded DNA genome at its origin and, together with *E2,* recruits cellular DNA replication proteins that then synthesize the viral DNA.[172–174] Thus, *E1* and *E2* both represent potentially useful targets for intervening in the viral life cycle.

One desirable, long-term public health strategy for dealing with this and other human tumor viruses is generation of an effective, prophylactic vaccine for prevention of initial infection. Such a vaccine has recently received FDA approval in the case of the mucosotropic HPVs that are implicated in cervical cancer, although several issues complicate the potential success of this strategy. This vaccine is discussed later. Another approach that is being pursued is the generation of microbicides that could be used to prevent infection by sexually transmitted HPVs.

Human T-Cell Leukemia Virus I

Adult T-cell leukemia/lymphoma (ATLL), a tumor of $CD4^+$ T cells, is caused by human T-cell leukemia virus type I (HTLV-I), the only retrovirus that is now accepted as being oncogenic in people. HTLV-I is found worldwide, with approximately 10 million to 20 million people estimated to be infected today. This number is likely an overestimate because of a failure to distinguish serologically between HTLV-I and HTLV-II.[175,176] HTLV-I is particularly prevalent in restricted sites, including southern Japan, the Caribbean, and West Central Africa. ATLL is prevalent in those areas in which HTLV-I is common, and it is estimated that as many as 5% of HTLV-I-positive carriers will develop ATLL in their lifetime.[177] HTLV-I also causes a progressive, paralytic myelopathy termed *HTLV-I-associated myelopathy* or *tropical, spastic paraparesis.* This neurologic disorder appears to arise preferentially in patients whose HLA haplotypes fail to limit viral load.[178]

The data that link HTLV-I causally to ATLL are varied. ATLL can occur in familial clusters. It is characterized by an average age at onset of 56 years and proves rapidly fatal, 50% of patients dying within 6 months of diagnosis.[177] Patients generally have antibodies to HTLV-I-encoded proteins,[179] and in 88 of 88 primary biopsies of ATLL examined, all had single copies of integrated HTLV-I proviruses.[180] The presence of the provirus of HTLV-I in all of the tumors makes it likely that infection with the virus is an early, contributing event in the evolution of the tumor. The presence of ATLL in familial clusters is consistent with the routes of transmission of HTLV-I. HTLV-I is passed from male to female via semen and from mother to child by breast milk. The latter route has been demonstrated prospectively. Encouraging carrier mothers to refrain from breast-feeding has decreased transmission of HTLV-I to their children by 80%.[181] It appears highly likely that this form of public health intervention will lead to a corresponding decrease in ATLL in Japan in the future. Such a decrease would constitute formal proof of the oncogenic role of HTLV-I in ATLL.

HTLV-I clearly differs from the highly oncogenic animal retroviruses that encode oncogenes derived from cellular proto-oncogenes. HTLV-I is a complex retrovirus that encodes multiple open reading frames in addition to the *gag, pol,* and *env* genes that are common to simple retroviruses (Fig. 11-4). However, none of these additional viral genes is obviously related to known proto-oncogenes, and all are thought to affect the viral life cycle either directly or indirectly by

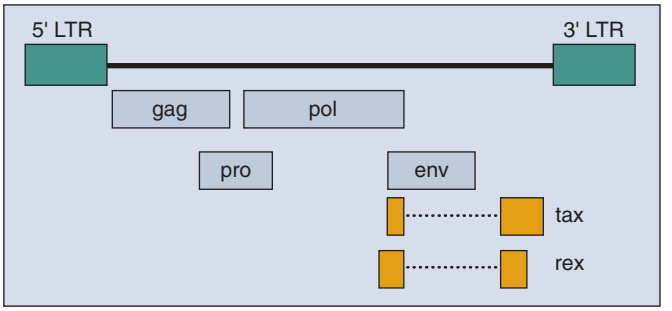

Figure 11-4 • Map of the HTLV-I genome. Indicated by the line drawing is the approximately 9000-bp DNA proviral form of the HTLV-I genome as it is found integrated into the host genome. The genome as present in the viral particle consists of two copies of a single-stranded positive-strand, RNA. Shown are the long terminal repeats (LTRs, *green*) flanking the unique region that contains the translational open reading frames (*boxes*) for structural *(blue)* and nonstructural *(yellow)* viral proteins. The LTRs contain *cis*-acting elements that are required for transcription and replication of the viral genome. The structural genes are transcribed late in the viral life cycle from the 5′ LTR while the nonstructural proteins are transcribed early from the 5′ LTR from different, spliced transcripts. See Green and Chen[282] for details of the genome and life cycle of HTLV-I.

affecting the host cell.[182,183] It is accepted that one viral protein Tax (see Fig. 11-4), which regulates both viral and cellular gene expression, is a major contribution of HTLV-I to leukemogenesis. It is also evident that viral infection precedes onset of ATLL by 50 years or more, that many cells are infected, and that only a minority of infected people develop this clonal tumor. These combined observations indicate that multiple rare events in an HTLV-I-infected $CD4^+$ T cell must occur for that cell to evolve into ATLL.

Multiple approaches demonstrate that Tax can transform cells in culture and be oncogenic in animal models. The introduction of a vector that expresses Tax into established, adherent rodent cells can transform them to grow in an anchorage-independent fashion.[184] Strains of rodent cells can be transformed with Tax in combination with the *ras* oncogene to yield cells that are tumorigenic in nude mice.[185] Tax has also been recombined into *Herpesvirus samiri* and has been introduced into resting human T cells. These infected cells can proliferate and yield infected, immortalized progeny, whereas the Tax-negative parental virus cannot do so.[186] In accord with these data, variants of HTLV-I from which the Tax gene has been deleted no longer can immortalize human T cells in culture.[187] These results in culture are paralleled and bolstered by others in transgenic animal models. Expression of Tax from the HTLV-I long terminal repeat, LTR (the viral promoter), in transgenic mice leads to mesenchymal tumors.[188] When its expression is directed to lymphoid cells, the transgenic animals develop leukemias.[189] However, the exact means by which Tax transforms cells in culture or is oncogenic in animal models is not obvious.

Tax can be considered a paradigm for viral proteins that affect host cells in that it has multiple, distinct functions that are not found in any one cellular protein. Apparently, HTLV-I during its evolution has assimilated multiple cellular activities in this one gene product. Tax can be viewed as having at least three kinds of activities: It activates transcription via NF-κB and CBP, the CREB (cyclic AMP response element-binding protein)-binding protein; it inhibits transcription, perhaps through binding histone deacetylase-1, HDAC-1; and it inhibits several tumor suppressor gene products.[182,190–194] Tax potently activates transcription from HTLV-I's own LTR[195] and activates the promoters for IL-2, IL-2 receptor α chain, and c-fos.[196–198] This transcriptional activation could obviously contribute to proliferation of an infected T cell. It also can activate the promoter for Bcl-x and thereby help to inhibit apoptosis.[199] Tax can positively regulate transcription by binding CREB and CBP as well as some members of the NF-κB family.[200–202] Tax not only binds members of the NF-κB family directly, but also can activate NF-κB's homing to the nucleus by binding to IκBα and promoting its degradation.[203,204] Some of Tax's protein : protein associations have been functionally validated through chromatin immunoprecipitations that have documented the binding of Tax, CREB, and CBP to HTLV-I's LTR in intact, HTLV-I-transformed T cells.[205]

Tax can also inhibit transcription. It has been shown to inhibit both expression of the β-DNA polymerase gene[190] and some promoters that are regulated by CBP/p300.[206] It has been proposed that the latter inhibition occurs by Tax's binding to CBP and effectively sequestering CBP such that it is unavailable to bind other DNA-binding transcriptional factors. It has also been shown that Tax binds HDAC-1 as measured by coimmunoprecipitations.[191] Were Tax to tether HDAC-1 to a promoter, the resulting localized histone deacetylation would presumably lead to its decreased support of transcription.[207]

A third activity of Tax is its inhibition of some cellular tumor suppressors. Tax has been shown to bind to and inhibit the function of p16INK4A.[192] p16INK4A binds cyclin-dependent kinase 4 (CDK4), a kinase that, when activated, can phosphorylate pRb, yielding release of E2F transcription factors and promotion of the G1 to S transition of the cell cycle. On binding p16INK4A, Tax can increase the kinase activity of CDK4 kinase.[192] p16INK4A is often found to be mutationally inactivated in tumors. Consistent with Tax's functionally inactivating p16INK4A, p16INK4A was shown to be wild-type in sequence in two HTLV-I-infected T-cell lines in which Tax is expressed but deleted in four uninfected T-cell lines.[192] Tax also appears to bind cyclin D3 and might thereby foster, by a second means, the activity of CDK4 and CDK6.[193] Tax's binding to p16INK4A and cyclin D3 would inhibit control of the cell cycle and promote cell proliferation. Tax can also inhibit the transcriptional activity of *p53* by an NF-κB-dependent mechanism that culminates in the phosphorylation of *p53* as certain residues.[194,208] Such an inhibition of *p53* is likely to limit its induction of apoptosis and increase the rate of survival of HTLV-I-infected, proliferating T cells.

The multiple activities of Tax likely contribute to HTLV-I's associated leukemogenesis but must be insufficient for the development of ATLL. Multiple T cells are initially infected by HTLV-I, but over the course of the 50 to 60 years of its development, only one infected cell and its progeny give rise to the tumor. The additional genetic and epigenetic events that are necessary for this evolution are not known. It is also clear that the expression of viral genes in infected cells is surprisingly low; measurements of RNAs encoding Tax indicate that between 0.1% and 10% of freshly harvested, infected T cells express any Tax message in vivo.[209] These findings indicate that the regulation of HTLV-I expression, be it at the level of T-cell development or immune response to viral antigens, is likely also to be critical to the development of ATLL.

Human Hepatitis C Virus

Human HCV is accepted as an etiologic agent for hepatocellular carcinoma (HCC) along with HBV. Approximately half of the cases in the U.S. are ascribed to HCV.[210] Infection with HCV constitutes a 20-fold risk for men in Taiwan to develop HCC.[211] HCV represents the most common chronic viral infection among blood-borne pathogens in the United States, where the rate of infection during the period from 1988 to 1994 was estimated to be 1.8%.[212] The World Health Organization estimates the worldwide infection rate to be 3%, yielding over 170 million infected individuals.[213] The rates of infection vary widely, with rates as low as 0.01% to 0.1% in Scandinavia and the United Kingdom and as high as 17% to 26% in Egypt.[212] Infection is thought to arise from contaminated blood, use of shared needles among intravenous drug users, organ transplantation, hemodialysis, sexual transmission, and vertical transmission. The establishment of sensitive tests for identifying contaminated

blood and blood products fortunately has now greatly reduced the rate of infection in the general population. As with people who are chronically infected with HBV, HCC in HCV-positive individuals correlates with chronic hepatitis and cirrhosis. Di Bisceglie has estimated that 20% of people who are chronically infected with HCV develop cirrhosis per decade, and by two decades, 2% to 7% of chronically infected people develop HCC.[214] It is argued that the hyperproliferative state that is induced by chronic hepatitis and cirrhosis leads to an accumulation of genetic changes and contributes to the onset of liver cancer. What specifically HCV contributes to this scheme is not known.

HCV is a flavivirus, indicating that it is unique among the human tumor viruses for having RNA as its only genetic material (Fig. 11-5). It was identified in 1989 during a search for the causal agent of non-A, non-B hepatitis.[215] This flavivirus contains a 9.6-kbp, positive-stranded RNA as its genome, which encodes a single translation product of approximately 3000 amino acids (see Fig. 11-5). This polyprotein is cleaved by both cellularly and virally encoded proteases to yield at least 10 proteins.[216] The study of HCV has been daunting for at least two reasons. Its sequence varies in infected people such that there are six recognized genotypes with multiple subtypes among patients and a spectrum of quasispecies within any one infected individual.[217] Members of these quasispecies within one patient vary by 1% to 2% in their sequence.[218] In addition, there is no available cell culture for HCV. Researchers have made heroic efforts to overcome this latter hurdle and have met with partial success.

In 1999, Lohmann and colleagues described the replication of a subgenomic derivative of HCV in a cell line derived from a human hepatocellular carcinoma.[219] These subgenomic replicons were difficult to establish, but once established, they exhibited bona fide characteristics of flaviviral nucleic acid replication. One thousand to five thousand molecules of plus-strand RNA were present in each cell; minus-strand RNA was present at 10% to 20% of the level of the plus-strand; and this viral RNA replication was insensitive to treatment of cells with actinomycin D.[219] This mode of nucleic acid replication in cells will allow the elucidation of the *cis* and *trans* elements it requires but with an unexpected twist. The efficient replication of the subgenomic derivatives of HCV requires mutations in at least two viral genes that enhance replication in cells but abrogate infectivity of intact HCV RNA.[220] Chimpanzees are the only nonhuman host for HCV. The parental strain of HCV that is used to derive the subgenomic replicons is infectious in this primate host, while a derivative of it, containing the mutations required for the efficient replication of the subgenomic replicons, is not.[220] This finding must limit the conclusions to be drawn from the analyses of replication of these mutated subgenomic replicons in cells. They also indicate that the generation of the many sequence variants that constitute the quasispecies within any one infected patient might contribute to the successful replication of HCV.

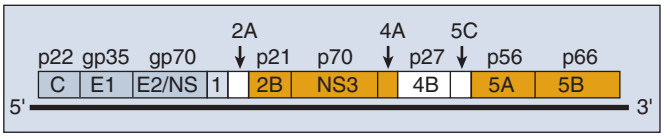

Figure 11-5 • Map of the HCV genome. The 9500-nucleotide-long positive-strand RNA of HCV is shown in *black.* It encodes a single 3000-amino-acid polyprotein that is proteolytically cleaved into mature proteins (indicated on the map by *labeled boxes* with alternative names indicated above the boxes) by virally encoded proteases (NS3/4A and possibly 2B). At the 5′ and 3′ ends are short noncoding regions that contain signals for replication of the viral genome. The 5′ NCR also contains an internal ribosome entry site. Structural proteins are shown in *blue.* Nonstructural proteins, including proteases, helicases and RNA polymerase, are shown in *yellow.* See Majo and colleagues[283] for details of HCV's genome and life cycle.

The lack of a cell culture host for infection with HCV and/or a practicable animal host has led researchers to seek chimeric animal models of infection. Researchers formerly developed a chimeric animal model for HBV, which has been adapted to the study of HCV. Mice that are transgenic for the plasminogen activator urokinase, expressed in the liver (uPA), have hepatocytes with a selective disadvantage such that transplanted, nontransgenic hepatocytes repopulate the liver.[221] When these animals are crossed with nu/nu mice, they not only can tolerate rat hepatocytes, but also support rat hepatocytes reconstituting their livers.[222] These findings paved the way for Petersen and colleagues to cross mice that are transgenic for uPA with mice that are null for Rag-2, which eliminates their B- and T-cell responses, and to repopulate their livers with woodchuck hepatocytes.[223] These chimeric animals now supported infection with woodchuck HBV and became chronically infected with 106 to 1011 virions per milliliter of serum.[223] Human hepatocytes can also repopulate the livers of uPA-transgenic animals as long as they cannot reject the xenograft. SKID mice that are homozygously transgenic for uPA accept human hepatocytes such that 50% or more of their hepatocytes are of human origin.[224] These animals can be infected with HCV such that 75% of them become persistently infected with 104 to 106 viral RNA molecules per milliliter of serum, and the infections can be passaged serially in them.[224] These reconstituted animals are obviously difficult to generate but should provide some insights into the life cycle of HCV and could serve as models in which to test inhibitors of HCV infection.

Evidence for a direct role of HCV in HCC has come from studies of the HCV Core protein. The HCV Core protein can cooperate with an activated form of the *ras* oncogene to transform primary rodent cells in tissue culture.[225] Mice that are transgenic for the HCV Core protein develop HCC.[226] Several potential mechanisms have been invoked to explain the transforming potential of HCV Core protein. It has been found to enhance cell proliferation through the stimulation of the mitogen-activated protein kinase[227,228] In addition, HCV Core protein can inactivate a transcription factor, lZIP, and this inactivation correlates with transformation in rodent cells.[229]

More recently, the Core protein has been found to activate STAT3, and this activation may contribute to its transforming potential.[230] Whether the HCV Core protein contributes directly to human HCC is uncertain. Neither replication of subgenomic replicons in cell culture nor infection of chimeric mice populated with human hepatocytes will allow ready testing of the possible role of the Core protein in HCV's oncogenesis.

Current treatments for HCV are unsatisfactory. The combination of interferon α plus ribovirin, a general antiviral nucleotide analog, has supported a clearance of detectable HCV in 40% of a treated group over 1 year. Those who responded had higher titers of the virus.[231] These observations may indicate that treatments with multiple, independently acting drugs are the most likely route to successful treatments for HCV.[232] In the United States, approximately 10,000 deaths are attributed to HCV each year, and today infection with HCV is the leading indication for liver transplantation.[212] Clearly, this mode of treatment is not practical for most infected people. The lack of satisfactory treatments for chronic HCV infection and its associated HCC make it important to continue to develop tractable means for studying HCV's life cycle and to elucidate its mode of oncogenesis.

Kaposi's Sarcoma Herpes Virus

The identification of Kaposi's sarcoma herpesvirus (KSHV) represents the culmination of much scientific detective work. Kaposi's sarcomas (KS) were known before the AIDS epidemic[233,234] but increased markedly among HIV-positive people. Researchers therefore looked for molecular evidence of an infectious agent present in KS lesions. In 1994, Chang and Moore and their colleagues used a newly developed enrichment procedure based on PCR to identify

DNA sequences that are present in KS but absent in normal cells. They identified a new herpesvirus, KSHV (also termed *human herpesvirus 8,* or HHV-8), which is related to EBV and *Herpesvirus saimiri.*[235] Retrospective studies indicate that KSHV was prevalent in different parts of the world prior to the spread of HIV and that in Africa, for example, the prevalence of KSHV has not changed. What has changed there is the incidence of KS; in regions where it was formerly infrequent, the incidence of KS rose threefold between 1988 and 1996.[236] Similarly, the frequency of infection with KSHV of certain cohorts in the United States has not altered with the advent of HIV,[237] but the incidence of KS has.[238] KSHV has also been detected in one class of lymphomas termed *body-cavity-based lymphomas* or *primary effusion lymphomas* (PEL)[239] and in an atypical lymphoproliferative disorder termed *multicentric Castleman's disease.*[240]

KSHV is now accepted as contributing causally to KS and PEL. Each of these malignancies displays intriguing features that are likely to reflect their viral etiology. Single-cell assays of early KS lesions have detected KSHV in a minority of cells that surround their vascular spaces, while in the more advanced, nodular lesions, more than 90% of the spindle cells characteristic of these lesions are KSHV-antigen-positive.[241] The viral antigen-positive cells also stain with antibodies against the VEGF receptor-3, indicating that they are lymphatic or proliferating endothelial cells.[241] That only a subset of the cells that are characteristic of early KS lesions appear to be infected with KSHV likely indicates that infected cells affect the development of their neighbors. This possibility is supported by the multiple cellular homologs of cytokines and receptors encoded by KSHV that may allow infected cells to interact with adjacent, uninfected cells.[242,243]

PEL cells are B cells in origin and, in six of seven cases examined, have nongermline immunoglobulin mRNAs, indicating that they are likely derived from B cells that have encountered antigen.[244] They often, however, fail to express B-cell activation antigens.[245] PEL cells usually, but not always, are coinfected with EBV.[239,245] The role of EBV in the etiology of this lymphoma has not yet been clearly determined. However, because EBV is often retained in these cells as they are propagated in vitro and is maintained in them in vivo, EBV is likely to provide the tumor cells some selective advantage.

KSHV encodes many genes with clear homologies to cellular genes, some of which are candidates for contributing to viral oncogenesis (Fig. 11-6). Three categories of these cellular homologs are particularly likely to be important for tumor development: cyclins, inhibitors of apoptosis, and cytokines and receptors. KSHV encodes

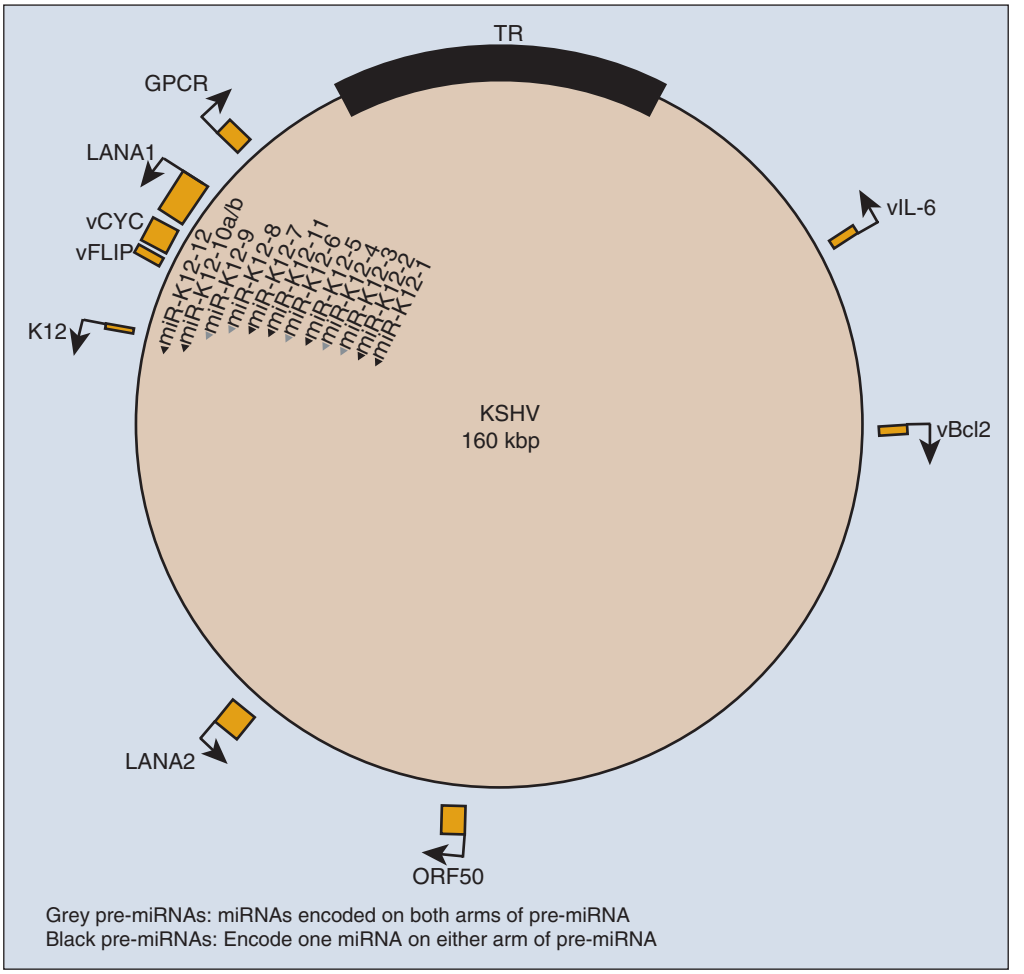

Figure 11-6 • Map of the KSHV genome. The genome of KSHV consists of approximately 160 kbp of linear double-stranded DNA in the viral particle. The viral genome becomes circularized on infection via the 20 to 40 copies of terminal repeats found at the ends of the linear genome. The terminal repeats also contain the origin of plasmid replication used during the latent phase of the viral life cycle. Shown by the *boxes* are positions of those viral genes that are expressed during latency and/or are thought to contribute to oncogenesis by KSHV. The *arrows* represent the positions from which the RNAs encoding the labeled proteins are expressed. Several of these primary transcripts are polycistronic. Shown on the inside of the circle are the positions of the recently identified miRNAs that are encoded by KSHV. These also are derived from a polycistronic message.

its own cyclin. Cellular cyclins bind specific, dependent kinases (CDK) whose activities promote progression through the cell cycle and are controlled by cellular inhibitors, including p16INK4A, p21CIP1, and p27Kip1. The KSHV-encoded cyclin can promote cellular proliferation in part by overcoming these cellular inhibitors. It does so apparently by extending the substrates that are phosphorylated by CDK6 to include p27Kip1.[246,247] Phosphorylation of p27Kip1 at position 187 leads to its downregulation and promotes passage through the G1 phase of the cell cycle. One measure of the activity of the KSHV cyclin CDK6 complex is that it can foster progression of nuclei isolated from cells in G1 to undergo DNA synthesis.[248] The KSHV cyclin can also induce cells to undergo apoptosis.[249] It is striking that in cells lacking *p53,* the expression of the KSHV cyclin promotes cells both to become aneuploid and to survive so that they continue to proliferate. In fact, mice that are transgenic for KSHV cyclin and are *p53*-null develop T- and B-cell lymphomas with a mean latency of 3 months, which is shorter than the latency for the *p53*-null mice alone.[250]

KSHV also encodes its own inhibitors of apoptosis: viral Bcl-2 and viral FLIP (an inhibitor of cellular FLICE, a protein that mediates Fas ligand–induced cell death) (see Fig. 11-6). The viral Bcl-2 shares its limited sequence homology with cellular Bcl-2 in those regions that are critical for inhibiting apoptosis and fails to dimerize with cellular Bcl-2 and Bcl-XL, thus avoiding regulation by potential cell-binding partners.[251] It can inhibit the apoptosis that is induced by efficient expression of KSHV's cyclin.[252] Viral FLIP can inhibit apoptosis mediated by the Fas pathway and induced by cytotoxic T-lymphocytes.[253] Finally, KSHV encodes homologs of cytokines and cytokine receptors (see Fig. 11-6). Its viral IL-6 may promote proliferation of PEL cells, although they appear to be dependent on cellular IL-6 and not viral IL-6 for their continued growth.[254] KSHV also encodes a G protein-coupled receptor, viral GPCR, which is likely to be pivotal for the development of KS. The expression of viral GPCR in endothelial cells in mice leads to KS-like tumors, while the individual expression of KSHV cyclin, KSHV Bcl-2, or KSHV FLIP does not.[255] What is particularly exciting is that cells that are inoculated into mice that express viral GPCR promote tumor formation by coinoculated cells that individually express viral cyclin, viral FLIP, or both.[255] These findings support a model in which viral GPCR contributes to the development of KS by affecting neighboring cells not infected by KSHV. The model is also supported by the findings that viral GPCR induces expression of the cellular VEGF receptor-2 in endothelial cells that proliferate in the presence of VEGF and that viral GPCR induces expression of VEGF.[256,257] Clearly, these observations define an autostimulatory loop in which KSHV GPCR alone can maintain proliferation of endothelial cells. These collected observations help to explain the viral contributions to KS and perhaps PEL. These explanations are not yet complete, however, because several of these putative viral oncogenes, including viral IL-6, viral Bcl-2, and viral GPCR, are expressed during the lytic phase of KSHV's life cycle. The lytic phase of a herpesvirus is traditionally thought to lead to death of the host cell. How these putative viral oncogenes could affect oncogenesis and be expressed only in cells that are destined to die soon is an enigma that has yet to be resolved.

Recent studies of cell lines derived from PEL and human endothelial cells are providing the foundation for understanding infections by KSHV in vivo. PEL cells maintain KSHV DNA extrachromosomally and consistently express the viral protein LANA-1 (see Fig. 11-6), which is required for viral plasmid replication.[258,259] In general, these cells support the latent phase of KSHV's life cycle and also express FLIP, the viral cyclin and the viral inhibitor of cellular FLICE, but few other viral proteins. Some PEL cell lines support an inefficient spontaneous conversion to the lytic phase of the viral cycle, which can be further induced by treatment of cells with tetradecanoyl phorbol acetate or introduction of a plasmid that includes ORF50 (see Fig. 11-6), a viral inducer of the lytic cycle.[260] The released virus is infectious on human dermal microvascular endothelial cells.[261,262] These dermal microvascular endothelial cell cultures can be passaged to yield populations in which all cells are infected, express LANA-1, assume a spindle-cell morphology, and can proliferate indefinitely.[262] The spindle shape is characteristic of cells in KS lesions in vivo. Staining of these infected dermal microvascular endothelial cell-derived spindle cells indicates that 5% to 10% of them spontaneously support early stages of KSHV's lytic cycle and 1% to 2% express genes diagnostic of the late stages of the viral life cycle.[262] If endothelial cells that are infected in vivo by KSHV display a similar distribution of cells supporting the latent, early, and late lytic phases of the viral life cycle, then the enigma of the oncogenic contribution of viral genes that are expressed only during the lytic cycle may be resolved. A sustained, spontaneous conversion of 5% to 10% of KSHV-infected cells to support the viral lytic cycle might allow enough infected cells to express enough KSHV GPCR to promote the bystander-dependent tumor evolution proposed by Bais and colleagues.[257]

TREATMENT AND PREVENTION OF VIRAL TUMORS

Tumors that are associated causally with viruses are treated variously: Surgical resections, when appropriate, are used in combination with chemotherapy and/or radiation therapy. These treatments are disappointing in that overall survival rates are often low and so far have not been able to capitalize on any specific antiviral therapies. Current survival rates after different therapies obviously vary with the malignancy, its stage, and the setting in which it is treated. For example, youngsters with Burkitt's lymphoma have a 4-year overall survival rate of 65%.[263] Approximately 45% of NPC patients remain disease-free after treatment for 10 years, but this value is highly dependent on the stage at which the NPC was diagnosed.[141] In the United States, 26% of HBV-positive, surgically resected HCC patients have a 5-year, local disease-free survival compared with 38% for the analogous HCV-positive group.[264] A retrospective study of German patients with a mix of HBV- and HCV-associated HCC found a median survival of 7 years.[265] The 5-year median survival for cervical carcinoma patients ranges from 65%[266] to 75% to 90%[267] in different studies. The median survival for patients once they have been diagnosed with ATLL is only 10 months.[268] The overall survival rates of KS patients who are HIV-positive have changed with the introduction of highly active antiretroviral therapies. Prior to this therapy, median overall survival was 13 months; with highly active antiretroviral therapies, it surpasses 28 months.[269] The median survival for PEL patients has been described as "dismal," but there are case reports of some combination therapies being helpful.[270] These actuarial findings indicate that developing antiviral therapies directed at those viral gene products that maintain tumor phenotypes is a highly desirable goal.

Early detection of premalignant disease has been an effective means for reducing the incidence of cervical cancer. The introduction of routine cytological (Pap smear) screening of women in the United States and other countries with well-developed health care systems has led to an approximate threefold decline in cervical cancers over the last 40 years. Pap smears represent a first-level screening tool for the clinician. Women with positive Pap smears are routinely subjected to further examination with histopathologic examination and, if necessary, removal of lesions. More recently, HPV DNA testing has emerged as an alternative means for identifying women who are at risk of developing cervical cancers, although the utility of this testing appears to be restricted to women 40 years of age or older. This restriction reflects the fact that many younger women who are sexually active will have nascent infections that will be detected by using the HPV DNA test but are not necessarily going to lead to cancer because many HPV infections will spontaneously resolve. The detection of high-risk HPVs in older women, on the other hand, is more likely to indicate the presence of persistent HPV infections, which are highly correlative with progressive cervical disease leading

to cancer. Another use of HPV DNA testing is as an adjunct screen for women with positive Pap smears, that is, to determine whether they are infected with high-risk HPVs associated with cervical cancer.

The ultimate goal, the development of effective vaccines that can prevent initial infection or induce the elimination of viral persistence, is being pursued for all human tumor viruses. Success or the glimmer of success has been achieved for two of them: HBV and HPV.

Hepatitis B Virus Vaccine

Although there are four serotypes of HBV, highly effective vaccines for HBV have been developed that consist only of its surface antigen, HBsAg. Today, this subunit vaccine is usually synthesized with a recombinant DNA that is expressed in yeast. Vaccines for HBV began to be used in the early 1980s, and since 2001, 129 countries throughout the world routinely vaccinate infants and/or adolescents against HBV.[271] These vaccinations are effective. The fraction of children who are infected with HBV has been reported to have declined between 7.5- and 10-fold in Taiwan and the Gambia, respectively.[54,55] This decline has been paralleled by a detectable drop in the frequency of HCC in children in Taiwan, an age group for which this viral tumor is rare.[56]

The current HBV vaccines apparently are free of unwanted side effects but can select for variants of HBV that are resistant to the neutralizing antibodies they elicit.[271] One domain of the HBsAg in particular elicits neutralizing antibodies efficiently, and mutations in it can allow for viral escape. The frequency of these escape mutants in populations of vaccinated children has risen significantly.[272] One means to overcome the selection for such escape mutants would be to generate vaccines for HBV that include more than the HBsAg as an immunogen. Such vaccines are now being developed.

Human Papillomavirus Vaccine

The second family of human tumor viruses for which an effective prophylactic vaccine has been developed are those human papillomaviruses that are associated with cervical cancer, other anogenital cancers, and certain head and neck cancers, in particular, HPV16 and HPV18. These two viruses account for approximately 85% of cervical cancers worldwide and, in a recent study, 16% of new infections.[273] Several HPV prophylactic vaccines, designed to prevent or eliminate acute infections by HPV16 and HPV18, have recently gone through clinical trials.[274] These vaccines are based on the production of virus-like particles (VLPs) composed of the major capsid protein of HPV16 and HPV18, L1, which self-assembles into icosahedrons (see Fig. 11-3). These L1-based VLPs induce neutralizing antibodies in vaccinated individuals. Preclinical studies with cottontail rabbit papillomavirus and canine oral papillomavirus demonstrated the effectiveness of VLP-based vaccines in protecting animals from cottontail rabbit papillomavirus and canine oral papillomavirus infection.[275,276] Clinical trials likewise demonstrated the effectiveness of HPV16 VLP-based vaccines in inducing neutralizing antibodies that are specific for HVP16 and preventing HPV16 infections and in reducing the incidence of premalignant disease.[277,278] One of these HPV vaccines, Gardosil, which is a product of Merck, received FDA approval in 2006 for administration to young women in the United States. It has also been approved for use in many other countries. A second vaccine, which is being developed by GSK, is expected to gain FDA approval in 2008. One issue that is of relevance to the effectiveness of these vaccines is the specificity of immune responses invoked by VLP-based vaccines for specific HPV genotypes. Approximately two dozen HPV genotypes are associated with anogenital cancers. VLP-based vaccines induce protective immunity that is highly specific for the genotype from which the VLP is generated. This specificity has led to the development of polyvalent vaccines composed of a mixture of VLPs generated with L1 proteins from multiple mucosotropic HPV genotypes. For example, Gardosil is a polyvalent vaccine that is composed of HPV16, HPV18, HPV6, and HPV11 VLPs. HPV6 and HPV11 are low-risk mucosotropic HPVs that induce genital warts but do not contribute to cervical cancer. It remains to be seen whether, once a population is protected from HPV-16- and HPV-18-induced cancers, other HPV genotypes arise to induce a greater incidence of cervical cancers than they currently cause. Studies now in progress are designed to increase the cross-genotype neutralizing capacity of the VLP-based vaccines. Incorporation of the minor capsid protein, L2, might contribute to this property, because neutralizing antibodies induced against L2 tend to be more generally effective at neutralizing multiple genotypes.[279] There is a concern whether the HPVs, particularly HPV16 and HPV18, will evolve to become resistant to VLP-based vaccines. Assuming a high effectiveness of the vaccines that are currently in development and their worldwide distribution and given the long latency of cervical cancer, it is estimated that prophylactic HPV vaccines will lead to a reduction of deaths due to cervical cancer no earlier than 2040.

12 Genetic Factors: Hereditary Cancer Predisposition Syndromes

Kenneth Offit, Peter Thom, and Donna Bernstein

SUMMARY OF KEY POINTS

- The discovery of inherited mutations of oncogenes and tumor suppressor genes associated with increased risk for cancer provides important clinical opportunities for early detection and prevention of common and rare forms of human malignancies.
- Syndromes of cancer predisposition often involve multiple organ systems, affect paired organs with bilateral or multifocal tumors, and have onset at an earlier age compared to nonfamilial tumors. The diagnosis of particular cancer predisposition syndromes can usually be confirmed with molecular genetic testing of patients who have hereditary malignancies. Genetic testing can then be extended to relatives as a predictive test to guide their preventive management.
- Medical, surgical, and radiation oncologists, genetic counselors, and allied professionals are playing a leading role in the integration of genetic testing into the practice of preventive oncology. This chapter reviews both common and more recently described familial cancer syndromes, with an emphasis on the clinical application of cancer genetic testing in the management of patients who have or are at risk for cancer.

Over the past decade, the availability of clinical testing for inherited mutations of cancer predisposition genes has had a major impact on the practice of clinical oncology.[1] As these genes were identified and characterized, guidelines for the responsible clinical translation of this information were developed by medical and surgical subspecialty societies (e.g., the statements of the American Society of Clinical Oncology in 1996[2] and 2003[3] and related educational materials[4–6]). These guidelines emphasized that in the process of offering a predictive genetic test to a patient or family that is affected by cancer, the provider and the individual who is being tested must be prepared to deal with all the medical, psychological, and social consequences of a positive, negative, or ambiguous result. These guidelines define the form and content of genetic counseling as a component of cancer risk assessment and management.

A selected set of syndromes of cancer predisposition, listed in Table 12-1, is reviewed in this chapter. More detailed discussions of breast and colon cancer susceptibility are found in the chapters that discuss these tumors. A more comprehensive list of syndromes is provided in Table 12-2. Whether offered by a physician, genetic counselor, or other health care professional, genetic testing for inherited cancer risk requires careful informed consent. The elements of informed consent for genetic testing are summarized in Box 12-1.

Genes whose alterations result in hereditary predisposition to cancers have been classified as oncogenes or tumor suppressor genes. The molecular mechanisms of these two classes of genes are presented in previous chapters. A minority of human cancer predisposition syndromes result from inherited mutations of oncogenes (e.g., *RET, MET, KIT*). The majority of cancer predisposition syndromes are due to inherited defects in tumor suppressor genes. The tumor suppressor genes have been subdivided into "gatekeepers" such as *APC, p53, Rb,* and *VHL,* which directly prevent runaway cell growth, and "caretakers" such as *ATM, MSH2,* and *MLH1,* defects which indirectly cause neoplasia by leading to increased mutations of other critical genes.[7] Yet a third class of genes, including *PTEN* and *SMAD4,* act as "landscapers," since defects in these genes cause alterations in the "terrain" for epithelial cell growth, leading to eventual neoplastic changes. Complicating this descriptive approach is the observation that the same gene may act as a "landscaper" for one tumor system and a "gatekeeper" for another, violating the principle of Occam's razor; furthermore, some recently characterized pathways do not fit any of these models. In practice, this etiologic nosology of genetic mechanisms is of less clinical relevance than are the phenotypes of these cancer susceptibility syndromes (see Table 12-2). For this reason, the discussion that follows is grouped by the major component tumors of the organ system that is primarily affected. The syndromes that are included in this chapter are the ones that are most commonly encountered in oncologic practice, as well as several recently defined entities associated with mutations of novel cancer susceptibility genes. The most common of these syndromes, predisposing to cancers of the breast, ovary, colon, and prostate, affect tens of thousands of Americans who are diagnosed with these cancers each year in the United States and result in increased risk for a second neoplasm for the millions of cancer survivors.

MAJOR SYNDROMES OF CANCER PREDISPOSITION

The major syndromes of cancer predisposition that affect adults include common syndromes associated with breast, ovarian, colon, and prostate cancer as well as a number of other less common but equally important cancer predispositions. Some of these syndromes, including multiple endocrine neoplasia type I, retinoblastoma, melanoma, and von Hippel Lindau syndrome, are described elsewhere in this text. For comprehensive reviews of these cancer predispositions, see the following sources: for multiple endocrine neoplasia type I, Lakhani and colleagues[8] and Marx[9]; for retinoblastoma, Balmer and colleagues[10]; for melanoma, Hayward[11] and Felsani and colleagues[12]; and for von Hippel Lindau syndrome, Kaelin[13], Woodward and

Table 12-1 Selected Cancer Predisposition Syndromes

Syndrome	Gene
Major cancer predisposition syndromes	
Hereditary breast and ovarian cancer syndromes	*BRCA1, BRCA2*
Familial adenomatous polyposis	*APC, MYH*
Hereditary nonpolyposis colon cancer syndrome	*hMSH2, hMLH1, hMSH6*
Hereditary prostate cancer	Multiple loci
Multiple endocrine neoplasias (I, II)	*MEN1, RET*
Hereditary melanoma syndromes	*CDKN2A^{p16}, CDK4*
Familial retinoblastoma	*RB1*
Neurofibromatosis I, II	*NF1, NF2*
von Hippel Lindau syndrome	*VHL*
Recently described cancer predisposition syndromes	
Gorlin syndrome	*PTCH*
Carney complex	*PRKAR1A*
Cowden syndrome	*PTEN*
Birt-Hogg-Dubé syndrome	*BHD*
Rhabdoid predisposition syndrome	*hSNF5/INI1*
Hereditary gastric cancer	*CDH1*
Hereditary leiomyomatosis and renal cell cancer syndrome	*FH*
Paraganglioma/chemodectoma syndromes	*SDH-A, -B, -C, -D*

Box 12-1. ELEMENTS OF INFORMED CONSENT FOR GENETIC CANCER TESTING

1. *What the test is intended to do,* that is, determine whether a mutation can be detected in a specific cancer susceptibility gene.
2. *What can be learned from both a positive and negative test,* including information on the magnitude of health risks associated with a positive test as well as the risks that may remain even after a negative test.
3. *The possibility that no additional risk information will be obtained* after testing or that the test will result in a finding of unknown significance (e.g., a polymorphism) that might require further studies.
4. *The options for approximation of risk without genetic testing,* for example, using empiric risk tables for breast cancer given differing family histories.
5. *The risk of passing a mutation on to children,* including options for assisted reproduction (e.g., preimplantation genetics, if discussion appropriate).
6. *The importance of notification of family members that they might share a hereditary risk for cancer* with every effort made to assist in contacting of family members and providing them access to counseling and testing.
7. *The medical options and limited proof of efficacy for surveillance and cancer prevention for individuals with a positive test* as well as the accepted recommendations for cancer screening even if genetic testing is negative.
8. *The technical accuracy of the test,* that is, the sensitivity and specificity of the analytic methodology.
9. *The risks of psychological distress and family disruption* whether a mutation is found or not found.
10. *The risk of employment and/or insurance discrimination* following disclosure of genetic test results and the *level of confidentiality of results* compared to other medical tests and procedures.
11. *The risks that nonrelatedness of family members will be discovered* and how this information will be disclosed (or not disclosed).
12. *The fees and costs of testing,* including the laboratory test and the associated consultation by the health professional who is providing pretest education, results disclosure, and follow-up, and the costs of preventive procedures, which might not be covered by third-party payers.

Breast and Ovarian Cancer Syndromes

Clinical Features

Although only about 18,000 cases of breast cancer each year are associated with an obvious hereditary predisposition, over 200,000 breast cancer survivors in the United States developed primary cancers as a result of a hereditary predisposition and remain at risk for secondary cancers.[19,20] Genetic testing has emerged as one of the most important indicators of risk factors pointing to a need for intensified screening for breast cancer.[21] When detected at an early stage, more than 90% of breast cancers are curable. These statistics underscore the rationale for the use of genetics in clinical oncology. The details of the management of women and men who are at hereditary risk for breast cancer have recently been reviewed in detail[22] and will be summarized here.

From 1 in 150 to 1 in 800 individuals in the population carry a genetic susceptibility to breast cancer,[23–25] and the prevalence is much higher in certain ethnic groups. Syndromes of breast cancer susceptibility are linked to mutations of *BRCA1* and *BRCA2,* as well as a smaller number of cases with germline mutations of *p53, PTEN, CHEK2,* and rarer syndromes (Table 12-3).

Cowden syndrome was initially described as a dominant inheritance of multiple hamartomatous lesions, including papillomas of the lips and mucous membranes and acral keratoses of the skin.[26] As described following, this syndrome was ultimately linked to germline mutations of *PTEN*. In Li-Fraumeni syndrome, early-onset breast cancer occurs with soft-tissue sarcomas, osteosarcoma, leukemia, brain tumors, adrenal cortical tumors, and other cancers. Rarely, a typical breast-ovarian kindred may be found to have a germline *p53* mutation.[27] In Northern European families, specific mutations of *CHEK2* are associated with familial breast cancer.[28] However, the common European *CHEK2* mutation is rare in North America.[29] Both benign and malignant breast tumors occur in Muir-Torre syndrome, a variant of hereditary nonpolyposis colon cancer that is associated with germline mutations of *MSH2* and *MLH1*. Women with Peutz-Jeghers syndrome carry germline mutations in the *STK11* gene and are at increased risk for breast cancer. Although this situation is still under study, initial studies of selected kindreds demonstrated that carriers of some *ATM* mutations have an elevated breast cancer risk.[30]

All told, linkage studies suggest that in about 50% of breast cancer kindreds, the cancer was linked to *BRCA1,* in 30% to *BRCA2,* and in the remainder to *BRCA3* and other as yet unidentified genes.[31] In up to two thirds of families with both male and female breast cancer, the cancers were due to *BRCA2,* while over 80% of families with both breast and ovarian cancer harbored *BRCA1* mutations.[32] Multiple, common, lower-penetrance genes are likely to account for a significant component of currently unexplained familial breast cancer

risk.[33] Two such low-penetrance breast cancer alleles that were revealed in large population studies are *BRIP1* and *PALB2*.[34–36] Recently, a host of putative lower-penetrant gene mutations have been identified through whole-genome association studies,[37,38] although the clinical relevance of these associations remains unclear.

Compared to the 10% breast cancer risk for women in the general population, estimates of the breast cancer risk that is conferred by a common susceptibility gene ranged from 67% to 69% by age 70 based on epidemiologic analyses.[23,24] Genetic linkage studies of families that were selected because of early-onset breast or ovarian cancer gave risk estimates as high as 70% to 90% in families in which mutations of either of these two genes were segregated.[39–41] Ovarian cancer risks in these families varied from 10% to 80%, and risk for a second breast cancer was as high as 64% by age 70. More recent estimates based on population studies led to slightly lower risk estimates, with a lifetime breast cancer risk of 56% by age 70 (confidence interval: 40% to 73%), and ovarian cancer risk estimated at 16%.[42] Penetrance estimates that were determined through clinic-based ascertainment of families revealed a 64% risk for breast or ovarian cancer by age 70.[43] The role of ascertainment and other possible biases in deriving these estimates as well as risks for cancer of the prostate, colon, pancreas, and other sites in *BRCA* mutation carriers has been reviewed.[44] In addition to Fanconi anemia, individuals with compound *BRCA2* mutations may develop childhood medulloblastomas.[45]

Genetics

BRCA1 is a large gene, spanning over 100,000 bases of genomic DNA with 22 coding and 2 noncoding exons. *BRCA2* is also large, consisting of 27 exons across 70 kb of genomic DNA. Both genes, by coincidence, have a large exon 11. An update of reported mutations is accessible through the Internet at http://www.nhgri.nih.gov/Intramural_research/Lab_transfer/Bic.

The majority of *BRCA1* mutations cause premature truncation of the peptide by frameshift or nonsense sequence changes. However, many of the 5% to 10% of *BRCA* mutations that are missense are problematic because they are of unknown clinical significance. The proportion of these variants that are of unknown significance was as high as 10% to 23% in some series, posing counseling challenges.[46,47] The role of *BRCA1* and *BRCA2* in DNA damage response and homologous recombination is reviewed elsewhere.[48]

Founder *BRCA* mutations have been documented in genetically isolated populations. In North American families, the most common founder mutations occur in individuals of Ashkenazi Jewish origin. These include a two-base-pair deletion in codon 23 of *BRCA1,* termed 185delAG, another *BRCA1* mutation, 5382insC, and the 6174delT mutation in *BRCA2*.[49–51] About 1 in 40 Ashkenazi Jews harbor one of the common *BRCA1* or *BRCA2* mutations,[42,43,50] a relatively high carrier frequency for an inherited cancer predisposition syndrome. Other mutations in *BRCA1* and *BRCA2* occur in the Ashkenazim; 16 out of 737 Ashkenazi Jews who were tested in a clinic-based ascertainment had a nonfounder mutation (2%).[52] In another study of Ashkenazi individuals with a personal history of breast or ovarian cancer who had previously been shown not to have a founder mutation, 3 of 70 (4.3%) had a deleterious nonfounder mutation.[53] Founder mutations in populations other than the Ashkenazim have also been observed.[54–56]

BRCA1-linked tumors are associated with a medullary subtype and higher mitotic indices.[57] They were of higher grade, were more frequently estrogen and progesterone receptor negative,[58,59] and demonstrated a basal-like phenotype.[60] They displayed a more "aggressive" phenotype, including a higher proportion of cells in S phase, and other indices.[57,59,61–63] The prognostic significance of *BRCA* mutations is still being defined.

Clinical Management

Three elements of breast surveillance that are recommended to *BRCA* heterozygotes are self-examination, clinician examination, and mammography. The evidence base underlying these recommendations has been reviewed,[22,64] and updated guidelines are available on the Web.[65]

Increasingly, breast cancer screening including mammography and magnetic resonance imaging (MRI) together have been shown to have greatest sensitivity.[66] For women who are at the highest hereditary risk for breast cancer, those whose breasts are difficult to examine, or those who have had biopsies showing atypia, it might be appropriate to discuss the option of removing the healthy breasts as a preventive measure (prophylactic mastectomy). Retrospective studies support the risk-reducing role of surgery in high-risk patients[67,68] (also reviewed in the work of Kinzler[7]). Prospective and combined consortium studies have also shown the efficacy of this approach.[69,70]

Because of their antiestrogen properties, tamoxifen, raloxifene, and a newer class of synthetic estrogen receptor modulators emerged as hormonal chemopreventive agents that have been shown to decrease breast cancer rates in individuals who are at increased risk.[71] The safety of these drugs in premenopausal women remains to be established. Two studies on the impact of tamoxifen on subsequent breast cancer risk in *BRCA1* and *BRCA2* mutation carriers have shown conflicting conclusions,[72,73] though only one of these studies was sufficiently powered to reach significant results. Tamoxifen was confirmed to decrease contralateral breast cancer risk in a follow-up of one of these studies of *BRCA* mutation carriers.[74]

Small trials have demonstrated the ability of ultrasound with Doppler and CA-125 to find early-stage ovarian cancers in *BRCA* mutation carriers.[75,76] However, the efficacy of this approach has not been proven in large, prospective studies. Therefore, prophylactic removal of the ovaries is presented as an option to women with strong family histories of ovarian cancer, in families linked to *BRCA1* or *BRCA2,* or to women who are considering hysterectomy in the setting of a germline mutation associated with nonpolyposis colon cancer syndrome. Studies have confirmed that such surgeries may not only decrease the incidence of subsequent breast and ovarian cancer, but also find occult early stage ovarian neoplasms,[77,78] decreasing mortality.[79] These studies have also confirmed that serous surface carcinoma, also called *papillary serous carcinoma,* can still occur following prophylactic oophorectomy,[80,81] leading most authors to use the term *risk-reducing* salpingo-oophorectomy.

Combination oral contraceptives that contain estrogen and high-dose progestin result in a time-dependent, protective effect against ovarian cancer in some but not all studies of *BRCA* mutation carriers.[82–84] There remains the concern of a small increased risk of breast cancer due to oral contraceptives in this group, particularly in those with *BRCA1* mutations.[85]

Common Colon Cancer Predisposition Syndromes

Highly penetrant, dominant, susceptibility syndromes account for about 5% of colon cancer. The most common syndrome is hereditary nonpolyposis colon cancer, with familial adenomatous polyposis constituting a rarer familial syndrome. For adults, genetic epidemiologic analyses suggested a common susceptibility allele for both colon cancer and adenomatous polyps that accounted for at least 15% and possibly half of cases.[86,87]

Polyposis Syndromes

FAMILIAL ADENOMATOUS POLYPOSIS

CLINICAL FEATURES. Familial adenomatous polyposis (FAP; adenomatous polyposis coli) presents with hundreds to thousands of adenomatous polyps at a young age. Virtually all affected individuals exhibit polyposis by age 35 years, and all will develop colon cancer. Colon cancer is therefore inevitable if the colon is not removed; the cancer occurs at an average age of 39 years. Flexible sigmoidoscopy at an early age establishes the diagnosis, and prophylactic colectomy is performed in the teen years. Patients remain at risk for primary

adenomas and carcinomas of the duodenum and rectum as well as desmoid tumors, osteomas, thyroid carcinoma, hepatoblastoma, and other hepatopancreatic tumors.[88]

Genetics. FAP arises from germline mutations in the *APC* gene.[89] Genotype phenotype correlations have been described, particularly for congenital hypertrophy of the retinal epithelium and the number of polyps observed. An attenuated form of FAP is associated with mutations at the extreme 5′ and 3′ ends of the gene.[90,91] Up to 30% of patients with multiple adenomas (15 to 100 adenomas) who test negative for *APC* mutations carry biallelic mutations in *MYH,*[92] discussed in detail later.

Clinical Management. In classic FAP, *APC* gene testing should be performed by 10 to 12 years of age, about the time that sigmoidoscopy begins. Unaffected individuals with wild-type *APC* who have an affected family member with a known mutation are screened in the same way as the general population.[93] In the case of attenuated FAP, in which adenomas might not occur until the twenties or thirties, the age at which genetic testing and clinical surveillance begin is not clearly defined. Once an *APC* gene mutation has been identified and when adenomas are found, prophylactic colectomy is performed, usually in the teen years.[94] Sulindac, a nonsteroidal anti-inflammatory drug, may reduce adenoma development in individuals with FAP, and similar effects were noted with celecoxib, a COX-2 inhibitor.[95,96] However, the possibility of delaying colectomy while patients are treated pharmacologically has not yet been established. Patients require lifelong surveillance for extracolonic tumors, including tumors of the upper GI tract as well as the ileal pouch (if proctocolectomy is performed).[97]

***MYH*-ASSOCIATED POLYPOSIS.** Some FAP probands carry biallelic mutations in the base excision repair gene, *MYH.*[92,98] *MYH*-associated polyposis (MAP) is considered a recessive syndrome; parents of affected homozygote or compound heterozygote mutation carriers have been reported to be unaffected.[99] However, both monoallelic and biallelic germline mutations in *MYH* have been associated with multiple adenomas.[99,100] Biallelic carriers have a higher frequency of CRC than do monoallelic patients.[101] Patients with multiple adenomas (more than 15) without *APC* mutations are more likely to have biallelic *MYH* mutations than are controls[100,102] Combining *APC* and *MYH* sequencing increases the yield of diagnosis from 34.4% to 41.3%.[103] The mutations Y165C and G382D are recurring in Caucasian Europeans, making up 86% of biallelic mutations in three series.[99–101] In 358 early-onset polyposis cases that were unselected for *APC* mutation status, two cases carried biallelic *MYH* mutations, and eight *MYH* mutation heterozygotes were identified. No *MYH* mutations were detected in 354 controls, leading the authors to conclude that biallelic *MYH* mutations might account for up to 3% of early onset colorectal cancer. Patients in this series did not exhibit profuse polyposis, consistent with previous reports, and distally located tumors were prevalent.[104,105]

Management. As with FAP, prophylactic colectomy is generally recommended for *MYH*-associated polyposis. Because over one third of biallelic *MYH* mutation carriers might not develop multiple polyps but remain at elevated colorectal cancer risk, colonoscopy with polypectomies is thought to be not sufficiently preventive for this population.[106] Surgical options for *MYH* mutation carriers include ileorectal anastomosis for younger patients with few rectal adenomas and a milder family history or with attenuated FAP or total proctocolectomy with the creation of an ileal pouch and anal anastomosis for more diffuse polyposis.

Hereditary Nonpolyposis Colon Cancer

CLINICAL FEATURES. A constellation of colon and endometrial cancers became known as Lynch syndrome or hereditary nonpolyposis colon cancer (HNPCC).[107] Five additional tumor sites demonstrated increased observed/expected (O/E) ratios in HNPCC kindreds: cancers of the stomach (O/E = 4.1), ovary (O/E = 3.5), small intestine (O/E = 25), ureter (O/E = 22), and kidney (O/E = 3.2).[108] There is a 70% to 75% risk of colon cancer by age 65 in HNPCC families.[109,110] The penetrance was 92% by age 60 in one series,[111] with a median age at colon cancer diagnosis of 44 to 46 years. A 40% to 60% endometrial cancer risk by age 70 was reported,[112–115] with a median age of onset from the late forties to early fifties.[116] The risk for endometrial cancer in the general population is 3%.

At a 1991 meeting in Amsterdam, the International Collaborative Group on HNPCC defined the syndrome as (1) histologically verified colorectal cancer in three or more relatives, including a first-degree relative of the other two; (2) colorectal cancer involving at least two generations; and (3) one or more colorectal cancers diagnosed before 50 years of age. The subsequent "Amsterdam II criteria" for HNPCC were redefined to include extracolonic HNPCC-associated cancers.[117] In 1996, guidelines known as the Bethesda criteria delineated individuals at risk for HNPCC for whom molecular genetic analysis may be considered.[118] A revised set of Bethesda Guidelines was developed to identify subjects who are at high risk of having a germline mismatch repair gene mutation[119] Multivariate logistic regression risk models using personal and family medical histories estimate the probability of carrying an HNPCC mutation.[120–122]

While there do not appear to be defining histologic features of HNPCC tumors, mucinous types are more common. Adenomas, like the cancers in HNPCC, appear more frequently on the right side. Multiple lesions occur in about 20% of at-risk individuals. Generally, fewer than 100 polyps present in these cases.[123]

GENETICS. About 45% to 70% of HNPCC families harbor mutations in one of the three genes: *MSH2, MLH1,* and *MSH6.*[124–127] Mutations in two other genes, *PMS1* and *PMS2,* have been associated with HNPCC syndrome,[128] and rare, atypical Lynch syndrome pedigrees with identifiable *MLH3* mutations have also been described.[129] Of these, mutations of *MSH2* and *MLH1* were far more frequent than the others, accounting for about 30% each of families meeting Amsterdam criteria for HNPCC. Over 75% of mutations in *MSH2* and *MLH1* were inactivating insertions, deletions, alterations in premessenger RNA splicing signals, and nonsense mutations. However, 23% of 120 mutations surveyed were missense mutations.[130] Mutations of *MSH6* less frequently result in the "replication error repair" phenotype but account for a significant number of familial colon cancer families.[131] The replication error repair phenotype is commonly detected as microsatellite instability (MSI) utilizing polymerase chain reaction screening of tumors with microsatellite markers. The MSI phenotype is present in about 80% of HNPCC-associated colon cancers[132] and in about 15% of sporadic colon tumors,[133] as well as in other tumors associated with HNPCC (e.g., uterine, gastric cancers). MSI results in a genome-wide increased mutation rate, causing mutations in oncogenes, tumor suppressors, and in microsatellite regions.[134]

In young patients (less than 35 years old), the detection of the MSI phenotype is quite common (seen in 58%) and may be associated with detectable HNPCC gene mutations in only half of the cases.[135] Testing for MIS and/or immunohistochemistry (IHC) for HNPCC-associated protein expression is recommended in all patients with colorectal cancer who are younger than 50 years of age, have a family history of colon or endometrial cancer, or have a personal history of metachronous colon or endometrial cancers.[136]

Lack of MLH1 or MSH2 protein expression in tumors is correlated with MSI, allowing the use of immunohistochemistry along with MSI analysis.[137] Lack of expression of the *MLH1* protein indicates that germline testing should begin with the *MLH1* gene. Similarly, if there is no expression of MSH2, the germline testing should begin with *MSH2* gene. Immunohistochemical analysis can also be

utilized to evaluate MSH6 and PMS2 protein expression. In older patients with colorectal cancer, hypermethylation of the *MLH1* promoter may account for the lack of MLH1 protein expression.[138] This epigenetic (nonhereditary) mechanism of *MLH1* promoter hypermethylation is responsible for the majority of the remaining patients whose tumors are characterized by defective DNA mismatch repair.[139]

CLINICAL MANAGEMENT. It has been shown that screening for cancer in HNPCC improves patient survival.[140] Individuals with HNPCC are advised to undergo colonoscopic surveillance every 1 to 2 years, preferably annually, starting at age 20 to 25 years and perhaps at age 30 for *MSH6* mutation carriers.[141,142] Endometrial cancer screening generally includes transvaginal ultrasound and endometrial biopsy at age 30 to 35 years. Annual urinalysis with cytology is also recommended, although minimal data support the efficacy in detecting urothelial tumors. A baseline upper endoscopy should be performed, but the optimal subsequent screening interval has yet to be established. Prophylactic subtotal colectomy is generally performed after the first malignancy diagnosis, sparing the rectum.[143] A retrospective study of prophylactic bilateral oophorectomy and hysterectomy showed protection from uterine and endometrial cancer,[144] though the estimates were influenced by a retrospective study design.[145] Nonetheless, a combination of risk-reducing bilateral oophorectomy and hysterectomy is a reasonable option after childbearing or at the time of subtotal colectomy for a colon cancer occurring in women with HNPCC.

Prostate Cancer

Clinical Features

Of the quarter of a million men who will be diagnosed with prostate cancer in 2008, about 5% to 10% will have a strong family history of the disease. The estimated prostate cancer susceptibility allele frequency is 0.003 to 0.006, meaning that about 1 in 170 to 1 in 85 individuals has inherited a genetic mutation, which in males confers susceptibility to prostate cancer. The penetrance for this dominant prostate cancer susceptibility syndrome was estimated to be 88% by age 85. The syndrome may account for 43% of prostate cancers that are diagnosed before age 56 and 9% that are diagnosed by age 85.[146,147] While only an estimated 2% of prostate cancer in the general population is diagnosed before age 56, this proportion is increasing with the introduction of newer screening modalities. The clinical features, stage, histology, and PSA at diagnosis of hereditary prostate cancer were comparable to those of nonhereditary cases.[147]

As Table 12-4 shows, hereditary prostate cancer has enormous genetic heterogeneity.[148] The first putative gene that was identified, *HPC1,* emerged after a genome-wide scan of 66 high-risk prostate cancer families revealing linkage to 1q24-25. Subsequently, germline *RNASEL* mutations on chromosome 1q25 were identified in high-risk prostate cancer families.[149] Analysis of 600 individuals from 91 prostate cancer kindreds revealed linkage to a locus on chromosome 1q24-q25, as did a meta-analysis of 772 prostate cancer kindreds by the International Consortium for Prostate Cancer Genetics. However, it was suggested that this region might be responsible for only a subset of hereditary prostate cancer.[150] *RNASEL* polymorphisms have been inconsistently associated with prostate cancer susceptibility; a meta-analysis supported only a modest effect.[151]

Table 12-4 Genetic Heterogeneity of Hereditary Prostate Cancer

Locus Name	Location	Putative Gene
HPC1	1q24-q25	*RNASeL*
HPC2	17p11	*ELAC2*
PCAP	1q42-q43	?
CAPB	1p36	*EPHB2*
HPCX	Xq27-q28	?
HPC20	20q13	?
—	8q24	?
—	7q11-21	?
—	3p26	?

In 2001, Tavtigian and colleagues performed a study of high-risk prostate cancer families from the Utah Population Database, providing evidence for linkage to *HPC2* on chromosome 17p.[152] Common variants of *ELAC2* segregated with prostate cancer in two of the pedigrees. Among 266 prostate cancer cases that were unselected for family history and 359 controls, two variants, Ser217Leu and Ala541Thr, were identified in 31.6% and 2.9%, respectively. Interestingly, the Ala541Thr genotype was found only in individuals with the Ser217Leu variant, conferring an elevated prostate cancer risk with an odds ratio of 2.37.[153] These findings were not supported by a subsequent series of 159 hereditary prostate cancer probands, 249 incident prostate cancer cases, and 222 controls[154] or by other series. A review of pooled data from various *ELAC2* studies that were analyzed by the investigators who originally identified *ELAC2* as a prostate cancer susceptibility gene confirmed that this gene does confer increased prostate cancer risk for approximately 2% of prostate cancer cases in the general population.[152,155]

Linkage analyses of 360 prostate cancer kindreds from North America, Sweden, and Finland demonstrated significant linkage to *HPCX* on Xq27-28, estimated to account for up to 16% of hereditary prostate cancer,[156] a finding that was confirmed by two other studies with no male-to-male transmission.[157,158] Another Finnish genome-wide linkage analysis identified 3p26 as a major prostate cancer susceptibility locus.[159] Genome-wide linkage studies identified 7q11-21 as a putative region for prostate cancer susceptibility among 36 Ashkenazi Jewish prostate cancer kindreds.[160] Recently, whole-genome admixture scans in 1597 African Americans identified a 3.8 Mb interval on chromosome 8q24 as significantly associated with susceptibility to prostate cancer,[161] and subsequent studies have confirmed 8q24 as a locus for up to three prostate cancer susceptibility alleles.[162] Linkage to *HPC20* at 20q13 was implicated in one study of 162 North American kindreds[163] but not in another study of 172 unrelated prostate caner kindreds.[164] A French series of 159 affected individuals identified *PCAP* at 1q42.2-43 as a prostate cancer susceptibility locus among Southern and Western Europeans with prostate cancer diagnosed at age 65 or younger, with no evidence for linkage to the other regions that were analyzed, including *HPC1* at 1q24-25, *HPCX* at Xq27-28, and *CAPB* at 1p36.[165]

Prostate cancer with a family history of brain cancer has shown linkage to 1p36.[166] However, an international collaborative analysis did not confirm linkage to 1p36 with prostate and brain cancer susceptibility exclusively, assessing five brain-prostate cancer kindreds that did show linkage to this region as a chance association.[167] *EPHB2* at 1p36 was biallelically disrupted in prostate cancer lines of brain metastasis origin.[168]

Other putative prostate cancer susceptibility loci that have been identified by linkage studies include 17q22, 15q11 in late-onset kindreds, and 4q35 with four or more affected family members[169]; a 79 C→T polymorphism in the cell cycle gatekeeper/tumor suppressor gene *CDKN1B* at 12p13[170]; the polymorphism H6D in *MIC-1*, a regulator of macrophage activity in inflammatory response[171]; a tetranucleotide TTTA repeat number polymorphism in the *CYP19* estrogen synthesis aromatase gene[172]; and mutations in the *p53* regulator *CHEK2.*[173–175]

Genetic heterogeneity remains the central issue in prostate cancer genetics. A large study of 1233 prostate cancer kindreds found significant positive LOD scores, suggesting linkage to at least nine

different regions.[176] At least two population-based series suggested a recessive mechanism because risk of disease was greater in siblings than in children of those who were affected.[177,178]

Candidate susceptibility alleles for hereditary prostate cancers have also included genes that encode receptors for two steroid hormones that influence cell division within the gland. A case-control study of 57 prostate cancer cases and 169 controls revealed that individuals carrying polymorphisms in the genes encoding the androgen receptor and vitamin D receptors were at increased risk for prostate cancer.[179] Despite an extensive literature, associations of the CAG repeat number polymorphism in exon 1 of the androgen receptor gene have generally not been confirmed in large cohorts,[180,181] emphasizing the importance of ethnic variance and other factors.[182] In some families, prostate cancer may be associated with already known cancer predisposition syndromes, such as *BRCA2* and *p53*.[183–185]

Clinical Management

The normal concentration of prostate-specific antigen (PSA) in the serum is 0 to 4 ng/mL. Values greater than 10 ng/mL are more likely to be associated with cancer. Transrectal ultrasound is performed in the setting of an increased PSA, with transrectal needle biopsy of any suspicious area guided by ultrasound or digital rectal examination. Current recommendations of the American Cancer Society and other professional societies include digital rectal examination and PSA screening for men between the ages of 50 and 70.[186] Initial evidence for the efficacy of this approach in decreasing mortality was demonstrated in a trial of 45,000 men.[187]

A study of individuals at increased risk for prostate cancer by virtue of a family history demonstrated the efficacy of intensive screening (PSA, digital rectal examination, transrectal ultrasound, and systematic as well as directed core biopsies).[188] Additional studies of annual PSA and biopsy for PSA greater than 3.0 targeted to those who are at hereditary risk are in progress.[189] A future option for hereditary prostate cancer risk reduction may include hormonal chemoprevention.[190] A large-scale chemoprevention trial of finasteride showed a modest delay in the appearance of prostate cancer but also sexual side effects and an increased risk of high-grade prostatic neoplasms.[191]

Multiple Endocrine Neoplasia Type 2

Clinical Features

Multiple endocrine neoplasia type 2a (MEN2a) is characterized by multiple endocrine tumors, particularly medullary thyroid carcinoma and pheochromocytoma. There is also hyperplasia of the parathyroid in one quarter of cases. Hypertension is the common presenting symptom, with diagnosis classically made by measurement of urinary VMA and metanephrine. Routine MEN2a screening has been directed to thyroid medullary lesions, with pentagastrin challenge to measure calcitonin response.[192] Measurement of serum ionized calcium has also been performed in the diagnostic evaluation.

MEN2b has an earlier age of onset than MEN2a; enlarged, nodular lips; a Marfanoid habitus; ganglioneuromatosis of the intestine; and other abnormalities.[193] This phenotype also includes medullary thyroid carcinoma, which may be more aggressive, and pheochromocytoma. Parathyroid disease is less common than in MEN2a.

Medullary thyroid carcinoma runs in families about 25% of the time, as a syndrome of site-specific familial medullary carcinoma of the thyroid (FMCT) or as MEN2.[194] Cases usually present in the third and fourth decades and are often bilateral and multifocal. Familial papillary thyroid cancer is distinct from FMCT and is associated with an increased incidence of colorectal cancer.[195]

Genetics

In 1993, it was observed that *RET* gene mutations were associated with MEN2a, MEN2b, and FMCT.[196,197] Specific *RET* gene mutations have been associated with MEN2a, MEN2b, and FMCT.[196,198–200] *RET* testing of sporadic cases of medullary carcinoma of the thyroid will yield a relatively low (5%) rate of diagnosis of MEN2a in the absence of a family history of the disease, C cell hyperplasia, or multifocality.[201,202] Nonetheless, *RET* testing is more sensitive than traditional biochemical screening is. Asymptomatic children with *RET* mutations and normal plasma calcitonin levels had small foci of medullary carcinoma of the thyroid at time of "prophylactic" surgery.[203] These findings were confirmed in a large study in the United States.[204]

A study of 477 MEN2a families showed an association between codon 634 mutations and pheochromocytoma and between mutations at codons 768 and 804 and FMCT, while codon 918 mutation is MEN2b-specific. Rare families with both MEN2 and Hirschsprung disease have MEN2-specific codon mutations.[205] A 611 codon mutation is associated with a mild form of FMCT with slow progression. The classic M918T mutation in exon 16 is found in MEN2b, and a less common mutation in *RET* codon 883 has also been reported.[206,207]

Clinical Management

RET testing has been established as the gold standard for MEN2a screening, and prophylactic thyroidectomy has been established as the primary preventive intervention. The age at which surgery is recommended is 3 to 5 years at most centers. Genetic testing should therefore be performed by this age and perhaps even earlier in families with MEN2b, since the thyroid cancers can occur at an earlier age.[208] Heterozygotes for *RET* mutations in the setting of MEN2a are screened with abdominal ultrasound and computed tomography (CT), as well as 24-hour urine studies through the adult years, at least to age 35. Plasma screening for the pheochromocytomas has been suggested (see the section on von Hippel Lindau syndrome). The treatment of choice for patients with MEN2a or MEN2b with a unilateral pheochromocytoma is unilateral resection, since substantial morbidity and mortality are associated with the Addisonian state after bilateral adrenalectomy.[209]

RECENTLY CHARACTERIZED CANCER PREDISPOSITION SYNDROMES

Gorlin Syndrome and Nevoid Basal Cell Carcinoma Syndrome

Basal cell carcinomas (BCCs) are the most common malignancy in humans, with three quarters of a million cases each year. In a small subset of families, BCCs occur at early age and in great numbers. The nevoid basal cell carcinoma syndrome (NBCCS) consists of multiple BCCs, usually presenting after puberty, accompanied by odontogenic jaw cysts, congenital skeletal abnormalities, ectopic calcification of the falx cerebri, and characteristic pits in the skin of the palms and soles.[210,211]

A hallmark of the syndrome is the increased susceptibility of the skin to the damaging and tumor-inducing effects of ionizing radiation.[212] Multiple BCCs have developed within 6 to 36 months following radiation therapy. Unlike Bloom syndrome or ataxia telangiectasia, there is no in vitro evidence of chromosome fragility.

One estimate of the prevalence of the syndrome, 1 in 57,000, comes from a study of a population of 4 million people in northwest England.[213] As described by Gorlin in 1987, penetrance for the syndrome is virtually 100% over a lifetime.[211] NBCCS is diagnosed in individuals with two major and one minor criterion or one major and three minor criteria.[214] Major criteria include bilamellar calcification of the falx cerebri at less than 20 years of age; odontogenic (jaw) keratocyst; palmar/plantar pits (three or more); multiple (more than 2) BCCs or a BCC before the age of 20 years; bifid, fused, or markedly splayed ribs; or a first-degree relative with NBCCS.[215,216] Minor criteria include childhood medulloblastoma (also called primitive

neuroectodermal tumor); lymphomesenteric or pleural cysts; macrocephaly; cleft lip/palate; vertebral anomalies on X-ray; bifid vertebrae; preaxial or postaxial polydactyly; ovarian/cardiac fibroma; and ocular anomalies (cataract, developmental defects, and pigmentary changes of the retinal epithelium). One study showed that approximately 5% of Gorlin syndrome patients develop medulloblastoma in the first few years of life and that 10% of patients with medulloblastoma diagnosed at age 2 years or under have Gorlin syndrome.[217] For diagnostic purposes, it might be salient that one study found that the only histopathologic subtype of medulloblastoma in NBCCS patients is the desmoplastic subtype, which occurs in only 20% of sporadic medulloblastoma cases. The authors suggest that the occurrence of the desmoplastic subtype in a patient younger than 2 years of age is pathognomic.[218]

Genetics

In 1996, Johnson and coworkers found mutations in exon 15 of the human homolog of the Drosophila *patched* gene (called *PTH* or *PTCH*)[219] in two of 60 typical NBCCS kindreds. An analysis of 71 unrelated individuals with NBCCS revealed 26 with mutations scattered throughout the 23 exons of the gene. In 86%, the mutations caused a truncated protein.[220] NBCCS is caused by germline mutations of the gene *PTCH* mapped to chromosomal locus 9q22.3. The *PTCH* gene consists of 23 exons and encodes an integral membrane protein with 12 transmembrane regions and two extracellular loops and a putative sterol-sensing domain. Mutations of *PTCH* are the only known genetic alterations associated with NBCCS.[221] However, several studies have found no genotype/phenotype correlations,[220,222,223] which suggests that other factors might add to the development of patients' clinical features. For kindreds with diagnostic clinical findings of NBCCS that test negative for a mutation by sequence analysis, Southern blot analysis may be performed to detect large deletions. About 70% to 80% of probands have inherited the condition from a parent, and about 20% to 30% of probands have a de novo mutation.

Risk Management Recommendations

Life expectancy in NBCCS is not significantly different from average. The major clinical issues revolve around the cosmetic effects of treating multiple skin tumors and jaw keratocysts, which can recur. The jaw cysts may also undergo malignant transformation.[224] Interaction with oral and plastic surgeons and dermatologists is important. Because of early-onset disease risk, for example, for medulloblastomas, genetic testing of children is appropriate for this condition. Evaluation of members of NBCCS kindreds includes skin examination; measurement of head circumference; and radiographic examination of the skull, spine, ribs, and jaws.[225] Ophthalmologic and dental examination and radiographic monitoring of the jaw cysts (oropantomography) may be performed on affected individuals. MRI scans of at-risk children can diagnose medulloblastomas, though it is unclear whether this improves outcome. If no physical or radiographic stigmata are noted by 5 years of age in the child of an affected patient, the chances that the child is a heterozygote are small.[214] As has been mentioned, radiotherapy for large basal cell cancers should be avoided, because this can lead to the development of thousands of BCCs in the radiation field.[211,212] Prenatal testing for NBCCS is possible if the disease-causing mutation has been identified in an affected family member.

Carney Complex

Clinical Features

Carney complex (CNC) is a multiple neoplasia syndrome that is referred to by acronyms such as NAME[226] and LAMB syndrome in the medical genetics literature.[227,228] As described by Carney in 1985,[229] the complex is characterized by myxomas, skin pigment abnormalities, endocrine tumors, and schwannomas. The median age at diagnosis is 20 years, spotty skin pigmentation and heart myxomas being the most common initial clinical manifestations.[230] The skin abnormalities involve the lips, the conjunctiva and inner or outer canthi, and the mucosa of the vagina or penis. Atrial myxomas are by far of greatest clinical concern, since they usually result in a decreased life span and account for the major causes of mortality in affected individuals; cardiac myxoma can cause stroke and death.[230] Ductal breast adenoma has been described as part of the Carney complex, as well as myxoid fibroadenomas and other findings on breast imaging.[231] In one study of 338 individuals diagnosed with CNC, 34 of 194 (17.5%) females had breast myxomas, often bilateral.[232] Large-cell calcifying Sertoli cell tumor, a frequent component of CNC in males, detected as early as 2 years of age, has been associated with infertility due to hormonal imbalance.[233]

Primary pigmented nodular adrenocortical disease occurs most frequently in association with CNC. A study by Stratakis in 1999 showed that for 95% of the patients, primary pigmented nodular adrenocortical disease occurred as a component of CNC, and 14% had Cushing syndrome.[234] Thus, the diagnosis of primary pigmented nodular adrenocortical disease should prompt screening for CNC. Other organs that are involved in CNC are the thyroid gland and ovaries. Thyroid gland lesions include follicular hyperplasia, follicular adenoma, and follicular and papillary carcinoma. Ultrasonography is useful for screening and diagnosis of these lesions.[235] Ovarian serous cystadenomas have been described in the literature, suggesting that pelvic ultrasound may be indicated as a part of evaluating women with CNC.[236]

Diagnostic criteria for CNC[232] require two or more of the manifestations or one major manifestation and one of the minor criteria. Major criteria are skin pigmentary abnormalities (multiple lentigines of the face, blue nevus, or epithelioid blue nevus); myxoma (cutaneous or mucosal myxomatosis); cardiac myxoma; endocrine tumors/overactivity (primary pigmented nodular adrenocortical disease, a micronodular form of adrenal hyperplasia, growth hormone-producing pituitary adenoma, large-cell calcifying Sertoli cell tumor, or thyroid adenoma or carcinoma); psammomatous melanotic schwannoma; thyroid carcinoma or multiple thyroid nodules on ultrasound in a young patient; multiple breast ductal adenomas; and osteochondromyxoma. To make the diagnosis, an individual must have two of the components listed or one of the manifestations in addition to an affected first-degree relative or have an inactivating mutation of the *PRKAR1A* gene. A malignant neoplasm is a relatively uncommon finding in affected patients.

Genetics

Mutations in *PRKAR1A* (17q23-q24) are identified in about 40% of individuals with CNC.[237] *PRKAR1A* codes for the RI-α subunit of *PKA,* a critical cellular component of a number of cyclic nucleotide-dependent signaling pathways.[238] *PRKAR1*-α frameshift mutations cause haploinsufficiency of R1-α and manifest as CNC. As predicted by the Knudson "two-hit" hypothesis, loss-of-heterozygosity of the normal allele supports the model that R1-α may have tumor suppression function in the target tissues in this syndrome. The most common mutation in CNC patients, a two-base-pair deletion (TGdel) in exon 5 of *PRKAR1,* has also been found de novo in several kindreds, suggestive of a mutational hot spot in the gene.[239] About 17% of diagnosed individuals harbor de novo mutations.

Clinical Management

Recommendations include annual echocardiography, annual measurement of urinary free cortisol, testicular sonogram in males at their initial visit, thyroid ultrasound at initial visit and as needed thereafter, pelvic ultrasound in female patients at their initial visit, breast imaging, spine MRI, pituitary MRI, and adrenal CT scan.[239] Children should have echocardiography during the first 6 months of life and annually thereafter to detect potentially lethal myxomas. Children with large-cell calcifying Sertoli cell tumor may require

monitoring of growth rate and pubertal status. Bone age determination and further laboratory evaluation might be necessary if gynecomastia is present.[212]

Cowden Syndrome

Clinical Features

Cowden syndrome (CS) is an autosomal dominant disorder characterized by multiple hamartomas with a high risk of benign and malignant tumors of the thyroid, breast, and endometrium. Consensus diagnostic criteria for CS establish three diagnostic categories.[240]

Pathognomonic criteria include mucocutaneous lesions, facial trichilemmomas, acral keratoses, papillomatous lesions, and mucosal lesions. Major criteria include breast cancer, thyroid cancer (especially follicular histology), macrocephaly, Lhermitte-Duclos disease (defined as presence of a cerebellar dysplastic gangliocytoma),[241] and endometrial carcinoma. Minor criteria include other thyroid lesions (e.g., goiter), mental retardation, hamartomatous intestinal polyps, fibrocystic breast disease, lipomas, fibromas, and GU tumors (e.g., uterine fibroids, renal cell carcinoma) or GU malformation. The diagnosis of CS is made if an individual meets any one of the following criteria: pathognomonic mucocutaneous lesions alone if there are: six or more facial papules, of which three or more must be trichilemmoma, or cutaneous facial papules and oral mucosal papillomatosis; or oral mucosal papillomatosis and acral keratoses; or six or more palmoplantar keratoses. Alternatively, the individual may fulfill two major criteria, but one must have either macrocephaly or Lhermitte-Duclos disease. Alternatively, the individual may have one major and three minor criteria or four minor criteria.

The palmar and plantar hyperkeratotic pits usually become evident later in childhood. Subcutaneous lipomas and cutaneous hemangiomas are seen in CS with low frequency.[242] An increased risk of early-onset male breast cancer has been noted in mutation carriers.[243]

Genetics

The gene for CS, *PTEN,* was mapped to 10q22-23.[244] *PTEN* acts as a tumor suppressor by mediating cell cycle arrest, apoptosis, or both.[245] Full sequencing and molecular testing by Southern blot are available clinically and on a research basis. Heterozygous germline mutations in *PTEN* cause most cases of CS. Nonsense, missense, and frameshift mutations that are predicted to disrupt normal *PTEN* function have been identified in certain families,[246] including mutations that disrupt the protein tyrosine/dual-specificity phosphatase domain. A *PTEN* mutation can be detected in about 80% of patients with CS.[247]

Risk Management Recommendations

Individuals with known germline *PTEN* mutations should undergo appropriate cancer screening.[228,248] Female patients with CS should be screened for breast cancer, starting clinical breast examination at age 25 and annual mammography at age 30 or 5 years younger than the earliest age of breast cancer diagnosis in the family. Men should perform monthly breast self-examination. Female patients should receive endometrial cancer screening beginning around age 35 years or 5 years before the youngest endometrial cancer diagnosis in the family, as well as a comprehensive annual physical examination starting at age 18 years with screening for skin and thyroid lesions, including a baseline thyroid ultrasound. Individuals with CS should undergo a colonoscopy at age 50 years and annual urinalysis to detect renal carcinoma. Finally, prenatal testing for CS can be done if a mutation is described in a parent.

Birt-Hogg-Dubé Syndrome

Clinical Features

Birt-Hogg-Dubé (BHD) cancer predisposition syndrome was recently molecularly characterized, though it was first described in 1977.[249] This rare genodermatosis comprises an interesting triad of findings: fibrofolliculomas that appear as white or skin-colored papules on the face and upper torso, spontaneous pneumothorax, and kidney tumors.[250] Approximately 15% to 30% of patients with cutaneous BHD syndrome develop renal tumors. A recent review of 130 solid renal tumors resected from 30 patients with BHD in 19 different families revealed that renal tumors were multiple and bilateral and were noted at an early age (mean: 50.7 years). The vast majority were hybrid oncocytic neoplasms with areas reminiscent of chromophobe renal cell carcinoma and oncocytoma, while a significant number were chromophobe renal cell carcinomas, and a minority were conventional clear cell renal carcinomas.[251,252] The cutaneous lesions usually appear in the region of the head, neck, and upper part of the trunk in the third or fourth decade of life, and about 15% to 30% of patients with skin lesions of BHD syndrome develop renal tumors. Khoo and colleagues described an association with colorectal neoplasia in some families with BHD.[253] However, other reports did not confirm this.[254] Individuals with BHD syndrome are at markedly increased risk of spontaneous pneumothoraces. In a recent study, 64 of 198 (32%) BHD-affected individuals had a history of spontaneous pneumothorax.[255] The syndrome is also associated with a progressive flecked chorioretinopathy with constricted visual fields.[256]

Genetics

BHD is inherited in an autosomal dominant manner. The recently identified *BHD* gene has been mapped to chromosome 17p11.2[257] expressing a novel protein folliculin.[258] The exact function of this protein is not known. Affected individuals exhibit loss of protein function, usually due to a frameshift mutation in the coding sequence. In a recent study, 27 of 52 BHD-affected families had an insertion/deletion in exon 11 of the gene (c.1733insC or c.1733delC). Phenotype manifestations among those with either the insertion or the deletion were similar for fibrofolliculomas and pneumothoraces. However, the incidence of renal tumors was significantly higher among those with the C-insertion compared to the C-deletion (33% versus 6%).[255]

Risk Management

Patients with BHD syndrome and their relatives should undergo abdominal CT and renal ultrasound screening for renal tumors. Lung cysts are best seen on CT scans. Dermatologic consultation is advised. Ophthalmologic examination should be performed in patients with BHD syndrome owing to the high incidence of chorioretinopathy.

Rhabdoid Predisposition Syndrome

Clinical Features

Rhabdoid predisposition syndrome (RPS) was initially described in 1999 by Sévenet and colleagues.[259] RPS results in pediatric cancer predisposition, including renal and extrarenal malignant rhabdoid tumors; choroid plexus carcinomas; central, primitive, neuroectodermal tumors; and medulloblastomas.[260,261] In the families that have been described with RPS, the penetrance appears to be quite high at a very young age. In the initial study, all of the first cancers occurred before the age of 3 years in mutation carriers, and no mutation carriers were unaffected.[259] Pediatric brain tumors are emerging as an important component of this syndrome.[262] The spectrum of cancers that have been observed in RPS overlaps somewhat with Li-Fraumeni syndrome. Pediatric medulloblastomas may also occur in Gorlin syndrome and in compound *BRCA2* heterozygotes, as was noted previously.

Genetics

RPS is caused by mutations in *hSNF5/INI1* at 22q11.2 (also known as *SMARCB1*). Most mutations in the *hSNF5/INI1* gene are truncating.[263] The *hSNF5/INI1* gene encodes a subunit of the *SWI/SNF* family of chromatin-remodeling complexes. The spectrum of tumors

with somatic mutations of *hSNF5/INI1* is similar to the tumors that are seen in the hereditary syndrome.[263] A recent paper[264] describes a family with two children, one affected with rhabdoid tumor of the kidney and the other with atypical teratoid/rhabdoid tumor. Though both children satisfied the morphologic and clinical features for a diagnosis of RPS, neither of their tumors showed *hSNF5/INI1* inactivation, both had normal expression of the gene in nuclei of tumor cells, and haplotype analysis showed that each received a different set of maternal/paternal alleles. This suggests genetic heterogeneity and warrants further molecular studies to determine the etiology of this syndrome.

Risk Management

Since this syndrome has only recently been described, clinical management is still evolving. As with Li-Fraumeni syndrome, screening for component tumors is unproven. The average survival of infants following diagnosis of malignant rhabdoid tumors with abnormalities of chromosome 22q11 is less then 6 weeks.[265] Fewer than 25% of infants and young children with rhabdoid tumor of the kidney survive.[262,266,267]

Familial Gastric Cancer

Clinical Features

The International Gastric Linkage Consortium specifies criteria for a clinical diagnosis of familial diffuse gastric cancer. These criteria consist of either two or more documented cases of diffuse gastric cancer in first- or second-degree relatives, with at least one diagnosed before age 50, or three or more cases of diffuse gastric cancer in first- or second-degree relatives, independent of age of onset.[268]

Genetics

Approximately 30% of familial diffuse gastric cancer kindreds have mutations in the E-cadherin (*CDH1*) gene.[269] The lifetime penetrance of *CDH1* mutations is estimated to be 70% to 80%.[269] However, diffuse gastric cancer has been diagnosed in affected individuals as young as 14 years of age, and the majority of mutation carriers die younger than age 40.[270,271] Clinical consensus is that individuals with diffuse gastric cancer who are younger than 35 years of age should be considered for *CDH1* testing.[271] Because of the early age of onset, similar to that of FAP, and the estimated 10% 5-year survival rate after diffuse gastric cancer diagnosis, individuals who are as young as 13 years and able to give informed consent or assent should be considered for genetic counseling.

Clinical Management

The management options are surveillance upper GI endoscopy or prophylactic gastrectomy. Gastrectomy has a significant effect on quality of life and should be undertaken only after extensive genetic counseling. The long-term morbidity that can result from gastrectomy includes weight loss, lactose intolerance, fat malabsorption and steatorrhea, dumping syndrome, bacterial overgrowth, postprandial fullness, and vitamin deficiencies. On the basis of the experience of Japan, which has population-based upper endoscopy screening programs to detect gastric cancer, early detection of gastric cancer can lead to 5-year survival rates greater than 90%.[271] Therefore, upper endoscopy surveillance may be a viable approach to management. Clinical consensus is for a 30-minute endoscopy exam every 6 months by experienced practitioners.[270] Because of the diffuse distribution of the lesions, chromoendoscopy may be more sensitive for early detection, and ultrasound is less likely to be effective. It is currently not well established whether any other sites develop cancer with increased frequency with *CDH1* mutations, except for the elevated risk of lobular breast cancer. There are no clear guidelines for additional surveillance, though breast cancer screening 5 to 10 years younger than the earliest breast cancer in the family may be advisable.[272,273]

Asian, African, and Caribbean families with Lynch syndrome generally have greater incidence of stomach cancer compared to kindreds from North America, South America, and Europe, where colorectal cancer predominates.[274–276] An important clue in this clinical presentation is the existence of both endometrial and stomach cancer in the same family. It has been speculated that the shift in the GI cancer susceptibility to a rostral-caudal axis has reflected changes in food preparation and content. In particular, the decreased use of smoked and cured meats resulting from refrigeration and the high fat content of the modern European-American diet have been proposed as important factors.[276] The smoking process of meats can introduce heterocyclic amine byproducts, and the curing process involves nitrate salts that cause nitroso-compounds, which may act as potential mutagens. Epidemiologic and animal model studies provide evidence for this model.[277,278] The first HNPCC family to be identified was described by a pathologist, Aldred Warthin, in 1913 in Europe and is referred to as Family G.[276,279] In the early twentieth century, the GI tumors in Family G and other similar kindreds were distinguished largely by an excess of stomach adenocarcinoma.[280] In the middle and late twentieth and early twenty-first centuries, the GI cancer susceptibility has shifted to include mostly colorectal cancers.

Hereditary Leiomyomatosis Renal Cell Cancer Syndrome

Clinical Features

The autosomal dominant, hereditary leiomyomatosis and renal cell cancer syndrome (HLRCC) predisposes to benign cutaneous and uterine leiomyomas (fibroids), uterine leiomyosarcomas, and papillary type II renal cell cancer or renal collecting duct carcinoma.[281–284]

Kidney tumors in HLRCC are aggressive, often single, small lesions of high malignant potential. The age of onset of four cases of kidney cancer in one HLRCC kindred with 11 affected family members ranged from age 33 to 48 years, and all were diagnosed in females.[281,285] A Finnish series of 98 HLRCC cases found a standardized incidence ratio of 6.5 for renal cell cancer and 71 for uterine leiomyosarcoma. In a separate series, renal cancer occurred in 62% of 21 patients with HLRCC, and 76% had cutaneous leiomyomas. Uterine leiomyomas occur in 90% to 100% of women with HLRCC.[286] One series also reports adrenal gland adenoma and kidney cysts as well as breast and bladder carcinoma.[287] However, a study of 85 breast cancer patients with a family history of HLRCC found no increased breast cancer risk, though a considerably larger sample size could be more informative.[288] Cutaneous leiomyomas were present in 14 of 16 cases from five kindreds. They arise from the arrector pili, can be red or skin colored, can be evident as only a few to about 100 lesions, and are sensitive to touch and to cold temperature. Cutaneous lesions may be diffuse and symmetric or present in segmental bands along the lines of Blaschko. Of 11 females, 9 had uterine leiomyoma and 9 presented with cutaneous leiomyomas.[289,290] Leiomyomas of the uterus resulted in hysterectomy by age 30 in over 44% of women with HLRCC.[283]

Genetics

The gene that is responsible for hereditary leiomyomatosis and renal cell cancer on 1q42.3-q43 encodes fumarate hydratase (*FH*), a tricarboxylic acid/Krebs cycle, mitochondrial enzyme. Dominant mutations in fumarate hydratase cause HLRCC in a manner that is consistent with Knudsen's two-hit tumor suppressor model. Germline biallelic mutations in *FH* cause the mitochondrial encephalomyopathy, fumarate hydratase deficiency, and obligate carriers have presented with HLRCC.[291–294] Mutations in the fumarate hydratase gene are detected in about 75% to 100% of patients with multiple cutaneous and uterine leiomyomatosis.[282,284,286] One mutation, R190H, was detected in 11 of 31 unrelated, North American HLRCC kindreds, and the mutation R58X has also been identified in multiple unrelated kindreds.[286] Additionally, a mutation, 905-1G>A, was

found in four Iranian HLRCC kindreds, possibly representing a founder mutation in this population.[295] Reduced *FH* activity in lymphoblastoid and fibroblast cells of HLRCC patients may facilitate confirmation of clinical diagnosis via enzymatic testing.[296]

Although the molecular mechanisms underlying HLRCC have yet to be fully characterized, glycolysis dependence appears to be a contributing factor.[297] The genes *HIF-1a* and *HIF-2a* target GLUT1, all of which are elevated in HLRCC tumors. This pathway is being explored for chemotherapeutic intervention, including the agent bevacizumab, as are Hsp90 inhibitors. NAD(P)H dehydrogenase quinone 1-mediated 17-AAG antitumor activity is also under exploration in treating HLRCC related cancers.[283]

Clinical Management

Screening at regular intervals for renal lesions utilizing CT with contrast is indicated in patients with fumarate hydratase mutations. MRI is recommended for uterine leiomyoma screening, and ultrasound can also be utilized.[298]

Chemodectoma and Paraganglionoma Syndromes

Clinical Features

Chemodectomas are also known as glomus tumors or paragangliomas of the head and neck. These tumors are formed from neuroectodermal and mesodermal origins and most frequently are observed in the carotid, aortic, jugular, or vagal bodies. Of 30 cases reviewed in one series, about half were bilateral, with a family history of chemodectoma in about one third of these cases.[299,300] Most of the familial cases presented with multiple tumors. The remarkable feature about hereditary chemodectomas is the evidence of imprinting; children of affected fathers develop chemodectomas, but the children of affected mothers do not.[301]

Genetics

In paraganglioma syndromes, mitochondrial succinate dehydrogenase gene complex (*SDH-A, -B, -C,* and *-D*) has been implicated, given the oxygen sensor function of the carotid body, a common site for chemodectomas.[302] Mutations in *SDH-D* exhibit autosomal dominant inheritance, with an imprinting mechanism,[302] whereas *SDH-B* and *SDH-C* mutations do not appear to be imprinting genes. Although maternally derived *SDH-D* cases have been reported, further analysis revealed that a paternal mutation on an 11p15.5 allele was also necessary to result in paraganglioma.[303] *SDH-D* mutations give rise to more frequent head and neck tumors, whereas *SDH-B* mutations exhibit a greater propensity for malignancy and also are associated with renal cell cancers.[304]

Of 271 paraganglioma and/or pheochromocytoma patients with no family history, germline mutations were identified in 66 patients (24%), with *SDH-D* and *SDH-B* mutations accounting for 23 cases. Of the remaining 43 germline mutation cases, 30 were attributed to von Hippel Lindau syndrome mutations, and 13 were caused by mutations in the *RET* gene.[305] Given the high frequency of germline mutations in paraganglioma cases, diagnosis should prompt consideration of genetic testing to be offered to these patients.[306]

Clinical Management

Treatment for paraganglioma is surgical. Minimal morbidity occurs with small tumors, but once the size is greater than 5 cm, cranial nerve loss and baroreceptor failure may be postoperative sequelae. Screening for pheochromocytoma is by serum and/or urinary metanephrines. Screening for renal cancers is unproven, but abdominal/pelvic imaging seems reasonable.

OTHER FAMILIAL NEOPLASMS

Familial aggregations of individuals affected by Wilms' tumors, leukemias, lymphomas, gastric cancer, testicular cancer, and lung cancer as well as other malignancies have been described. A group of autosomal recessive disorders, including Bloom syndrome, Fanconi anemia, ataxia telangiectasia, and xeroderma pigmentosum, are associated with an increased susceptibility to a variety of neoplasms. A number of additional hereditary syndromes are characterized by both nonmalignant (congenital) features as well as a predisposition to cancer.[1] With the identification of genes associated with many of these syndromes, presymptomatic testing and counseling will be available.

The highly penetrant susceptibility alleles associated with the syndromes reviewed in this chapter account for a minority of human cancers. Nonetheless, the number of molecularly characterized highly penetrant cancer syndromes continues to grow. A larger proportion of human cancers may be associated with genetic polymorphisms that confer a lesser cancer risk. It was predicted on the basis of the Utah genealogies[307] that inherited susceptibility to environmental carcinogens would emerge as a major focus for the next era of research in oncogenetics. Recent completion of whole-genome association studies for breast cancer,[37,38] prostate cancer,[161,162] and other common malignancies have begun to lay the foundation for genomic approaches to low-penetrance cancer predisposition. Integrating these new markers of significant but lesser cancer risk into clinical practice looms as the next challenge in preventive oncology.

ACKNOWLEDGMENTS

The authors are indebted to Colleen-Anne Campbell, who assisted in research and referencing of recently described cancer predisposition syndromes.

13 Genetic Factors: Finding Cancer Susceptibility Genes

Elaine A. Ostrander and Danielle M. Karyadi

SUMMARY OF KEY POINTS

- The identification of cancer susceptibility genes by either linkage studies within families or association studies in populations is a useful way to understand defining events in tumor development and to identify cellular pathways that are likely to be important in cancer.
- Cancer susceptibility genes can be either strongly penetrant, in which case individuals born with a mutant allele have a high probability of developing cancer, or weakly penetrant, for which the probability of developing cancer is lower.
- Ideal families for linkage studies are large, include many affected individuals who can be readily examined and interviewed, and include individuals with similar clinical features of disease from multiple generations. This allows large data sets associated with genetic heterogeneous forms of cancer to be stratified into homogenous subsets, thus increasing the power to detect genes.
- Linkage between polymorphic markers and a disease state is assessed by using a number of statistical tools, including the parametric LOD score and nonparametric NPL score.
- Association studies that include populations of affected cases and controls are useful for identifying and testing hypotheses about candidate genes and alleles that might be associated with disease. A precisely defined set of cases and matched controls is important.
- Association studies and linkage-based studies both require collection of accurate clinical and family history data by clinicians, and both offer hope for future genetic testing.

INTRODUCTION

Cancer susceptibility genes are those that, when mutated, increase an individual's risk of having cancer. If an individual is born with one mutant copy of a cancer susceptibility gene, subsequent mutations in the wild-type allele within the relevant tissues can result in a lack of functional gene product, leading to tumor formation.[1] Genetic mapping of cancer susceptibility genes allows identification of both genes and pathways that play a role in cancer susceptibility. Although the direct public health impact associated with cloning any specific cancer gene may be minimal, the contributions to understanding of tumor development and metastasis that such advances make are potentially enormous.

Population-based studies reveal excess familial cancer aggregation for most organ sites.[2] However, cancer susceptibility genes have been mapped for only a few cancer sites to date, and the underlying mutations have been identified for even fewer. Several studies suggest that the overall percentage of cancers in the general population that are caused by highly penetrant inherited mutations is low, likely less than a few percent, even when all organ sites are considered.[3] For breast cancer and prostate cancer, the numbers are probably among the best supported; 5% to 10% of cases of each are thought to be due to mutations in inherited susceptibility loci.[4–7] The remaining cancer cases, making up the majority, are considered sporadic in nature. They are probably caused by a mixture of specific environmental and weakly penetrant genetic factors, with genetic background remaining poorly understood.

Cancer susceptibility alleles associated with a given gene may be either strongly penetrant, leading to a high probability that individuals born with a mutant allele will have the disease in question, or weakly penetrant, with carriers having a proportionately lower probability of having the disease. Allele penetrance associated with susceptibility alleles is often age-dependent, with the probability of having the disease increasing with each decade of life. Genetic mapping of cancer susceptibility genes is extremely difficult, in part because genetic background and environmental exposures are likely to affect penetrance. In addition, both highly and weakly penetrant alleles can be associated with the same gene. Further, the same allele can be associated with widely varying age-dependent penetrance within a single family as different family members have independent genetic backgrounds as well as unique life experiences and environmental exposures. Finally, stochastic effects likely play a role as well.

Highly penetrant disease alleles are best identified by family-based linkage analysis studies. The segregation of a defined chromosomal segment with affected individuals in multiple families suggests the presence of a cancer susceptibility gene within the genomic region tested. Statistical analysis that is performed after genotyping of appropriate numbers of families with markers spanning the whole genome allows researchers to calculate the probability that any given chromosomal region carries a susceptibility gene. Weakly penetrant alleles are more easily identified by association tests after analysis of DNA from two distinct populations, for example, patients with cancer together with an appropriately matched set of control subjects. Weak alleles are hypothesized to be more common in the general human population and are therefore likely to account for a higher percentage of cancer in the population overall. In this chapter, we investigate the ways in which both highly and weakly penetrant disease alleles are identified and studied.

FUNDAMENTAL SCIENCE

Hereditary Cancer Families

Strong and Amos[8] have defined a general paradigm for population studies that can be applied to identifying genes that are important in predisposition to cancer. The hypothesis that a particular cancer has an identifiable genetic component usually occurs through family history analysis of sequential cancer cases, general clinical observations, and, finally, epidemiologic studies. Epidemiologic studies assess whether there is significant evidence for an increased cancer risk at a particular organ site that can be associated with a family history of the disease. If so, a segregation analysis may be undertaken to identify features of the putative susceptibility loci. Typical analyses address mode of inheritance (dominant, recessive, or X-linked) and estimate frequency and penetrance of the disease allele(s) in the general population, age-dependent penetrance, and potential number of loci contributing to the disease. In the event that genetic linkage studies are eventually undertaken, data from the segregation analysis are key in developing statistical models for analyzing subsequent linkage data.

Familial aggregation is a general term that describes the occurrence of multiple cases of cancer within a family (Fig.13-1). Such clustering may be due to shared environment, shared alleles of particular genes, or simply chance if the tumor is very common in the population. The successful mapping of cancer susceptibility genes for breast, colon, and prostate cancer has led to the development of a strictly defined term, *hereditary cancer,* which describes families with three or more first-degree relatives with a given cancer, three successive generations with cancer, or at least two siblings with the same cancer detected at a relatively young age.[4] First-degree relatives are defined as parents, offspring, or siblings.

Many epidemiologic studies indicate that a family history of a specific cancer within first-degree relatives is associated with a doubling or more of risk among relatives.[9] In the case of prostate cancer, for instance, studies of selected hospital-based patient populations,[10,11] population-based case-control studies,[12–14] and cohort studies[2,15] all demonstrate that a family history of disease increases an individual's risk. If the affected family members are first-degree relatives (e.g., brothers or fathers and sons), the risk increases from 1.7-fold to 3.7-fold. Younger ages at diagnosis and multiple affected relatives with the disease tend to be associated with even higher relative risk (RR). For example, men with three or more first-degree relatives with prostate cancer have almost an 11-fold increased risk of the disease compared with men who have no family history of the disease.[10] For this reason, families that are ascertained for linkage analysis studies tend to be large, have multiple affected individuals, and feature people who were diagnosed with the disease at a comparatively young age.

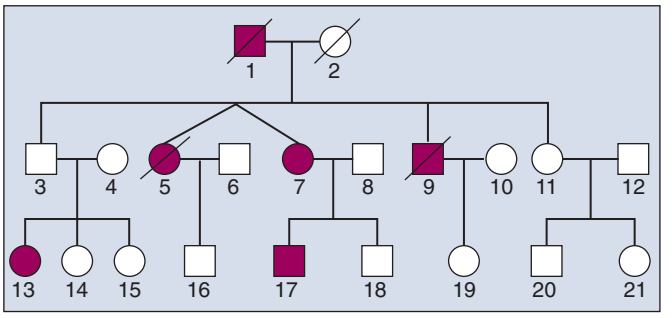

Figure 13-1 • Theoretical pedigree of a family segregating an autosomal dominant disorder. Individuals are numbered 1 to 21. Males are indicated by squares, and females are indicated by circles. Symbols for affected individuals are filled (numbers 1, 5, 7, etc.). A diagonal line through the symbol indicates that individual is deceased (1, 2, 5, and 9). A horizontal line between symbols indicates a mating (1+2, 3+4, etc.). Perpendicular lines drawn from mating lines indicate children (e.g., 13, 14, and 15 are all daughters of 3 and 4). Siblings are designated as shown for individuals 3, 5, 7, and 9; and individuals 5 and 7 are twins.

Linkage Mapping and Finding Cancer Susceptibility Genes

Several requirements must be met to successfully identify cancer susceptibility genes. First, a large number of so-called high-risk or hereditary families must be ascertained by using appropriate guidelines for working with human subjects. Clinical features and family history data must be recorded, and DNA samples must be obtained. Once purified, DNA samples from appropriate family members need to be screened by using a set of highly polymorphic markers that span the genome at a high density. Historically, genome scans have used microsatellite-based markers distributed approximately every 10 million base pairs. Recent studies suggest that a denser scan with highly polymorphic markers every 5 million base pairs or even biallelic markers, such as single nucleotide polymorphisms (SNPs) placed every 2 to 3 million base pairs may be preferable. Finally, the data must be interpreted or analyzed in the context of the disease in question. Creating stratified data sets, which allow analysis of families with a common disease or family history features, is important and may increase the chance of finding a susceptibility-associated locus. These issues are discussed in the following sections.

Family Collection

Most cancers are heterogeneous diseases that likely involve multiple susceptibility genes. In a statistically ideal situation, a given set of affected individuals within a family would all have cancer for the same reason; that is, each member would have inherited a mutated copy of the same gene. But in truth, for common cancers such as those of the breast, prostate, and colon, any given family may have individuals whose disease is due to mutations in multiple different genes, some highly penetrant and some weakly penetrant, as well as family members whose disease is sporadic.[16] Often, disease presentation is similar in genetic and sporadic cases, and examination of clinical or pathologic features is uninformative for determining whether a specific patient represents a genetic or sporadic case.

Figure 13-2 demonstrates two types of seemingly useful families for linkage-mapping studies. Both include a significant number of affected members. The first family, in particular, has a large number of affected individuals (see Fig.13-2A). However, some individuals were affected very early in life, whereas others were diagnosed at later ages. It is likely that some individuals have the disease because they inherited mutated copies of a particular gene, whereas others have the disease for sporadic reasons unrelated to the disease allele segregating in the family. Ideally, age at onset provides some guidance as to which individuals are more likely to have hereditary versus sporadic forms of the disease; but this is not absolute, and in the case of a disease with age-dependent penetrance, some people will be affected late in life even though they carry a mutant allele, and others will be affected early in life for sporadic reasons. The family shown in Figure 13-2B also appears to be informative for and conducive to linkage mapping studies. There are several affected individuals in the family, and all were affected at a relatively early age. However, the presence of disease segregating on both sides of the family should be noted. The affected individuals in the youngest generation could have cancer because they inherited mutant alleles from one or both sides of their family, and one or multiple genes could be involved. Therefore, the family is of limited utility for mapping studies.

Obtaining good clinical information for all individuals in a family mapping study gives geneticists the power to stratify the data into more homogenous subsets. This increases statistical power for finding the genes associated with any one particular aspect of a phenotype. If a subset of individuals in the family in Figure 13-2B all had tumors of similar stage and grade, the data from this homogenous subset of

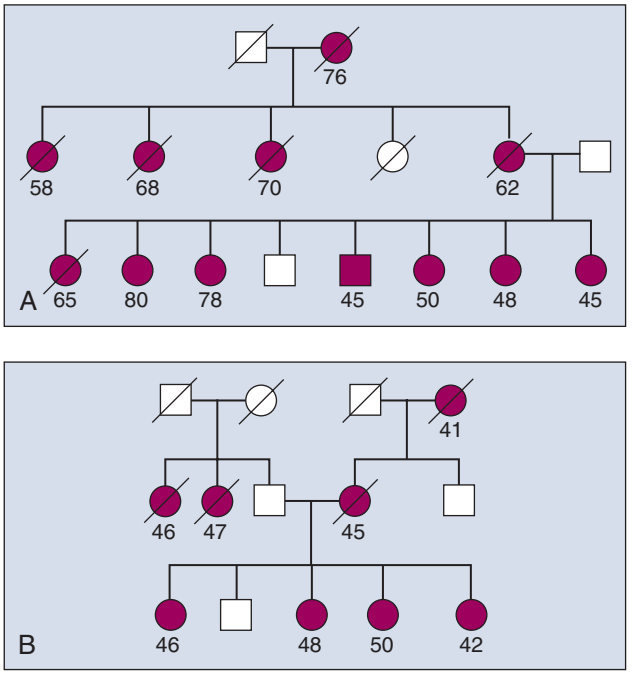

Figure 13-2 • Two theoretical breast cancer families. Age at diagnosis is indicated below the symbol; males are indicated by squares, and females by circles. **A,** The family has many members affected with breast cancer, but some were given diagnoses relatively early in life (<50 years), whereas others were much older at diagnosis (>70 years). The utility of this family for genetic-mapping studies is thus limiting, because it likely contains individuals with both sporadic and hereditary breast cancer. **B,** All individuals were affected at an early age, but breast cancer, caused by mutations in either the same or different genes, is present on both sides of the family. Because there is no way to distinguish the number of mutant genes a priori, the utility of this family for a genome-wide scan is also somewhat limited.

individuals could be considered in isolation from the rest of the affected cases, reducing heterogeneity and increasing power. In addition to clinical features of disease, family history, age at onset, and presence or absence of other cancers are all ways to stratify data into homogenous subsets and improve the likelihood of finding causative genes. In the case of prostate cancer, several recent studies have focused on families with an excess of men presenting with a high Gleason tumor grade at diagnosis. Recall that the Gleason score reflects the pathologic architecture of the tumor at diagnosis. Several regions are scored and assigned a grade of 1 to 5, representing a well to poorly differentiated pattern, respectively. The two predominant grades are added to give a summary score of between 2 to 10, most tumors being in the range of Gleason 5 to 7. Recent studies of prostate families reveal a set of specific loci for families in which two or more men from whom DNA could be genotyped presented with high Gleason scores or other measures of aggressive disease.[17] Indeed, some studies suggest a difference in men who present with a Gleason 3 + 4 versus 4 + 3, the latter representing a higher-risk class of study subjects with regard to higher frequency of biochemical failure, systemic recurrence, and cancer-specific death.[18,19]

Identification of cancer families and collection of critical medical information, including family history, medical record data, and DNA samples, are generally regulated by institutional review boards. Families must be identified in a way that is neither intrusive nor coercive. For these reasons, genetic epidemiologists are increasingly turning to advertisement in periodicals such as supplements to popular newspapers or widely read periodicals[20] to recruit eligible families. A particularly innovative approach used by investigators trying to find hereditary prostate cancer families was to establish a toll-free telephone number, which was then advertised on a popular syndicated television talk show.[21] Listeners whose family history matched that described were encouraged to call for a preliminary phone screening and to obtain more information about the study.

For linkage-based approaches to correctly identify associated loci, rigorous quantitative data regarding strength of phenotype must be available for multiple generations of the family. Medical record data must be carefully and systematically extracted into well-protected databases. Family history data must also be obtained redundantly from multiple members of the family, and care must be taken to resolve discrepancies. Consent to contact other family members regarding the study is needed, as is permission to obtain medical records. Individual privacy must also be protected and personal identifiers such as names and addresses must remain confidential.

Locus Heterogeneity

If a particular trait is controlled by a large number of genes, each of which contributes only minimally to the final complex phenotype, it will be difficult to dissect the contributions of any one gene by studying a small number of families. If the phenotype is controlled largely by a small number of genes, however, the underlying genetics will be much easier to resolve. The breast cancer susceptibility genes BRCA1 and BRCA2 were likely among the first to be mapped for several reasons related to this point.[22,23] First, only two genes appear to control the majority of the hereditary breast cancer in the general population.[24] Had the number of highly penetrant genes in the population been larger, the task would have been proportionately greater. Second, in both cases, large and well-characterized families had been meticulously ascertained. This ensured that there was sufficient statistical power to undertake the genome scan. Third, the power of any given data set can be increased dramatically by identifying families in which several members share minor disease features, thus making it likely that their disease is due to mutations in the same gene. The presence of ovarian cancer in some families and not others and the presence of breast cancer in some male carriers allowed for the creation of data sets that were enriched for the BRCA1 and BRCA2 genes, respectively.[22,23] Finally, it is always useful to remove from a data set families whose disease is known to be caused by any given gene. The identification of the BRCA1 gene and subsequent removal of BRCA1-linked families from remaining data sets provided further useful enrichment for BRCA2-linked families.[23,25]

Initially, in the case of breast cancer, investigators did not know the number of genes likely to be involved in genetic susceptibility. Detailed segregation analysis had suggested that the gene or genes responsible for breast cancer were likely to be highly penetrant and autosomal and to produce patterns of age-dependent penetrance. A segregation analysis typically involves interviewing a large number of sequential case patients who share common features of the disease. Once a segregation analysis is complete, the resulting data can be factored into the resulting genome-wide scan. This allows data from some individuals to be weighed more significantly. Segregation analyses have now been done for nearly all types of cancer,[4,7,26–29] providing investigators with an array of clues with which to begin their search for genes of interest.

After families are designated for a genome-wide scan, a power analysis is performed to determine whether there is sufficient statistical power in the specific group of families collected to find linkage to the trait in question, given a certain set of assumptions. The assumptions include how many markers are being tested, how informative each marker is likely to be, and the composition of the families in question. The scenario in which a given set of families offers sufficient power to find a gene only if one of the markers is extremely close to the locus occurs frequently and is particularly associated with diseases such as cancer, for which locus heterogeneity is common. The power to find genes decreases dramatically as the number of genes that contribute to a phenotype increases.[30]

Another way to reduce locus heterogeneity is by studying families from isolated or inbred populations. Fewer disease alleles are predicted to segregate with a particular phenotype in a population derived from a limited number of founders. Studies of colon cancer in Finland and studies of breast cancer in Iceland and in Ashkenazi Jewish populations illustrate these points very well. In Finland, two variants in the DNA mismatch repair gene, MLH1, termed mutations 1 and 2, account for 51% of all Finnish families with verified or putative cases of hereditary nonpolyposis colorectal cancer.[31] Nineteen mutation 1 and six mutation 2 families were further investigated by haplotype analysis using 15 microsatellite markers surrounding the MLH1 locus. The presence of two distinct large conserved disease haplotypes, one in mutation 1 and the other in mutation 2 families, indicated that these families are likely to descend from two common ancestors born in the sixteenth century and eighteenth century, respectively.[31]

For the breast cancer susceptibility genes, BRCA1 and BRCA2, several founder mutations have been identified in different populations.[32] For instance, a single BRCA2 mutation, 999del5, was found in 16 of 21 Icelandic breast cancer families.[33] All 16 of these families share a haplotype or pattern of alleles within the BRCA2 gene, suggesting a common ancestral origin. Studies of breast cancer in Jewish families have also demonstrated this point, contributing enormously to our knowledge of founding mutations for both BRCA1 and BRCA2.[34,35] The three common founder mutations in this population, BRCA1-185delAG, 5382insC, and BRCA2-6174delT, have a combined prevalence of 2% to 2.5%.[32,34,36,37] With these observations in mind, investigators have frequently sought families for genetic-mapping studies from regions of the world where marriage between related individuals is not taboo and where geographic barriers have restricted gene flow. This is especially important for genetically heterogeneous diseases, such as prostate cancer. Indeed, support for the existence of a locus on the X chromosome, HPCX, was found in a subset of Finnish families, suggesting that the HPCX locus might contain a founder mutation in Finland.[38]

Principles of Genetic Linkage Analysis

The principles of meiotic recombination are key to understanding linkage analysis. In meiosis, the cell division leading to gamete formation, homologous chromosomes are paired. Each chromosome consists of two identical strands (chromatids), each chromosome pairing being composed of four strands. Homologous chromosomes separate from each other during the process of meiosis except at one or two zones of contact in a process that leads to genetic recombination (Fig.13-3). Mendel's second law, of independent assortment, states that alleles of genes at unlinked loci segregate or assort independently of one another. Deviations from independent assortment occur when genes are located close to one another, in which case alleles assort together more than 50% of the time. In this scenario, the associated loci are said to be linked. However, if two loci are located on different chromosomes or far apart on the same chromosome, their alleles will assort randomly, a given set of alleles being transmitted to the same gamete 50% of the time. Such loci are said to be unlinked.

For any given chromosomal segment, the probability of a genetic recombination event occurring between a pair of markers or a marker and a gene is proportional to the distance between them. This probability is expressed as a recombination frequency (q), where

$$\theta = \text{Number of recombinant offspring/Number of total offspring}$$

Recombination frequency ranges from 0 for genes that are so closely linked that crossover events essentially never occur to 0.5 for genes that assort randomly. Within small intervals, when the probability of multiple crossovers is negligible, the relationship between the recombination fraction (θ) and the distance between two genes (x) is simply $x = \theta$.[39] After a minor mathematical adjustment for the possibility of double recombinants is made, recombination fractions

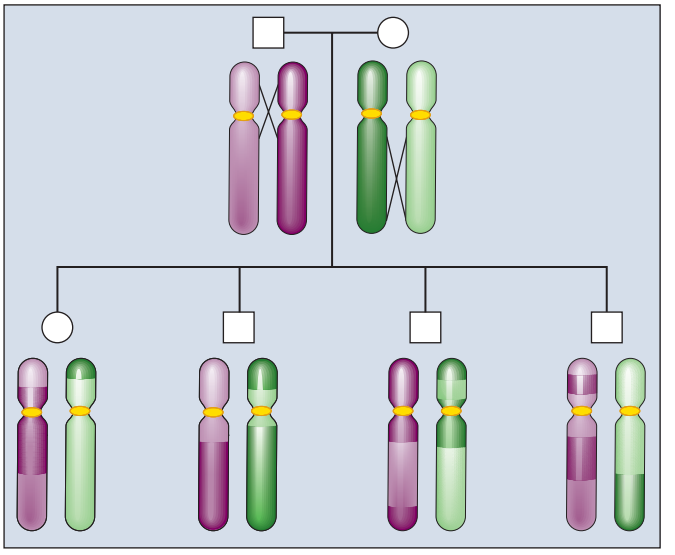

Figure 13-3 • Genetic recombination is the process of exchanging genetic information between two chromatids during meiosis. The recombination events for a single chromosome within a family are illustrated. The father's homologous chromosomes are light and dark purple, and the mother's are light and dark green. Recombination events occurring during meiosis create unique parental chromosomes.

are expressed in units called *centimorgans* (cM), named after the geneticist Thomas Hunt Morgan.[40] One percent recombination ($\theta = 0.01$) is equal to 1 cM, which in the human genome corresponds to about one million base pairs. The entire human genome is estimated to be about 3300 cM.

Genetic linkage mapping queries whether any given portion of the genome is consistently inherited with the disease status. The ordered set of alleles associated with a particular part of the genome received by an offspring from one parent is called a haplotype (Fig. 13-4). Recombinant haplotypes are generated when a crossover occurs between two linked markers (see Fig.13-3). In Figure 13-4, the father is a heterozygote for two loci (AB for locus 1 and XY for locus 2). The mother is homozygous at both of the same loci but with different alleles (CC and ZZ), and as a result, all offspring will inherit the C, Z haplotype. If these two markers are unlinked, as they would be if they were on different chromosomes or far apart on the same chromosome, four types of gametes would be expected from the father (A,X; B,Y; A,Y; and B,X) in approximately equal proportions (see Fig.13-4A). However, if the markers are linked (see Fig.13-4B), the father would be expected to produce an excess of the two "parental" haplotypes (A,X and B,Y) over a smaller number of the "nonparental" or "recombinant" haplotypes (A,Y and B,X).

GENOME-WIDE SCANS

Marker Informativeness

Key to the success of any genome scan is the development of a well-defined set of markers that completely span the genome at defined intervals. The number of markers used determines the resolution of the resulting scan. A 10-cM genome scan, for instance, will allow localization of a disease locus only to within 5 million base pairs, whereas a 1-cM density scan, composed of approximately 3000 informative markers, will localize a gene to within half a million base pairs.

A genetic marker, by definition, has two or more alleles. If the frequency of the most common allele is less than 95%, the marker is said to be polymorphic. One measure of polymorphism is called *polymorphism information content* (PIC).[41] PIC defines the probability

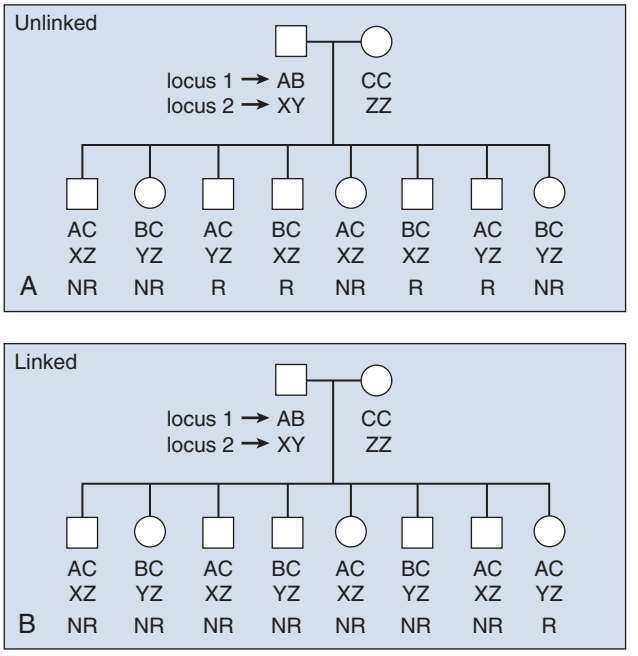

Figure 13-4 • Linked and unlinked markers segregating in two families. Below the symbols, the genotypes for both markers are listed. Offspring have either recombinant (R) or nonrecombinant (NR) haplotypes. The father is heterozygous for marker 1, AB, and marker 2, XY; and the mother is homozygous for both markers, CC and ZZ. **A,** If the markers were unlinked, there would be equal numbers of R and NR haplotypes from the father (AX, BY, AY, and BX). **B,** There is an excess of NR haplotypes (AX and BY), and only one R haplotype appears. Therefore, these loci are linked.

that the genotype of a specific offspring will be sufficiently informative to determine which of two parental alleles has been inherited. Markers are assigned PIC values between 0 (minimally informative) and 1.0 (perfectly informative). A second measure of polymorphism is called heterozygosity. Heterozygosity (H) is calculated as $H = 1 - \sum(\text{Pi})^2$. Pi is a measure of the allele frequencies for a given marker in the population under consideration.[42] There are currently several thousand well-characterized genetic markers with assigned PIC and/or heterozygosity values whose chromosomal locations in the human genome are well known.

Several different types of genetic markers are currently in use for genetic linkage mapping, each with different strengths. Microsatellites are small stretches of repetitive DNA composed of repeated motifs of mono-, di-, tri-, or tetranucleotides, such as (CA)n or (GAG)n, located randomly in the genome.[43–45] They occur frequently in mammalian populations, with a dinucleotide (CA)n repeat found, on average, every 30 to 60 kilobases.[45,46] Microsatellites occurring in human DNA are extremely polymorphic, a given marker occasionally having in excess of 20 alleles. Microsatellite alleles are sufficiently stable in the population and therefore can be reliably used to track inheritance of chromosomal segments through several generations in a family. Yet with an estimated mutation rate of 5×10^{-4} to 10^{-5} per allele per meiosis, new alleles appear frequently in the population, contributing to their overall utility as genetic markers.[47]

Individual microsatellite markers are distinguished from one another after amplification of the locus by polymerase chain reaction and separation of the resulting alleles by electrophoresis[48,49] (Fig. 13-5). Among the most popular platforms is the Applied Biosystems (ABI) Capillary system using the GeneScan software.

One disadvantage of (CA)n repeat–based microsatellite markers is that the resulting variant alleles are so similar in size that they can sometimes be hard to separate on a gel. For this reason, most genome scans today are done by using commercially prepared sets of markers based largely on trinucleotide and tetranucleotide repeats.[50] Although less frequent than (CA)n repeats in the genome, they are easier to automate, and the resulting data are assessed with generally lower error rates. Sets of markers that are known to be very polymorphic and to have 5-cM or 10-cM spacing, and are thus optimized for genome-wide scans, are commercially available for the human, mouse, rat, and dog genomes. Commercially prepared marker sets are optimally designed so that the markers can be multiplexed, making it possible to analyze several markers simultaneously in a single gel lane.

SNPs (pronounced "snips") occur when a single base in the genome is altered. It is estimated that polymorphic SNPs with a minor allele frequency greater than 5% occur once every 450 base pairs in the human genome and thus offer an unending resource for tracking variation.[51] However, since SNPs are biallelic, the overall informativeness of a single marker is less then the average microsatellite. As a result, thousands of SNPs are required to perform a complete genome-wide linkage scan.

The recent development of high-throughput SNP genotyping platforms for linkage studies by Affymetrix (10K GeneChip microarray, Fig. 13-6) and Illumina (Linkage IV panel, Fig. 13-7) have not only made SNP-based linkage scans realistic, but significantly reduced the time required to interrogate a complete genome. Dense SNP genotyping also increases the information content in families in which the parental genotypes are not available, as is typically the case for late-onset diseases like most cancers. For example, researchers at the Mayo Clinic analyzed a linkage study of prostate cancer families with both a 10-cM spaced microsatellite and the Affymetrix 10K SNP genome-wide scans.[52] They concluded that for families that lack parental genotypes, the SNP scan had significantly higher information content than did the microsatellite scan (61% versus 41%). This concept is an important consideration in experimental design. Measures of linkage can be limited by both lack of critical family members and marker informativeness. The increase in information content associated with a dense SNP genome-wide scan will improve measures of linkage at loci, which are truly linked.

However, genome-wide SNP linkage scans do have some limitations. Each individual SNP is not very informative; therefore, tracking the inheritance of chromosomal segments through a family or the detection of Mendelian errors requires the assembly of data into haplotypes (Fig. 13-8). A haplotype represents a set of alleles associated with an ordered set of markers inherited together on a

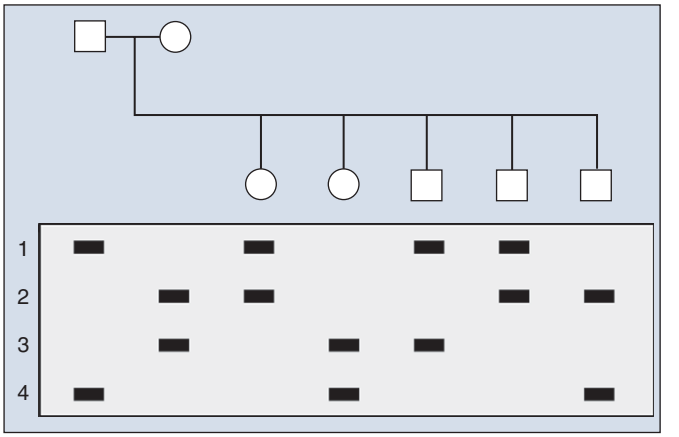

Figure 13-5 • Schematic agarose gel electrophoresis of a microsatellite marker analyzed on a single family. Males are indicated by squares, and females by circles. Four alleles are segregating; the father has alleles 1 and 4, and the mother carries alleles 2 and 3. Each child has inherited one allele from each parent, together with the surrounding genomic information.

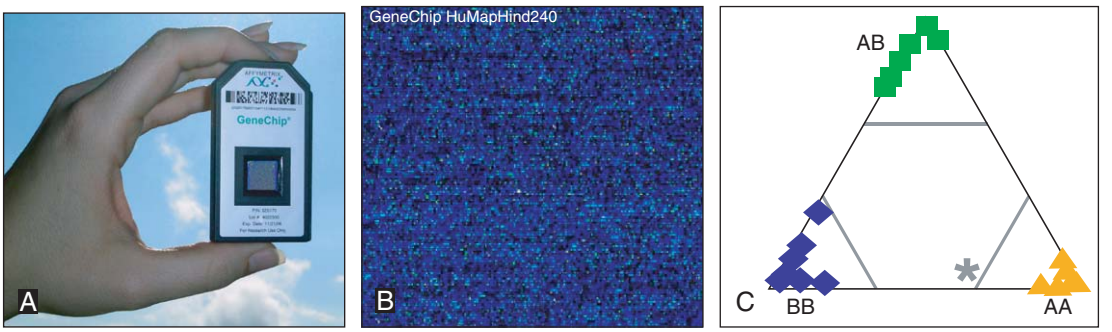

Figure 13-6 • Affymetrix's high-throughput SNP genotyping platform. **A,** Affymetrix GeneChip can assay over 250,000 SNPs per sample on a single GeneChip. Oligonucleotide probes are spotted to a glass microchip, where each SNP is interrogated with approximately 40 different probes. **B,** A pseudocolored scan of a single Human Mapping 100K Hind GeneChip. **C,** The GTYPE software displays the genotype calls of several samples for a single SNP (C versus T). The orange triangles are homozygous CC, the green squares are heterozygous CT, and the blue diamonds are homozygous TT.

chromosome that form either the maternal or paternal ancestry. Computer programs such GENEHUNTER and MERLIN are available to assist in assembling haplotypes.[53,54] The process is most efficiently expedited, however, by the collection and genotyping of critical family members, such as grandparents, whether they carry the disease in question or not. It is also important to note that linkage disequilibrium between SNPs can artificially inflate measures of linkage. This is more problematic with SNPs then with microsatellites, as the SNP markers are most closely spaced and are thus more likely to be coinherited as a block. So for any data set, the linkage disequilibrium between SNPs needs to be carefully assessed and SNPs that are in high linkage disequilibrium with other SNPs need to be removed from the data set.

Measures of Linkage

Calculating LOD Scores

On completion of a genome-wide scan, extensive checking is done by using programs such as PEDCHECK, PREST, RELPAIR, and MERLIN to detect potential genotyping errors by checking, for instance, Mendelian inheritance.[54–57] Data are then analyzed to determine which, if any, markers are closely linked to a putative disease locus. The likelihood for linkage ($\theta < 0.5$) versus the likelihood for recombination ($\theta = 0.5$) is calculated on the basis of the number of observed recombinant and nonrecombinant offspring produced by a given mating. Conventionally, the logarithm of the likelihood ratio, or LOD score, is

$$Z(\theta) = \log_{10}[L(\theta)/L(0.5)]$$

and is used as the measure of support for linkage versus nonlinkage. For example, if n observations consist of k recombinants and $n - k$ nonrecombinants, the corresponding LOD score is given by

$$Z(\theta) = n \log(2) + k \log(\theta) + (n - k)\log(1 - \theta), \text{ if } \theta > 0$$

$$Z(\theta) = n \log(2), \text{ if } \theta = 0$$

It is often stated that linkage is "found"; that is, a marker under consideration is said to be linked to a putative disease locus when a recombination fraction of $\theta < 0.5$ is supported by a LOD score of at least 3.0.[58] However, in searching for genes, it is important to distinguish between pointwise significance levels and genome-wide significance levels.[59] The pointwise or nominal significance level is the probability that one would encounter such an extreme deviation at a specific locus by chance. The genome-wide significance level is the probability that one would encounter such a deviation somewhere in the whole genome scan (Box 13-1). The former is an evaluation of a single test of the null hypothesis of no linkage (testing for linkage of a favorite candidate gene to a disease locus); the latter involves screening over a large number of tests (i.e., running a large number of markers spanning the genome) to find the most significant result.

In assessing the significance of a putative linkage result, Lander and Kruglyak[59] have assigned the following descriptors. Suggestive linkage is that which would be expected to occur one time at random in a genome scan. Significant linkage would be expected to occur 0.05 times in a genome-wide scan. Highly significant linkage that is considered statistically significant is expected to occur 0.001 times in a genome scan. It is generally the norm to report all regions with a nominal P value of $P = 0.05$ in a complete genome scan. These may indicate places in the genome where additional families, markers, or both are needed. A LOD threshold of 3.3, corresponding to $P = 5 \times 10^5$, is the value that is now accepted as indicating a genome-wide significance level of 5%. Thus, in the context of a genome-wide scan, a marker is said to be linked to a disease locus if a LOD score of 3.3 is achieved[59] (Box 13-2).

Limitations and Sources of Error

Linkage analysis is an inherently error-prone approach. It is fairly easy to arrive at an incorrect conclusion because of the large number of

Box 13-1. LOD SCORES VERSUS PROBABILITY MEASURES

It is noteworthy that there is frequent confusion in the literature about LOD scores versus probability measures. Again, according to the example provided by Lander and Kruglyak, a LOD score of 3.0 means that the observed data are 1000 times more likely to arise under a specific hypothesis of linkage than under the null hypothesis of independent assortment. A P value of 10^{-3} means that the probability of encountering as large a LOD score as is observed is 10^{-3} under the null hypothesis.

Box 13-2. CONFIRMATION LINKAGE STUDIES

Clinicians often choose to participate in studies that are aimed at confirmation of previously published linkage reports. For confirmation of published findings of linkage in an independent data set, a nominal P value of 0.01 is required. Because linkage from any previously published reports may hinge on precise features of the clinical diagnosis or stratification of the data set based on features of family history, it is vital that participating physicians record their clinical observations as accurately as possible.

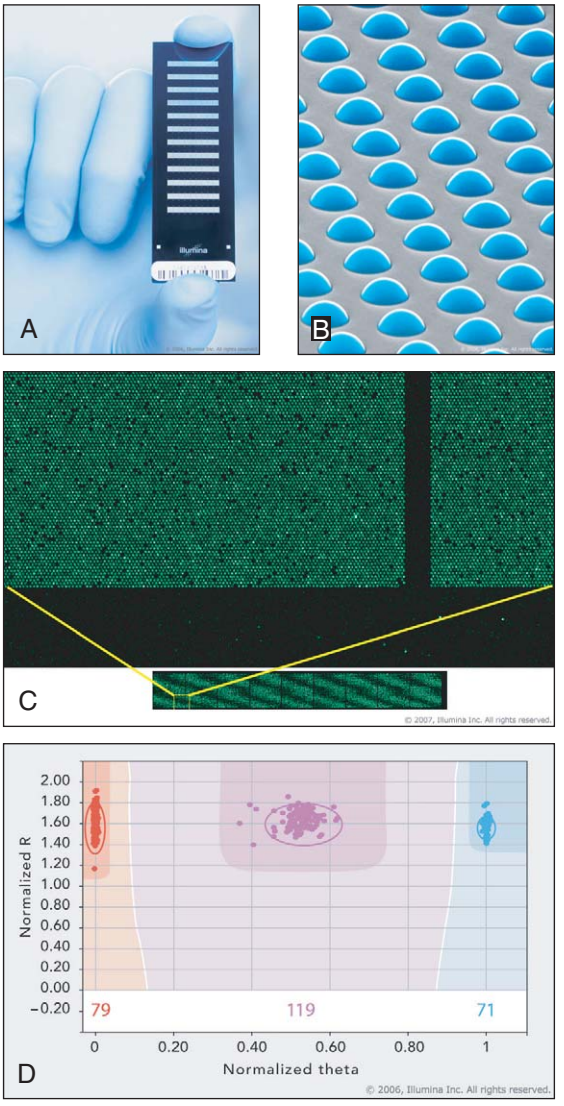

Figure 13-7 • Illumina's high-throughput SNP genotyping platform. **A,** Illumina's Infinium BeadChip can assay over 650,000 SNPs per sample on a single BeadChip. **B,** Illumina's BeadArray Technology is based on 3-micron silica beads. Each bead is covered with over 100,000 copies of a specific oligonucleotide that act as the capture sequence in the Illumina assay. **C,** BeadScan Software scans the results of a single-color BeadChip. Each green dot represents one 3-micron bead and the specific oligonucleotide attached to it. **D,** BeadStudio Genotyping Software displays the cluster plot for the results of a single SNP (A versus G). The genotypes of the 79 red samples are homozygous AA, the 119 purple samples are heterozygous AG, and the 71 blue samples are homozygous GG.

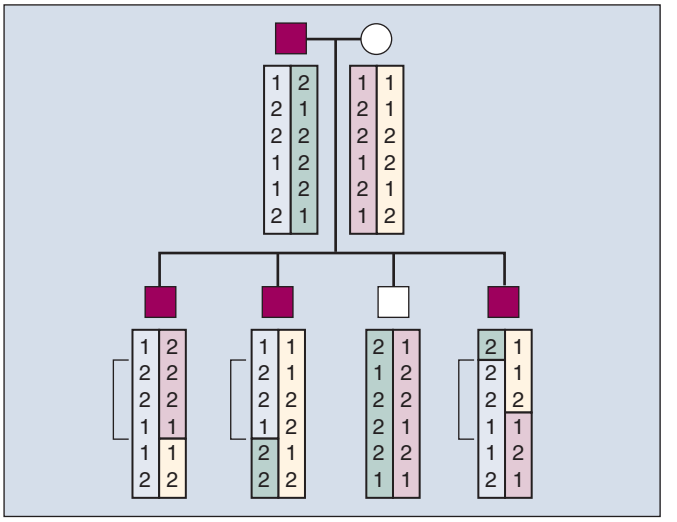

Figure 13-8 • SNP haplotypes in a prostate cancer family. Males are indicated by squares, and females are indicated by circles. Each individual's haplotype for a chromosomal region of interest is drawn below the symbols. The father's two haplotypes are blue or green, and the mother's are red or yellow. The three affected brothers and father all share the haplotype shaded blue, whereas the unaffected brother has inherited the haplotype shaded green. There are recombination events in brothers 2 and 4, restricting the region of interest to that defined by SNPs 2, 3, and 4 (indicated by the brackets).

assumptions that must be made in the calculation. For instance, calculation of LOD scores is dependent on accuracy of the linkage model.[60] The model is typically based on assumption regarding mode of inheritance or frequency of mutant alleles in the population which may be derived from segregation analysis conducted in one geographic region at one hospital, thus introducing potential bias. In addition, studies have shown that LOD score analysis of a small number of families is very sensitive to changes in a few key data points. Small errors in genotyping or misclassification of affected status have the potential to artificially inflate or deflate a particular LOD score. Consider, for example, age at onset. The linkage calculation will weigh the value of information provided by any given family member compared with that of every other person in the study. So if early-onset disease is a defining part of the phenotype, the genotyping data from an individual woman who was diagnosed with the disease at the age of 30 years will be weighted more in the linkage statistic than will data from a person who was diagnosed at 80 years. Therefore, it is vitally important that the clinician participating in the study obtain the most current and accurate information available from any patient who is likely to be a study participant, including the age at which various family members had cancer.

One additional problem with linkage calculations is the loss of power associated with missing data. In principle, an individual who is a heterozygote at two loci A and B (AaBa) could have received his or her A allele in coupling with either the B or the b allele from one parent. To distinguish recombinants from nonrecombinants, the parental and nonparental haplotypes must be known. If the A and B alleles were inherited together on the same chromosome, they are said to be in phase. Unfortunately, when mapping diseases such as cancer, in which late age of onset is common, two-generation families are typically all that are available for sampling, thus limiting the ability to determine phase. However, collection and analysis of data from spouses or offspring of deceased affected individuals may allow researchers to reassemble the genotype of the deceased individual. Similarly, collection of DNA samples from unaffected siblings can be very useful for establishing parental phase.

Nonparametric Analysis

Because calculation of LOD scores is dependent on models of linkage that are notoriously difficult to derive,[61] researchers are turning increasingly to nonparametric linkage (NPL), or nonmodel-based approaches for mapping genes.[53] Such approaches use only the data from affected individuals; therefore, no assumptions are made as to whether an unaffected person is more or less likely to have cancer and, if so, at what age. In an NPL analysis, haplotypes are built across the relevant regions of the genome by using computer programs such as GENEHUNTER or MERLIN.[53,54] The data are compared, and *P* values are calculated to assess the degree of significance observed between inheritance of a disease state and a specific haplotype.

Nonparametric approaches have the disadvantage of being less powerful than LOD score–based approaches because data from unaffected individuals, which could have contributed to the LOD score, do not contribute to the NPL score. For diseases that are genetically heterogeneous, such as common cancers, this is more than made up for by the lack of reliance on incomplete or inaccurate linkage models.

One final consideration is that of age at diagnosis versus age at onset, which, depending on the disease and available diagnostics, can differ by several years. Diagnosis of prostate cancer by prostate-specific antigen (PSA) testing provides an interesting example. The widespread use of screening for prostate cancer by serum PSA measurements has dramatically changed the patterns of disease diagnosis in the United States.[62] Reported rates increased rapidly between 1986 and 1993, in part because of the detection of latent prostate tumors in the general population as a result of PSA screening.[63] It is generally believed that PSA can detect tumors from 2 to 5 years earlier than methods such as digital rectal examination.[64–66] Therefore, data from a man who was given a diagnosis of prostate cancer at age 65 in 1995 should contribute differently to a genome scan than data from a man given the diagnosis at the same age in 1975. The man who was given the diagnosis in 1975, assuming that he participated in screening, would probably have been given the diagnosis in his early sixties if he were alive today. Developing statistical methods to account for these differences can be extremely difficult.

It is also important to note the difference between untested and unaffected individuals. Patients are more likely to know that they are truly unaffected with a disease such as prostate cancer (as defined by PSA status) than they are likely to know they are truly unaffected with other cancers, such as pancreatic or ovarian cancer, for which vigilant screening is not the norm. For this reason, in some genome-wide scans for cancer susceptibly genes, clinical status of putatively unaffected individuals may be coded as "unknown" rather then "unaffected." It is important that the interviewing physician make the distinction when recording any patient's family and medical history.

Positional Cloning Resources

Meiotic linkage studies may define a region of interest as small as a few thousand bases or as big as several million bases. The latter may span more than a hundred genes[67,68] and must be further reduced before mutation scanning can realistically begin. Several strategies exist for narrowing the search. Among the most common is the search for genomic rearrangements in tumors, which may indicate chromosomal regions where cancer susceptibility genes are likely to be located. Expression arrays identify genes that are differentially expressed in tumors compared to matched normal tissue. Additionally, intriguing candidate genes within the region of interest may be selected for priority sequencing based on known biologic function or a previous association with cancer.

Comparative Genome Hybridization

Comparative genome hybridization (CGH) can be used to acquire information about gains and losses of chromosomal regions in tumors.[69,70] CGH allows investigators to perform genome-wide analysis of DNA sequence copy number in a single tissue. Traditionally, differentially labeled genomic DNA from a "test" and a "reference" cell population are cohybridized to normal metaphase chromosome spreads. Regions of gain or loss of chromosomal segments, such as deletions, duplications, or amplifications, are seen as changes in the ratio of the intensities of the two fluorochromes. The procedure works because the ratio of fluorescence intensities along the length of the chromosome is proportional to the ratio of the copy numbers of the corresponding DNA sequences in the test and reference genomes at each point in the chromosome. More recent innovations with this technique allow investigators to circumvent the low resolution associated with metaphase spreads and very precisely determine DNA copy number by combining traditional CGH with arrays of bacterial artificial chromosomes (BACs) or oligonucleotides.[71,72] Array CGH studies have contributed to the identification of the genetic alterations involved in cancer progression and metastasis and highlight the importance of studying tumors at various stages of progression.

Expression Arrays

Another method for refining linkage data before proceeding with candidate genome analysis is the use of expression arrays. Expression arrays analyze differences in gene expression on a large scale by assaying thousands of genes in one experiment. For one type, DNA microarrays, DNA sequences from the coding regions of known or putative genes are assayed with probes made from messenger RNA, which determines an expression profile of genes for a certain cell type or under specific experimental conditions. In terms of cancer genomics, normal cells may express different portions of the genome or different genes at different levels when compared with their neoplastic counterparts, which may indicate biologic networks or pathways involved in disease pathogenesis.[73] Microarray experiments have led to molecular classification of many cancer types according to differences in gene expression, including breast cancer,[74] lymphomas,[75] and soft-tissue tumors.[76] Integration of DNA microarray data with genetic mapping results will help to prioritize candidate genes in regions of known linkage. As single gene traits are defined and researchers' interest turns increasingly to multigene traits, a combination of traditional and twenty-first century approaches will most likely define the genes of interest.[77]

Tissue Banks

One problem that is not infrequently encountered with CGH and expression array studies is lack of reproducibility across studies. This is due to both the limited number of tumors typically available for studies and the heterogeneity in the tumors themselves. One way to circumvent both problems is to develop tumor banks in which investigators can deposit well-characterized tissues for a variety of research purposes.[78] One potential complication is the rigor with which such banks must be maintained. It is important that complete pathologic records accompany each tissue and that the tissue deposited be as free as possible of adjacent noncancerous tissue. Toward this end, researchers have turned increasingly to the use of laser capture microdissection as a way to isolate virtually pure populations of tumor for CGH and expression array studies.[79]

ASSOCIATION STUDIES

Association studies are distinct from linkage analysis in that specific alterations in the DNA are assessed in both affected and unaffected individuals to determine whether the variant is found more often in individuals with the disease and whether this difference in the frequency of the variant allele is statistically significant. Association studies are widely used to assess the significance of variants in candidate genes and just recently are being used to identify susceptibility genes in genome-wide association studies.

Assessment of Candidate Genes

Once a candidate gene is proposed, association studies are important to determine whether sequence level changes in the gene are associated with the disease of interest. Candidate genes are identified in a variety of ways. For instance, the biologic function of a known gene might suggest a role in cancer susceptibility. Alternatively, the sequence of the gene might suggest that it is a member of a protein family that is known to play a role in cancer biology. Genes that are important in DNA repair, apoptosis, and cell cycle regulation are all

likely candidates. Finally, the gene in question might be located at a locus identified by linkage analysis of high-risk families. Thus, it may be one of a large number of genes under consideration.

Genome-wide Association Studies

Since association studies have greater power to identify common genetic variability compared to linkage studies, the ability to conduct these experiments has been highly anticipated. Genome-wide SNP association studies have become more practical in the past few years owing to the information gained from the HapMap project (www.hapmap.org) and the development of technologies to genotype hundreds of thousands of SNPs in a single experiment. The International HapMap project aimed to identify genetic similarities and differences in human populations. The initial data were generated from four different populations with African, Asian, and European ancestry. These data allow for the identification of minimal sets of informative SNPs to tag variation throughout the genome for a given population. Also important for the advancement of genome-wide association studies was the development of high-throughput genotyping assays, which are cost-effective, accurate, and reproducible. Currently, the two leading high-throughput genotyping platforms are from Affymetrix and Illumina. The Affymetrix GeneChip microarrays (see Fig. 13-6) are available to genotype 10K, 100K, or 500K genome-wide SNPs in a single experiment. From Illumina, the Infinium HumanHap300 and HumanHap550 (see Fig. 13-7) are specifically designed for whole-genome genotyping of tag SNPs derived from the HapMap project. The study design and caveats for genome-wide association studies are similar to the candidate gene approach and will be discussed briefly in the following sections. However, adjusting for multiple testing is a particular concern for genome-wide association studies as the number of SNPs tested in a given experiment is large.

Study Design

Two primary types of study design are typically used: cohort and case-control studies. In a cohort study, subjects are selected, individuals with the disease of interest (i.e., prevalent cases) are excluded, one or more exposures of interest are measured, and then the cohort is monitored over time to determine who develops cancer or the outcome(s) of interest and the degree to which the exposure is associated with disease incidence. In genetic epidemiology, the primary "exposure" is the genetic variant under consideration. This type of cohort study is prospective in nature, the health outcomes (presence or absence of cancer over time) occurring after the enrollment of study subjects. Exposure is measured at baseline, when the cohort is initially established, and may be updated over the period of follow-up for those exposures that may change over time (obviously, the germline variant or variants a given individual carries do not change over time). The advantages of cohort studies include minimized information and selection biases and the ability to directly calculate disease incidence in exposed and unexposed groups and thus the relative risk (RR) and absolute risk (attributable risk, AR). RR is the risk of developing a disease given a particular exposure and is calculated as the incidence of cancer among a set of individuals with a particular genotype, divided by the incidence of cancer among a set of individuals who do not carry that genotype. Disadvantages include the fact that prospective cohort studies are expensive and time-consuming and large numbers of study subjects are typically required to obtain sufficient numbers of outcomes (e.g., cancer cases) to have adequate power to determine associations. Loss of subjects to long-term follow-up over time is also an issue because it may affect the ability to draw conclusions.

Cohort studies may also be retrospective in nature, when the exposure and subsequent development of the disease occur before the study begins. For the purpose of finding associations between disease status and genotype, retrospective cohorts depend on existing medical records to identify all cancer diagnoses in the population of interest during a specified time period. As such, if any of the medical information documenting either the exposure(s) or the disease is not completely accurate, then bias or error would be introduced into the study.

Case-control studies differ from cohort studies in that the selection of subjects is based on their disease status. Case-control studies have the potential to examine multiple risk factors simultaneously. Two very popular case-control designs are population-based and hospital-based. For each, it is important to select case patients and control subjects who are similar with respect to recognized confounding factors such as age, sex, race, and ethnic background.[80–85] Another critical factor for study design is that the controls must be selected from the same underlying population from which the cases were ascertained. The purpose of the control group is to provide valid data on exposure prevalence (e.g., distribution of genotype) in the same population from which cases were accrued.

Population-based case-control studies draw on a well-defined source population such as a particular geographic region defined by state, county, or city for ascertainment of both case patients and unaffected control subjects. Popular mechanisms include use of cancer registries, such as Surveillance Epidemiology and End Results, or health care provider databases. Control subjects should be selected from the same source population or geographic region by a method designed to randomly sample individuals, such as random-digit telephone dialing.[86] Selection bias, in which selection of case patients, control subjects, or both is influenced by prior exposures, is a particular concern in case-control studies.[83–85,87,88] Proper design of the selection process can help to reduce this problem. Multiple studies have shown, for instance, that nonparticipants in such studies are more likely to smoke than are individuals who agree to participate.[88] Thus, there is concern that participants might be more health conscious than nonparticipants.

In comparison, hospital-based case-control studies enlist a sequential series of patients who are admitted to the hospital or clinic during a specific period. Case patients are enrolled because they have the cancer of interest, whereas control subjects are determined to be cancer-free, although they may be patients at the same clinic or hospital for unrelated reasons. Significantly more potential for bias exists in hospital-based case-control studies. Depending on the clinic or hospital from which patients are drawn, disease presentation, severity, and treatment outcome may be nonrandom among study subjects. Often, cases are drawn from so-called high-risk clinics. In such situations, both case patients and control subjects might be more likely to carry a specific genotype. They might have been referred to a high-risk clinic because of their family history status. A particular concern is that hospital- or clinic-based controls might not accurately reflect the frequency of the exposure in the underlying population from which cases were ascertained. Thus, it might be difficult to generalize results from a hospital-based case-control study to the general population.

Confounders and Sources of Bias

Confounders are factors that are associated with both the exposure and the disease and are outside of the causal pathway of the exposure. Age is a frequent confounder, as it is often associated with the frequency and level of exposures and many diseases increase in incidence with advancing age. In the study of genetic risk factors and disease, an important confounder is ethnic background. For example, in a study of the association between human leukocyte antigen (HLA) genotypes and cervical cancer, ethnic background must be addressed as a potential confounder because HLA genotypes can vary by ethnic background and lifestyle factors that contribute to disease can be associated with ethnic differences.[89] When the association between HLA genotype and cancer was calculated, ethnic background was adjusted to minimize the potential for bias caused by this confounder.[89] In addition to statistical adjustment for ethnic background,

exposure-disease associations can also be examined and reported separately according to ethnic background.

Another source of bias that is specific to case-control studies and retrospective cohorts is recall bias.[90] Study subjects might find it difficult to correctly remember information related to subjective factors that are potentially important in disease susceptibility such as those related to environmental or lifestyle factors, such as diet, smoking, exercise, and stress levels.[91] Recall bias can lead to incorrect or incomplete measurement of exposures and potential confounders. This introduces error into the calculation of the association between the exposure and the disease because of the inability to fully adjust for the effects of confounders.

SNP Genotyping and Association Studies

In an ideal situation, collection of blood samples from all eligible study subjects, both cases and controls, is undertaken as part of any genetic epidemiology study. The resulting DNA samples can then be used to test for association of candidate genes and features of disease. Several types of low- to mid-throughput assays are frequently used to genotype SNPs, including direct sequencing, Sequenom, Taqman and SNPlex (both by Applied Biosystems), as well as custom Illumina's GoldenGate bundles and many others. Most assays available start with small quantities of DNA, and polymerase chain reactions amplify specific regions of DNA before querying the different SNP alleles and calling the genotypes.

SNPs that introduce nonsense changes, causing premature termination of the protein, and SNPs that alter a key amino acid sequence in the encoded protein are the focus of much of the current literature with regards to nearly all cancers.[92] Other SNPs of interest change single amino acids in key protein motifs or occur in splice domains. Much less well understood are SNPs that are found to be in association with the disease state but located in noncoding regions of the gene.[93–95] Association studies are observational in nature and define genotypes or exposures that are simply "associated" with a particular disease, but they might not actually cause the disease of interest. In such situations, the SNP is thought to be in linkage disequilibrium with an as yet unidentified disease-causing mutation.

SNPs within the vitamin D receptor gene provide a set of interesting examples. Single base changes in intron 8 and within exon 9 affect recognition sites for the restriction enzymes BsmI and TaqI. Neither variant apparently affects the resulting protein sequence, but both have been associated with prostate cancer risk.[93,95] Additionally, variation in the 3′ untranslated region of the poly A tail is similarly associated with prostate cancer risk,[94] but the alteration appears to have no obvious effect on mRNA stability.[96] All three polymorphisms have been reported to be in at least partial association with one another in a subset of studies and, in all likelihood, serve as markers for an as yet undiscovered disease-causing variant.[96,97] In addition to these variants, some investigators report a variant in exon 2, which creates a FokI restriction enzyme site and results in a new start codon for the protein, generating a transcript with three additional amino acids.[98] It is unknown whether this change itself is disease-associated or whether it, too, is simply a marker for an unknown variant. Functional studies are needed to test the role of all of these variants on protein function.

Relative Risks

Results of an association study are evaluated by calculation of a RR or an odds ratio (OR), which is an estimate of the RR derived from a case-control study. Values greater than 1.0 indicate that the exposure (in this case, a particular genotype) is associated with an increased risk of the cancer under consideration. In comparison, values less than 1.0 indicate a decreased risk for the disease associated with that genotype. In cohort studies, RR can be calculated directly as the likelihood of developing cancer among a set of individuals with a particular genotype, divided by the likelihood of developing cancer among a set of individuals who do not carry that genotype. Thus, the RR is the risk or probability of developing cancer in the defined source population, given a particular genotype.

A different statistical method is used for assessing risk in case-control studies, because subjects are selected according to disease status and not exposure, as they would be in a cohort study. The OR is an estimation of the RR and is calculated as the odds of exposure for cases divided by the odds of exposure for controls. For both point estimates of the RR and OR, 95% confidence intervals are calculated to determine statistical significance of the risk estimate. For example, at the $\alpha = 0.05$ level, statistically significant risk estimates are those in which the 95% confidence interval excludes 1.0, that is, the null hypothesis of no association. For a more stringent test, 99% confidence intervals may be calculated.

Logistic regression is often used to calculate ORs when multiple potential confounding factors are expected to affect the risk of the disease. Such calculations are made to account for the contribution of other disease-associated factors that are also correlated with the exposure of interest. If high-quality information about other characteristics of subjects is collected, data sets can be stratified by age, family history, or clinical features of the disease before calculation of the association between genotype and disease, as a way of identifying important modifiers of risk in relation to genotype.

GENETIC COUNSELING AND TESTING

Patients will frequently approach clinicians with questions about genetic-testing opportunities for specific cancers. If appropriate tests are available, identifying a person with increased risk for a particular cancer is useful for at least three reasons. First, it can suggest a particular clinical course that will reduce the chance of having cancer, such as treatment with tamoxifen or prophylactic surgery for women who are at risk for hereditary breast cancer.[99–101] Second, it can induce patients at risk to undergo more vigilant screening, such as frequent colonoscopy examinations for patients who are at risk for colon cancer. Finally, an individual's quality of life can sometimes be improved by having specific knowledge about the more precise risk for disease or recurrence. In addition, such information is frequently sought by unaffected individuals who perceive themselves to be at increased risk.

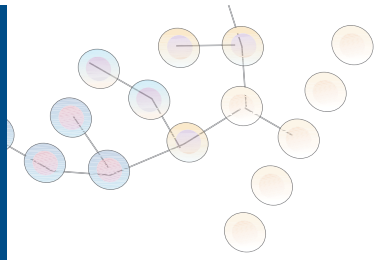
The National Society of Genetic Counselors defines genetic counseling as a "the process of helping people understand and adapt to the medical, psychological, and familial implications of the genetic contributions to disease."[102] Therefore it should be offered only in consultation with certified genetic counselors who serve to (1) help patients comprehend the medical facts and risks associated with their disease, (2) help patients understand their alternatives for dealing with both risk of disease and recurrence, (3) help patients choose a clinical course that best meets their needs, and (4) provide support and guidance for patients experiencing difficulty in dealing with unexpected results. Patients often approach genetic testing with strong preconceived notions about the likelihood that they either do or do not have an inherited mutation. Thus, "unexpected" is likely to apply to both carriers and noncarriers.

In advising patients whether it is appropriate to consider genetic testing, it is important to remember that many currently available tests have limitations. *Clinical validity* is the term that is used to describe the predictive value of a test for clinical outcomes.[103] It is affected by both the sensitivity and the specificity of the test, as well as a host of factors that are beyond laboratory control, such as penetrance of the mutant allele. The latter may itself be a function of genetic background, environmental exposures, or both. Most mutations associated with cancer susceptibility genes are not fully penetrant. There will therefore be a small group of individuals who, even if they live into their eighties, will not get cancer even if they carry protein-truncating mutations in a gene associated with a particular cancer. Helping patients to understand these concepts can be difficult.

One additional concern is what to tell patients who do not have obvious protein-truncating mutations but who do carry missense changes in the coding region of a cancer susceptibility gene. Again, particularly interesting examples are provided by the BRCA1 gene. More than 300 independent missense changes have been reported for BRCA1 to date.[104] Disease association status is known for only a fraction of these, such as those occurring in the RING finger domain[105] and the C-terminal region of the protein.[106,107] In the case of RING finger mutations, these conclusions are supported by the existence of dozens of families in which RING finger mutations are shown to closely segregate with disease state.[108,109] Other single amino acid changes are known to be inconsequential polymorphisms that clearly do not affect protein function. For instance, some 40% of the population is heterozygous for the substitution of leucine for proline at position 871, as reported in the canonical sequence. Both residues are hydrophobic, and the location is not one that is well conserved evolutionarily; and this is likely to be an inconsequential polymorphism in the gene. Of particular concern, rather, are the large number of missense changes that are reported in patients with breast cancer whose disease association status is unknown. Phylogenetic analysis provides some insight as to which are likely to be important,[110] and functional assays are useful for testing mutations in some regions of the gene.[107,111] However, at this time, little guidance is available for most patients carrying such changes.

IMPLICATIONS FOR THE FUTURE

The sequence of the human genome has been referred to as an "instruction book for human biology."[112] Locked within the sequence of each individual's DNA is the genetic code necessary to develop a complete and healthy individual, but encoded as well is the sequence-level variation that will determine each person's susceptibility to a host of diseases. Variation is important in defining the field of genomic medicine. A more complete understanding of the molecular pathways involved in cancer susceptibility will suggest avenues for the development of both methods of diagnosis and treatment. Identification of specific genes offers the promise of genetic testing to individuals who are at risk, as well as the hope for targeted therapeutics. Finally, understanding the specific variation offers the promise of twenty-first century "personalized medicine" in which lifestyle, diet, and preventative therapies come together to offer patients a full spectrum of choices for maintaining their personal health.



It is clear that the Human Genome Project has had and will continue to have an effect on human health and biology.[112] What remains to be seen is the rate at which the successes of the Human Genome Project will move from bench to bedside. In a sense, that rate will be determined by practicing physicians. Knowledge of the underlying principles of genetic analysis is fundamental for today's practicing clinician. The ability to accurately record family history and medical record data affects the integrity of all subsequent studies for which those data are used. An understanding by physicians of the findings generated through both association studies and family-based linkage studies is key to both moving research forward and prioritizing new hypotheses for researchers to consider. Finally, as twentieth century–born patients struggle to make personal health care choices in the twenty-first century, communicating what genomic medicine has to offer is a complicated task at which every physician must now excel.

14 Progressing from Gene Mutations to Cancer

Eric R. Fearon and Guido T. Bommer

SUMMARY OF KEY POINTS

- A root cause of cancer is the accumulation of defects in genes that play critical roles in regulating cell proliferation, cellular differentiation, and cell death. The mutations in cancer cells are of two types: gain-of-function mutations in oncogenes and loss-of-function mutations in tumor suppressor genes.
- Epigenetic mechanisms can substantially alter expression of proto-oncogenes and tumor suppressor genes, leading to essentially the same consequences as if the structure and/or sequence of the genes were affected by mutation.
- Clinical and pathologic studies indicate that most cancers arise from pre-existing benign lesions, and it is estimated that six to seven mutations are needed for development of a clinically recognizable cancer. On the basis of molecular analyses of cancers, multiple gene defects may often accumulate in a cancer cell during its development, and benign lesions generally have fewer defects than do their malignant counterparts.
- A process termed *clonal selection* has a key role in determining the particular constellation of genetic and epigenetic defects that are present in a cancer cell. Clonal selection is essentially a punctuated evolutionary process that promotes outgrowth of precancerous and cancerous cells carrying those mutations and gene expression changes that confer the most potent proliferative and survival properties upon the cancer cells, in a given context.
- Although a diverse array of mutations and gene expression changes have been implicated in cancer pathogenesis, the defects appear to affect a more limited number of conserved signaling pathways or networks. The proto-oncogenes and tumor suppressor genes that are most frequently mutated in cancer cells most likely represent particularly critical hubs in the cell's regulatory circuitry.
- Although cancer represents a very heterogeneous collection of diseases, the development of all cancers, regardless of type, appears to be critically dependent on the acquisition of certain traits that allow the cancer cells to grow in an unchecked fashion in their tissue of origin and to grow as metastatic lesions in distant sites in the body. Signature traits that are likely to be inherent in the majority, if not all, of cancer cells include the following: (1) an increased tendency to manifest a stem cell or progenitor-like phenotype, (2) an enhanced response to growth-promoting signals, (3) a relative resistance to growth inhibitory cues, (4) an increased mutation rate to allow for the rapid generation of new variant daughter cells, (5) the ability to attract and support a new blood supply (angiogenesis), (6) the capacity to minimize an immune response and/or evade destruction by immune effector cells, (7) the capacity for essentially limitless cell division, (8) a failure to respect tissue boundaries, allowing for invasion into adjacent tissues and organs as well as blood vessels and lymphatics, and (9) the ability to grow in organ sites with microenvironments that are markedly different from the one where the cancer cells arose.
- Certain gene defects in cancer cells may contribute to a few or perhaps even only one of the signature traits of cancer cells. However, many of the gene defects and expression changes might have been selected for in large part because they exert pleiotropic effects on the cancer cell phenotype.
- Despite the fact that some gene defects may arise early in the development of certain cancer types, advanced cancer cells might still be critically dependent on the "early gene defects" for continued growth and survival. Such findings imply that agents that specifically target key signaling pathways and proteins could have utility in advanced cancers even if the signaling pathway defect arose very early in cancer development.
- Future studies will further clarify the role of gene defects in cancer phenotype, allowing more definitive and more specific strategies for inhibiting cancer cells.

INTRODUCTION

A genetic basis for human cancer has been recognized for perhaps more than a century and has been supported by data from familial and epidemiologic studies and animal studies. However, only in the past 25 years has convincing molecular evidence been obtained to support the view that cancer is a genetic disease. Studies from many different fields, including tumor virology, chemical carcinogenesis, molecular biology, somatic cell genetics, and genetic epidemiology, have provided fundamental insights into mechanisms underlying cancer development. While environmental and dietary factors as well as other genes undoubtedly have substantial roles in cancer development, it is now well established that the accumulation of multiple mutations in a single cell plays a fundamental role in the pathogenesis of cancer. The mutations occur in two distinct classes of cellular genes: oncogenes and tumor suppressor genes. As was noted in earlier

chapters, some mutations may be present in individuals' germline and may predispose to particular cancers. Such mutations can also be passed on to future generations. The nature and role of germline mutations in cancer development are of great interest to cancer biologists because the mutations provide powerful clues about the identity of genes and pathways that play particularly critical roles in the malignant conversion of cells. Nevertheless, germline mutations in oncogenes or tumor suppressor genes likely have a major contributing role in only a small fraction of cancers, and the vast majority of mutations in cancer are somatic (i.e., present only in the tumor cells).

A subset of the cellular genes that are affected by inherited and somatic mutations in human cancer will be discussed in more detail later. Brief mention will be made here of some general properties of the genes. Oncogenes, when mutated, act in a positive fashion to promote tumorigenesis. Their normally functioning cellular counterparts, termed *proto-oncogenes*, have been found to be important regulators of many aspects of cell growth. The proteins that are encoded by various proto-oncogenes can be found in virtually all subcellular compartments. The term *proto-oncogene* does not imply that genes of this class lie dormant in the cell with the purpose of promoting tumorigenesis. Rather, the terminology reflects the fact that mutations in cancer cells alter the normal structure and/or expression pattern of the proto-oncogene, generating oncogenic variant forms with altered function. In genetic terms, oncogenic alleles have gain-of-function mutations that confer enhanced or novel functions.

In contrast to the activating mutations in oncogenes, loss-of-function defects in tumor suppressor genes are found in cancer cells. The term *antioncogene* has sometimes been used with respect to the tumor suppressor class of genes. The term suggests that the primary function of the genes might be to act in direct opposition to activated oncogenes. While some of the proteins that are encoded by tumor suppressor genes do in fact bind to and regulate the function of proto-oncogenes or function in pathways that directly regulate proto-oncogene activity, it is not by necessity a general principle.[1] Hence, genes that contribute to cancer by virtue of inactivating or loss-of-function mutations in human cancers will be referred to here as *tumor suppressor genes*. Similarly to the proto-oncogenes, the normal functions of tumor suppressor genes are diverse, and the proteins that are encoded by these genes are found in essentially all compartments of the cell. Compared to the vast array of oncogenic alleles that are seen in human cancer, a somewhat more limited number of tumor suppressor genes have been identified at the molecular level thus far. This finding might not be an accurate representation of the prevalence of oncogene versus tumor suppressor gene mutations in cancer. Rather, it might reflect the practical difficulties that are associated with experimental strategies to identify genes that negatively regulate the growth of cells.

Much evidence indicates that mutations in genes that regulate the recognition and repair of DNA damage play critical roles in tumorigenesis. The DNA damage recognition and repair genes could be considered to constitute a distinct class of cancer genes. However, because DNA repair genes appear nearly invariably to be affected by loss-of-function mutations in cancer, they will be classified here as tumor suppressor genes. Nevertheless, on the basis of certain features, DNA damage recognition and repair genes might constitute a potentially unique subset of tumor suppressor genes. Specifically, in comparison to the presumed direct role of many tumor suppressor genes in regulation of cell growth and programmed cell death, at least some of the DNA repair proteins might have a more passive role in growth, differentiation, and cell survival. Their inactivation in tumor cells might lead predominantly to the acquisition of a "mutator phenotype," with a resultant increased rate of mutations in other cellular genes with rate-determining roles in the cancer process, that is, oncogenes and tumor suppressor genes.

In addition to the well-established role of oncogene and tumor suppressor gene mutations in cancer, there is a large and growing body of data indicating that epigenetic mechanisms might play critical roles in altering the patterns and levels of expression of certain proto-oncogenes and tumor suppressor genes in cancer. For instance, in some cancers, defects in transcriptional regulatory mechanisms can lead to markedly increased levels of proto-oncogene expression, akin to the level that is seen in cancer cells with mutational defects that alter the structure or copy number of the proto-oncogene. Conversely, gene-silencing mechanisms can exert dramatic effects on the expression of certain tumor suppressor genes in cancer cells, essentially rendering the genes functionally inactive in the absence of any mutations.

Given the enormous advances over the past two decades in defining oncogene and tumor suppressor gene mutations and gene expression defects in cancer, it will not be possible in this chapter to review in a comprehensive fashion the vast collection of gene defects that have been identified in human cancers. Nor will it be possible to discuss in great detail the possible contributions of the many different gene defects to alterations in cell signaling and cell physiology. Rather, the primary aim of this chapter will be to offer a framework for understanding the relationship between gene defects in cancer cells and the impact of the accumulated defects on the cancer cell phenotype. Although some details on the identity and nature of gene defects in cancer will be offered here, the emphasis will be on concepts that are likely to have biologic and clinical significance.

CANCERS ARISE FROM THE ACCUMULATION OF MULTIPLE GENE DEFECTS

On the basis of a simple consideration of the likely large number of mutations that arise in normal cells during the many years of life, it would seem quite unlikely that cancers arise as the result of any single gene defect. Even in individuals who are strongly predisposed to cancer as a result of a germline mutation in a specific oncogene or tumor suppressor gene, the vast majority of cells in the individual never develop into cancer or even display definitive morphologic changes akin to those that are seen in benign tumors. In fact, depending on the inherited cancer syndrome, a significant fraction of those that carry specific germline mutations in oncogenes or tumor suppressor genes never develop cancer. Therefore, any model for cancer must incorporate these data, suggesting that cancers likely arise as the result of the accumulation of multiple gene defects in an affected cell. Another issue to consider before formulating genetic models for cancer development is that clinical and histopathologic data indicate that the development of nearly all cancers, regardless of the organ site, is often, if not invariably, preceded by precancerous phases or stages in which the neoplastic cells manifest increasing disordered patterns of differentiation and morphology.

Given this background, it would appear that there is compelling evidence that cancers arise from accumulated defects in several genes and precancerous (benign) precursor lesions contain by necessity fewer of the key gene defects. One question, therefore, is how many rate-limiting defects or "hits" are required for cancer development? While a definitive answer to this question cannot be given at this point, some estimates can be offered. Most common cancers show dramatically increased incidence with increasing age. On the basis of analysis of the age-specific incidence of a number of common cancers and some straightforward assumptions about the rate of mutations and the size of the target cell population, it was argued as early as the mid-1950s that most common epithelial cancers arise as the result of four to seven rate-limiting events.[2,3] It was inferred that these rate-limiting events represented mutational events. Moreover, benign lesions were inferred to arise as the result of fewer gene defects, consistent with the fact that recognizable benign lesions that are often found show an age-incidence distribution that was shifted roughly one to two decades earlier in life than cancers arising in the corresponding organ or tissue sites. Nevertheless, confounding the use of age-incidence data to model the number of rate-limiting mutations

were questions about certain key biologic assumptions underlying the multihit models. Given the attendant uncertainties with estimates of rate-limiting mutation numbers derived largely or solely from age-incidence data and the practical difficulties in defining the nature and significance of all inherited and somatic gene defects in cancer, a definitive answer to the number of rate-determining mutations for a particular cancer type has not yet been obtained. However, at the very least, it is encouraging to note that molecular analyses of a number of common cancers, such as those of the colon,[4,5] breast,[5] lung,[6] and pancreas,[7] indicate that five or more gene defects are not infrequently seen in cancers, and fewer of the gene defects are seen in certain of the precancerous precursor lesions that are associated with these common cancers.

CLONAL SELECTION AND EVOLUTION IN CANCER

As was noted previously, most, if not all, cancers are thought to arise from pre-existing precancerous populations of cells, and multiple rate-limiting mutations (events) are likely needed for conversion of a normal cell to a cancerous cell. Molecular studies of cancers of various types and their corresponding associated precancerous lesions have yielded some fundamental insights into the processes likely to be critical in emergence of the cancer. First, while normal tissues and tissues from noncancerous disease states display polyclonal (balanced) cell populations, the neoplastic component that is present in benign lesions and cancers invariably displays a clonally related cell population, consistent with the notion that neoplastic transformation of one or at most a few cells within a tissue gave rise to all daughter cells that are present in the tumor. Second, in tumors where it has been possible to analyze both cancer cells and associated precancerous cell populations, a subset of the somatic gene defects that are present in the cancer are clonally represented in the precancerous cell population. Other somatic gene defects appear to be acquired during progression from the precancer subclones to the dominant subclone in the cancer.

These molecular findings in benign and malignant tumors are essentially consistent with a model that was initially proposed by Foulds[8] and subsequently advanced by Nowell[9] (Fig. 14-1). In brief, the clonal evolution model predicts that cancers arise as the result of successive expansions of clonally related cell populations. The successive expansions are driven by the punctuated acquisition of mutations and gene expression changes that endow a particular cell and its progeny with a selective growth and survival advantage over cells that do not harbor the gene defects. In essence, clonal selection is an evolutionary process that allows the outgrowth of precancerous and cancerous cells that carry mutations and gene expression changes that confer the most potent proliferative and survival properties on the cancer cells. It is important to note the specific constellation of genetic and epigenetic changes that are present in precancerous and cancerous cells is context-dependent and likely varies considerably from one cancer type to another and perhaps even to a significant degree among cancers that display quite similar clinical and histopathologic features. The basis for the context-dependent relationship of the changes that confer a selective growth advantage in a particular cancer may reflect physiologic differences in organ site and the tissue microenvironment within the organ site, the identities of the preceding somatic gene defects in the precancerous or cancerous clone, and even the constitutional sequence variations and particular gene expression patterns that are present in nonneoplastic tissues of a given patient. This issue of context-dependent effects of gene defects that promote clonal selection in neoplastic cells will be addressed further in the following sections.

The clonal evolution model has some important biologic and clinical ramifications, just a few of which will be mentioned here. First, the clonal gene defects that are present in a cancer can be traced in precancerous lesions from the same organ site with a goal of attempting to clarify the preferred order in which gene defects arise in the natural history of a particular cancer type. The particular order in which defects accumulate during the initiation and subsequent progression of one cancer type often differs from that in another

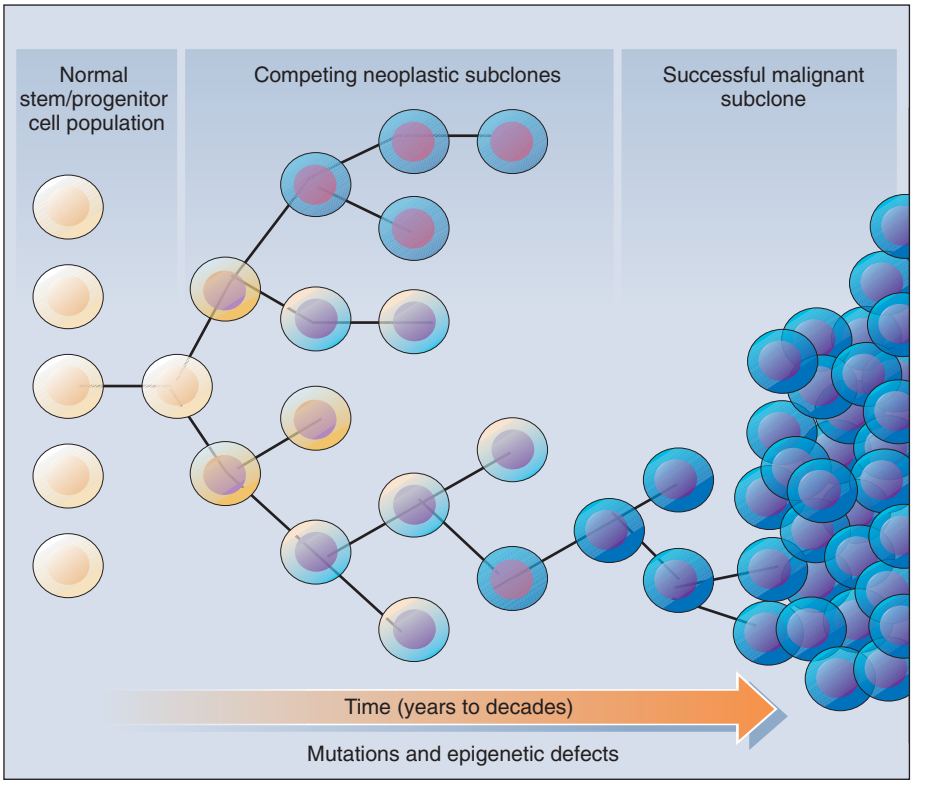

Figure 14-1 • Role of clonal selection in cancer development and progression. Clonal selection is essentially a punctuated evolutionary process that promotes outgrowth of precancerous and cancerous cells that carry the mutations and gene expression changes that confer the most potent proliferative and survival properties on the cancer cells in a given context. The schematic diagram indicates that the stepwise emergence of benign and malignant cells over time is critically influenced by mutations and epigenetic defects. Neoplasms most likely arise from a stem cell or progenitor cell population that is capable of additional cell divisions and acquisition of certain differentiated characteristics. Following the accumulation of a particular constellation of mutations and epigenetic defects in oncogenes and tumor suppressor genes, a successful malignant subclone will outgrow the various competing neoplastic subclones. Further genetic heterogeneity within the malignant subclone (not depicted) is possible, and the genetic heterogeneity in the malignant subclone might give rise to new subclones that display increased invasive and metastatic potential. (Modified from Kern SE: Progressive genetic abnormalities in human neoplasia. In Mendelsohn J, Howley PM, Israel MA, Liotta LA [eds]: The Molecular Basis of Cancer, 2nd ed. Philadelphia, WB Saunders, 2001, pp 41–69.)

cancer type. As a result, a genetic or epigenetic change that is critical in tumor initiation in one cancer type might contribute to tumor progression in another tumor type and vice versa. Second, defects that arise at "early" stages of tumorigenesis might play a vital role not only in tumor initiation but also in the aggressive behavior of advanced stage cancers. Third, the model predicts that the acquisition of further genetic heterogeneity will be a common and important factor in primary cancer lesions and metastases. Genetic heterogeneity likely plays a significant role in resistance to chemotherapy and the emergence of aggressive cell populations in patients with advanced cancer.[10]

It is important to note that clonal somatic mutations are often presumed to have a causal role in promoting further tumor outgrowth or progression because somatic mutations can become clonal (i.e., present in all neoplastic cells) by only a limited number of mechanisms. For instance, the genetic alteration itself could have been selected for because it provided the neoplastic cell with a growth advantage, allowing it to become the predominant cell type in the tumor (clonal expansion). Genes with critical roles in promoting clonal outgrowth in a given cancer have been termed *drivers*.[11] Alternatively, a somatic mutation, when detected, might have arisen essentially coincident with another, perhaps undetected, alteration that was the crucial change underlying clonal outgrowth. Somatic mutations of this latter type have been termed *passengers*.[11] Genes that are mutant in a significant fraction of cancers and for which other lines of evidence link them to the cancer process can more readily be classified as drivers. However, on the basis of early data from some large-scale sequencing analyses that reveal large numbers of distinct genes that are each mutated in only a minority of cancers of a given type,[5,12,13] sorting out drivers and passengers might not be entirely straightforward, based solely on sequencing data, but will likely require a significant body of functional studies and data.[11]

Given this discussion about the potential uncertainties associated with linking specific somatic mutations to cancer development, it is perhaps apparent why it is even more problematic to assign causal significance to gene expression changes in precancerous and cancerous cells. In particular, the ambiguities in assigning a causal role to gene expression and epigenetic changes in the absence of mutations are in large part due to difficulties in determining whether these changes merely reflect or are causally involved in the cancer process. Nonetheless, if a specific gene alteration can be shown to promote tumorigenesis or neoplastic transformation in in vitro models or animal model experiments or if the same gene or chromosomal region is recurrently altered in tumors, then it might be reasonable to infer that the particular defect might indeed have a causal (driver) role in tumorigenesis.

ONCOGENE AND TUMOR SUPPRESSOR GENE DEFECTS IN CANCER TARGET CONSERVED SIGNALING PATHWAYS

Recurrent Mutational Targets in Cancer

As was noted previously, in genetic terms, oncogenic alleles have gain-of-function mutations. Oncogenic variant alleles that are present in cancer are generated from the normal counterpart proto-oncogenes by various mutational mechanisms, including point or localized mutations, gross chromosomal rearrangements, or gene amplification. Some representative oncogene mutations in human cancer are summarized in Table 14-1. From a brief review of the data in Table 14-1, several generalizations are apparent. First, the mutations affect proteins functioning in various compartments of the cell, including growth factor receptors, cytoplasmic signal tranducers, and nuclear proteins, such as transcription factors. Second, although some oncogene mutations may be unique to cancers of a particular type, such as the specific chromosomal translocations and resultant fusion proteins that are seen in cancers of hematopoietic origin (e.g., the BCR-ABL translocation that is seen in chronic myelogenous leukemia and a subset of acute lymphoid leukemias and the PML-RARα translocation that is seen in acute promyelocytic leukemia), other mutations, such as those affecting the K-RAS, β-catenin, and c-MYC genes, are found in a broad spectrum of different cancer types. Third, oncogene mutations in cancer are nearly always somatic, as only a very limited number of germline mutations in proto-oncogenes have been linked to cancer predisposition thus far.[14] Fourth, some proto-oncogenes, such as K-RAS or BCL2, are somatically altered in cancer by a single mutational mechanism, namely, point mutations in the K-RAS gene and chromosomal translocations affecting the BCL2 gene. In contrast, other proto-oncogenes, such as c-MYC, may be activated by more than one mechanism in cancer, including chromosomal translocation and gene amplification. Both mutational mechanisms lead to increased levels of c-MYC transcripts and protein. In fact, specific missense mutations at threonine58 of the c-MYC gene in some lymphomas may further enhance c-MYC protein levels by abrogating a phosphorylation-ubquitination mechanism targeting c-MYC for proteasomal degradation.[15,16]

In contrast to the activating mutations that generate oncogenic alleles from proto-oncogenes, inactivation of the normal function of tumor suppressor genes is critical in tumorigenesis. Akin to the proto-oncogenes, the functions of tumor suppressor genes are diverse, and proteins that are encoded by these genes reside in practically all subcellular compartments (Table 14-2). Many tumor suppressor genes were identified by virtue of the fact that they are mutated in the germline of individuals who are affected by a known Mendelian cancer syndrome or who at the very least display a markedly elevated risk of cancer. The link between a germline-inactivating mutation in a purported tumor suppressor gene and increased cancer predisposition provides very persuasive evidence of the functional significance of the gene in the cancer process. Nevertheless, for the vast majority of tumor suppressor genes, in terms of their magnitude, somatic inactivating mutations play a far more significant role in cancer development than do germline mutations.

Another important point to consider is that much of the attention for tumor suppressor genes has been focused on demonstrating that cancer cells carry biallelic inactivating mutations. Clearly, a diverse array of mechanisms can inactivate gene function, including nonsense, frameshift, and nonconservative missense mutations, as well as gross deletions of the gene or even the chromosome region that contains the gene. In a number of cases, studies of the chromosomal mechanisms associated with tumor suppressor gene inactivation in cancer tissues, such as loss of the parental heterozygosity (i.e., LOH) that is present in normal tissues, have even been used to infer the existence of tumor suppressor genes in particular chromosomal regions prior to the actual identification of the tumor suppressor gene of interest. The emphasis on defining biallelic inactivating mutations in tumor suppressor genes has been stimulated in large part by the Knudson hypothesis,[2,17] which predicted that recessive genetic determinants played a critical role in retinoblastoma and many other cancers and that inactivation of both alleles of a tumor suppressor gene was needed to abrogate tumor suppressor gene activity. Nevertheless, as will be discussed in a bit more detail in the following sections, a variety of observations indicate that epigenetic (nonmutational) mechanisms might play a prominent role in inactivating tumor suppressor gene function in sporadic tumors. Furthermore, for certain tumor suppressor genes, inactivation of only one of the two alleles of a tumor suppressor gene might significantly impair cell growth regulation or programmed cell death. For example, p53 proteins that carry missense mutations in the central (DNA-binding region) of the protein likely potently interfere via dominant negative mechanisms with the wild-type p53 protein in the cell because p53 functions as a homotetrameric protein and all subunits must be wild type for intact p53 function in transcriptional regulation.[18,19] In addition to the likely dominant negative role of mutant p53 in inhibiting the function of wild-type p53, several lines of evidence suggest that

Table 14-1 Representative Oncogene Mutations in Cancer

Gene	Activation Mechanism	Protein Properties	Tumor Types
K-RAS	Point mutation	Signal transducer	Pancreatic, colorectal, lung (adeno), endometrial, other carcinomas
N-RAS	Point mutation	Signal transducer	Myeloid leukemia, colorectal cancer
H-RAS	Point mutation	Signal transducer	Bladder carcinoma
EGFR (ERBB)	Amplification, mutation	Growth factor (EGF) receptor	Gliomas, lung (non-small cell) carcinoma
NEU (HER2/ERBB2)	Amplification	Growth factor receptor	Breast, ovarian, gastric, other carcinomas
c-MYC	Chromosome translocation	Transcription factor	Burkitt's lymphomas
	Amplification		Small cell lung carcinoma (SCLC); other carcinomas; glioblastoma
N-MYC	Amplification	Transcription factor	Neuroblastoma, SCLC; glioblastoma
L-MYC	Amplification	Transcription factor	SCLC, ovarian carcinoma
BCL-2	Chromosome translocation	Antiapoptosis protein	B-cell lymphoma (follicular type)
CYCD1	Amplification	Cyclin D, cell cycle control	Breast and other carcinomas
	Chromosome translocation		B-cell lymphoma, parathyroid adenoma
BCR-ABL	Chromosome translocation	Chimeric nonreceptor tyrosine kinase	CML, ALL (T cell)
RET	Chromosome translocation	GDNF receptor tyrosine kinase	Thyroid cancer (papillary type)
	Point mutation		Thyroid cancer (medullary type: germline mutations)
CDK4	Amplification	Cyclin-dependent kinase	Sarcoma, glioblastoma
	Point mutation		
MET	Point mutation	Hepatocyte growth factor (HGF) receptor	Renal carcinoma (papillary type: germline mutations)
SMO	Point mutations	Transmembrane signaling molecule in sonic hedgehog pathway	Basal cell skin cancer
β-CAT (CTNNB1)	Point mutation, in-frame deletion	Transcriptional coactivator, links E-cadherin to cytoskeleton	Melanoma; colorectal, endometrial, ovarian, hepatocellular, and other carcinomas, hepatoblastoma, Wilms' tumor
HST	Amplification	Growth factor (FGF-like)	Gastric carcinoma
PML-RARα	Chromosome translocation	Chimeric transcription factor	APL
E2A-PBX1	Chromosome translocation	Chimeric transcription factor	Pre-B ALL
MDM-2	Amplification	p53 binding protein	Sarcoma
GLI	Amplification	Transcription factor	Sarcoma, glioma
TTG	Chromosome translocation	Transcription factor	T-cell ALL
AKT2	Amplification	Signal transducer (serine/threonine kinase; downstream effector of PI3K)	Pancreatic and ovarian carcinoma
PIK3CA	Amplification	Catalytic subunit of PI3K	Ovarian carcinoma
STK15	Amplification	Centrosome-associated kinase	Breast, colon, ovarian, and prostate carcinomas gliomas
TMPRSS2-ERG	Chromosome translocation	Transcription factor (ETS family)	Prostate cancer
TMPRSS2-ETV1			
TMPRSS2-ETV4			

ALL, acute lymphocytic leukemia; APL, acute promyelocytic leukemia; CML, chronic myelogenous leukemia; EGF, epidermal growth factor; FGF, fibroblast growth factor; GDNF, glial-derived neurotrophic factor; GTPase, guanine trinucleotide phosphatase; HGF, hepatocyte growth factor; PI3K, phosphatidylinositol 3-kinase; SCLC, small cell carcinoma of the lung.

mutant p53 protein might have some gain-of-function properties that contribute to the tumor phenotype.[18,19] For other tumor suppressor proteins, such as the cyclin-dependent kinase inhibitory protein p27, reduction of protein levels to 50% of the levels present in normal cells might result in significant detrimental effects on the ability of the cell to appropriately regulate growth.[20,21]

Epigenetic Mechanisms of Proto-oncogene Activation and Tumor Suppressor Inactivation

The preceding discussion largely emphasized the role and significance of somatic and germline mutations in proto-oncogenes and tumor suppressor genes in cancer. The rationale for focusing on the role of

Table 14-2 Representative Tumor Suppressor Gene Mutations in Cancer

Gene	Associated Inherited Cancer Syndrome	Cancers with Somatic Mutations	Presumed Function of Protein
RB1	Familial retinoblastoma	Retinoblastoma, osteosarcoma, SCLC, breast, prostate, bladder, pancreas, esophageal, others	Transcriptional regulator; E2F binding
TP53	Li-Fraumeni syndrome	Approximately 50% of all cancers (rare in some types, such as prostate carcinoma and neuroblastoma)	Transcription factor; regulates cell cycle and apoptosis
$p16^{INK4A}$	Familial melanoma, familial pancreatic carcinoma	Approximately 25% to 30% of many different cancer types (e.g., breast, lung, pancreatic, bladder)	Cyclin-dependent kinase inhibitor (i.e., CDK4 and CDK6)
$p14^{Arf}$ ($p19^{Arf}$)	Familial melanoma(?)	Approximately 15% of many different cancer types	Regulates Mdm-2 protein stability and hence p53 stability; alternative reading frame of $p16^{INK4A}$ gene
APC	Familial adenomatous polyposis coli (FAP), Gardner syndrome, Turcot's syndrome	Colorectal carcinomas, desmoid tumors hepatocellular carcinoma, breast (rare)	Regulates levels of β-catenin protein in the cytosol; binding to EB1 and microtubules
WT-1	WAGR, Denys-Drash syndrome	Wilms' tumor	Transcription factor
NF-1	Neurofibromatosis type 1	Melanoma, neuroblastoma	p21ras-GTPase
NF-2	Neurofibromatosis type 2	Schwannoma, meningioma, ependymoma	Juxtamembrane link to cytoskeleton at adherens junction
VHL	Von Hippel Lindau syndrome	Renal (clear cell type), hemangioblastoma	Regulator of protein stability
BRCA1	Inherited breast and ovarian cancer	Ovarian (~10%), rare in breast cancer	DNA repair; complexes with Rad 51 and BRCA2; transcriptional regulation
BRCA2	Inherited breast (both female and male), pancreatic cancer	Rare mutations in pancreatic, others (?)	DNA repair; complexes with Rad 51 and BRCA1
MEN-1	Multiple endocrine neoplasia type 1	Parathyroid adenoma, pituitary adenoma Endocrine tumors of the pancreas	Nuclear protein; unknown function
PTCH	Gorlin syndrome, hereditary basal cell carcinoma syndrome	Basal cell skin carcinoma, medulloblastoma	Transmembrane receptor for sonic hedgehog factor; negative regulator of smoothened protein
PTEN/MMAC1	Cowden's syndrome; sporadic cases of juvenile polyposis syndrome	Glioma, breast, prostate, follicular thyroid carcinoma, head and neck squamous carcinoma	Phosphoinositide 3-phosphatase; protein tyrosine phosphatase
SMAD4	Familial juvenile polyposis syndrome	Pancreatic (~50%), approximately 10% to 15% of colorectal cancers, rare in others	Transcriptional factor in TGF-β-signaling pathway
BMPR1A	Familial juvenile polyposis syndrome	Not known	Receptor for bone morphogenetic protein
MSH2, MLH1 PMS1, PMS2, MSH6	Hereditary nonpolyposis colorectal cancer	Colorectal, gastric, endometrial, ovarian	DNA mismatch repair
CDH1	Familial diffuse-type gastric cancer	Gastric (diffuse type), lobular breast carcinoma, rare in other types (e.g., ovarian)	E-cadherin cell-cell adhesion molecule
LKB1/STK11	Peutz-Jeghers syndrome	Lung adenocarcinoma (~30%); rare pancreas cancers; absent in most other cancers	Serine/threonine protein kinase
EXT1	Hereditary multiple exostoses	Not known	Glycosyltransferase; heparan sulfate chain elongation
EXT2	Hereditary multiple exostoses	Not known	Glycosyltransferase; heparan sulfate chain elongation
TSC1	Tuberous sclerosis	Not known	Hamartin; binds tuberin (TSC2); regulates cell size by inhibiting target of rapamycin (TOR) function and protein synthesis
TSC2	Tuberous sclerosis	Not known	Tuberin (see above regarding TSC1)

DNA sequence alterations in cancer initiation and progression is based chiefly on the view that it is arguably more straightforward to ascribe a causal role in cancer to specific mutations in the tumor cell genome than it is to attribute a causal role in cancer to apparent changes in the levels and/or patterns of gene expression in cancer cells. Potential difficulties in assigning a causal role in cancer to changes in the expression of various proto-oncogenes or tumor suppressor genes include uncertainties about whether the apparent differences in gene expression reflect authentic changes in gene expression or simply the possibility that the cancer might have arisen from neoplastic transformation of a cell type that had differences in gene expression than the majority of normal cells in the tissue from which the cancer originated.

In spite of the fact that changes solely in the expression, but not the structure or sequence, of proto-oncogenes and tumor suppressor genes have been more difficult to implicate definitively in the cancer process, genuine progress in the cancer epigenetics area has been made. Arguably the most compelling data for assigning a critical and likely causal role to changes in gene expression in the cancer process are for those genes that have already been well established in prior studies to function as tumor suppressor genes. Hence, the emphasis here will be placed on illustrating how epigenetic mechanisms have been assigned a causal role in silencing tumor suppressor genes in cancer. This emphasis is largely due to space limitations and not simply because of the absence of data implicating epigenetic mechanisms in proto-oncogene activation in cancer. Indeed, a priori, there is no reason why epigenetic mechanisms cannot lead to substantial increases in the expression of proto-oncogenes, with expression changes in some cancers perhaps on the order of those that are seen in cancers with high copy amplification of the respective proto-oncogene. In some cases, epigenetic mechanisms likely do lead to overexpression of certain proto-oncogenes in a variety of cancer types, such as for c-MYC,[22] the epidermal growth factor receptor,[23] and the aurora-2 kinase and closely related kinases.[24]

As is summarized in Table 14-2, somatic inactivation of tumor suppressor genes resulting from well-established genetic mechanisms has been seen in many cancers. However, there is also a robust and growing body of data to support the view that epigenetic mechanisms somatically inactivate selected tumor suppressor genes in certain cancer types[25] (Fig. 14-2). While data are only now emerging on the specific transcriptional and chromatin remodeling mechanisms that are responsible for epigenetic silencing of tumor suppressor genes, many studies have demonstrated that increases in the methylation of CpG-rich sequences (CpG islands) in the regulatory regions (i.e., promoter/enhancer) of tumor suppressor genes are often linked to loss of tumor suppressor gene expression. For instance, while the *VHL* gene is inactivated by mutational mechanisms in roughly 80% of renal carcinomas of clear cell type, in the majority of the clear cell renal carcinomas in which specific *VHL* mutations cannot be detected, loss of *VHL* gene expression appears to be tightly linked to hypermethylation of the *VHL* promoter.[25] For some other tumor suppressor genes, including the $p16^{INK4a}$, *BRCA1*, and *MLH1* genes, promoter hypermethylation has also been implicated as key mechanism of inactivation.[26] In fact, on the basis of studies of genes that display extensive CpG island methylation and decreased or absent gene expression in cancer cells of one type or another, it has been suggested that aberrant CpG methylation might play a very broad and important role in the cancer process.[25,26]

Nevertheless, at this point, it might be reasonable to offer a few cautionary comments regarding the linkages between CpG island methylation, gene silencing, and tumor suppressor genes. One issue to reflect on is the uncertainty about what fraction of the genes whose promoters show increased methylation in cancers actually function in vivo as tumor suppressor genes. Promoter hypermethylation and loss of gene expression might be best considered as potentially useful but insufficient criteria for establishing tumor suppressor gene function in the absence of other supporting data. For instance, additional supportive evidence of tumor suppressor gene function might include data indicating that the methylation status of a promoter is tightly linked to its expression in a large panel of primary cancer specimens and data showing that gene expression can be readily and fully restored by treatment of cancer cells with demethylating agents and/or other agents that affect chromatin functional state, such as histone deacetylase inhibitors. In addition, data showing that biallelic inactivation of the methylated gene occurs by mutational mechanisms (e.g., localized mutation and LOH) or a combination of mutational and epigenetic mechanisms in at least some cancers might also represent a potentially critical set of observations. Yet another caveat to be aware of is that because several transcription factors that specifically act to repress tumor suppressor gene expression have been identified, such as the Snail and Slug proteins and their ability to repress E-cadherin in breast cancer[27] and the bmi-1 oncoprotein and its

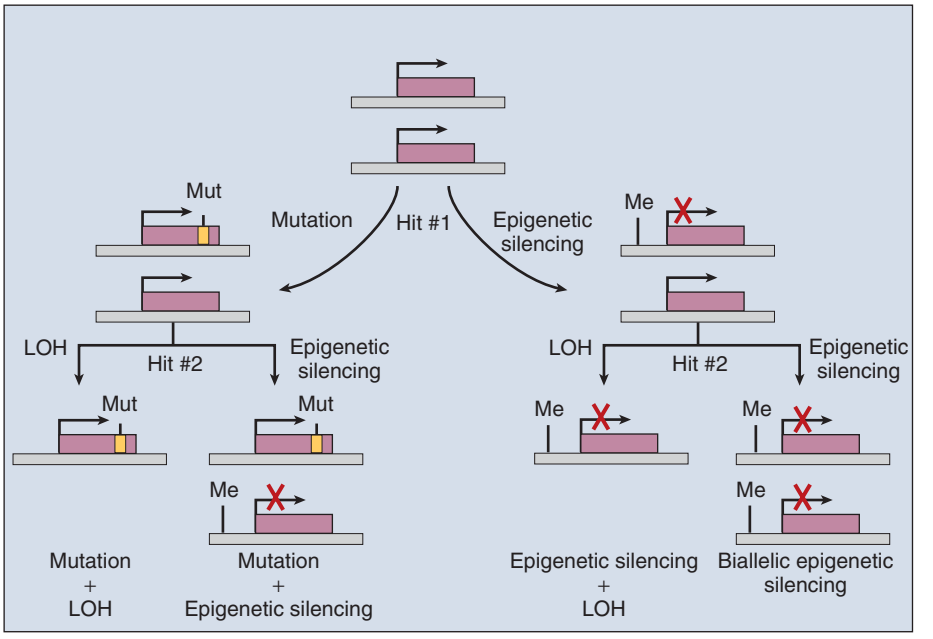

Figure 14-2 • Knudson's two-hit hypothesis revised. In brief, Knudson's hypothesis predicted that both alleles of a tumor suppressor gene would need to be inactivated by germline and/or somatic mutations to elicit critical phenotypic alterations associated with cancer development. The revised version of Knudson's two-hit hypothesis considers the possibility that tumor suppressor gene inactivation can result from either genetic (mutation) or epigenetic silencing events. The two functional alleles of a given tumor suppressor gene are indicated by the two purple boxes (*top*). The first inactivating event affecting one of the two tumor suppressor gene alleles could be either a mutation, such as the localized defect indicated by the yellow box (*left*), or transcriptional silencing associated with or caused by hypermethylation of CpG-rich sequences in the promoter/regulatory region (*right*). The inactivating event for the second tumor suppressor gene allele (i.e., "Hit #2") could be a nondisjunction event resulting in loss of the chromosome containing the wild-type tumor suppressor gene allele (loss of heterozygosity, LOH) or epigenetic silencing. (Modified from Jones PA, Laird PW: Cancer epigenetics comes of age. Nat Genet 1999;21:163–167.)

repression of *p16*^{INK4a} and *p19*^{ARF},[28] in some cases promoter hypermethylation may be principally a reflection rather than a proximate cause of tumor suppressor gene inactivation in cancer. It should be noted, however, that certain subtypes of colorectal cancers have been identified that preferentially inactivate genes by promoter hypermethylation, suggesting that in at least some of the cases, a so far unidentified alteration in the methylation/demethylation machinery might support the development of cancers.[29]

Alterations in Cancer Target Conserved Signaling Pathways and Networks

As was noted previously and summarized in Tables 14-1 and 14-2, the protein products of proto-oncogenes and tumor suppressor genes have been implicated in diverse cellular processes. In light of the potentially vast complexity that is suggested by the diverse array of gene defects in cancer, it is somewhat reassuring to note that some general concepts have emerged with respect to the means by which genetic and epigenetic alterations contribute to cancer initiation and progression. Perhaps the principal overarching theme is that the protein products of oncogenes and tumor suppressor genes function in highly conserved signaling pathways and regulatory networks.

The network in which the pRb tumor suppressor protein functions is one of the more intensively studied oncogene-tumor suppressor gene networks.[30,31] The pRb protein regulates cell cycle progression, in large part via its ability to bind to E2F transcription factor proteins.[30,31] In addition to its role as a cell cycle regulator, the pRb protein has been implicated in regulation of cellular differentiation, survival, and even angiogenesis in certain settings.[32,33] The binding of pRb to E2F proteins allows pRb to silence expression of E2F-regulated or "target" genes, such as those needed for the DNA synthetic (S) phase of the cell cycle. The ability of the pRb protein to bind to E2F proteins and to function in transcriptional repression appears to be tightly linked to its phosphorylation status, with the hyperphosphorylated forms of pRb incapable of binding to and regulating E2F proteins. Strong evidence indicates that the cyclin D1 protein and its associated protein kinase, cyclin-dependent kinase 4 (CDK4), negatively regulate pRb by phosphorylating it. The *p16*^{INK4a} tumor suppressor protein is a critical inhibitor of the CDK4/cyclin D1 complex (Fig. 14-3) and can therefore prevent the inactivation of pRb. As is noted in Table 14-2, a subset of sporadic cancers of various types has inactivating mutations in the *RB1* gene.[34] In other cancers, pRb function appears to be critically compromised as a result of mutations in other components of the network or pathway.[34] For example, in many cancers that lack *RB1* mutations, inactivating mutations in the *p16*^{INK4a} gene have been noted. In others, including some breast cancers, gene amplification and overexpression of cyclin D1 is found. In yet others, such as some glioblastomas and sarcomas, amplification and overexpression of the *CDK4* gene has been seen. The net effect of mutations in the pRb pathway, whether in *RB1* itself or in other genes, such as *p16*^{INK4a}, *cyclin D1*, or *CDK4*, is to inactivate pRb function and its ability to regulate expression of critical E2F target genes (see Fig. 14-3).

Studies of other proto-oncogenes and tumor suppressor genes have also supported the existence of conserved regulatory networks in which multiple different tumor suppressor gene and proto-oncogene protein products function. Although the APC (adenomatous polyposis coli) tumor suppressor protein may have roles in regulating various processes in the cell,[35–37] a key function of APC is to participate in a multiprotein complex that regulates the levels of the β-catenin protein in the cytoplasm and nucleus (see Fig. 14-3). Components of the multiprotein complex that regulates β-catenin include the APC protein, another tumor suppressor protein known as AXIN1, and a kinase known as glycogen synthase kinase 3β (GSK3β). Inactivation of APC or AXIN1 function in cancer cells appears to lead to an inability to phosphorylate β-catenin and hence target it for recognition and subsequent ubiquitination by the βTrCP ubiquitin ligase and ultimately its destruction by the proteasome. As a result, cancer cells with APC or AXIN1 inactivation display increased levels of β-catenin in the cytoplasm and nucleus and essentially constitutive complexing of β-catenin with transcription factors of the T cell factor (TCF) family, such as TCF-4. When bound to TCF-4, β-catenin can function as a transcriptional coactivator, and in cancers with APC inactivation, such as colorectal carcinomas, or cancers with AXIN1 inactivation, such as hepatocellular carcinomas, TCF transcriptional activity is clearly deregulated. In a subset of the colorectal carcinomas that lack APC inactivation and in a variety of other cancer types (see Table 14-1), activating (oncogenic) mutations in the β-catenin protein have been found.[38] These missense and in-frame deletion mutations affect key phosphorylation sites in the

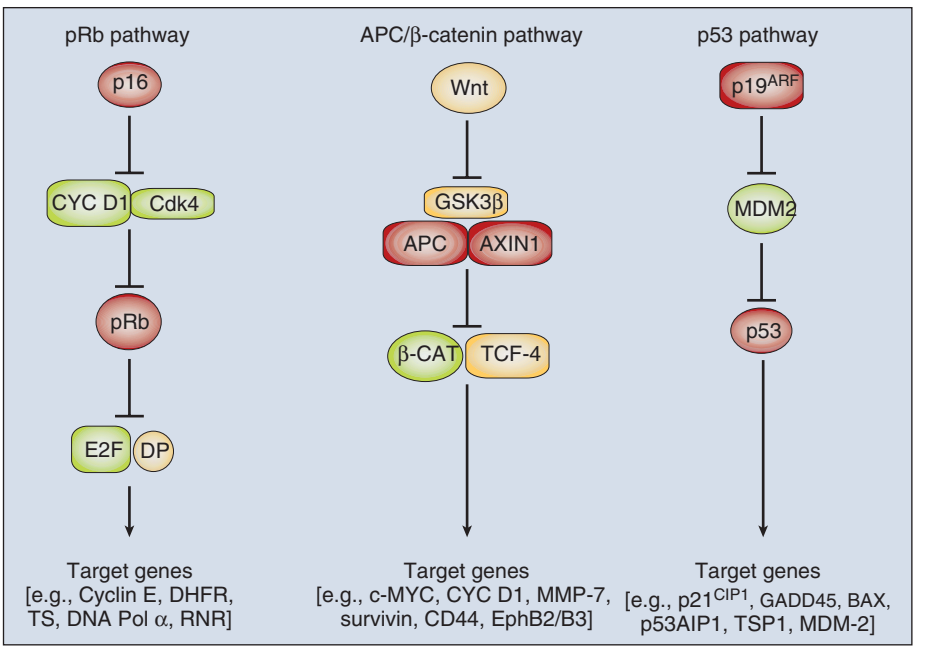

Figure 14-3 • Recurrent gene defects in conserved signaling pathways in cancer. Three signaling pathways that are commonly affected by mutations in various cancers are shown. Selected interactions between components of the pRb (*left*), APC/β-catenin (*middle*), and p53 pathways (*right*) are shown. Tumor suppressor proteins are indicated with *red* symbols, oncogene products are indicated by *green*, and those proteins that are not known to be affected by mutational or epigenetic defects in human cancer are indicated in *yellow*. Inhibitory interactions between proteins are indicated by *perpendicular lines*, and activating effects are indicated by *arrows*. Presumptive downstream genes whose expression is affected by the pathways are noted. APC, adenomatous polyposis coli; β-CAT, β-catenin; Cdk4, cyclin-dependent kinase 4; CYC D1, cyclin D1; DHFR, dihydrofolate reductase; DNA Polα, DNA polymerase α; GADD45, growth arrest and DNA damage inducible gene 45; GSK3β, glycogen synthase 3β; MMP-7, matrix metalloproteinase 7, p21^{CIP1}, p21 CDK-interacting protein 1; p53AIP1, p53-regulated apoptosis-inducing protein 1; RNR, ribonucleotide reductase; TCF-4, T-cell factor-4; TS, thymidylatesynthase; TSP1, thrombospondin 1.

N-terminus of β-catenin, essentially rendering β-catenin resistant to regulation by the APC/AXIN/GSK3β complex. Hence, the mutant β-catenin protein accumulates in the cell and deregulates TCF transcription. Of some interest, and a point that will be discussed more later, transcription of several proto-oncogenes appears to be activated directly by the β-catenin/TCF complex, including the *c-MYC* and *cyclin D1* genes.[38]

Other tumor suppressor gene regulatory networks have been defined, including the p53/MDM2/$p19^{Arf}$ pathway (see Fig. 14-3), the PTCH/SMO/GLI pathway, and the MSH2/MLH1/PMS2 DNA mismatch recognition and repair pathway. Similar to the situation for the pRb, APC/β-catenin, and p53 pathways, mutations in cancer cells not infrequently target the PTCH/SMO/GLI and MSH2/MLH1/PMS2 pathways, either activating an oncogene within the pathway (e.g., SMO or GLI for the PTCH/SMO/GLI pathway) or inactivating one of the key tumor suppressors (e.g., either MLH1 or MSH2 in the mismatch repair pathway).

Although a large collection of genetic and biochemical data support the proposed protein functions and interactions depicted in Figure 14-3, it seems likely that the situation in vivo is far more complex. For example, on the basis of the regulatory scheme outlined for the pRb pathway in Figure 14-3, it might appear that the phenotypic consequences of pRb or $p16^{INK4a}$ inactivation are functionally equivalent. However, patients with germline mutations that inactivate pRb are predisposed to retinoblastomas and osteosarcomas, while those with germline defects in $p16^{INK4a}$ are predisposed predominantly to melanoma and pancreatic cancer.[39,40] Furthermore, while those with germline mutations that affect pRb or $p16^{Ink4a}$ are predisposed to a rather limited spectrum of cancers, somatic defects in the pRb pathway (e.g., including mutations in pRb, $p16^{Ink4a}$, cyclin D1, and CDK4) are seen in the majority of a broad array of cancer types.[39,40] Unfortunately, at present, although there is no compelling mechanistic explanation for these observations, perhaps a general explanation can be offered. Specifically, the genetic pathways in which certain oncogenes and tumor suppressor genes function are not simply linear pathways as indicated schematically in Figure 14-3 but more likely represent much more complex networks. The branches of the network may even vary considerably, depending on cell type and developmental context, though it seems reasonable to predict that the genes and the protein products recurrently affected by mutation in human cancer represent particularly critical hubs in the pathways and networks.

CONTRIBUTION OF GENE DEFECTS TO THE SIGNATURE TRAITS OF CANCER CELLS

Defining Signature Traits of Cancer Cells

Cancer represents a highly heterogeneous collection of diseases. Each cancer type has distinct biologic and clinical features and a variable prognosis. Even cancers that arise in a single organ site, such as the ovary, kidney, or lung, represent a hodgepodge of different diseases. Morphologic features often allow the particular cancer types to be distinguished to some degree from one another. Yet even for patients whose cancers have essentially identical gross and microscopic appearances and very similar clinical manifestations, there may be vast differences in outcome. In spite of this complexity, the development of all cancers, regardless of type, is likely to be critically dependent on the acquisition of certain phenotypic features that allow the cancer cells not only to grow in an unchecked fashion in their tissue of origin, but also to gain the ability to disseminate into surrounding tissues and organs, lymphatics, and the bloodstream and ultimately to grow as metastatic lesions in distant sites in the body.[41] As is indicated in Figure 14-4, among the signature traits that are likely to be inherent in the majority, if not all, of cancer cells are the following: (1) an increased tendency to manifest a stem cell or progenitor-like phenotype, (2) an enhanced response to growth-promoting signals, (3) a relative resistance to growth-inhibiting cues, (4) an increased mutation rate to allow for the rapid generation of new variant daughter cells, (5) the ability to attract and support a new blood supply (angiogenesis), (6) the capacity to minimize an immune response and/or evade destruction by immune effector cells, (7) the capacity for essentially limitless cell division, (8) a failure to respect tissue boundaries, allowing for invasion into adjacent tissues and organs as well as blood vessels and lymphatics, and (9) the ability to grow in organ sites with microenvironments markedly different from the one where the cancer cells arose. The development of some traits is likely to be associated with certain stages of tumorigenesis (see Fig. 14-4), but acquisition of signature traits in cancers is far more likely to show a preferred order than an invariant order.[41] Furthermore, many of the signature traits of cancer cells that were elaborated previously represent complex biologic capabilities (e.g., angiogenic activity, immune evasion/resistance, metastatic competence). Therefore, it is likely that substantial changes in many signaling pathways are needed for the cancer cell to manifest the traits.

An exhaustive cataloging of the observations that link specific gene defects to the altered phenotype of cancer cells will not be offered here, in part because of space limitations and in part because of uncertainties about the significance of some of the linkages between single gene defects and cancer phenotype. Nonetheless, some general concepts regarding the relationships among gene defects and cancer cell phenotype have emerged, and two of these concepts are offered here. First, while some specific mutations and major gene expression defects that are seen in cancer cells may contribute predominantly to a few or perhaps even only one of the signature traits of cancer cells listed in the preceding list, it seems likely that many of the gene defects and expression changes have been selected for in large part because they exert pleiotropic effects on the cancer cell phenotype. Second, for some tumor types, it has been possible to gain insights into the apparent order in which genetic and epigenetic changes might arise and contribute to cancer pathogenesis. The data suggest that defects in certain genes and signaling pathways might be strongly selected for at certain point in cancer development and progression, perhaps in large part because the alterations allow the precancerous or cancerous cells to acquire certain critical phenotypic features. Of some interest, gene defects that might be nearly uniformly present in early-stage lesions of one tumor type might preferentially arise in later-stage tumors in another organ site. These data suggest that cellular and tissue context have critical, albeit poorly understood, modifying effects on the specific genetic defects that give rise to neoplastic transformation and clonal outgrowth. The two concepts—the often pleiotropic effects of the gene defects that are present in cancer cells and the context-dependent effects of the defects—will be expanded on later, with presentation of some concrete examples.

Contribution of APC Inactivation and β-Catenin Deregulation to Cancer Phenotype

As was noted previously, mutational defects that lead to deregulation of the signaling activity of the β-catenin protein are present in a relatively broad array of cancer types, including colorectal tumors, in which upward of 80% to 90% of colorectal adenomas and carcinomas harbor inactivating mutations in APC or AXIN1 or AXIN2 or gain-of-function mutations in β-catenin itself.[36] On the basis of the observation that germline-inactivating mutations in APC markedly increase the rate at which adenomatous lesions arise in the colon and rectum and extensive descriptive molecular studies showing that somatic mutations in APC or β-catenin are present in even microscopic adenomatous lesions in the colon,[42,43] it appears that dysregulation of β-catenin likely plays a central role in the earliest stages of colon cancer development. In other cancer types in which β-catenin

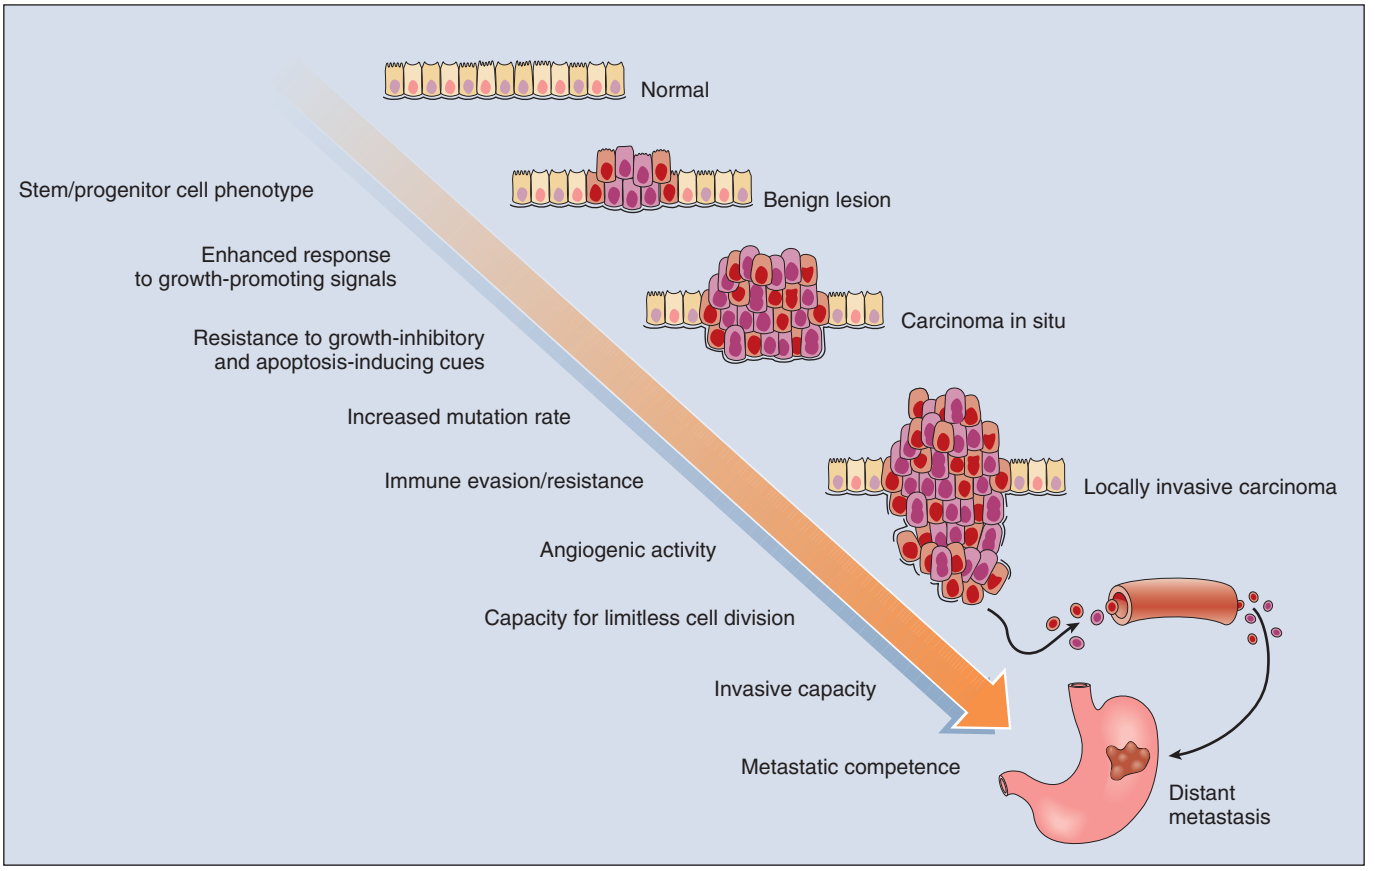

Figure 14-4 • Acquisition of signature traits in neoplastic cells during cancer progression. Depicted in the figure are representative stages in the development of a cancer, perhaps a typical epithelial cancer, such as those that typically arise in the lung, colon, breast, or prostate. The schema suggests that most advanced cancers arise via clonal selection from subclones present in earlier stage benign and localized lesions (e.g., carcinoma in situ and locally invasive carcinoma). Some of the properties of advanced cancer cells are depicted by the ability of the cells to enter the bloodstream and to seed and grow in distant organ sites, such as the liver (*bottom*). Nine signature traits of cancer cells are listed. The relative time at which neoplastic cells acquire some of the traits is uncertain, though it seems likely that some traits, such as the expression of a stem/progenitor cell phenotype or enhanced response to growth-promoting signals, may be acquired earlier in cancer development. Other traits, such as invasive capacity and/or metastatic competence, may be acquired later. Many signature traits of cancer cells are in fact complicated biologic capabilities (e.g., angiogenic activity, immune evasion/resistance, metastatic competence) and likely depend on defects in a number of different factors and signaling pathways.

is often deregulated by mutational mechanisms,[36] such as hepatocellular and endometrial cancers, the timing of β-catenin mutations in the natural history of disease is less certain.

Given this background, what might be the contribution of β-catenin defects to the development and biologic behavior of colon and perhaps other cancers? As was highlighted previously, β-catenin, upon its association with TCF transcription factors, has been implicated in activating expression of genes that likely play critical roles in stimulating progression through the G_1-to-S transition, including cyclin D1 and c-MYC. Effects of cyclin D1 activation on the pRb pathway and progression through the G_1/S phase of the cell cycle were mentioned in the preceding discussion. As is indicated in Figure 14-5, one of the apparent consequences of c-MYC activation of colon cancer cells is repression of the expression of the $p21^{CIP1}$ cyclin-dependent kinase inhibitor,[44,45] and inhibition of $p21^{CIP1}$ might contribute to defective cell cycle control.[44–46] In addition to effects on cyclin D1 and c-MYC, deregulation of β-catenin/TCF transcription has been implicated in activation of a number of genes that might play a role in maintaining or inducing a progenitor cell or stem cell-like phenotype in colon cells that should otherwise be destined for differentiation or apoptosis[38,45] (see Fig. 14-5). Genes that might play a role in conferring a progenitor cell phenotype include the cell surface protein CD44 and the EphB2 and EphB3 receptors and their ligand ephrin-B1.[45,47] Either individually or collectively along with other molecules, the cell surface proteins might exert potent effects on colonic epithelial cell fate, perhaps in part by inhibiting appropriate migration of cells in the crypt and hence favoring response to proliferation-inducing signals over differentiation-inducing cues.[45,47]

Another presumptive β-catenin/TCF target gene with a potential role in acquisition of several critical cancer phenotypic traits is the matrix metalloproteinase-7 (MMP-7, also known as matrilysin)[48] (see Fig. 14-5). MMP-7 itself has a number of potential roles in cancer progression,[49,50] including the ability to cleave and downregulate the activity of the E-cadherin tumor suppressor protein[51] and the ability to cleave osteopontin and apparently activate osteopontin's cell migration-stimulating activity.[52] Besides the role of dysregulated β-catenin in activating transcription of TCF target genes, there is evidence that elevated levels of nuclear β-catenin in cancer cells can interfere with NF-κB function and NF-κB's ability to activate key downstream effectors of apoptosis, such as Fas and TRAF1[53] (see Fig. 14-5). Finally, the carboxyl-terminus region of the APC tumor suppressor protein confers binding to the EB1 protein, a microtubule-binding protein, as well as to microtubules.[35] Given the apparent role of EB1 in regulating microtubule dynamics, cell polarity, and chromosome stability and the evidence that APC inactivation in certain cellular contexts could confer a chromosome instability phenotype, it is possible that APC inactivation also contributes to a chromosomal instability phenotype in colorectal cancer cells.[35,54,55]

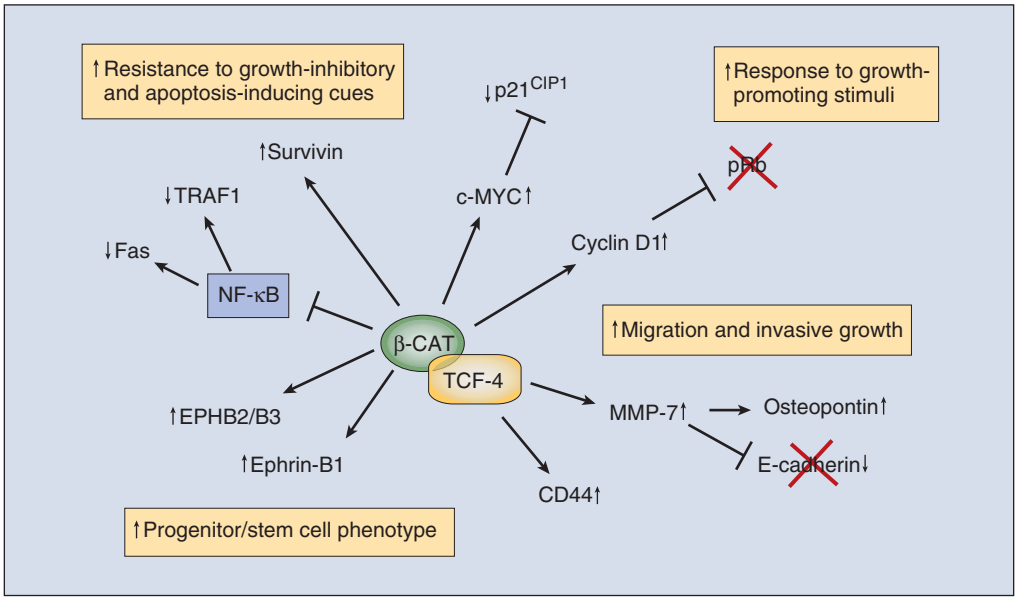

Figure 14-5 • Potential contributions of β-catenin deregulation to cancer cell signature traits. Inactivation of the APC tumor suppressor protein or activating (oncogenic) mutations in β-catenin can lead to marked increases in the levels of free β-catenin protein in the cytoplasm and nucleus, enhanced binding of β-catenin to the TCF-4 (T cell factor-4) transcription factor, and activation of β-catenin/TCF-4 regulated genes. Some of the genes that might be directly regulated by the β-catenin-TCF-4 transcription process include the genes for c-MYC, cyclin D1, MMP-7, survivin, CD44, the EPHB2 and EPHB3 receptors, and their ligand Ephrin-B1. Some of the potential effects resulting from activation of these target genes are indicated. In addition to β-catenin's role in activating expression of TCF-4-related genes, β-catenin appears to inhibit the activity of NF-κB and NF-κB's ability to activate genes with potential roles in apoptosis, such as Fas and TRAF1. The potential contributions of β-catenin to cancer cell traits are discussed in more detail in the text.

Contribution of RAS-Signaling Pathway Defects to Cancer Phenotype

RAS gene mutations were the first somatic gene defects to be characterized at the molecular level in cancer cells, and we now know that mutations in the three RAS genes—H-RAS, K-RAS, and N-RAS—are among the most common oncogene defects in cancer, with an estimated 20% of all cancers carrying a point-mutated, activated RAS allele.[56–58] RAS proteins appear to play key roles in several important signaling pathways (Fig. 14-6), and proteins that function upstream or downstream of the RAS proteins are affected by mutations in certain cancers. For instance, mutational activation and/or overexpression of growth factors upstream of RAS, such as epidermal growth factor receptor and/or ERBB2 (also known as HER2/Neu), can be commonly seen in a number of epithelial cancers, including breast and ovarian carcinomas (see Table 14-1). Mutations in effectors downstream of RAS can also be seen in cancers, including defects in the mitogen-activated protein kinase (MAPK) pathway as a result of BRAF gene mutations[56,59] or defects in phosphatidylinositol 3-kinase (PI3K) signaling, as result of amplification and overexpression of AKT2, activating mutations of AKT1, or inactivating mutations in the PTEN (phosphatase and tensin homolog) tumor suppressor gene.[58–61] Sometimes mutations in Ras and the downstream effectors are mutually exclusive (e.g., Ras and B-Raf), while in other cases (e.g., Ras and PI3K catalytic subunit), the mutations coexist.[5,58]

The consequences of RAS mutations specifically and RAS-signaling pathway defects more generally are varied and undoubtedly depend on cell context, because constitutive activation of RAS signaling in certain contexts can promote apoptosis rather than cell proliferation or neoplastic transformation.[62,63] In brief, activated mutant RAS alleles have been implicated in enhanced response to proliferative cures, perhaps to a certain extent owing to the ability of RAS-MAPK activation to enhance expression of cyclin D1, and cyclin D1's ability to inactivate pRb function via phosphorylation[59,63] (see Fig. 14-6). RAS pathway activation can also interfere with apoptosis induction, perhaps in part via activation of the PI3K pathway and its ability to antagonize the proapoptotic factor BAD and perhaps other molecules that are important in promoting programmed cell death[59,61] (see Fig. 14-6). In addition to the potential ability of RAS pathway activation to enhance cell proliferation and inhibit programmed cell death in cancer cells, RAS activation has been implicated in transcriptional activation of vascular endothelial growth factor (VEGF),[64] a potent stimulator of angiogenesis. Furthermore, RAS activation has been linked to increased invasive potential.[59] The role of RAS in promoting invasiveness might be mediated through RAC-dependent effects on the cytoskeleton as well as MAPK pathway-dependent activation of matrix metalloproteinases,[59] such as MMP-9, which can function in degradation of the basement membrane component type IV collagen[50] (see Fig. 14-6). Interestingly, MMP-9 has also been implicated in promoting angiogenesis in some settings via its ability to stimulate release of VEGF from poorly defined extracellular reservoirs.[65]

MicroRNAs as Post-transcriptional Regulators of Gene Function

It has been recognized in the last few years that the translation of mRNA transcripts into proteins is highly regulated by a novel class of short noncoding RNAs, the so-called microRNAs (miRNAs). The mature forms of miRNAs are 18 to 24 nucleotides in length and are generated by successive cleavages by the Drosha and Dicer nucleases from longer precursor transcripts that contain characteristic hairpin formations.[66] Recognition of target transcripts occurs by binding of the miRNA to the 3′ untranslated regions (3′UTR). Depending on the degree of homology to their target sequence, miRNAs induce translational repression or cleavage of mRNAs. More than 500

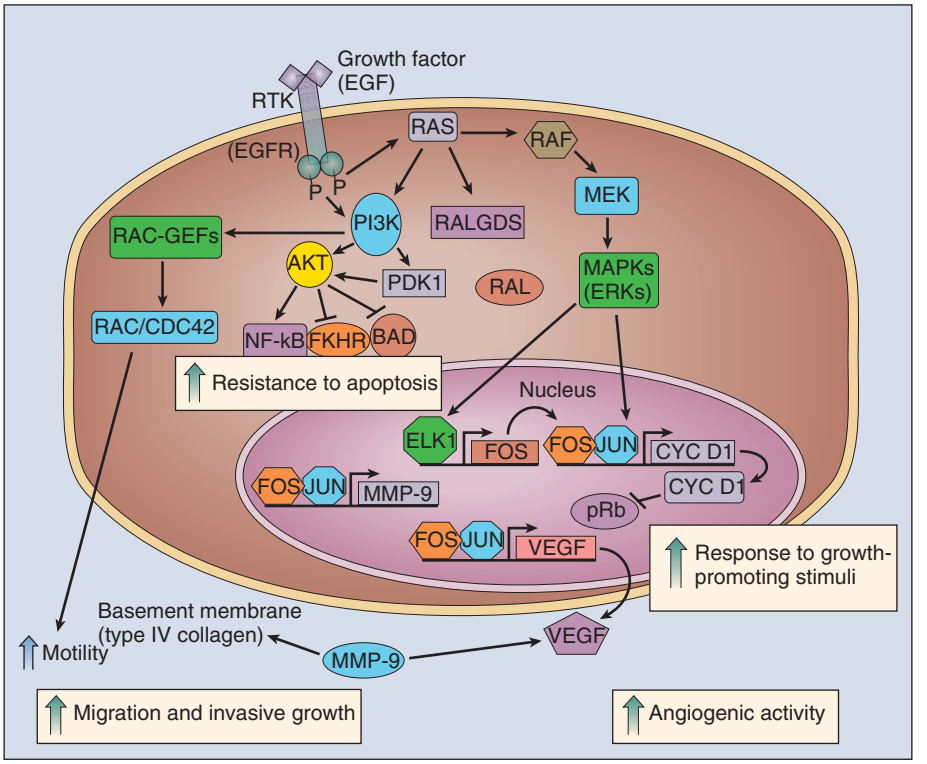

Figure 14-6 • Potential contribution of RAS pathway defects to the cancer cell phenotype. The RAS protein is indicated near the top of the figure, and selected upstream and downstream factors are also indicated relative to their likely location in the cell. RAS pathway-signaling interactions are complex, and only selected functional interactions upstream and downstream of RAS are indicated. As is indicated in the figure and discussed in more detail in the text, RAS pathway activation can likely enhance the response to growth-promoting stimuli via effects on cyclin D1 (CYC D1) expression and pRb phosphorylation and activity. These effects on cyclin D1 expression are likely to be mediated by the RAF/MAPK (mitogen activated protein kinase) signaling cascade and its effects on downstream conscription factors, including JUN and the ETS-related protein ELK1, which activates expression of JUN's dimeric partner, FOS. RAS pathway activation also likely acts to increase resistance to apoptosis in some settings through effects on AKT and its ability to inhibit factors with proapoptotic roles (e.g., Forkhead in human rhabdomyosarcoma [FKHR] or BAD) or AKT's ability to activate NF-κB's survival function. Besides these effects, RAS pathway activation might act to stimulate vascular endothelial growth factor (VEGF) production and angiogenesis. RAS can enhance cell migration and invasion via RAC/CDC42-mediated effects on the cytoskeleton and possibly FOS/JUN-mediated increases in the expression of some matrix metalloproteases, such as MMP-9. Finally, MMP-9 can also promote release of VEGF from extracellular reservoirs, perhaps further enhancing VEGF effects on angiogenesis.

human miRNAs have been described, and each single miRNA can target hundreds to a thousand or more mRNAs.[66] This ability allows for substantial combinatorial complexity and functional redundancy, making the identification of specific functions of miRNAs as well as their involvement in oncogenic or tumor suppressive networks difficult. The fact that miRNAs act via base-pairing of the miRNA with the 3′UTR also implies that alterations of both miRNA sequence and miRNA target sequence might have functional consequences. So far, large-scale sequencing efforts have been focused mainly on the coding sequence of genes, which means that a significant number of functionally relevant alterations might have been missed.

Several lines of evidence make it likely that miRNAs do play a role in the development of cancers. For instance, global inhibition of miRNA production seems to facilitate the acquisition of a neoplastic phenotype in primary mouse cells, suggesting that the net effect of all miRNAs might be a tumor suppressive effect.[67]

The genomic location of many miRNAs maps close to common chromosomal breakpoints in cancer. In most cases, however, it is still unclear whether the miRNAs are actually involved in conferring the selective advantage that is gained by these translocations or whether miRNAs for other reasons are localized in regions of high genomic fragility.[68]

Comprehensive analyses of miRNA expression patterns in human cancers have revealed that different cancer types have distinct miRNA expression patterns. In fact, in many instances, miRNA expression patterns might be more precise in determining the tissue of origin than mRNA expression profiles.[69] Similar to the situation with protein-coding genes, in most cases, it is unclear which expression changes are causative and which are secondary to the development of the tumors.[70]

Several miRNAs seem to play a role as part of classical tumor suppressive or oncogenic signal transduction pathways (Table 14-3). The miRNA17–92 locus has been described as a direct transcriptional target of the c-MYC and E2F oncogenes.[71] This polycistron locus encodes for seven miRNAs and has been shown to be genomically amplified and overexpressed in some human B-cell lymphomas and lung cancers. When overexpressed, it can cooperate with c-MYC to accelerate lymphoma development in a murine model system. In

Table 14-3 Putative Tumor Suppressor or Oncogenic miRNAs

miRNA	Chromosomal Location	Expression	Target Genes/Effect
PUTATIVE TUMOR SUPPRESSOR miRNAs			
miRNA15/16	13q14	CLL and pituitary adenoma	BCL2
miRNA34a	1p36	p53 target gene; loss in neuroblastoma	BCL2, MET, Cyclin E2
miRNA34b/c	11q21	p53 target gene; loss in NSCLC	BCL2, MET
let-7a-2	11q24	Loss in lung cancer	K-RAS, HMGA2
PUTATIVE ONCOGENIC miRNAs			
miRNA17–92	13q14	c-MYC target gene Up in B-cell lymphoma, lung cancer	Cooperates with c-MYC and regulates E2F1
miRNA372/373	19q13	Up in germ cell tumors	LATS2 tumor suppressor → p53 inactivation
miRNA10a	19q13	Up in metastatic breast cancer	Metastatic phenotype
miRNA155	21q21	Up in breast cancer, lymphoma	?
miRNA21	17q23	Up in pancreatic, breast and CNS cancer	PTEN tumor suppressor
TRANSLOCATIONS INVOLVING miRNAs OR miRNA TARGET SITES			
miRNA142	t(8;17)(q24;q22)	B-cell lymphoma	miRNA promoter drives c-MYC expression
HMGA2	12q15 translocations	Benign salivary gland tumors	Translocation removes let-7 recognition sites from the HMGA2 transcript

CLL, chronic lymphocytic leukemia; NSCLC, non-small-cell lung cancer.

Modified from Calin GA, Croce CM: Chromosomal rearrangements and microRNAs: a new cancer link with clinical implications. J Clin Invest 2007;117:2059–2066; and Garzon R, Fabbri M, Cimmino A, et al: 206 MicroRNA expression and function in cancer. Trends Mol Med 2006;12:580–587.

addition, miRNA372 and miRNA373 have been implicated as oncogenes in the development of germ cell tumors at least in part by inactivating the p53 tumor suppressor pathway.[72] Recently miRNA10a has been suggested to be a major driving force behind the metastatic progression of breast cancer cell lines.[73]

Members of the let-7 family of miRNAs have been proposed as tumor suppressor genes in lung cancer, supposedly in part by their ability to inhibit the translation of the K-Ras and HMGA2 oncogenes.[74] The members of the miRNA34 family have recently been shown to be direct transcriptional targets of the p53 tumor suppressor gene and seem to play a significant role in p53 activity.[75,76]

Role of Tissue and Context Differences in the Contributions of Gene Defects to Cancer Cell Phenotype

The published literature on the potential contributions of gene defects to the altered phenotype of cancer cells has offered some suggestions about how to consider the role of the gene defects in cancer pathogenesis. For instance, terms such as *gatekeeper* and *caretaker* have been used to classify the contributions of genes to cancer development.[77] "Gatekeeper" genes have been suggested to be those genes that play particularly critical roles in regulating cell proliferation and inhibiting cancer development in certain tissues, such as the APC gene in colorectal cancer, and the tumor suppressive function of the genes must be overcome for cancers to arise in a given tissue or organ site.[77] "Caretakers" have been generally defined as those genes that do not play direct roles in growth control but rather likely play important roles in a number of tissues in maintaining the fidelity of the genome via their role in DNA damage recognition and repair processes. The MLH1 and MSH2 mismatch repair genes have been proposed to be representative caretaker genes,[77] and some researchers have suggested that perhaps the BRCA1 and BRCA2 genes also represent caretaker genes.[78] The use of terms such as *gatekeeper* and *caretaker* might have some merit. However, as will be illustrated in the following discussion, given the apparently important role of "gatekeeper" gene defects in cancers that arise in various organ sites but the quite variable timing of "gatekeeper" gene defects in the natural history of one cancer type versus another, the term *gatekeeper* might be more confusing than illuminating. In the case of some presumed "caretaker" genes, the genes might not be playing the passive role in the cancer process that has been assigned to them. This view is based on three lines of argument: (1) the apparent tissue specificity of the tumors that arise in individuals who harbor germline mutations in the "caretaker" genes, such as in individuals who are affected by hereditary nonpolyposis colorectal cancer and germline MLH1 or MSH2 mutations[79]; (2) the likely variable time in cancer development at which "caretaker" mutations may arise from one tumor to the next, with sporadic colon tumors not usually manifesting mismatch repair gene inactivation and microsatellite instability until the carcinoma stage, despite the fact that adenomas in individuals with hereditary nonpolyposis colorectal cancer often show high-frequency microsatellite instability[80,81]; and (3) the evidence that "caretaker" genes might actually play key roles in regulating cell proliferation and promoting apoptosis in certain contexts.[82]

In general, individuals who harbor a germline mutation in a specific tumor suppressor gene or proto-oncogene are predisposed to a very limited spectrum of cancer types. This observation is puzzling for a couple of reasons. The majority of genes that are affected by germline mutations in specific inherited cancer syndromes are essentially ubiquitously expressed in adult tissues. Furthermore, for a number of the tumor suppressor genes, mutations are often found to inactivate the gene in a much broader collection of sporadic cancer types than the types that commonly arise in germline mutation carriers. Children who carry a germline mutation in the *RB1* gene have a very elevated risk of developing retinoblastoma and a more modest risk of developing osteosarcoma but no dramatic increase in the risk of most common adult cancers. Yet somatic defects in pRb have been found and are believed to be critical in the development

of many different cancers, such as small cell lung carcinomas, in which the vast majority have pRb defects.[40,82]

There are potential explanations for these puzzling observations. For instance, while pRb might have an essential role in regulating retinoblast cell proliferation and/or differentiation, in other tissues, such as lung or breast epithelial cells, pRb might have a redundant role in growth control, perhaps because of the contribution of pRb-related proteins, such as p107 and p130.[30,31] Under this scenario, pRb inactivation in most cell types might not promote neoplastic growth unless other defects, such as those in pRb-related proteins, are also present. An alternative and perhaps more likely possibility is that somatic inactivation of pRb might trigger apoptosis in many cell types unless other somatic gene defects have arisen previously and these other defects interfere with the cell's ability to undergo apoptosis following disruption of *RB1* function (Fig. 14-7). Evidence that pRb inactivation can act in a context-dependent fashion to promote apoptosis versus neoplastic transformation has been offered.[83,84] The tissue specificity of cancers that are seen in individuals who carry germline mutations in inherited cancer genes is not restricted to the case of pRb. Germline *p53* mutations predispose primarily to osteosarcoma, soft tissue sarcoma, leukemia, brain tumors, and breast cancer in women; and $p16^{INK4a}$ germline mutations predispose primarily to melanoma and pancreatic cancer. In spite of the relatively limited spectrum of cancer types that are seen in people who carry germline p53 or $p16^{INK4a}$ mutations, the *p53* and $p16^{INK4a}$ genes are very commonly altered in human cancer, each of the genes being inactivated in upward of 35% to 50% of many different sporadic cancer types.

Finally, some genes with prominent roles in the development of a variety of different cancer types are sometimes presumed to have essentially singular functions in the cancer process in spite of data that suggest otherwise. As an example, the E-cadherin protein plays an important role in cell-cell adhesion via the ability of its extracellular domain to form adhesive interactions with E-cadherin molecules on opposing cell surfaces and the ability of the E-cadherin cytoplasmic domain to link to the actin cortical cytoskeleton via interactions with catenin proteins at the plasma membrane.[85] Early functional studies have suggested that restoration of E-cadherin in cancer cells that had endogenous E-cadherin defects interfered with the invasive properties of cancer cells in selected in vitro assays.[86] Perhaps in large part because of these observations, the loss of E-cadherin expression in cancer has nearly invariably been assigned a role in promoting invasive behavior in advanced cancer cells. While loss of E-cadherin function might indeed contribute to invasive behavior in cancers arising in vivo, it is worth bearing in mind that defects in E-cadherin could in fact play a distinct role in altering cell

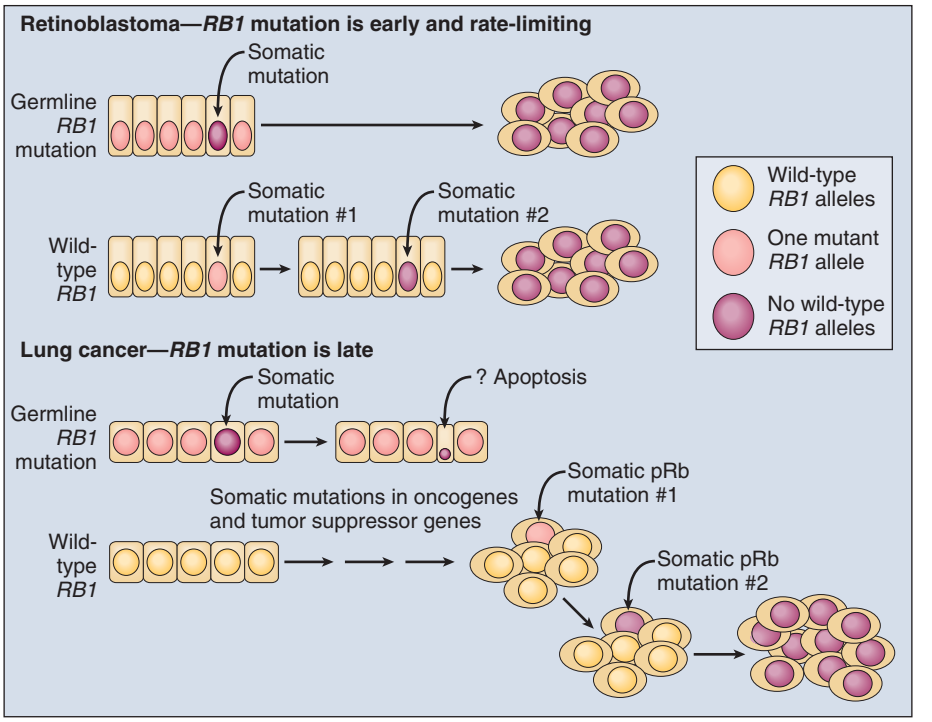

Figure 14-7 • Mutations in the retinoblastoma tumor suppressor gene (*RB1*) contribute to inherited and sporadic cancers. The figure indicates that cell context affects the contribution of *RB1* mutations to cancer development. In individuals who carry a germline mutation in one *RB1* allele, somatic inactivation of the remaining *RB1* allele is an early and rate-limiting event in retinoblastoma formation. Sporadic forms of retinoblastoma are dependent on inactivation of both *RB1* alleles. Because somatic inactivation of both *RB1* alleles must occur in a single developing retinoblast before tumor formation can ensue, retinoblastoma is a rare disease in people who do not carry a germline *RB1* mutation (i.e., the general population). Those who carry a germline *RB1* mutation do not manifest a markedly increased risk to many common cancers, such as lung cancer, despite the fact that *RB1* mutations are frequently observed in sporadic forms of lung cancer (e.g., small cell lung carcinoma). These observations imply that *RB1* mutations might contribute to tumor progression rather than tumor initiation in most cancer types other than retinoblastoma and perhaps osteosarcoma. Possible explanations for this phenomenon include the possibility that inactivation of both *RB1* alleles prior to the acquisition of defects in other oncogenes or tumor suppressor genes is not associated with any growth advantage and *RB1* activation in some contexts might even induce apoptosis. (Modified from Haber DA, Fearon ER: The promise of cancer genetics. Lancet 1998;351[suppl 2]:1–8.)

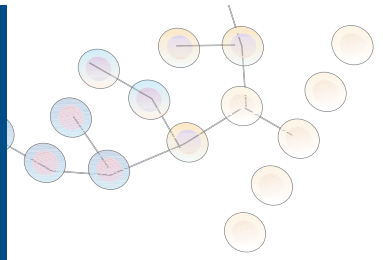
growth very early in the neoplastic transformation process in some tumor types, such as the gastric carcinomas that arise in patients who carry germline E-cadherin mutations.[87]

CLINICAL IMPLICATIONS

On the basis of review of the data on the apparent contributions of gene defects to cancer phenotype, some clinical implications are apparent. The genes and the protein products that are recurrently altered by mutations and/or epigenetic defects in human cancer more than likely represent particularly critical hubs in the pathways and networks that regulate cell growth, differentiation, and programmed cell death. Hence, efforts to target the proteins and pathways with apparently central roles in the pathogenesis of a number of different cancer types would appear to offer potentially the broadest impact. Additionally, because the gene defects that promote clonal selection during cancer development might have particularly pleiotropic effects on the cancer cell phenotype, targeting of the central pathways in cancer might also be expected to have some of the most dramatic effects on cancer cells. For example, in light of the important role of RAS pathway defects in a broad array of cancer types and the view that RAS pathway deregulation exerts pleiotropic effects on the cancer cell phenotype, drugs that inhibit the activity of Raf, MEK, or MAPK might have potent anticancer activity in a subset of the many cancers with RAS pathway defects.[88] Moreover, even though RAS pathway defects may arise at early to intermediate stages of tumor development in some cancer types, such as colorectal cancer, it is encouraging to learn that quite dramatic effects can be seen on the growth of advanced cancer cells when the activity of the mutant RAS protein is antagonized.[89,90]



In spite of the generally optimistic view that is offered as a result of our rapidly expanding understanding of the nature and contribution of gene defects in cancer pathogenesis, some significant challenges remain if novel and specific new anticancer therapies are to be achieved in the near term. In particular, for a fair number of the specific signaling pathways that are commonly disrupted in cancer, it might prove difficult to define readily tractable targets for therapeutic intervention. For instance, in the case of the p53 pathway, it is unclear how effectively p53 function can be restored in the proteins that carry missense substitutions or when the p53 protein is intact and simply antagonized by upstream defects (e.g., $p19^{ARF}$ or MDM2 defects). In the case of cancers with mutations leading to β-catenin deregulation, a potential goal might be to define agents that specifically interfere with the nuclear function of β-catenin in transcriptional activation of β-catenin/TCF-regulated target genes. While this is not an unreasonable notion, given the rather limited successes to date in defining small molecules that specifically affect transcription factor complexes, it could be very challenging to target β-catenin via conventional pharmacologic approaches. Similar concerns could be perhaps raised regarding the merits of attempting to specifically target other nuclear proteins and transcription factors that are deregulated in cancer cells.

Given these concerns regarding the likelihood for success in defining small molecules that effectively target some of the pathways that are most commonly deregulated in cancer, emphasis for therapeutic targeting in the near term might be placed on potentially more promising molecular targets in cancer, such as CDK4 (e.g., for cancers with an intact pRb protein but defects in $p16^{INK4a}$, cyclin D1, or CDK4) or various effector molecules in the PI3K-AKT pathway, such as the AKT or mTOR proteins (e.g., for cancers with PTEN defects).[61] While the success of approaches to target cancer cells more selectively remains to be broadly established, it is obvious that the efforts to understand the relationship between gene defects, altered cell signaling and physiology, and cancer phenotype have already shaped and will continue to shape our views of how best to proceed with novel therapeutic interventions.

15 Immunodeficiency and Cancer

Alexandra H. Filipovich and Thomas G. Gross

SUMMARY OF KEY POINTS

- Neoplasms are the second most common cause of mortality (after infections) among patients with primary and acquired immunodeficiencies.
- Infections, whether de novo, reactivated, or chronic, play a pivotal role in promoting development of both lymphomas and carcinomas. Examples include the following:
  - Epstein-Barr virus (EBV) associated with lymphoproliferative disorders
  - *Helicobacter pylori* associated with gastric carcinomas and mucosa-associated lymphoid tissue (MALT) lymphomas
  - Human papillomavirus associated with skin and cervical carcinomas
- Categories of genetic immunodeficiencies with increased risk of developing tumors include the following:
  - Combined defects with T-cell dysfunction (e.g., Wiskott-Aldrich syndrome)
  - Defects that inhibit lymphoid apoptosis (e.g., autoimmune lymphoproliferative syndrome [ALPS])
  - Defects of genomic instability (e.g., ataxia telangiectasia)
- Categories of acquired immunodeficiencies with increased risk of developing tumors include the following:
  - Recipients of solid-organ allografts
  - Recipients of T-cell-depleted mismatched allogeneic hematopoietic stem cells
  - HIV/AIDS patients
- The risk of lymphoproliferative disorders in immunodeficient hosts can be reduced by the following:
  - Correction of primary immunodeficiencies with bone marrow transplant
  - Reduction of immune suppression in allograft recipients
  - Aggressive treatment for HIV

INTRODUCTION

Retrospective surveys of patients with primary and acquired immune deficiencies have revealed several patterns of increased risk for specific cancer types. In the majority of immunodeficiency conditions—whether de novo, reactivated, or chronic—infections play a pivotal role in promoting the development of both lymphomas and carcinomas. Specifically, patients with primary (genetically determined) or acquired immune deficiencies that affect primarily T-cell function are at increased risk of developing cancer. This risk group includes patients who are immune suppressed following solid-organ allografting, hematopoietic stem cell transplantation (HSCT), or secondary to human immunodeficiency virus (HIV) infection. Chronic immune suppression also increases the risk for carcinomas that are linked to infection with viruses, such as human herpesvirus 8 or Kaposi's sarcoma–associated herpesvirus associated with Kaposi's sarcoma or human papillomavirus associated with squamous cell carcinoma of the skin and cervix. People with congenital humoral immune defects (especially IgA deficiency) who are persistently colonized with *Helicobacter pylori* experience a higher rate of gastric carcinomas and gastric mucosa–associated lymphoid tissue (MALT) lymphoma. A minor, but biologically instructive, category of individuals at increased risk of tumors of both hematopoietic and epithelial origin are those with inherited defects of genomic instability, which may lead to both immunodeficiency and propensity to tumor development. Examples of such disorders include ataxia telangiectasia and Bloom's syndrome.

Although tumors in immune-deficient persons remain a major cause of morbid and fatal complications, progress has been made in reducing the risk of malignant transformation in many patients through better understanding of the etiopathogenesis. The risk of life-threatening "lymphomas" can be reduced substantially by correcting the underlying primary immune defect via HSCT, by minimizing immune suppression in transplant recipients, and by aggressive anti-HIV therapy in HIV/AIDS patients. More recently, the availability of sensitive methods for monitoring reactivation of EBV in immune-compromised populations using quantitative polymerase chain reaction (PCR) techniques, combined with the pre-emptive or therapeutic use of anti-CD20 antibodies to thwart EBV-associated lymphoproliferation, have led to successful control of post-transplant "lymphomas." Highly active antiretroviral therapies (HAART) and other approaches that maintain and strengthen cell-mediated immunity in HIV-infected individuals have reduced their risk of "opportunistic" cancers. Rapid and reliable diagnosis of *H. pylori* infection and appropriate antibiotic treatment for susceptible hosts diminishes the risks of both carcinomas and lymphomas of the stomach.

HISTORY

In 1959, Lewis Thomas[1] proposed the concept that immune surveillance was an active process controlling the emergence of malignant clones from somatic cells that undergo precancerous mutations during the lifetime of a normal, immune-competent individual. This hypothesis predicted that immune-deficient subjects should

experience much higher rates of all types of cancers as compared with the general population. Indeed, surveys of patients with primary and acquired immune deficiencies have demonstrated increased incidence of cancer but not substantiated an increased risk of all cancer types.[2] Retrospective clinical investigations have revealed several patterns of association between certain malignancies and underlying disease types. In many cases, de novo, reactivated, or chronic infections play a substantial role in tumor development. Specifically, patients with primary (genetically determined) or acquired immune deficiencies that affect primarily T-cell function are at increased risk of developing lymphomas, often associated with EBV.[3,4] Chronic immune suppression also increases a patient's risk of developing carcinomas that are linked to infection with viruses. For example, HIV-infected subjects and solid-organ allograft recipients run an increased risk of Kaposi's sarcoma, which is associated with human herpesvirus-8 or also known as Kaposi's sarcoma–associated herpesvirus. Solid-organ allograft recipients are also at greater risk of developing squamous cell carcinoma of the skin and cervix associated with HPV. Persons with congenital humoral immune defects (especially IgA deficiency) who are persistently colonized with *H. pylori* experience higher rates of gastric carcinomas and gastric MALT lymphomas. The third category of patients at increased risk of tumors of hematopoietic and epithelial origin is individuals with inherited defects of genomic instability, which lead to both immune deficiency and propensity to tumor development.[5]

Even among classic primary immunodeficiencies, the array of tumors observed varies among the specific immunodeficiency diagnoses. The recent delineation of precise genetic causes for many of the primary immune deficiencies has made possible initial molecular dissection of affected pathways of cellular proliferation and programmed cell death in distinct disorders and has helped to reconcile the differences in tumors seen among patients with those disorders.

Although tumors in immune-deficient persons remain a major cause of morbid and fatal complications, progress has been made in reducing the risk of malignant transformation in many patients through better understanding of the etiopathogenesis. The risk of life-threatening "lymphomas" can be reduced substantially or even eliminated in some patients by correcting the underlying primary immune defect via HSCT, by minimizing immune suppression in recipients of transplantation, or by aggressive anti-HIV therapies in HIV/AIDS patients.[6–8] More recently, the availability of sensitive methods for monitoring reactivation of EBV in immune-compromised populations using quantitative PCR techniques, combined with the pre-emptive or therapeutic use of anti-CD20 antibodies to thwart EBV infection, have led to successful control of post-transplant "lymphomas."[9–11] Newer antiretroviral therapies and other approaches that maintain and strengthen cell-mediated immunity in HIV-infected individuals have reduced their risk of "opportunistic" lymphomas. Rapid and reliable diagnosis of *H. pylori* infection and appropriate antibiotic treatment for susceptible hosts diminishes the risks of both carcinomas and lymphomas of the stomach.[12–14]

At the same time, new medical advances could create new populations of patients at risk for lymphoid tumors in particular. Use of ever more intensive therapies to eradicate cancer in adults, such as nonmyeloablative but highly immunosuppressive HSCTs, and use of immune-ablative chemotherapy in the setting of autologous transplants for underlying autoimmune diseases place subjects at risk for reactivation of EBV for many months or years after these procedures.[15–17] In all of these settings there is a significant probability of prolonged erasure of the immune repertoire "memory," with a limited capacity to restore thymopoiesis. Finally, genetic manipulation of the immune system that bypasses normal regulatory mechanisms has the potential to create rather than reduce lymphoproliferative consequences, as is seen in murine and human trials of gene therapy for primary immunodeficiencies.

LYMPHOMAS AND IMMUNODEFICIENCY

Contributors to Increased Risk of Lymphoproliferative Disorders in Primary and Secondary Immunodeficiencies

Three general biologic circumstances, often occurring in concert, predispose individuals with primary or acquired immunodeficiencies to the development of lymphoproliferative disorders:

1. The endemic incidence of EBV infection
2. The predominance of type 2 cytokine production in susceptible hosts and in the case of primary immune defects
3. Disruption of normal pathways that regulate lymphocyte cell cycling and survival by genetic mutations

EBV is a major cofactor in many lymphomas (lymphoproliferative tumors) in the setting of immune compromise, as a result of the unique properties of EBV as a transforming agent of B cells and its expression of genes that inhibit human cell-mediated immunity. Because of the ubiquitous presence of EBV, most people become infected during their lifetime, leading to a state of lifelong viral latency. The latent state of EBV is maintained by host-specific, cell-mediated immune responses (conferred by T and natural killer [NK] cells). In cases in which cell-mediated control of EBV latency is inadequate (because of genetic immunodeficiency) or fails (after immune suppression or destruction), EBV-immortalized B cells are able to proliferate unchecked, which can result in sequential loss of heterozygosity mutations and/or frank cytogenetic rearrangements. The emergence and persistence of EBV-transformed B cells and resultant lymphoproliferative disorders is further favored by a type 2–skewed cytokine milieu, inhibiting the type 1 cellular immunity that is essential for the control of EBV-bearing B cells.[18] Type 2 cytokine skewing has been observed in patients with several different primary immune defects characterized by compromised quantity, maturity, diversity, and/or responsiveness of T cells. Disorders such as Omenn's syndrome (a form of severe combined immunodeficiency [SCID]) and Wiskott-Aldrich syndrome (WAS) are examples of such primary immunodeficiencies. Patients recovering from HSCT and solid-organ allograft recipients immunosuppressed with calcineurin inhibitors (FK506 or cyclosporine A) also develop type 2 skewing, as do HIV-infected patients, who demonstrate progressive loss of CD4 cells. Identification of many of the specific molecular defects responsible for primary immunodeficiencies reveal additional mechanisms that could contribute to lymphomagenesis in some of the diseases.

Clinical Characteristics of Lymphomas in Primary Immune Deficiencies

Advances in prevention and treatment of opportunistic infections now allow patients with primary immunodeficiencies to enjoy longer lives than ever before; however, neoplastic disorders—particularly lymphoproliferative complications—remain the second most common cause of premature mortality (still preceded by infections).[19] The incidence of tumors in patients with certain immunodeficiency diseases, such as WAS, ataxia telangiectasia, and common variable immunodeficiency, is estimated at between 15% and 25%, with a substantially increased risk of developing lymphoma that increases with advancing age.[20,21]

An important early contribution to the relationship between primary immunodeficiency and cancer was provided by the international Immunodeficiency Cancer Registry (ICR), which evolved in the 1970s as an outgrowth of the observations of Good and Gatti[22] regarding cancers diagnosed in immunodeficient children. This voluntary registry was pivotal in the description of the distribution of tumor types in patients with primary immunodeficiencies, pointing to the remarkable predominance of lymphomas across

Table 15-1 Immunodeficiency Cancer Registry Cases: Distribution of Tumors and Immunodeficiencies

Immunodeficiency	Adenocarcinoma	Lymphoma	Hodgkin's Disease	Leukemia	Other Tumors	Total
Severe combined immunodeficiency	1 (2.4%)	3 (73.8%)	4 (9.5%)	5 (11.9%)	1 (2.4%)	42 (8.4%)
X-linked agammaglobulinemia	3 (14.3%)	7 (33.3%)	3 (14.3%)	7 (33.3%)	1 (4.8%)	21 (4.2%)
Common variable immunodeficiency	20 (16.7%)	55 (45.8%)	8 (6.7%)	8 (6.7%)	29 (24.2%)	120 (24.0%)
IgA deficiency	8 (21.1%)	6 (15.8%)	3 (7.9%)	0 (0%)	21 (55.3%)	38 (7.6%)
Hyper-IgM syndrome	0 (0%)	9 (56.3%)	4 (25.0%)	0 (0%)	3 (18.8%)	16 (3.2%)
Wiskott-Aldrich syndrome	0	59 (75.6%)	3 (3.8%)	7 (9.0%)	9 (11.5%)	78 (15.6%)
Ataxia telangiectasia	13	69 (46.0%)	16 (10.7%)	32 (21.3%)	20 (13.3%)	150 (30.0%)
Other immunodeficiencies	1 (4.0%)	12 (48.0%)	1 (4.0%)	4 (16.0%)	7 (28.0%)	25 (5.0%)
Total immunodeficiency categories	46 (9.2%)	252 (50.4%)	43 (8.6%)	63 (12.6%)	96 (19.2%)	500 (100%)

virtually all diagnoses. Table 15-1 is a reproduction of earlier publications of the ICR data listing tumor types reported for various immunodeficiency diseases. In recent times, with the advantage of retrospective review of clinical and pathologic materials from the early cases, we recognize imperfections in the original cataloging. For example, it is likely that a significant proportion of the boys listed as having hypogammaglobulinemia, because they had normal numbers of lymphocytes, who developed lymphomas were actually affected with X-linked severe combined immunodeficiency (XSCID). Similarly, review of slides from cases of "leukemia" in patients with SCID, hypogammaglobulinemia, and WAS suggest that these were actually disseminated lymphoproliferative disorders of mature B cells. Nonetheless, the general outline of tumor types and their proportional distribution among patients with various immunodeficiencies that was provided by the ICR has withstood the test of time.

The descriptive information provided by the ICR has made possible a comparison of clinical characteristics and response to chemotherapy for non-Hodgkin's lymphomas (NHL) and Hodgkin's disease between patients with primary immunodeficiencies and the general population, guiding clinicians with these unique cases. Table 15-2, also a reproduction of previously published ICR data, summarizes clinical characteristics of reported cases of NHL. The data highlight several features, including the following:

- Male predominance, even in patients with autosomal recessive disorders such as ataxia telangiectasia
- Young median age at diagnosis
- High frequency of extranodal presentation involving predominantly gastrointestinal, central nervous system (CNS), or disseminated sites

EBV has been identified as a common cofactor in the predominant B-cell phenotypes but also in cases of T-cell NHL and Hodgkin's disease. In contrast to tumors in patients with other types of immunodeficiency, lymphomas in patients with ataxia telangiectasia are usually EBV^-. This finding is consistent with the hypothesis that genetic predisposition to tumorigenesis in patients with ataxia telangiectasia occurs as a result of mutations arising from the chromosomal repair defect.

Lymphoproliferative disorders or "lymphomas" in both primary and secondary immunodeficient states span the spectrum from reactive hyperplasias through frank malignancy. Not all lymphomas in immunodeficient hosts, despite clonal origin or malignant histologic appearance, require intensive chemotherapy to achieve remission.

Table 15-2 Characteristics of Non-Hodgkin's Lymphomas in the Immunodeficiency Cancer Registry*

Immunodeficiency	*N*	Gender† (M:F)	Median Age at Diagnosis (Yr)	Primary Tumor Sites (%)‡			
				CNS	GI Tract	Lymph Node	Multiple
Severe combined immunodeficiency	31	23:7	1.6	6.5	3.2	9.7	48.4
X-linked agammaglobulinemia	7	7:0	1.2	0	14.3	14.3	14.3
Common variable immunodeficiency	55	30:23	23.0	1.8	12.7	12.7	25.5
IgA deficiency	6	4:1	9.4	16.7	0	0	0

GI, gastrointestinal tract.
*This table excludes cases of non-Hodgkin's lymphoma in immunodeficiency categories with fewer than two cases reported.
†Sex reported where known.
‡For 51.3% of ICR cases, primary tumor site is other or unknown.

Resolution has occurred with antibiotic therapy in MALT lymphomas and with steroids, interferon-α, low-dose chemotherapy, or rituximab in EBV$^+$ tumors.

Historically, treatment of NHL with conventional doses of chemotherapy and radiation met with inferior results in immunodeficient patients.[23,24] Tumor responses were reported as inferior to those observed in the general population for reasons that remain quite obscure, although the major reported causes of early mortality in the 1950s to 1980s were opportunistic infections. In the current era, improved antiviral and antifungal therapies allow most patients with immunodeficiencies who have cancer to be treated more aggressively. Ideally, achievement of remission should be followed by reconstituting HSCT if a suitable donor is available.

Based on ICR reporting, Hodgkin's disease accounts for approximately 10% of tumors arising in patients with immunodeficiencies and occurs at an early median age—less than 10 years of age.[25] A case-control study performed by the ICR in the late 1980s compared the immunodeficiency cases with other pediatric cases from a multiinstitutional international cooperative study group. Immunodeficient patients with Hodgkin's disease presented earlier in life (mean age, 7.8 years vs. 11.5 years in the general population) and were significantly less likely to achieve initial remission. Hodgkin's disease in immunodeficient patients far more commonly presented with histologies of mixed cellularity and lymphocyte depletion (now recognized as representing feeble immune response to the true malignant population) when compared with presumed nonimmunodefcient subjects.[25] For immunodeficient patients who achieved remission of Hodgkin's disease, the probability of survival is also inferior as compared with patients in the general population. Patients with primary immunodeficiency who achieve remission of Hodgkin's disease should be considered for allogeneic bone marrow transplantation.

Primary Immunodeficiencies Associated with Lymphomas

Table 15-3 lists some of the primary immunodeficiencies associated with lymphomas and epithelial cancers, identifying the underlying molecular defects and other biologic characteristics associated with predisposition to lymphoma development.

Severe Combined Immunodeficiencies

SCID is a collection of more than a dozen genetically distinct disorders with severe impairment of both cellular and humoral immune function, leading to early mortality from opportunistic infections during infancy in the absence of aggressive medical intervention.[26] SCID patients who have developed lymphomas share the characteristics of presence of B cells (targets for EBV transformation) and severe quantitative or qualitative defects in T cells. Examples of such conditions include the following:

- XSCID, in which loss of function mutations in the X-linked common γ-chain gene of multiple interleukin receptors block T-cell development, but B-cell numbers are generally plentiful
- Purine nucleoside phosphorylase deficiency, in which T-cell expansion and function are impaired by accumulation of toxic intracellular metabolites, with lesser effects on B cells
- Omenn's syndrome, caused by mutations in *RAG1* genes predominantly, resulting in severe restrictions on both B- and T-cell repertoire development leading to marked skewing toward a type 2 cytokine production

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS), an X-linked disorder of broad-ranging and variable immunodeficiency and microthrombocytopenia, results from mutations in the *WASP* gene.[27] The *WASP* gene encodes a large intracellular protein with several functional domains involved with cytoskeletal integrity and signal transduction. Several molecules reported to be associated with *WASP* are involved in normal progression through the cell cycle. WASP is expressed in cells of hematopoietic origin and in the thymus. Experimental evidence suggests that WAS B cells are relatively resistant to apoptosis, and rare reports of EBV$^-$ B-cell lymphomas have surfaced, especially among adult males with clinically milder forms of WAS that are sometimes termed X-linked thrombocytopenia.

Table 15-3 Primary Immunodeficiencies: Predominant Reported Tumors

Disorders	Inheritance	Gene Defect	Susceptibility to EBV	Type 2 Cytokine Skewing	Disruption of Normal Apoptosis	Tumors
Severe combined immunodeficiency						
X-SCID	X	Common γ- chain†	+			Lymphoma
Omenn's	AR	*RAG 1/2*‡	+	+		Lymphoma
PNP deficiency	AR	*PNP*§	+	+		Lymphoma
Wiskott-Aldrich syndrome	X	*WASP*	+	+	+	Lymphoma*
CD40-L deficiency	X	*CD40 L*	+		+	HD, biliary tract tumors
X-linked lymphoproliferative syndrome	X	*SH2D1*	+			Lymphoma*
Chédiak-Higashi syndrome	AR	*LYST*[16]	+			Lymphoma*
ALPS	AD, AR	*FAS*[21]			+	Lymphoma
Hyper-IgE syndrome	AD	?		+		Lymphoma
IgA deficiency/CVID	AD, S	?				Lymphoma*, GI carcinoma

AD, autosomal dominant; ALPS, autoimmune lymphoproliferative syndrome; AR, autosomal recessive; CVID, common variable immunodeficiency; EBV, Epstein-Barr virus; GI, gastrointestinal; HD, Hodgkin's disease; PNP, purine nucleoside phosphorylase; S, sporadic; SCID, severe combined immunodeficiency; X, X-linked.

*Frequently associated with EBV.

X-Linked Lymphoproliferative Syndrome

X-linked lymphoproliferative syndrome (XLP), long recognized as a condition associated with severe or fatal complications of EBV infection and a high risk of lymphoma, results from mutations in the *SH2D1A* or *SAP* (slam-associated protein) gene on the X chromosome.[28,29] Clinical features of XLP include an excessively intense immune reaction to EBV associated with hemophagocytosis and liver failure, lymphomas, aplastic anemia, and/or acquired hypogammaglobulinemia. SAP, an adaptor protein linked to at least four known regulatory molecules, can alter T and NK cell functions in both activating and downregulating directions and is thought to be involved in T-cell/B-cell interactions through cytokine regulation.[28] Analyses from the XLP (Purtilo) registry indicate that many of the lymphomas occurring in patients with XLP are EBV^-, contrary to early predictions.[30] More recently, cases of boys who have developed separate, clonally distinct tumors years apart have been found to be due to XLP.[31]

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome (CHS) is an autosomal recessive disorder characterized by recurrent bacterial infections, oculocutaneous albinism, abnormal platelets, varied neurologic dysfunction, and a 90% probability of developing a lethal hemophagocytic complication associated with EBV infection (referred to as the accelerated phase) before age 20.[32] As part of the "accelerated phase," some patients develop disseminated lymphoproliferative disorder. CHS is caused by mutations in the *LYST* gene (lysosomal trafficking regulator), and giant lysosomes are characteristic findings in leukocytes on blood smear. Because lysosomes are the key storage compartments for cytolytic proteins (including perforin and granzyme B), the cytotoxic effector function of NK and T cells is typically impaired in CHS, presenting a vulnerability to control of EBV infection.[33] A transport defect inhibiting peptide loading and antigen presentation by human lymphocyte antigen class II molecules on EBV-transformed CHS B lymphocytes has also been proposed as an additional mechanism contributing to escape of transformed B cells from immunologic control.

X-Linked Hyper-IgM Syndrome (X-Linked CD40 Ligand Deficiency)

X-linked hyper-IgM (XHIM) results in failure of immunoglobulin switching by B cells (which requires signaling through CD40) and in decreased development and maintenance of type 1 cell–mediated responses (including NK cell function) due to impaired responsiveness of CD40-expressing monocyte-derived antigen-presenting cells.[34] Patients with XHIM seem to have an increased risk of lymphomas, but especially of Hodgkin's disease associated with EBV infection. Presumably, depressed cell-mediated function required for control of EBV is responsible for this occurrence. Patients with XHIM are also at increased risk for biliary carcinomas, because there is a high rate of sclerosing cholangitis in patients with a history of chronic cryptosporidiosis.[35] In parts of the world where cryptosporidial infection is less prevalent, this complication of XHIM is rarely observed.

Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (ALPS) represents a constellation of genetic apoptosis defects associated with mutations in FAS, Fas ligand, and caspase 8 genes.[36] Most of the cases described have had heterozygous, dominant-negative mutations involving FAS. Characteristic clinical features of the syndrome present in early childhood or even at birth. These include chronic multifocal lymphadenopathy, splenomegaly, autoimmune hemolytic anemia (and often other immune cytopenias), with increased proportions of circulating senescent T cells ($CD3^+$, αβ T-cell receptor $[TCR]^-$, $CD4^-CD8^-$), so-called double-negative T cells. The majority of patients experience symptomatic improvement with steroid therapy, and generally, autoimmune complications lessen in severity with advancing age. The estimated risk of lymphoma, B-cell, T-cell or Hodgkin's disease, in such patients ranges around 30%, however, and some patients have developed more than one lymphoid tumor over time.[37] Patients who have the most severe forms of ALPS should be considered for correction with HSCT. Recently, use of rituximab and rapamycin, agents that induce apoptosis in the senescent lymphocytes bypassing the FAS/FAS ligand signal, have been shown to reduce lymphadenopathy and autoimmune symptoms in patients with ALPS.[38] Whether such strategies will ultimately reduce the risk of lymphomas remains to be determined.

Clinical Characteristics of Lymphoproliferative Disorders in Acquired Immunodeficiencies

Patients recovering from HSCT or solid-organ allografting and patients with HIV infection all demonstrate rates of lymphoproliferative complications substantially exceeding those seen in the general population.

Epstein-Barr Virus Post-transplant Lymphoma after Hematopoietic Stem Cell Transplantation

After HSCT, the incidence of post-transplant lymphoma (PTLD) ranges from approximately 1% or less after unmanipulated matched-sibling donor transplants or autologous transplants to greater than 30% after T-depleted haploidentical (mismatched) transplants in patients with certain underlying immunodeficiencies (e.g., WAS).[39] Virtually all cases of PTLD are associated with EBV and generally present during the first 6 months after transplantation—the period when T-cell immune reconstitution is still very poor. The majority of cases of PTLD occur in donor-derived EBV-transformed B cells, although occasionally EBV reactivation in host cells is demonstrated. Several risk factors for development of PTLD—both host- and transplant-related—have been identified. These include the following:

- T-cell depletion of the stem cell product (a procedure aimed at decreasing the risk of graft-vs.-host disease after allogeneic transplantation); T-cell specific depletion increases risk more than pan–lymphocyte depletion methods
- HLA mismatching
- Older age of the transplant recipient
- Use of anti-T-cell antibody therapy, which is commonly used in newer, reduced-intensity protocols

PTLD after HSCT has several symptomatic presentations. Failure to diagnose and treat patients early and effectively can lead to dissemination with B-cell infiltration of the marrow, lungs, reticuloendothelial system, and CNS, which once developed is usually fatal. It is likely that many cases of PTLD still go unrecognized premortem, and given the low rate of autopsy in post-transplant deaths, the actual incidence has probably been underestimated. Sustained remission of PTLD has been shown to coincide with the development of donor-type EBV-specific cytotoxic T lymphocytes. A common strategy is to monitor the EBV level in peripheral blood by PCR in high-risk patients and initiate anti-CD20 (rituximab) as pre-emptive therapy to "buy time" for EBV cytotoxic T lymphocyte reconstitution.[11,40] Adoptive T-cell therapy with EBV-specific cytotoxic T lymphocytes has been demonstrated to be effective at preventing and treating PTLD following HSCT, but this therapy is limited to few centers.[41]

Post-transplant Lymphoma after Solid-Organ Grafting

The use of immunosuppression after allografting heightens the risk of PTLD in previously immunocompetent subjects. Use of more intensive and prolonged immunosuppression—especially use of

anti-T-cell monoclonal antibody for treatment of graft rejection—has been associated with an increased PTLD risk in patients with all types of organ transplants.[42] Rates of PTLD range from 1% to 5% after kidney transplantation (increased 30- to 50-fold over age- and sex-matched general population) to as high as 25% after visceral organ transplants (liver and small bowel), especially in EBV^- pediatric recipients of EBV^+ organs, who have a higher rate of PTLD than adult transplant recipients.[43] As opposed to HSCT, PTLD after solid-organ transplantation is associated with EBV in only 70% to 80% of cases, with late-occurring PTLD (more than 1 year post-transplant) more likely not to be EBV-associated.[44] Presentation of PTLD varies considerably, ranging from a systemic mononucleosis-like disease, to solid lymphoid lesions (often in extranodal sites that include the CNS), or even with disseminated lymphoma. Histologies range from B-cell hyperplasia to frank lymphoma and may be polyclonal, oligoclonal, or monoclonal.[43] Although the incidence of PTLD as a complication of immune suppression after organ transplantation has declined, the mortality rate from this cause remains at approximately 50% in affected patients and has changed little over time.[24,42,45] The critical role of intact cell-mediated immunity in control of EBV-associated PTLD is demonstrated in cases in which regression occurs after reduction in immune suppression, at the risk of organ rejection. Surgical excision and/or radiation of limited disease are associated with a high rate of durable remissions.[43] In more aggressive or persistent tumors, rituximab and other anti-B-cell therapies have been used successfully.[46,47] Chemotherapy is usually reserved for the most resistant disease because of high treatment-related mortality.[24,46] A low-dose chemotherapy approach has been shown to be effective in PTLD observed in children.[48] It is still unclear whether use of rituximab alone or in combination with chemotherapy is optimal.

Lymphomas Associated with HIV Infection

The incidence of lymphomas among HIV-infected adults during the early years of the worldwide epidemic was reported to exceed 20%.[49] Incidence of cancer has decreased since the introduction of HAART.[8] However, the incidence of Hodgkin's disease seems to be increasing in the HIV population,[50] and causes of death in a U.S.-based population that had received HAART shows increasing proportions of death from non-AIDS-defining malignancies and chronic disorders of adulthood.[51] Although the reported association of lymphomas with EBV in HIV-infected persons ranges between 30% and 60%, extranodal and CNS sites are more frequently seen in HIV-infected patients than in age- and gender-matched controls in the general population.[52] In the current era of supportive care, it is recommended that HIV patients with cancer be treated with standard therapies used for nonimmunocompromised patients; however, infectious complications are increased and outcomes usually inferior to the general population.

CARCINOMAS ASSOCIATED WITH IMMUNE DEFICIENCIES

Gastric Carcinomas and Mucosa-Associated Lymphoid Tissue Lymphoma

A relationship between gastric atrophy, long-standing dyspepsia and gastric ulcer disease, and the development of gastric carcinomas in adults with common variable immunodeficiency was observed decades before the discovery of a causal link to chronic *H. pylori* infestation.[53] A retrospective study of banked sera from a group of presumed nonimmunodeficient adult patients diagnosed with gastric carcinoma revealed an increased incidence of IgA deficiency in cancer-bearing subjects (1 in 20) as compared with the general blood donor pool (1 in 400), further implicating defective humoral immunity as contributory to this unusual type of tumor.[54]

It is now recognized that *H. pylori* infection is the most common cofactor for gastric carcinoma and is associated with MALT lymphomas in nonimmunodeficient whites.[54] Chronic inflammation from *H. pylori* incites local cytokine production, which alters adhesive properties of local epithelial surfaces and promotes ectopic lymphoid proliferation. Mucosa-associated lymphoid tissue is not present in healthy gastric mucosa, but it can develop in sites of long-persisting inflammation.[55] MALT lymphomas are generally monoclonal and can take on the appearance of aggressive, large B-cell lymphomas. These tumors are reported not only in adults with primary immunodeficiency but also in immunosuppressed organ transplant recipients, to the extent that diagnostic endoscopy is now recommended as part of the post-transplant follow-up for symptomatic individuals.[14] Fortunately, effective eradication of *H. pylori* with antibiotics, antacid therapy, and (occasionally) surgical excision is highly curative for many of these gastric carcinomas and MALT lymphomas.[14] Presumably, surveillance for *H. pylori* infection and antibiotic suppression can prevent these tumors in immune-deficient populations in the future.

Carcinomas after Allografting

The risk of post-transplant carcinomas after bone marrow transplantation is influenced by several factors, the strongest of which is probably the patient's inherent susceptibility to carcinogenesis. For example, patients who have an underlying systemic defect in DNA repair (e.g., Fanconi anemia) might be "cured" of their marrow failure or acute leukemia by replacement of genetically normal hematopoietic stem cells but remain at high risk for epithelial cancers, especially in areas of transplant-related radiation such as the head and neck.[56] Even among patients without obvious susceptibility to DNA damage, differences in response to the radiation commonly used in transplant treatment of patients with hematologic malignancies could account for future risk of skin, bone, and CNS tumors (Box 15-1).

The incidence of cancer in solid-organ transplant recipients increases greater than 1% per year after transplant such that about 20% of patients will experience a cancer within 10 years following transplantation.[42,57] Many of these cancers involve the skin and are enhanced by increased sun exposure (i.e., time to development of skin cancer decreases with increasing latitude). Compared with the

Box 15-1. FOSTERING AWARENESS ABOUT CARCINOMAS IN ORGAN TRANSPLANT RECIPIENTS

The cumulative risk of cancer in solid organ transplant recipients exceeds 50% 20 years after grafting. Compared with the general adult population, the risk of developing cancer after organ transplantation increases three- to fivefold. Patient education about specific cancer risks and preventive lifestyle, coupled with regular medical examinations screening for early malignancy, might reduce cancer mortality in organ recipients. The skin and lips are the most common sites of cancer in allograft recipients; development of squamous cell carcinomas is markedly accelerated by sun exposure in this population. In addition to squamous cell carcinoma, unusual skin cancers such as Merkel cell cancer and Kaposi's sarcoma occur with markedly increased incidence after organ transplantation. Cervical cancer accounts for 10% of cases of post-transplant cancers in women; although the rate of breast cancer does not seem to increase, mortality from more advanced-stage disease is increased. De novo lung cancer in immune-suppressed individuals carries a particularly poor prognosis regardless of histologic type. Thus, recommendations regarding avoidance to sun exposure, regular dermatologic and gynecologic screening, and intervention to achieve sustained smoking cessation should be included as part of routine long-term transplant follow-up.

Table 15-4 Incidence of Carcinomas following Solid-Organ Transplantation

Incidence	Incidence vs. General Population	Factor Increasing Risk
Skin cancer		
Squamous cell carcinoma	40- to 50-fold	Sun exposure, latitude
Basal cell carcinoma	10-fold	
Melanoma	5-fold	
Cervical cancer*	14-fold	Human papillomavirus infection
Endometrial cancer	2-fold	
Bladder cancer	4-fold	
Kidney cancer	8-fold	Usually developing in native kidney
Ureteral cancer	1000-fold	
Kaposi's sarcoma	1000-fold	Kidney transplant, Mediterranean descent

*Majority in situ.
Data provided by the Israel Penn Transplant Tumor Registry, Cincinnati, Ohio.

general population, the risk of developing cancer after organ transplantation is increased three- to fivefold. Table 15-4 tallies the relative increased risks of certain carcinomas in organ transplant recipients as collected through the Israel Penn Tumor Transplant Registry in Cincinnati, Ohio.[42]

Skin and lip cancers account for nearly 40% of all post-transplant cancers, showing a male predominance of 2:1. With close surveillance, deaths are infrequent. An unusual "skin" cancer diagnosed in transplant recipients is Merkel cell cancer, a highly aggressive neuroendocrine tumor arising principally in the head and neck region. No clear association with an inciting pathogen is known for this unusual tumor, which is usually seen in elderly whites; organ transplant recipients account for nearly 8% of the fewer than 1000 cases of Merkel cell cancer reported worldwide.[42]

Kaposi's sarcoma has long been identified as one of the "opportunistic tumors" in organ transplant recipients, with a nearly 1000-fold increase over the general population, although it is not reported after HSCT or in primary immunodeficiencies. Kaposi's sarcoma is more commonly reported after renal transplantation and in individuals of "Mediterranean" descent, such as Greeks, Italians, Turks, and Arabs. In this setting it is usually not associated with HIV infection. Other de novo sarcomas also account for some of the post-transplant risk of malignancy and seem to have a particularly aggressive biologic activity.[42]

Cervical cancer accounts for about 10% of post-transplant cancers in women. Fortunately, 75% of the lesions are in situ. It is hoped that future vaccine interventions against human papillomavrus can lower the rate of this complication for women in general. The number of breast cancer cases after allografting is comparable to that expected among women of like age; however, a higher mortality has been observed among stage III and IV patients when compared with non-immunosuppressed women.[58] Thus, more frequent screening, if it identifies earlier, lower grade malignancies, could be indicated for female organ transplant recipients.

Immunodeficiency and Cancer in Genetic Disorders of DNA Repair

Table 15-5 lists several rare genetic disorders of DNA repair in which resultant immune deficiency and intrinsic susceptibility to carcinomas have been identified. DNA is constantly exposed to potentially damaging insults, both external (e.g., environmental radiation) and intrinsic (e.g., byproducts of cellular metabolism). Several molecular strategies have evolved to maintain genomic stability. Mechanisms used in eukaryotes include those involved in the following processes:

- Recognition and direct repair of DNA damage
- Cell-cycle checkpoints that pause cell-cycle progression in the presence of damage, allowing the time needed for repair
- Mechanisms for removal of irreversibly damaged cells, such as the triggering of apoptosis (discussed previously in the section on ALPS)

DNA double-strand breaks represent the most potentially serious damage to the genome. Two major pathways exist to repair such damage: homologous recombination repair and nonhomologous end joining. Defects in either of these pathways can result in chromosomal rearrangements, loss of heterozygosity, and gene mutations leading to cancers.

On the other hand, generation of immunologic diversity among both B and T cells requires a well-orchestrated "creation" of DNA breaks followed by rearrangement of immunoglobulin and T-cell

Table 15-5 Genetic Disorders Associated with Chromosomal Instability That Result in Immunodeficiency and Predisposition to Cancer

Disorder	Gene Defect	Immune Defects	Cancers Reported
Ataxia telangiectasia	*ATM*[60]	IgA deficiency, ↓T cells	Lymphoma, leukemia, hepatocarcinoma, genitourinary carcinoma, skin cancer
Nijmegen breakage syndrome	*NBS1*[64]	Hypogammaglobulinemia, lymphopenia	Myeloid leukemia, lymphoma
Bloom's syndrome	*BLM*[65]	Hypogammaglobulinemia, natural killer cell deficiency	Lymphoma, epithelial cancer
Werner's syndrome	*WRN*[66]	Antibody deficiency?	Lymphoma

receptor gene sequences and repair to stabilize the final genetic product. In this process of gene rearrangement, sequence changes such as mutations and additions, which contribute to the desired diversity of new coding regions, occur frequently. Mechanisms creating this immunologic diversity probably include helicases, polymerases, and DNA ligases. Several of the known genetic defects associated with immunodeficiency and predisposition to cancers are described in the following sections. Many other rare cases with immunodeficiency and cancers have been identified, but the specific molecular defects are still unknown.

Ataxia Telangiectasia

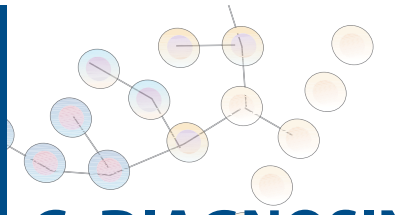
Ataxia telangiectasia is an autosomal recessive disorder with cancer predisposition that has variable and profound immunologic and other systemic manifestations, principally cerebellar degeneration.[59] For some time, it has been recognized that ataxia telangioectasia cells fail to activate cell-cycle checkpoints normally after exposure to γ-irradiation or radiomimetic agents. The mutant gene in ataxia telangiectasia (*ATM*) is a member of the phosphotidylinositol kinase family of molecules involved in signal transduction and has also been implicated in meiotic recombination.[60] *ATM* seems to act as a sensor of double-stranded DNA breakage (e.g., in response to oxidative stress), activating numerous damage repair pathways, including cell-cycle checkpoint control, *p53* activation, and DNA repair. Mutations in *ATM* lead to accelerated telomere loss and premature aging.[61] In the context of normal lymphopoiesis, *ATM* is clearly involved in control of productive gene rearrangements of the B- and T-cell immune receptor molecules, in that lymphocytes from persons with ataxia telangiectasia demonstrate a 25-fold increase in nonrandom rearrangements of immunoglobulin and TCR genes as compared with lymphocytes from normal individuals.[62] Thymic output in ataxia telangiectasia is very reduced. The consequent restricted T-cell repertoire emerges from oligoclonal post-thymic expansion.[63] Some of the nonrandom rearrangements involve translocation of immunoglobulin chains with c-Myc, reflecting, in magnified proportion, commonly seen cytogenetic rearrangements in general lymphomagenesis. In addition to the predominant lymphoid tumors (both lymphomas and leukemias), individuals with ataxia telangiectasia experience high rates of epithelial cancers involving the skin, gastrointestinal tract, genitourinary tract, and CNS. Multiple tumors can be present simultaneously or can develop sequentially. Early reports from the ICR discussed concordance of histologies in tumors affecting ataxia telangiectasia siblings from the same family—an intriguing but still mysterious observation. The extent of response of tumors in ataxia telangiectasia patients to conventional chemotherapy remains controversial; however, the frequent development of chronic lung disease in ataxia telangiectasia and the tendency by treating physicians to reduce chemotherapy intensity could contribute to poorer outcomes.

Nijmegen Breakage Syndrome

Nijmegen breakage syndrome (NBS) is another rare autosomal recessive syndrome, which, like ataxia telangiectasia, is associated with both humoral and T-cell defects, clinical radiosensitivity, chromosomal instability, and predisposition to lymphoid and epithelial cancers.[64] Other characteristics of patients with NBS are growth retardation, microcephaly, and "birdlike" facies. The protein defective in NBS (NBS1, nibrin, or p95) seems to function together with ATM to "sense" DNA double-strand breaks and activate a diversity of corrective actions. As in ataxia telangiectasia, lymphocytes of patients with NBS display frequent chromosomal aberrations at the sites of TCR and IgH rearrangement.

Bloom's Syndrome

Bloom's syndrome has autosomal recessive inheritance involving mutations in the *BLM* gene.[65] In addition to immunodeficiency—especially humoral defects and predisposition to cancer—patients with Bloom's syndrome experience growth retardation, progeria, impaired fertility, sun-sensitive erythema of the face, and chronic lung disease (similar to patients with ataxia telangiectasia). The protein defective in Bloom's syndrome is a member of the RecQ helicase family and seems to function during DNA replication or in the postreplication process to resolve aberrancies incurred during replication. The BLM protein colocalizes with a gene, *hMLH1,* which is linked to mismatch repair. A propensity to colonic adenomas, epidermal carcinomas, and acute myeloid leukemia has been reported in patients with Bloom's syndrome.



Werner's Syndrome

Werner's syndrome, an autosomal recessive disorder with features of progeria and multiple endocrine neoplasias, results from loss-of-function mutations in the *WRN* gene, which encodes a helicase/exonuclease.[66] Reports of immunodeficiency are not well substantiated, but predilection to sinopulmonary infections is noted. Genomic instability in Werner's syndrome is typified by elevated illegitimate recombination events and accelerated loss of telomerase sequences.

C. DIAGNOSING CANCER: PATHOLOGY AND LABORATORY MEDICINE

SECTION NOTES

The number and types of diagnostic modalities available to characterize cancer has increased dramatically over the past few decades. Although histopathologic diagnosis using techniques that date back over a century remains the gold standard, radiologic techniques are becoming increasingly precise diagnostic instruments, and more and more supplemental laboratory techniques are becoming critical to accurate diagnosis. These latter methods, including cytogenetics and flow cytometry, first introduced in the 1970s and 1980s, and molecular pathology, a more recent addition, greatly expand the armamentarium of tests now available. The past few years has seen an even more rapid evolution in these newer tests. Fluorescence in situ hybridization is a very powerful technique that is changing the way many cytogenetics labs operate. Molecular diagnostics, which originally had a limited test menu largely applicable to hematology, now has a much larger range of tests with applicability to both inherited and sporadic cancers of all types.

Diagnostic radiology is also at a crossroads. The oncologist evaluating a patient can choose among everything from a simple roentgenogram to a complex alphabet of imaging studies—CT, CTA, MRI, MRS, PET, PET/CT and SPECT and SPECT/CT. In the right hands, newer imaging studies have incredible power to improve sensitivity and specificity of diagnosis. In the last several years, PET/CT using the radiotracer 18F-FDG has had a great impact on the management of many common cancers providing staging, treatment planning, and treatment response assessment information more quickly and robustly than by standard anatomic metrics. These technological advances present both opportunity and challenge. The opportunity is to provide better and more accurate methods for detecting and defining the presence of cancer. The challenge is to use the right techniques for the right indications. The overuse of highly sensitive tests results in increased false-positive diagnoses, whereas using highly specific tests inappropriately increases the risk of a false-negative diagnosis. Many newer diagnostic tests are expensive, so that cost is a critically important factor for the clinician to consider, but the cost implications of inappropriate intervention due to inappropriate testing go far beyond the simple expense of the test. Thus, the right algorithm of test use is critical to getting the right diagnosis in the most cost effective and timely manner to optimize patient outcome.

The expertise of the diagnostic pathologist or clinical laboratory scientist is critical in both the selection and interpretation of modern tests for cancer diagnosis. For more subjective tests such as routine histology, flow cytometry, or cytogenetics, experience and skill are well recognized as key determinants for accurate interpretation. More analytically precise tests such as serum tumor marker assays or molecular diagnostics also require a high degree of sophistication by the lab director to ensure the data obtained are accurate and not the result of artifact or sampling error. Experience and skill in both test use and interpretation are critically important in dealing with analytic as well as biologic predictive value. Similarly, for imaging, as in pathology, experience and skill in test use in different modalities such as nuclear medicine, MRI, cross-sectional imaging and ultrasound are critical to optimal use of the technologies to assure that results are robust and technical artifacts are avoided. Given the complexities involved, such expertise may not lie in the hands of a single physician.

The goal of this section is to provide the clinical oncologist with an understanding of the use and interpretation of the current diagnostic modalities available for the evaluation of cancer patients. The goal is not to provide an exhaustive review of tests and details that would be more appropriate for pathologists or radiologists. We have somewhat arbitrarily grouped the many laboratory cancer diagnostics that are now available into five chapters: surgical pathology, flow cytometry, cytogenetics, molecular diagnostics, and clinical chemistry; each chapter outlines the methods, applications, and interpretation of the tests in that area. Following these, there is separate chapter on radiologic diagnosis. This section will provide insight on the best use of tests in different settings and pitfalls in interpretation, so as to be of value to clinical oncologists in interacting both with their patients and with their colleagues in pathology, laboratory medicine, and radiology.

16 Principles of Oncologic Surgical Pathology

Peter B. Illei and William Westra

SUMMARY OF KEY POINTS

Key Method

- Routine histopathologic examination is the cornerstone of cancer diagnosis.
- Immunohistochemistry is an important adjunct that allows more precision in diagnosis, classification, and prognosis.
- Fine-needle aspiration, when used properly, is very valuable to guide treatment decisions.

Specific Roles of Pathologic Examination of Tissues

- Histologic diagnosis and classification of cancer
- Assignment of pathologic grade and stage
- Intraoperative consultation to direct a surgical procedure and ensure that appropriate diagnostic tissue is obtained
- Triage of tissue for specialized testing, and banking for research purposes

INTRODUCTION

Pathology as a medical discipline can be traced back to Renaissance Italy, when the autopsy was valued for correlating clinical history with pathologic findings.[1] During the nineteenth century, pathologists were primarily academicians who studied and taught the causes, mechanisms, and consequences of disease. Direct diagnostic application was, at best, a peripheral concern of a small group of full-time autopsy pathologists whose primary role was to confirm a diagnosis in the dead rather than to formulate a diagnosis in the living.[2] At the turn of the twentieth century, pathology became a more clinically relevant discipline for several reasons. Technical innovations in microscopy permitted detailed microscopic descriptions of tissue patterns and cell structures that, in turn, dramatically improved diagnostic capabilities. The introduction of anesthesia and aseptic techniques allowed surgeons to perform longer and more complicated procedures that required improved diagnostic skills, which, together with the invention of the freezing microtome,[3] made intraoperative consultation possible. Finally, an enlightened medical community and the public at large came to recognize that small and subtle tumors were easier to eradicate than were large and conspicuous ones.[4]

Given this new emphasis on early cancer detection and treatment, oncologic surgeons no longer could rely on their own clinical skills and gross observations to evaluate the presence and full extent of tumor growth. Instead, a new breed of physician/pathologist evolved with specialized training in the histologic characteristics of tumors. Beginning in 1926, the American College of Surgeons insisted on properly staffed hospital laboratories under the direction of physicians trained in clinical pathology and called for the mandatory systematic examination of all surgical specimens to culminate in a report detailing the pathologic findings.

The role of the modern surgical pathologist is that of a consultant clinician who is closely affiliated with many branches of medicine, including all surgical specialties, internal medicine, medical oncology, dermatology, neurology, and diagnostic and therapeutic radiology.

ONCOLOGIC SURGICAL PATHOLOGY REPORT

The surgical pathology evaluation of a presumptive tumor specimen strives to specify clearly and comprehensively the presence, nature, and extent of a tumor in a way that guides further therapy, measures results, and predicts future outcome. The report integrates the macroscopic and microscopic findings and the results of ancillary techniques such as immunohistochemistry and molecular genetic analysis. The scope and complexity of the surgical pathology report have increased dramatically over recent years, and groups such as the Association of Directors of Anatomic and Surgical Pathologists and the Cancer Committee of the College of American Pathologists recently have issued a number of standardized protocols that are organ and/or tumor specific.[5–9]

For any style and format, the contents of the surgical pathology report always include information regarding the presence or absence of tumor, size and location of the tumor, histologic classification, pathologic staging, adequacy of tumor removal (i.e., status of the surgical margins), and tumor grade.[10] These anatomic measurements are supplemented by relevant immunohistochemical, cytogenetic, and molecular biologic information to refine tumor classification and to guide the selection of therapeutic options.

Tumor Classification

As strategies for the treatment of oncology patients become increasingly sophisticated and individualized, current classification schemes aim to categorize tumors in ways that are precise, reproducible, and clinically relevant. The classification of tumors is hierarchical, progressing from fundamental distinctions in biologic potential (e.g., benign vs. premalignant vs. malignant) to broad separation in cellular differentiation (e.g., epithelial vs. mesenchymal vs. lymphoid vs. melanocytic) to much finer dissection of phenotypic expression (e.g., squamous vs. glandular, chondroid vs. osteoid, B cell vs. T cell).

Standardized international nomenclature for tumor classification has been promoted successfully by a variety of professional organizations. Most notably, the Armed Forces Institute of Pathology (AFIP) continues to update its series on tumor pathology, the *Atlas of Tumor Pathology,* in an effort to "promote a consistent, unified, and biologically sound nomenclature; guide the surgical pathologist in the diagnosis of the various tumors and tumor-like lesions; and provide relevant histogenetic, pathogenetic, and clinicopathologic information on these entities."[11] The World Health Organization also has implemented a program with similar aims. Its recent collection of books on the classification of tumors has taken a more deliberate approach to incorporate relevant genetic data as a component in naming and characterizing tumors.[12]

Pathologic Staging

Stage and grade traditionally have been used as parameters to characterize the clinical severity of a tumor. Stage outweighs grade in importance as an indicator of patient outcome for most cancers, with the notable exception of many soft tissue sarcomas. Stage is a measure of tumor growth. It takes into account the size of a tumor and the anatomic extent to which it has spread. Tumor staging permits valid comparison between groups of patients, facilitates exchange of information among treatment centers, guides selection of therapy, and allows empirical estimation of patient outcome.[13] The widely used TNM system uses three components to express the anatomic extent of disease: *T* is a measure of the local extent of tumor spread (size of tumor); *N* indicates the presence or absence of metastatic spread to regional lymph nodes; and *M* specifies the presence or absence of metastatic spread to distant sites. T, N, and M classifications are combined to provide a stage grouping. Additional histologic features also can be important in certain tumor types and may provide prognostic information (e.g., presence and amount of necrosis in osteosarcoma after neoadjuvant therapy). The TNM system is not used for lymphomas, though staging still is an important parameter to predict outcome.

Clinical staging (cTNM) defines the anatomic extent of a tumor based on clinical evidence before the initiation of treatment. It incorporates findings obtained from the physical examination, imaging studies, surgical exploration, and tissue biopsy. Clinical stage is used as a guide for the selection of primary therapy. In contrast, pathologic staging (pTNM) is based on examination of the surgically resected specimen. Assessment of pathologic stage is contingent on the recognition and removal of tumor to allow meaningful anatomic assessment of tumor origin and local extension. Thus, the pathologist's ability to render an accurate pathologic stage sometimes is compromised by the surgical approach, especially when a tumor is fragmented or removed laparoscopically. Pathologic staging is used mainly to direct adjuvant therapy, estimate prognosis, and report results, but does not invalidate the clinical stage (and vice versa).

Tumor Grading

Tumor grade is a semiquantitative measurement of histologic differentiation compared to the normal tissue from which the tumor arises. Well-differentiated tumors (grade 1) closely resemble their non-neoplastic counterparts; poorly differentiated tumors (grade 3 or 4) do not. As a rule of thumb, the more poorly differentiated a tumor, the more aggressive its behavior; however, the impact of tumor grade on tumor behavior is highly tumor-specific. For example, the expected behavior and treatment of soft tissue sarcomas is profoundly influenced by tumor grade. In contrast, most lung carcinomas are uniformly aggressive, regardless of histologic grade. For other tumor types, the utility of histologic grading falls somewhere between these two extremes.

No single uniform scheme has been established for the histologic grading of malignant neoplasms; grading schemes are tumor-specific. For some tumors, histologic classification defines tumor grade. Small cell carcinoma of the lung, anaplastic carcinoma of the thyroid, and Ewing sarcoma are, by definition, high-grade (i.e., poorly differentiated) tumors, whereas carcinoid tumor of the lung, polymorphous low-grade carcinoma of the salivary glands, and small lymphocytic lymphoma are, by definition, low-grade (i.e., well-differentiated) tumors. Some tumor types are graded based on the severity of cytologic atypia (e.g., leiomyosarcoma, renal cell carcinoma); others are graded on the basis of architectural growth patterns (e.g., adenocarcinoma of the prostate); and still others are graded by the combination of cellular atypia and architectural disarray (e.g., ductal carcinoma of the breast). Effective grading strategies strive to minimize inconsistency in application and maximize the prognostic significance of tumor stratification.

INTRAOPERATIVE CONSULTATION

The aim of intraoperative consultation is to provide rapid assessment of the tissue and to answer specific questions raised by the surgeon. The term "intraoperative consultation" is preferred over "frozen section," because in a significant number of cases no frozen section is performed. It is the surgical pathologist's responsibility to decide which method should be used and whether the diagnosis can be made on careful gross examination alone or on touch imprint preparations without the need for freezing the tissue, thus preserving the morphology for permanent sections. Touch preparations are made by gently touching or scraping the surface of the tissue without causing permanent damage to the rest of the tissue, whereas for frozen sections the tissue must be thinly sectioned, then frozen, and, finally, sectioned using a special microtome. To benefit fully from the diagnostic value of intraoperative consultation, the surgeon and the pathologist must communicate clearly and must have a balanced appreciation for its strengths and limitations.[14]

Requests for intraoperative consultation are appropriate in four common situations (Box 16-1):[15]

1. To establish a diagnosis or determine pathologic stage to guide the type or extent of the operation. For example, the use of a frozen-section or touch preparation to detect metastatic melanoma in sentinel lymph nodes now makes possible the identification of patients who would benefit from one-step lymph node dissections.
2. To determine the adequacy of tumor removal. Frozen-section analysis of surgical margins provides assurance of complete tumor removal at the time of surgery and thus minimizes the need for additional operations for revisions of positive margins.
3. To confirm the nature of the lesion. This is important to guide fresh tissue distribution for appropriate laboratory studies, e.g., to the microbiology laboratory for culture studies, to the flow-cytometry laboratory for immunophenotypic analysis, and to the genetics laboratory for cytogenetic or molecular analysis. Confirmation can be achieved with either touch preparations or frozen sections, depending on the specimen and suspected process.
4. To assess the presence and quality of lesional tissue before the operation is completed. In this instance, the frozen section serves not to establish an intraoperative diagnosis but to ensure that adequate, lesional tissue has been secured such that a definite diagnosis can be rendered on permanent histologic examination.

Accurate frozen-section diagnosis is compromised by inherent limitations of the technique,[16,17] especially suboptimal preservation of cytologic and histologic detail. Tissue fragmentation due to the presence of fat, bone, or foreign material and tissue distortion secondary to ice crystal formation may obscure the true identity of the pathologic process. Some specimens, particularly delicate tissue fragments in which important diagnostic distinctions are made on the basis of subtle architectural and cytologic alterations, are particularly susceptible to frozen section-induced morphologic alterations. In these cases, frozen-section analysis may be counterproductive and may compromise an accurate tissue diagnosis. For example, frozen-section evaluation of nonpalpable breast lesions, once a routine practice, is no longer encouraged because of a high error rate and a propensity to obscure irrevocably the subtle morphologic distinction between benign hyperplasia and intraductal carcinoma.

Accuracy of the frozen section also is limited by time constraints, so that a cursory microscopic evaluation of large specimens is highly vulnerable to sampling error. Thus, invasion within a large villous adenoma of the colorectum, transcapsular extension of an encapsulated follicular neoplasm of the thyroid, or malignant transformation within a benign mixed tumor of the parotid may elude detection when microscopic examination is limited to one or two frozen sections.

When the frozen section is used properly, its diagnostic accuracy now routinely exceeds 97% in both academic centers and general practice settings.[18,19] Diagnostic accuracy is especially high when the frozen section is used to make broad and fundamental distinction between pathologic processes (e.g., presence of tumor vs. absence of tumor, inflammatory process vs. neoplastic process, benign tumor vs. malignant tumor). Conversely, accuracy diminishes with increasing demands for precise tumor subclassification. Regardless of the situation, accuracy is improved when the pathologist is provided with appropriate clinical information and the indication for the consult.

Box 16-1. APPROPRIATE USE OF FROZEN SECTIONS IN SURGICAL PATHOLOGY

Frozen section, used appropriately, is an important tool in the management of a cancer patient. Several important indications can lead to a specific action on the part of the surgeon, but inappropriate uses run the risk of compromising care.

Frozen sections should be used to establish the following:

- A diagnosis or pathologic stage, and thereby determine the type and extent of the operation needed
- The status of the surgical margin to determine whether a wider local excision is necessary
- The presence and nature of appropriate lesional tissue to distribute fresh tissue for additional laboratory studies, such as microbiology culture, flow cytometry, or molecular assays
- The adequacy of a biopsy, thereby ensuring that a definitive diagnosis will be rendered on permanent histology.

Frozen sections should not be used in the following situations:

- For curiosity with no clear-cut plan to use results, as this is unnecessarily costly, may tie up pathology resources, and may result in artifacts that limit interpretation of the permanent sections.
- To establish a diagnosis when there is a threat of irreparable damage to tissue architecture that would preclude a definite diagnosis on permanent histology
- To document a focal microscopic finding in a large specimen, because sampling error may lead to an erroneous conclusion and, consequently, an inappropriate surgical approach.

IMMUNOHISTOCHEMISTRY

Immunohistochemistry (IHC) localizes specific constituents in tissues based on antibody recognition of tissue antigens. It was developed initially by Coons in 1940 as an investigative immunofluorescence technique to detect antigens in frozen tissue sections.[20] However, technical advances over the past three decades have thrust the technique into the forefront of diagnostic pathology.[21] The development of nonfluorescent chromogens has allowed visualization of antigen-antibody binding by using the conventional light microscope. The introduction of various amplification steps (e.g., peroxidase-antiper-

oxidase method, avidin-biotin conjugate method, polymer-based labeling system) has significantly improved sensitivity and specificity. The development of novel protocols that use two or more primary antibodies that are detected by two different detection systems has enabled us to make more accurate diagnoses, even in small biopsies with limited amount of tissue. The discovery of means to "unmask" antigens (e.g., enzyme digestion, heat-induced epitope retrieval) in formalin-fixed archival tissue has permitted consistency in staining despite variations in tissue fixation and processing. Finally, the development of techniques to manufacture highly specific monoclonal antibodies has greatly expanded the arsenal of probes that can target virtually any immunogenic marker.[22] With the adaptation of the technique to formalin-fixed and paraffin-embedded tissues, IHC now is compatible with standard tissue-processing procedures and can even be performed retrospectively on tissue blocks that have been archived for many years. IHC now is used routinely to address a range of key diagnostic questions.[23]

Is It a Tumor?

In some specific instances, markers identified by IHC can help make the fundamental distinction between a malignant tumor and some benign process. For example, the demonstration of kappa or lambda light-chain restriction by IHC is a good indicator of monoclonality in B-cell processes, and can help distinguish malignant lymphoma from an inflammatory process. In the prostate, loss of a basal cell layer, as indicated by the absence of high-molecular-weight cytokeratin and p63 immunostaining, helps to distinguish adenocarcinoma of the prostate from benign adenosis and other conditions that may mimic malignancy.[24,25] As our understanding of the molecular genetic basis of human tumors expands, antibodies to products of oncogenes and tumor-suppressor genes hold much promise in recognizing neoplastic processes.

What Type of Tumor Is It?

The most basic application of IHC is tumor classification. For tumors that show no specific differentiation at the light-microscopic level, IHC can make critical distinctions among epithelial, mesenchymal, lymphoid, melanocyctic, and germ cell neoplasms (Fig.16-1). Even for differentiated tumors, IHC provides a detailed phenotypic description that goes well beyond the resolution capabilities of the standard light microscope. In studies emphasizing the importance of second-opinion surgical pathology, the use of IHC has been identi-

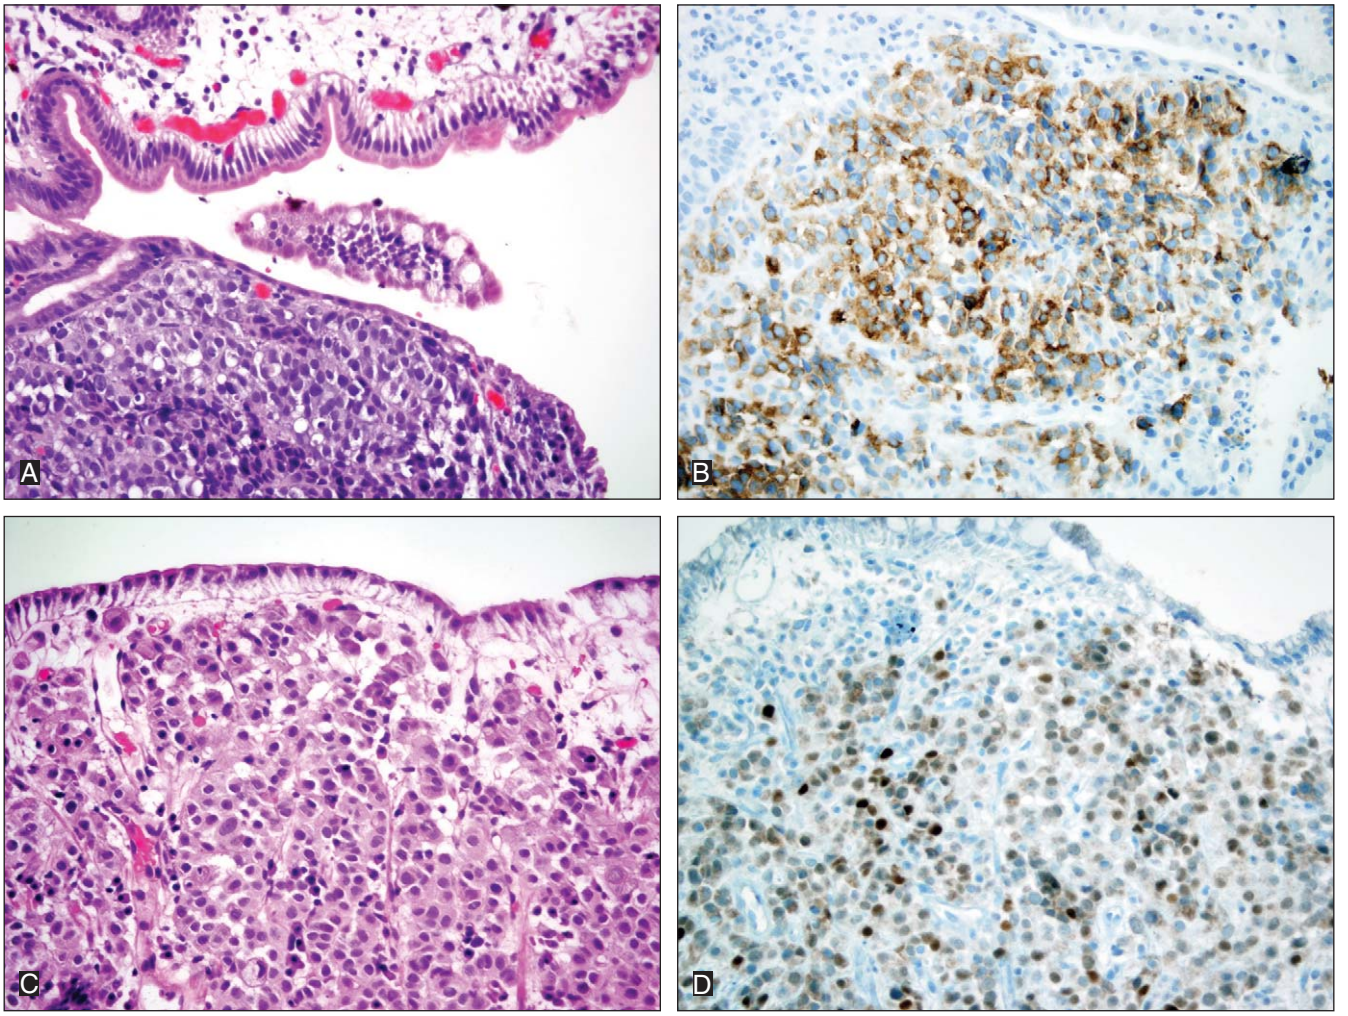

Figure 16-1 • Impact of immunohistochemistry on tumor classification. **A,** The small bowel biopsy shows sheets of histologically uniform epithelioid tumor cells in the lamina propria (H&E stain). **B,** Immunohistochemistry demonstrates that the tumor cells are diffusely positive for Melan-A, consistent with metastatic malignant melanoma. **C,** The gastric biopsy of another patient shows sheets of histologically similar-appearing tumor cells in the lamina propria (H&E stain). **D,** Immunohistochemistry demonstrates that the tumor cells are positive for estrogen receptors. The tumor cells are also positive for progesterone receptors, growth cystic fluid protein, and Her2/Neu, consistent with metastatic adenocarcinoma of the breast. In both examples, the differential diagnosis on H&E sections includes a primary or metastatic carcinoma and metastatic melanoma. The accurate diagnosis can be made easily if immunohistochemistry is used as an adjunct test.

fied as a key factor resulting in major therapeutic and prognostic modifications for patients sent to large referral hospitals for oncologic surgery.[26,27] Hematopathology is one example of a field that has become increasingly reliant on IHC, where the availability of antibodies to lineage-restricted antigens has made possible high-resolution and clinically relevant classification of hematolymphoid neoplasms.[28] IHC is having a similar impact on soft tissue sarcomas, primitive round blue cell tumors, and other areas of diagnostic pathology in which precise tumor classification is beyond the reach of conventional hematoxylin and eosin (H&E) histology.[29,30]

What Is the Tissue of Origin for the Tumor?

Expression of some markers is so highly tissue specific that a single IHC stain can establish the most likely primary site for a neoplasm of unknown origin. Most tumors, however, display a distinctive pattern of IHC staining against a selected array of antibody probes, a pattern sometimes referred to as an "immunohistochemical profile." For example, metastatic adenocarcinoma of the prostate may present as a tumor of unknown origin, and because most adenocarcinomas of the prostate are positive for prostate-specific membrane antigen (PSA) or prostein (p501s), prostatic origin can be readily identified by one or both of these markers in almost all cases.[31] In another application, the difficult distinction between malignant mesothelioma and peripheral lung adenocarcinoma is aided by unique IHC fingerprints when using a panel of antibody probes.[32] With the regular introduction of new antibodies into the diagnostic armamentarium, these profiles are becoming increasingly elaborate. Internet-accessible databases have become very useful in disseminating updated information regarding IHC profiles of various tumor types based on published data.[33]

Is There Evidence of Metastasis?

IHC can optimize detection of micrometastases when traditional microscopic examination is too crude to detect scattered individual tumor cells. Staining of sentinel lymph nodes with cytokeratin to detect metastatic breast carcinoma and melanocytic markers (e.g., Hmb-45, Melan-A) to detect metastatic melanoma is now used routinely for the accurate pathologic staging of regional lymph nodes.[34,35]

What Is the Prognosis?

IHC also can help to measure determinants of disease outcome. For various tumor types, a high proliferation rate portends aggressive tumor behavior and poor outcome. The traditional practice of counting mitotic figures as a crude measure of tumor proliferation is being replaced by more quantitative assessment of proliferation activity as measured by IHC detection of certain nuclear antigens that are expressed during stages of active cell division (e.g., Ki-67).[36] Perhaps more important, IHC can help predict tumor response to certain therapies. Detection of estrogen receptors, progesterone receptors, and HER-2/neu has direct and immediate therapeutic implications for breast cancer treatment, as do prognostic indicators that now are routinely incorporated into surgical pathology reports of all invasive breast carcinomas.[37,38] A wave of new antibody probes against oncogene products, tumor-suppressor gene products, and various cell cycle signaling proteins (e.g., activated kinases) may help individualize treatment regimens based on specific expression profiles.[39] However, the application of these markers to prognosis will require standardized technical protocols, defined cutoff values for positive results, and clinical validation studies with uniform treatment arms and adequate follow-up.[40]

FINE-NEEDLE ASPIRATION

In contrast to tissue histopathology with its strong reliance on architectural patterns of tumor growth, cytopathology extracts diagnostic information from the appearance of individual cells and cell clusters. Although its use has surged over the last two decades, cytopathology is hardly a new technique. Indeed, attempts to define distinctions between benign and malignant cells scraped from the surfaces of tumors constitute the origin, not the pinnacle, of contemporary diagnostic pathology.[3] George Papanicolaou (1883–1962) usually is credited with the rediscovery of cytopathologic examination. He not only demonstrated its value regarding diagnostic accuracy, but he launched its routine use as a highly effective means of reducing cancer-related morbidity and mortality.

Fine-needle aspiration (FNA) uses a fine-gauge needle to remove cells from a suggestive mass for microscopic examination. Its primary role is to guide treatment decisions, and in this role, FNA offers several significant advantages over the frozen section:

- It provides a preoperative rather than intraoperative diagnosis. Some researchers estimate that up to 80% of all thyroid surgery can be avoided by routinely aspirating thyroid nodules.[41]
- It is cost-effective. FNA is a simple technique that is inherently economical and often circumvents the need for a much more costly surgical intervention.
- It is safe. FNA eliminates the need for general anesthesia and minimizes the risk of complications associated with more invasive procedures for tumor acquisition.

With notable exceptions (e.g., testicular masses, ovarian masses, primary malignant melanomas), FNA is no longer believed to facilitate tumor spread or induce severe hemorrhage, an occasional complication of larger-bore needles.[42]

Although reported accuracy rates for FNA range from 90% to 99%, divergent opinions persist about its reliability and its role in clinical management. Most authorities, however, would accept the following generalities:[43]

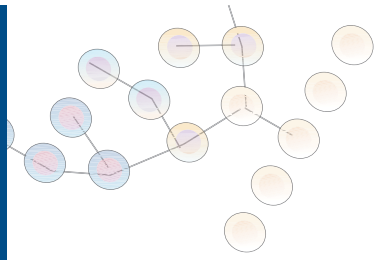
- Accuracy is related to the site and nature of the neoplasm. FNA is not very useful in those situations in which tumor classification depends less on cytologic features and more on architectural patterns, such as locally invasive tumor growth. When dealing with encapsulated neoplasms of the thyroid, for example, FNA is notoriously inaccurate in separating follicular adenomas from follicular carcinomas, because a diagnosis of malignancy is contingent on the histologic demonstration of tumor invasion.
- Accuracy is related to the scope of the clinical question. FNA is highly reliable when grappling with broad distinctions (e.g., presence of tumor vs. absence of tumor, inflammatory process vs. neoplastic process, benign tumor vs. malignant tumor), but accuracy diminishes for precise tumor subclassification. Moreover, largely due to the impact of limited tumor sampling by FNA, a malignant tumor is more likely to be misdiagnosed as benign (i.e., false-negative result) than a benign tumor is to be misdiagnosed as malignant (i.e., false-positive result).
- Accuracy is related to the experience of the cytopathologist and the quality of the slide preparations, which, in turn, depends on the experience of the aspirator. Under ideal conditions the aspiration is performed by a cytopathologist trained to do fine-needle aspirations or, alternatively, in the presence of a cytopathologist, thus allowing an immediate assessment of the quality and quantity of the aspirate. Because of the combined impact of these factors, FNA is best used as an adjunctive diagnostic tool. It should complement, not supplant, the clinical, radiographic, and laboratory findings.

FUTURE DIRECTIONS

Breakneck developments in molecular biology, biotechnology, and bioinformatics are driving a molecular revolution in pathology. Contemporary research resulting in the identification of thousands of new genes and providing insight into the function and complex interaction of these genes will present the pathologist with new opportunities for solving old diagnostic problems. The technologic

armamentarium of the surgical pathologist, once reliant solely on the light microscope to detect phenotypic alterations, now includes sophisticated tools to isolate and compare single cell populations in a tumor and to detect submicroscopic alterations in gene integrity, gene expression, and gene translation.[44,45]

The direct application of molecular techniques to diagnostic oncologic pathology has just begun, but as discussed in subsequent sections, a growing number of examples bolster the bold claims that molecular analysis will profoundly aid the diagnosis, prognosis, and treatment of tumors. For hematologic neoplasms, delineation of various chromosomal translocations has allowed more clinically relevant classification of leukemias and lymphomas.[46,47] Genetic analysis is having a similar impact on soft tissue tumors, as detection of tumor-specific translocations can be essential to classify these neoplasms.[48] Increased access to detailed genetic information also will provide a clearer picture of patient outcome and help individualize treatment plans. For hematopoietic neoplasms, detection of specific translocations already provides prognostic information independent of morphologic and immunophenotypic characterization. Moreover, the products of these transforming genes provide attractive targets for promising new therapeutic agents.



For sporadic epithelial neoplasms, the molecular genetic makeup of a tumor is not currently integrated into the inventory of more classic prognostic and predictive determinants. Efforts to do so have been stalled by the number and complexity of genetic alterations, the absence of standardized methods to measure and interpret test results, the high cost and limited availability of the technology, and the absence of well-designed clinical studies to assess clinical utility.[49] The application of such techniques is well appreciated in breast cancer, for which quantitative measures of hormone-receptor expression and HER-2/neu gene amplification now are routinely incorporated to assess outcome and guide therapy. These applications in breast cancer forecast a coming era when pharmacologic and radiation sensitivity profiles based on molecular genetic alterations will permit customized treatment of individual patients.

The molecular revolution will enhance the role of the surgical pathologist in the multidisciplinary approach to the patient with cancer, but it will not replace it. Advances in basic tumor research depend on the involvement of well-trained pathologists, not only to characterize tumors accurately with respect to site of origin and pathologic grade but also to distinguish normal and neoplastic tissue, and identify subtle degrees of morphologic changes in an individual section. With all the developments of new technology and approaches, classic light microscopy remains the cornerstone of tumor diagnostics and the starting point for the application of any new prognostic or therapeutic marker.

17 Flow Cytometry in Oncologic Diagnosis

Michael J. Borowitz

SUMMARY OF KEY POINTS

Key Methods
- Fluorescently conjugated antibodies, bound to cell-surface or intracellular proteins, allow enumeration and detailed characterization of subsets of cells in heterogeneous mixtures.
- Fluorescent DNA-binding dyes allow determination of tumor ploidy and can assess cell-cycle characteristics of tumors.

Applications

Acute Leukemia
- Used for lineage assignment and classification of leukemia
- Certain phenotypes correlate with molecular abnormalities.
- Minimal residual disease detection is prognostic in both acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML).

Lymphoma and Chronic Lymphoproliferative Disorders
- Suitable for use on cell suspensions of tissue, fine-needle aspirates, fluids, and blood and marrow.
- Clonality of B-cell processes readily detected by light-chain restriction assay.
- Many lymphoid disorders are defined by phenotypic profiles.

Solid Tumors
- DNA ploidy and S-phase fraction can be detected.
- Prognostic significance is controversial, but measurement has value in certain tumors.
- Methodologic difficulties have contributed to lack of acceptance.

INTRODUCTION

Flow cytometry is used to study attributes of individual cells in a suspension. Over the past two decades, flow cytometry has become increasingly sophisticated; high-speed sorters and analyzers capable of detecting more than a dozen colors simultaneously have kept flow cytometry in the forefront as a tool for the fundamental investigation into cancer. At the same time, flow cytometry has matured from a research technology to one that is part of the routine clinical laboratory. This chapter focuses on diagnostic aspects of flow cytometry.

METHODS

A flow cytometer analyzes large numbers of cells one at a time, making it an ideal tool for examination of the properties of populations of cells. It is complementary to imaging: although it does not provide as much detail about individual cells, it provides much better statistical measurements, and is able to characterize different groups of cells in heterogeneous mixtures. It also can physically sort specifc subpopulations of cells. Although a detailed discussion of the workings of a flow cytometer is outside the scope of this chapter, the chapter begins with a discussion of a few general principles.

Functional Components

A flow cytometer has three separate components: a fluidics system; an optical platform; and signal-processing electronics. The fluidic system aspirates the sample, mixes it with a sheath fluid to produce laminar flow, and conducts the cell suspension past the sensing zone where individual cells are examined. The optical platform consists of the laser light source(s), lenses to focus the light on the passing cell stream, band-pass filters to capture light of restricted wavelengths, and photomultiplier tubes (PMTs) that capture the emitted signals. The electronics convert photons to electrical signals in proportion to the total light contacting the PMTs, and amplify and scale the signals so that data can be readily analyzed. The value of each collected parameter is "quantitized" and assigned to a particular channel. Higher channels reflect brighter signals. Current software packages reprocess collected data electronically in a variety of formats; this flexibility of data analysis is a critical part of what makes this technology useful.

Electronically reprocessed data are displayed by software programs in the form of dot plots or histograms. The most useful displays usually correlate one parameter with another, with each dot representing a single event (i.e., cell) with the x- and y-channel values for the two chosen parameters. In addition to fluorescence, forward scatter and right-angle or side scatter can be displayed. Forward scatter is roughly proportional to the size of the cells, whereas side scatter is a measure of internal cellular complexity, which for hematopoietic cells usually means granularity. Typically, dot plots of either forward versus side scatter, or scatter versus fluorescence, are used to identify populations of interest in a process called *gating*, and additional displays show additional fluorescence or scatter characteristics of these populations. Because scatter measurements are made parallel to, and independent of, the fluorescence measurements, four-color flow cytometry, for example, is equivalent to six-parameter cytometry. The term *multiparameter flow cytometry* typically is used to define simultaneous analysis of five or more parameters on individual cells.

Fluorochromes and Fluorescence

Fluorochromes have spectral characteristics that allow them to absorb light of certain wavelengths and then to emit light at longer

wavelengths. Emission, a specific characteristic of the compound, is not limited to a fixed wavelength, but, rather, constitutes a spectrum, with variable numbers of photons emitted at different wavelengths. Different fluorochromes, including fluorescein isothiocyanate (FITC) and phycoerythrin (PE) as well as others, all have the capacity of absorbing light at 488 nm but emit it at different wavelengths, thereby making it possible to perform multicolor flow cytometry with a single laser emitting at 488 nm. Tandem conjugates, which covalently couple two fluorochrome molecules, allow emitted light to be transferred from one molecule to the other and can greatly increase the number of colors that can be detected with a single laser. Additional dyes such as allophycocyanin, which emit longer wavelengths, cannot be excited by a 488-nm laser but require a second light source, most frequently one emitting light at 635 nm. The combination of new dyes, more tandem conjugates, and new instruments with even more lasers has made it possible to perform flow cytometry to detect more than a dozen colors, and 6- or even 8- to 10-color flow cytometry is now being performed routinely in clinical laboratories.

APPLICATIONS OF FLOW CYTOMETRY TO CLINICAL ONCOLOGY

Flow cytometry plays a significant role in the diagnosis, classification, and management of patients with acute leukemia, chronic lymphoproliferative disorders, and non-Hodgkin's lymphoma. The early promise of this technology in the management of patients with solid tumors has not been completely realized, but it still plays a role in certain areas.

Acute Leukemia

Flow-cytometric immunophenotyping has become standard in the evaluation of new patients with acute leukemia. The most obvious role of flow cytometry is in distinguishing lymphoid from myeloid leukemia, but flow cytometry can help in the diagnosis and management of these patients in many ways (Box 17-1).

Lineage Assignment in Acute Leukemia

Phenotypic analysis of a bone marrow that is completely replaced by blasts is an almost elementary problem. Multiparameter flow cytometry, however, can dissect and categorize all populations in bone marrow, and, most important, can distinguish leukemic cells from normal, even when the leukemic cells are not the majority population. The antibody panel used to study patients with acute leukemia typically contains representative markers of all lineages, with some redundancy to allow recognition and classifcation because many antigens may be aberrantly lost or acquired in leukemic cells.[1,2] No standard combinations of antibodies are used by all laboratories, but certain combinations have proved particularly useful not only for the most economical classification of leukemia, but also for their ability to demonstrate characteristic aberrant patterns that may be extremely useful for the detection of residual disease in follow-up samples, as discussed later in this chapter.

Diffculties encountered in the interpretation of flow cytometry data derive largely from two problems. First, in cases in which leukemic cells are not an obviously dominant population, it is important to ensure that the cells of interest are analyzed. The most useful general approach for this takes advantage of the fact that the common leukocyte antigen CD45 is differentially expressed on different types of hematopoietic cells, and, when combined with side scatter, produces a display in which blasts occupy a unique position not occupied by normal cells (Fig. 17-1).[3] Thus,combining CD45 in one color with multiple combinations of antibodies in additional colors allows detailed characterization of blast populations in marrow even when they are present only in low numbers.

Failure to select the leukemic cell population for analysis, or including a mixture of leukemic and normal cells in a gate, may cause confusion in the reporting of flow cytometry results. It is best to identify the leukemic population visually and to provide a detailed description of the antigens expressed on the leukemic population, especially in myeloid leukemias, in which the dynamic patterns of maturation associated with morphologic variation in AML are

Box 17-1. APPLICATIONS OF FLOW CYTOMETRY IN HEMATOLOGIC NEOPLASIA

Acute Leukemia

Distinction of myeloid and lymphoid leukemia
Distinction of T-ALL from precursor B-ALL
Subclassification of lymphoid and myeloid leukemia
Identification of phenotypes associated with characteristic molecular and cytogenetic abnormalities
Identification, enumeration, and characterization of blasts in heterogeneous samples
Identification of abnormal phenotypes for purposes of monitoring patients after therapy (minimal residual disease)
Identification of hyperdiploidy in pediatric ALL
Identification of abnormal patterns of myeloid maturation in myelodysplastic syndromes

Lymphoma and Lymphoproliferative Disorders

Identification of clonal B-cell proliferations
Subclassification of B-cell lymphomas and leukemias
  Diagnosis of chronic lymphocytic leukemia
  Diagnosis of hairy cell leukemia
  Identification of characteristic phenotypes in other lymphomas
Prognosis of CLL (CD38 and ZAP 70 expression)
Identification of phenotypically abnormal T cells
Subclassification of T-cell lymphoproliferative disorders
Diagnosis of plasma cell dyscrasias
Identification of abnormal phenotypes for purposes of monitoring patients after therapy (minimal residual disease)

ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia.

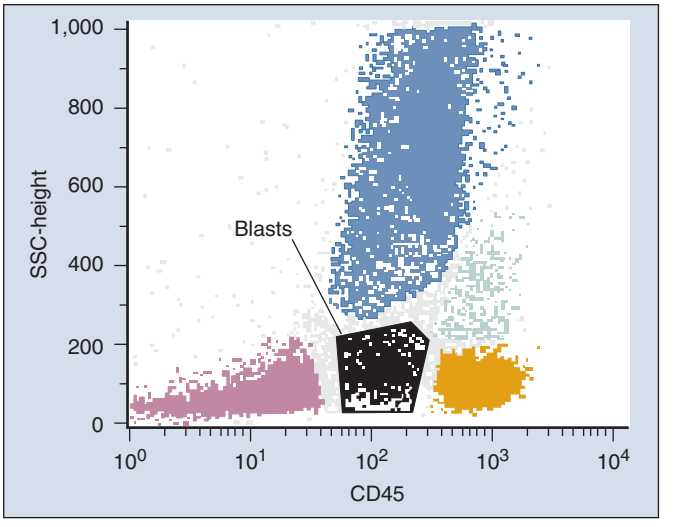

Figure 17-1 • CD45 gating in acute leukemia. Dual-parameter display of CD45 and side scatter of bone marrow containing increased blasts. These two parameters can readily separate lymphocytes (*yellow*), granulocytes (*blue*), monocytes (*light blue*), and nucleated red cells (*pink*). In normal marrow, a "hole" is found with few events in the low side scatter (SSC)/intermediate CD45 region, but in this case a distinct population can be identified. This distinction allows gating and analysis of antigen expression on just the blast population.

reflected in changes in both light scatter and antigen expression as the leukemic cells mature. Tabular arrays of "percentage positive" are not recommended as part of a flow cytometry report, because they cannot reflect this complexity and may cause confusion.[4]

The second problem in interpreting flow cytometry results in leukemia derives from the fact that most of the reagents used in classifying leukemia are only relatively rather than absolutely specific. Thus, correct classification requires not only a panel with some redundancy, but also an understanding of patterns of reactivity of the antibodies. Markers such as CD13 and CD33, which are considered *myeloid antigens* because they originally were produced against myeloid leukemia cells, are found in up to 50% of cases of lymphoid leukemia,[5] and interpretation of leukemias positive for these markers continues to be a cause of confusion. Generally speaking, the most specific markers of a given lineage are not highly sensitive, and the most sensitive ones are not specific. This is true more of myeloid markers than of lymphoid markers, so that lymphoid leukemias usually can be recognized precisely, whereas poorly differentiated myeloid leukemias usually are defined by the presence of myeloid markers in the absence of specific lymphoid antigens.

Acute Leukemias of Indeterminate or Ambiguous Lineage

Although almost all cases of acute leukemia can be categorized easily regarding lineage, the lack of absolute specificity of most markers, and the promiscuity of their expression, implies that some cases cannot be resolved easily. Unfortunately, considerable controversy exists about the use of the terms *mixed lineage* and *biphenotypic leukemia*. Leukemias that express myeloid- and lymphoid-associated markers in combination represent a heterogeneous group of diseases. A scoring system has been proposed[6] that assigns various point values to different antigens, with a diagnosis of "biphenotypic leukemia" rendered if the score is high for more than one lineage. Although this is an objective method of defining lineage, it mixes different kinds of cases with different molecular abnormalities. The scoring system as originally conceived also does not distinguish between cases in which blasts coexpress antigens of different lineages and those in which there are distinct leukemic blast populations. The latter situation is much less common, but can be thought of properly as true mixed-lineage leukemia. Certain of these, such as the combination of B-precursor ALL and AML in patients with the Philadelphia chromosome, represent distinct entities.

Association of Immunophenotype and Molecular Abnormalities

Many phenotypes in both ALL and AML are highly associated with characteristic cytogenetic abnormalities.[7] In ALL, these include cases associated with MLL rearrangements, TEL-AML1 or E2A-PBX1. In AML, the most important link is in promyelocytic leukemia with the t(15;17). Whereas lack of HLA-DR is the best-known abnormality, only about half of cases of DR-negative AMLs turn out to be acute promyleocytic leukemia (APL), and other combinations of marker expression are much more sensitive and specific for APL.[8] AML associated with the t(8;21) also shows a characteristic phenotype.[9]

Minimal Residual Disease Detection in Acute Leukemia

Several recent studies have demonstrated that the presence of residual leukemic cells in the marrow of patients in clinical and morphologic remission is a very strong adverse prognostic factor.[10–16] Although the most extensive data exist in childhood ALL,[10–12] the principle has also been shown to apply to adult ALL[13] and to AML.[14–16]

Both molecular and flow-based methods have been used to detect minimal residual disease (MRD). Flow-based assays of MRD are based on the principle that nearly all leukemias show a pattern of expression of antigens that is aberrant compared with the pattern seen in normal differentiation.[10–15] This aberrancy can take several forms. Some leukemic cells can abnormally express antigens of a different lineage or show loss of expression of a normal lineage marker. A more common finding is expression of normal differentiation antigens, but at an intensity that is different from that expected for a particular stage of differentiation. This latter attribute makes flow MRD analysis applicable to most cases of leukemia. Nonetheless, recognizing these deviations requires a clear understanding of patterns of maturation in normal differentiation, including marrow regeneration, as viewed in multiparameter space.

The pattern of antigen acquisition and loss during B-cell maturation in the bone marrow has been very well characterized, and certain markers are particularly useful for distinguishing normal and leukemic maturation. Consideration of markers including intensity of CD45, CD34, CD10, CD58 and CD38 or aberrant coexpression of myeloid or other unexpected antigens can allow detection of as few as 1 in 10^4 leukemic cells, even when normal B-cell precursors are present in significant numbers (Fig. 17-2). Marrow T-ALL can also be distinguished from normal T cells, most readily by coexpression of cytoplasmic CD3 and TdT, which is never seen on any normal cell.[10] Detection of myeloid MRD usually is a more elaborate process because of the greater phenotypic heterogeneity in AML. Certain aberrant combinations, including coexpression of CD34 and CD56, CD117 and CD15, or CD7 and myeloid antigens occur with sufficient frequency to be useful in a large number of cases.[14–16] To achieve 10^{-4} sensitivity in essentially all cases may require design of custom panels unique to a particular leukemia. Because abnormal populations at diagnosis may not persist at recurrence, monitoring patients with acute leukemia requires following more than one aberrant phenotype.

Myelodysplasia and Chronic Myeloproliferative Disorders

Recently it has become apparent that flow cytometry can detect abnormalities in marrow disorders other than acute leukemia. Patients with chronic myeloproliferative disorders invariably show abnormalities in either blast phenotype or maturation pattern,[17] although routine clinical phenotyping of MPDs is not performed in most cases. Interest in using flow cytometry as a primary diagnostic modality in myelodysplastic syndromes is increasing. In addition to finding phenotypically abnormal blasts, many studies have demonstrated characteristic phenotypic abnormalities in either myeloid or erythroid maturation in myelodysplastic syndrome (MDS), as well as describing abnormalities in granulocyte light scatter that correspond to the morphologic finding of hypogranularity.[18–20] Although a scoring system has been proposed to use flow cytometric characteristics to diagnose MDS,[20] the sensitivity and specificity of these findings have not been rigidly established, and it is not clear whether flow cytometry significantly improves the accurate diagnosis of early MDS. Nevertheless, it is clear that the technique can add useful adjunctive information to the diagnosis and possibly the prognosis of MDS.

Chronic Lymphoproliferative Disorders and Lymphoma

Lymphoid Tissue Analysis

Flow-cytometric immunophenotyping plays a major role in the evaluation of a patient with lymphoma (see Box 17-1).[21–23] Lymphoid tissue first must be disaggregated to produce a cell suspension suitable for flow-cytometric analysis. Although this is readily accomplished in most low-grade lymphomas, high-grade lymphomas may give a nonrepresentative sample because of the greater fragility of the neoplastic cells compared with residual normal cells. Fibrosis also may make disaggregation difficult or result in disruption of neoplastic cells. Consequently, flow-cytometric analysis of lymphoma requires careful gating to ensure that the cells of interest are analyzed.

In contrast to the situation with acute leukemias, no single antibody serves as a useful surrogate for the neoplastic population. However, in B-cell malignancies, neoplastic B cells usually greatly outnumber normal cells (although there may be normal T cells), so

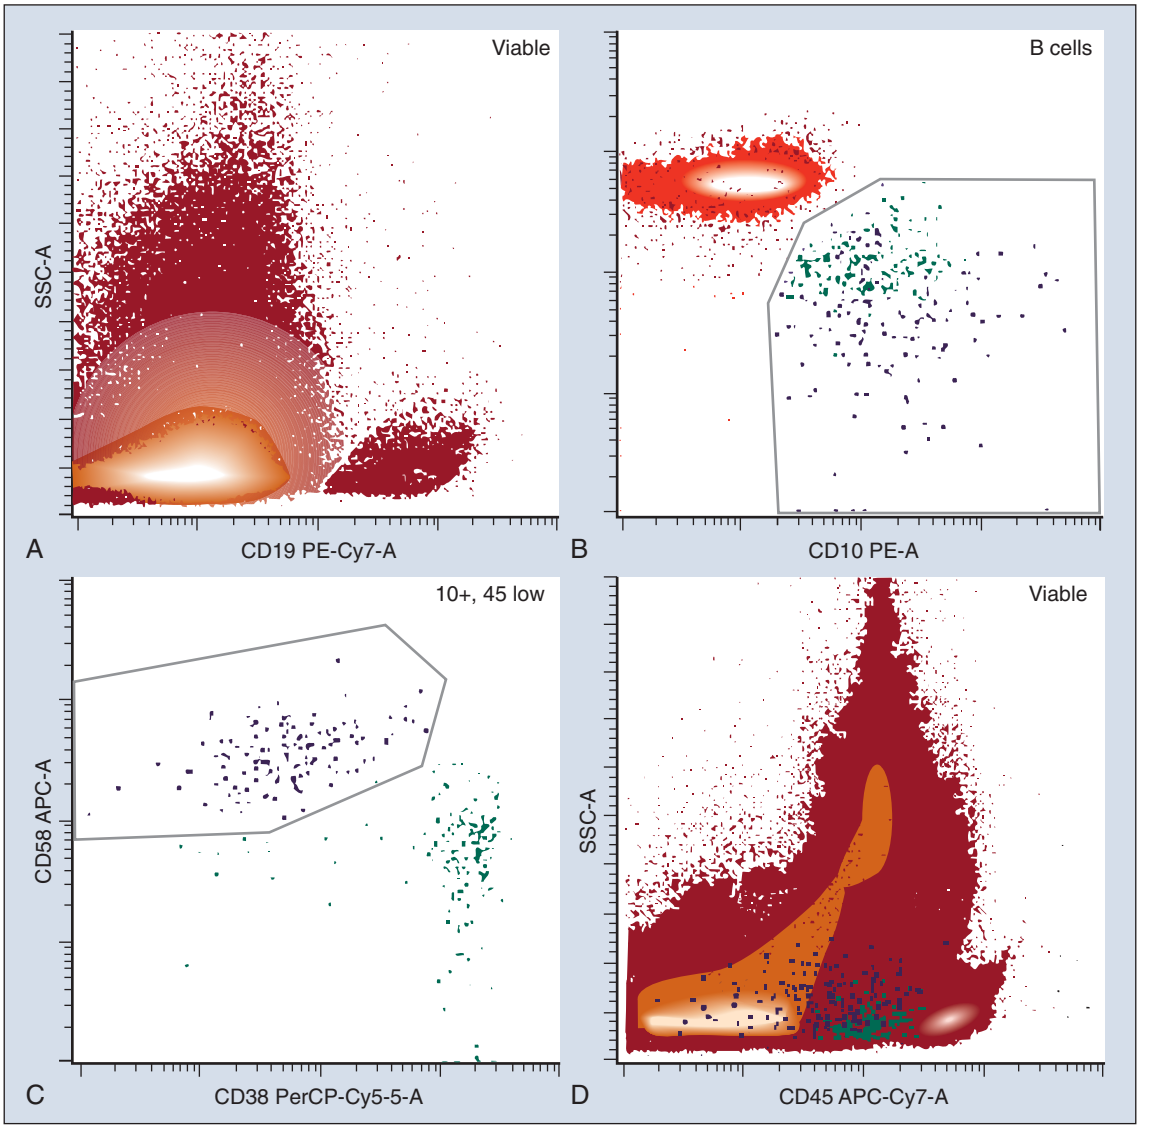

Figure 17-2 • Minimal residual disease detection in acute lymphoblastic leukemia. Normal B cells have a fixed pattern of expression of different antigens as they mature. Leukemic cells depart from this normal pattern. In this case, an end induction marrow was stained by 6-color flow cytometry with the combination CD20-FITC/CD10-PE/CD38-PerCPCy5.5/CD58-APC/CD19-PE-Cy7/CD45-APCCy7, and the abnormal population revealed by sequential gating. Only selected correlated antigens are displayed. **A,** CD19+ B cells are gated, so that the great majority of the 750,000 events collected are not displayed (**B,** which only shows B cells). CD45-low, CD10+ cells are gated and displayed in the next panel. **C,** Normal B cell precursors (*green*) are recognized because they have relatively bright CD38 and relatively dim CD58, while the leukemic cells (*blue*) are bright 58 and dim 38. **D,** The few leukemic cells are superimposed on a CD45 vs SSC display of the entire sample. MRD accounted for 0.02% of the total cells.

that use of a pan-B-cell antibody such as CD19 or CD20 can help to isolate the neoplastic cells for analysis. In addition, forward scatter, as a marker of cell size, may be a very useful parameter to help distinguish frequently larger neoplastic cells from smaller normal counterparts.

Although some laboratories prefer tissue immunohistochemistry to flow cytometry for phenotyping lymphomas, the two techniques are complementary. The principle advantages of flow cytometry relate to its speed and its ability to identify and phenotype precisely the neoplastic elements in a heterogeneous sample. A complete phenotypic characterization, and, in many cases, a diagnosis can be achieved within a few hours from the time of biopsy, rather than the several days needed for histopathologic examination and immunostaining. Flow cytometry also is far better than immunohistochemistry for demonstrating light-chain restriction, and therefore clonality, in B-cell neoplasms.

The disadvantages of flow cytometry come from the architectural disruption created by making a cell suspension and the aforementioned possible loss of cells of interest. Hodgkin's lymphoma, in particular, is not diagnosed by routine flow cytometry, although recent studies have demonstrated that careful attention to the procedures used for phenotyping can overcome this drawback.[24] Even in non-Hodgkin's lymphoma, grading may be difficult from flow-cytometric immunophenotyping alone, and precise classification can be accomplished only rarely; lymphoma classification still relies heavily on morphology, and this must be correlated with flow-cytometric information.

Classification of lymphoma and grading, in particular, can be improved by assessment of DNA content by flow cytometry (as discussed later in this chapter), because S-phase fraction is closely correlated with grade. Burkitt's lymphoma, which has the highest S

fraction of any neoplasm, usually can be reliably identifed by flow cytometry. However, in lesions such as follicular lymphoma, grading systems still are based on morphologic criteria, and although there may be reason to expect that flow-based methods might be more objective, these have not been validated in large series to the point at which they are generally accepted.

One of the most fruitful applications of flow cytometry in the diagnosis of lymphoma is in the analysis of specimens from fine-needle aspiration (FNA).[25,26] Cells obtained by FNA already are in suspension, and flow-cytometric analysis contributes significantly to the cytopathologic diagnosis of lymphoma, which is notoriously difficult. Although FNA has been used for years in the evaluation of recurrent adenopathy in patients with known lymphoma, it can serve as a primary diagnostic modality in lymphoma when combined with flow cytometry. Most non-Hodgkin's lymphomas can be recognized and graded, and, importantly, lymphomas also can usually be excluded. Optimal application of this technology, however, requires close collaboration between the cytopathologist and flow cytometrist, a clear understanding of the strengths and limitations of the two techniques, and a willingness to revert to open biopsy in ambiguous cases.

Blood and Marrow Analysis

Limitations attendant on generating cell suspensions do not apply to patients with blood or marrow involvement by chronic lymphoproliferative disorders. Subclassification of these lesions relies heavily on flow cytometry.[21,23,27–29] Chronic lymphocytic leukemia (CLL) is essentially defined by its immunophenotypic characteristics. Other B-cell lymphoproliferative disorders have characteristic, if not always absolutely specific, phenotypes.[21,23,27,28,30] Mantle cell lymphoma often can be recognized in its leukemic phase, although the most specific marker, cyclin D1, is very difficult to detect by flow with current techniques. Hairy cell leukemia, conversely, has not only a characteristic but also a highly specific phenotype[23,31]; occasionally patients with unexplained pancytopenia can be determined to have hairy cell leukemia when only a tiny number of blood cells with the classic phenotype are identified[31] (Fig. 17-3).

Recently, considerable attention has been paid to the use of flow cytometry to detect prognostic factors in CLL. Recognizing that CLL can be subdivided into a poor-prognosis type associated with nonmutated immunoglobulin V region genes and a better-prognosis mutated phenotype, several studies have attempted to identify flow surrogates. The first marker found to be prognostic was CD38, although the correlation with either mutational status or prognosis is imperfect.[32–34] Zeta-chain-associated protein kinase 70 (ZAP 70) appears to be a much better surrogate marker for either prognostication or V-region status.[35–37] However, even though this assay is widely available, particularly in commercial reference laboratories, there can be significant variability in how the assay is performed,[38,39] so that it is not always certain that a commercially available assay is the same as that in the published literature. For this reason, many researchers recommend caution in interpreting these results. Other attempts have been made to define prognostically significant subsets of patients with CLL using other combinations of markers,[40] but these have not been adopted in routine practice.

The primary value of flow cytometry in chronic leukemias is its ability to demonstrate clonality in B-cell populations, based on restricted expression of one type of immunoglobulin light chain.[21–23] This feature is particularly valuable in the evaluation of patients with unexplained lymphocytosis[41,42] and also is useful for staging patients with B-cell non-Hodgkin's lymphoma,[43,44] because the presence of as little as 0.5% to 1% of a clonal B-cell population, or even less, can be demonstrated in the marrow or blood of some patients. The high sensitivity of flow cytometry for detecting clonal populations has, however, demonstrated small clonal B-cell populations in some patients without obvious lymphoma or leukemia.[45] Thus, the finding of a small marrow clone, in the absence of other evidence of lymphoma, should be interpreted with caution, analogous to finding a monoclonal gammopathy in a patient without evidence of myeloma.

Some controversy exists about the applicability of flow cytometry to patients with myeloma. Whereas plasma cells have a characteristic phenotype, including very bright expression of CD38 and expression of CD138,[46,47] plasma cells are underrepresented on marrow aspirates studied by flow compared with the prevalence of cells on films or in biopsies. Nevertheless, the unique phenotype of plasma cells makes them easy to recognize, and with the use of membrane-permeabilization techniques, it is easy to demonstrate cytoplasmic immunoglob-

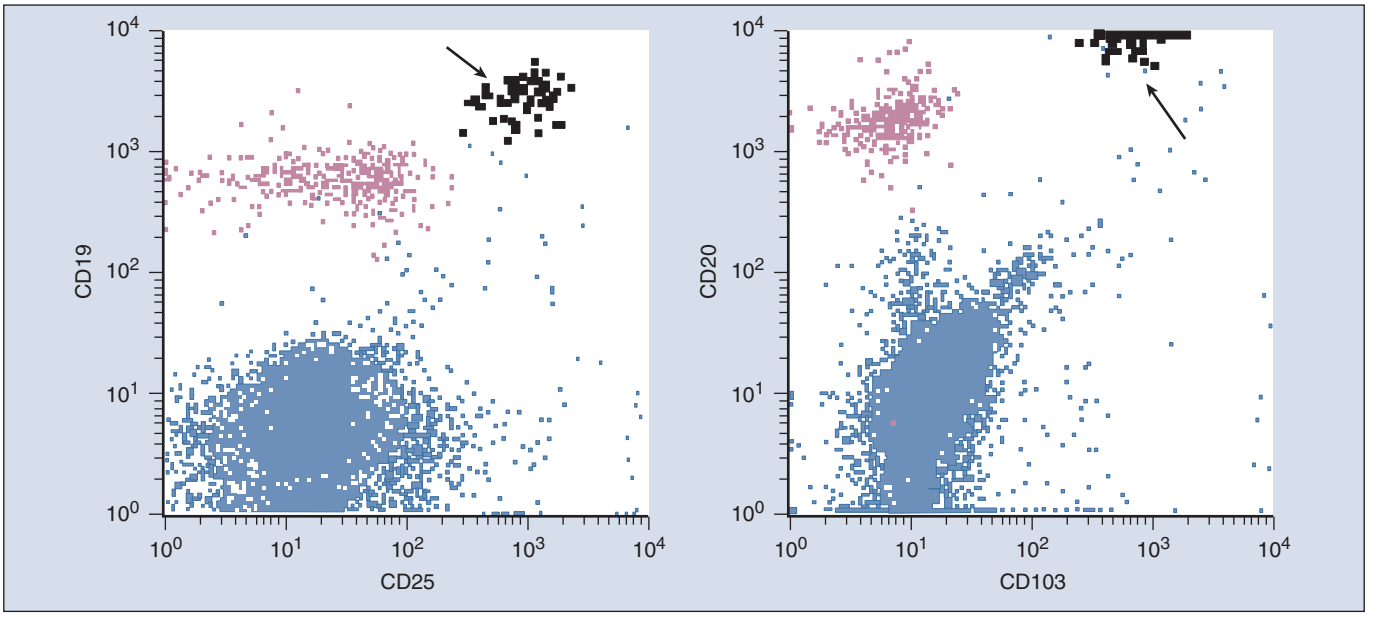

Figure 17-3 • Flow-cytometric detection of hairy cell leukemia. A small population (*arrows*) accounts for less than 1% of this peripheral blood sample and can readily be recognized. Expression of CD19 and CD20 is brighter than the background normal B cells (*blue*), and the abnormal cells also express CD103 and CD25.

ulin (Ig) light-chain restriction.[47] It is of more significance that neoplastic plasma cells usually have abnormal phenotypes. Although no single specific phenotypic abnormality permits distinction between benign monoclonal gammopathy and myeloma, the relative proportion of abnormal versus normal plasma cells has been suggested to be a predictor of behavior.[48] Moreover, flow cytometric detection of circulating plasma cells or persistence of an abnormal phenotype after therapy is predictive of outcome in patients with myeloma.[49–52]

Clonality of T cell populations also can be demonstrated by flow cytometry, although the method is more complex and is not as widely available as that used for B cells. This technique is based on demonstration of restriction of V-beta gene use in T-cell leukemias.[53,54] T-cell malignancies also often show abnormal T-cell phenotypes, most often characterized by loss of a normal pan-T antigen, or expression of a T-cell antigen at abnormal intensity.[55,56] Because certain small, unusual, and even clonal T-cell populations may be seen in small numbers in non-neoplastic conditions, this technique has more limited sensitivity than demonstration of a clonal B-cell population. However, when abnormal T cells account for more than a very small percentage of cells, multiparameter flow cytometry easily demonstrates them and plays a significant role in categorizing these uncommon tumors.

Residual Disease Detection in Chronic Lymphoproliferative Disorders

As with acute leukemia, MRD can be detected by flow cytometry in chronic lymphoproliferative disorders. The most work has been done with CLL. Although detection of light-chain-restricted clones is difficult when the level is much below 0.1%, aberrant phenotypes that allow detection with a sensitivity of at least 1 in 10^{-4} can be detected in most cases of CLL.[57,58] Just as in acute leukemia, the presence of MRD in patients considered to be in remission by standard criteria is associated with an adverse prognosis,[58] whereas clearance of MRD after therapy is associated with a good outcome.[59]

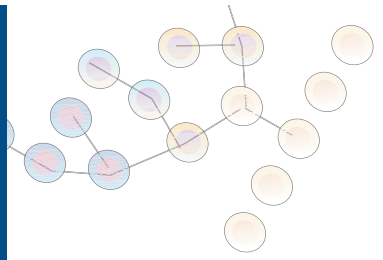
Solid Tumors: Analysis for DNA Content

Numerous fluorescent dyes bind stoichiometrically to cellular DNA and thus can provide an accurate assessment of DNA content of cells. In a single-parameter fluorescence histogram, tumors with abnormal numbers of chromosomes show a distinct peak separate from the normal G_0/G_1 peak of diploid cells. Such tumors are referred to as *aneuploid*. Moreover, cells progressing through the cell cycle show incrementally increased levels of DNA while they are in S phase, and those in G_2 or in mitosis show exactly twice the amount of DNA as that represented by the G_0/G_1 population. Thus, integration of the area under the curve between the G_0/G_1 and G_2/M peaks gives the proportion of cells in S phase, commonly referred to as *S-phase fraction*. A variety of software packages are available to calculate S-phase fraction from these histograms.

DNA content analysis in tumors was one of the earliest applications of flow cytometry in tumors. Many studies have attempted to define the prognostic significance of either ploidy or S-phase fraction in a large number of different solid tumors. This proliferation of studies was made possible by the finding that fixed, paraffin-embedded tissue sections could be used for DNA analysis by flow, which resulted in many retrospective studies on archival material for which outcome was already known.[60] However, the literature is confusing and contradictory, and the early promise of this measurement as an important diagnostic and prognostic marker in cancer has not been realized. Although some studies have demonstrated prognostic significance to measurements of ploidy, and especially S-phase fraction in a number of tumors—most specifically bladder, prostate, and breast cancer—many studies conflict, with the result that this technology has not been widely embraced in clinical oncology. In some practices, it is used occasionally to help manage certain subgroups of patients with some cancers. For example, some practices use S-phase fraction to help manage patients with early-stage, node-negative breast cancer, whereas others use ploidy of superficial bladder cancers to help identify patients whose tumors might progress. One reason for the lack of acceptance of this measurement is the difficulties that have been encountered in standardization. S-phase fraction, in particular, has shown very poor interlaboratory reproducibility.[61] The ultimate effect of these technical problems is that it is very difficult for an individual laboratory to offer clinicians a test result that helps them decide how to manage a particular patient. The inability of this technology to make significant inroads in the clinic is unfortunate, because some more recent studies, by using highly sophisticated analytic methods, suggest that in breast cancer, at least, both ploidy and S-phase fraction are powerful independent prognostic markers.[62] A detailed summary of all the controversies is outside the scope of this chapter, but several reviews have been published.[63,64]

FUTURE OF FLOW CYTOMETRY IN CLINICAL ONCOLOGY

Flow cytometry in the clinical laboratory is at something of a crossroads. On the one hand, improvements in standardization and the technology itself have made it possible to develop easy-to-operate instruments that fit well with the model of the clinical laboratory. On the other hand, with the notable exception of MRD assessment, no significant growth has occurred in the applicability of this technology to cancer. Empirical classification of leukemia and lymphoma with new markers has not, in general, been fruitful. At the same time, technologic advances in cancer diagnosis currently seem to be focusing on methods of assessing genetic lesions in cancer. However, although genetic abnormalities clearly produce cancer, they do so through production of abnormal proteins, and detection of a number of different proteins in specific cell populations is what flow cytometry does best.



Thus it would appear that flow cytometry is well suited to validate, and to translate into clinical practice, many of the exciting findings that derive from genomics. One of the areas that has seen significant attention is the flow cytometric detection of phosphorylated signaling molecules. These studies have greatly added to our understanding of the operation of signaling pathways,[65] can be used to demonstrate alterations in signaling in leukemia, and are ideally suited to use as surrogate markers to validate the action of new drugs.[66,67] While these measurements have not yet been incorporated into routine clinical practice, they are already being used in clinical trials,[68] and it is likely that the most robust and informative of them will soon find their way into the routine laboratory.

18 Conventional and Molecular Cytogenetics of Neoplasia

Linda D. Cooley and Kathleen S. Wilson

SUMMARY OF KEY POINTS

Key Methods

- Conventional cytogenetic analysis uses chromosome banding to analyze structural and numeric chromosomal aberrations; dividing cells are required.
- Molecular cytogenetic or fluorescence in situ hybridization (FISH) analysis complements and extends analysis for specific genetic aberrations; viable tumor is not required.
- Additional methods include multiplex (M-FISH), spectral karyotyping (SKY), comparative genomic hybridization (CGH), and microarray-based CGH (aCGH).

Applications

Acute Leukemias

- Document clonal aberrations at diagnosis.
- Subclassify genetic types of leukemias; provide diagnostic, prognostic, and patient management information.
- Monitor response to therapy; assess disease progression.
- Monitor post-transplantation engraftment; detect minimal residual disease.

Lymphoma and Chronic Lymphoproliferative Disorders

- Subclassify lymphomas with specific translocations.
- Provide prognostic genetic information for lymphoproliferative disorders.
- Detect diagnostic translocations in many tissue types.

Solid Tumors

- Differentiate and subtype small round cell tumors; differentiate spindle cell tumors.
- Detect prognostic or therapy-specific genetic information in many solid tumors.
- Detect and assess gene amplification.

INTRODUCTION

Cytogenetic analysis uses tissue culture and specialized techniques to provide genetic information about cells and tissues. Cancer cytogenetic analysis focuses on defining the genetic aberrations of neoplastic tissues. As early as 1890, David von Hansemann speculated that the abnormal mitotic figures in cancer biopsies were important to the origin and development of malignancy, and in 1914, Theodor Boveri[1] published a systematic somatic mutation theory of cancer positing that chromosome abnormalities were responsible for cellular changes that caused normal cells to become malignant. However, it was not until the 1960s that the first nonrandom chromosome abnormality was associated with a particular neoplastic disorder.

In 1960, Nowell and Hungerford[2] noted a very small "deleted" chromosome in cases of chronic myelocytic leukemia. Methods for banding and identifying individual chromosomes, developed in the early 1970s, made it possible to identify this chromosome as a deleted chromosome 22. This deletion chromosome 22 was named the "Philadelphia chromosome." Rowley[3] showed in 1973 that the del(22) was part of a reciprocal translocation with chromosome 9 [i.e., t(9;22)]. Since that discovery, rapid scientific and technological advances have profoundly changed the understanding of tumorigenesis and the genetics of cancer.

Conventional cytogenetic analysis, although one of the oldest methods, remains a powerful tool for genetic diagnosis and classification of hematologic malignancies and solid tumors. Cytogenetic detection of acquired clonal chromosome aberrations confirms that a process is neoplastic and rules out a reactive or non-neoplastic disorder. Chromosomal abnormalities occur nonrandomly and continually bring newly identified recurring breakpoints to attention as the sites of "disease" genes.[4] Molecular cytogenetic or fluorescence in situ hybridization (FISH) analysis targets these sites, permitting detection of specific diagnostic rearrangements. Disease or disease-subtype-specific chromosomal anomalies provide diagnostic information when histopathologic parameters are indeterminate. In addition, many abnormalities contribute prognostic information and guide therapeutic decisions.

Investigators have elucidated the physiologic function of many "disease" genes and shed light on the mechanisms of their mutations. This information provides the basis for the recent and rapid increase in tumor-specific or gene-mutation-specific therapeutic agents.[5] One example of this is the advent of tyrosine kinase inhibitors (TKIs), small molecules designed to affect molecular targets identified by recurrent cytogenetic aberrations. The efficacy of TKIs for several hematologic malignancies is now well established,[6,7] and there is increasing evidence that TKIs will play a major role in treatment of solid tumors.[8] The future holds promise for ever more effective therapies for preventing and treating malignancies. Conventional cytogenetic analysis, FISH, and newer array-based technologies have an increasingly important role in contributing information needed for optimal individualized patient management.

This chapter provides a brief overview of cytogenetics, clinical indications for conventional and molecular cytogenetic testing, and a synopsis of what the clinician should expect from a cytogenetic laboratory. A summary of diagnostic, prognostic, and clinically relevant chromosome aberrations is provided in tabular form.

METHODS AND APPLICATIONS

Specimens

Successful conventional cytogenetic studies of neoplastic tissues and cells require an adequate specimen of viable tumor cells, pertinent

patient information, and prompt delivery to the processing laboratory. Tumor cell viability is crucial, because metaphase chromosomes for cytogenetic analysis can be obtained only from dividing cells. Although tumor cells may be long-lived in the human body, they quickly lose viability once removed, making prompt delivery to the laboratory essential. Appropriate specimen processing depends on the information that accompanies the sample. Critical information includes patient demographics, differential diagnosis, symptoms, and other laboratory findings. The cytogenetics laboratory uses the information to choose the best methods for the suspected disease process. In the absence of adequate information, the specimen may not be processed optimally to yield the malignant clone.

For hematologic tumors, 2 to 3 mL of bone marrow aspirate collected in sodium heparin is the specimen of choice. When a bone marrow aspirate cannot be obtained because of marrow fibrosis, a packed marrow, or other reasons, a bone marrow trephine biopsy or a peripheral blood specimen may be successful. For a blood specimen to yield information about clonal chromosome aberrations, however, the peripheral blood white cell differential must be abnormal (i.e., abnormal or immature cells must be present). The laboratory needs the white blood cell count and differential to inoculate the cell cultures correctly with appropriate numbers of cells. For routine studies of neoplastic hematologic disorders, no cell mitogens are used in culture. The malignant cell population will divide spontaneously to yield metaphase cells. Only when the disease process is known to be a T-cell or B-cell disorder will T- or B-cell mitogens, respectively, be used in one of several initiated cultures.

Depending on the disease process, other specimen types may be appropriate for cytogenetic analysis. Virtually all body fluids and tissues are candidates for tissue culture and capture of metaphase cells. Useful sources include ascitic and pleural fluids, effusions, and, occasionally, cerebrospinal fluid. Tissues with solid aggregates of tumor cells (e.g., spleen or lymph node involved by lymphoma, or masses of myeloid sarcoma or neuroblastoma) also may be used. Such specimens should be acquired in a sterile fashion and placed in medium supplied by the cytogenetic laboratory for transport. The tissue sample should be selected to contain viable tumor, avoiding normal and necrotic tissues. Adequate sample size is variable, but if available, a sample volume of 500 mg or a sample measuring in aggregate $0.5 \times 0.5 \times 0.5$ cm is recommended.

Many specimen types may be used for FISH analysis. Cytogenetically prepared metaphase and/or interphase cells are most commonly used. However, formalin-fixed paraffin-embedded tumor, air-dried or alcohol fixed touch preparations, cytospin preparations, and blood or bone marrow smears may be used when fresh tumor material is unavailable or conventional cytogenetic analysis is unsuccessful. Tissues that have been processed with B-5 fixative or decalcified are not recommended, because probe hybridization may be suboptimal.

Assays

Conventional cytogenetic analysis allows visualization and screening of the entire genome for anomalies and remains one of the most basic and essential methods for genetic evaluation of hematolymphoid and solid tumors. Conventional analysis uses chromosome-banding methods to bring out the A-T and G-C rich band pattern intrinsic to each chromosome. This unique band pattern permits identification and description of each chromosome, normal or abnormal (Fig. 18-1). The chromosome bands are numbered so recurring chromosome breakpoints can be recognized, recorded, and communicated with a descriptive human cytogenetic nomenclature[9] (Table 18-1).

Molecular cytogenetic or FISH analysis[10] uses known fluorochrome-labeled DNA sequences or probes to hybridize to the DNA or chromosomes of the cells under investigation. The basis for the test is the natural tendency for a DNA strand to hybridize with its complementary DNA sequence. The specificity of the hybridization provides explicit information about the region probed.

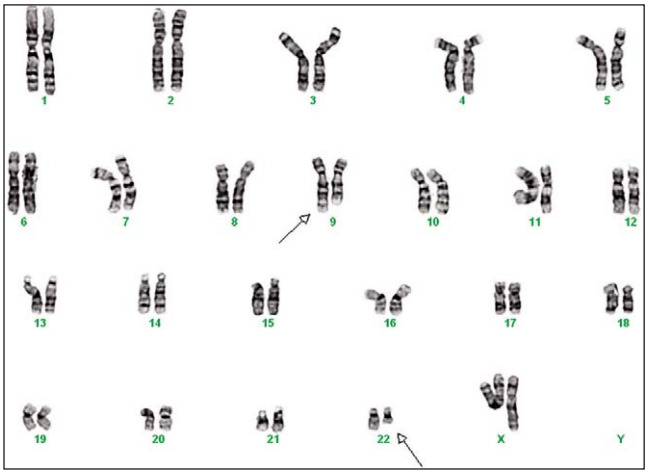

Figure 18-1 • Karyotype illustrates standard arrangement and Giemsa-trypsin banding of chromosomes in a female patient with chronic myeloid leukemia. The karyotype nomenclature is written as 46,XX,t(9;22)(q34;q11.2) (*arrows* to derivative chromosomes 9 and 22).

At the time of diagnosis, conventional cytogenetic analysis, with or without FISH analysis, should be done to characterize all malignancies as completely as possible to aid diagnosis, therapy selection,

Table 18-1 Cytogenetic Nomenclature

NOMENCLATURE ABBREVIATIONS
t(9;22)(q34;q11.2) example
t, translocation
(9;22), chromosomes involved
(q34;q11.2), breakpoints of chromosomes involved
q34, breakpoint of chromosome 9
q11.2, breakpoint of chromosome 22
q, long arm
p, short arm
del, deletion
dup, duplication
inv, inversion
add, added unidentified material
mar, marker; unidentified chromosome
+ or –, gain or loss of chromosome noted
XX, female
XY, male
TUMOR CELL DNA CONTENT: "PLOIDY"
Diploid, 2n or 46 chromosomes
Haploid, 1n or 23 chromosomes
DNA Index (DI), DNA content of cell
46 chromosomes, DNA Index of 1.0
Pseudodiploid, 46 chromosomes with aberrations
Tetraploid, 4n or 92 chromosomes
Aneuploid, chr number not exact multiple of haploid set
DI × 46 = approx chr number in clone: 1.16 × 46 = ~53 chr

Chr, Chromosome.

Table 18-2 Cytogenetic Analysis

INDICATIONS
Provide diagnostic and prognostic information
Provide information for therapy selection
Determine genetic subtype of myeloid disorders
Subclassify lymphoproliferative disorders
Distinguish prognostic groups in childhood ALL
Differentiate small round cell tumors
Differentiate sarcomas
Subtype solid tumors
Obtain information for follow-up testing
Detect clone after therapy or after transplantation
Determine donor cell engraftment status
Reassess clone at relapse for new anomalies
BENEFITS
Visualize entire genome with karyotype
Determine genetic aberrations at diagnosis
Detect disease progression
DISADVANTAGES
Turn-around time is days to weeks (solid tumors)

ALL, acute lymphoblastic leukemia.

and patient management. If assessment is inadequate at diagnosis, the interpretation and clinical utility of future studies will be compromised significantly. For example, without diagnostic genetic data, it would not be possible to determine whether clonal evolution had occurred; it might not be possible to distinguish between recurrent disease and a new disease process; and follow-up FISH studies might be misinterpreted.[11] Chronic myelogenous leukemia (CML) exemplifies the need for both cytogenetic and FISH evaluation at diagnosis, because certain FISH patterns that are associated with *BCR/ABL1* gene rearrangement may mimic a remission pattern. Monitoring these patients by FISH for minimal residual disease (MRD) requires knowledge of that particular patient's diagnostic pattern. Results from subsequent specimens in patients with this type of pattern must be interpreted using explicitly defined validation and control parameters to prevent an incorrect diagnosis of remission while *BCR/ABL1*-bearing cells with this unique pattern are actually still present.

Although conventional chromosomal analysis plays a defining role in characterizing tumors, FISH analysis now is an integral component of the diagnostic evaluation in a large percentage of cases (Table 18-2). FISH analysis has unique utility in the detection of gene rearrangements or gene amplification, chromosomal deletions, duplications, and aneuploidies, low-frequency chromosome aberrations, and elucidation of unbalanced or complex chromosome rearrangements[12] (Table 18-3). FISH analysis is the best method in diagnostic scenarios where a rapid result is needed,[13] such as in newly diagnosed acute promyelocytic leukemia, and an important adjunct when the yield of clonal aberrations by conventional cytogenetics is low,[14] as in chronic lymphocytic leukemia. FISH analysis is the preferred method when breakpoint heterogeneity compromises the usefulness of PCR-based assays or when detection of numerical aberrations is indicated. Although histopathologic evaluation is the currently accepted method to assess response to therapy in leukemias, FISH analysis offers a more reliable and sensitive method for detection of residual disease. FISH analysis is particularly useful in post-transplantation patients who have an identified clonal abnormality and an opposite-sex donor. A combination of sex chromosome- and clone-detecting probes can screen thousands of cells quickly for host cells and then determine whether the host cells carry the original clonal aberration.[15] This method provides crucial information for patient management that may not be obtained with other technologies.

Most cytogenetic laboratories provide a broad FISH test menu using commercially available FISH DNA probes. Other laboratories augment their capabilities by making "home brew" probes. In addition to identifying reciprocal translocations, deletions, and chromosome copy number aberrations, FISH may also provide additional patient-specific information beyond that obtained with conventional cytogenetic analysis. These data can be used to create FISH strategies for patients with unique aberrations that are not detectable with rt-PCR-based assays or specific translocation probe sets. This information, gathered at the time of diagnosis, is invaluable for follow-up assessment for therapy response and detection of residual disease.

FISH probes are designed to detect gene rearrangement in different ways with (1) "break-apart probes" that separate when a translocation has occurred, or (2) "single fusion, dual fusion, or extra signal translocation probes" that come together when a translocation has occurred. Chromosome enumeration probes and locus-specific probes detect copy number of either the centromere of a specific chromosome or a specific chromosome locus, respectively. Whole or partial chromosome paint probes cover the entire area of the chromosome for which they are designed with fluorescence.[12] Combinations of chromosome probes are available for specific disease entities, for example, Chronic Lymphocytic Leukemia panel (Vysis, Inc.) for use in assessing prognostic genetic anomalies in CLL, and Chromoprobe Multiprobe—System Octochrome (Cytocell Technologies) whole chromosome paint probes for use in determining unknown chromosomal material. New probes are coming on the market ever more rapidly, permitting detection of a much wider range of chromosome aberrations than was possible just a few years ago. This trend is likely to continue as individuals and companies use the genome database to design probes to keep up with the emerging gene-specific therapies.

Table 18-3 Fluorescence in situ Hybridization Analysis

INDICATIONS
Identify specific diagnostic and/or prognostic aberrations
Detect reciprocal translocations, gene rearrangements
Detect deletions, duplications
Detect chromosome or gene copy number
Detect gene amplification
Identify unrecognized chromosome material
Identify clonal aberrations for follow-up testing
Assess donor cell engraftment (opposite-sex donor)
Assess remission status
Detect recurrent disease
Detect minimal residual disease
BENEFITS
Analyze dividing and nondividing cells
Analyze fixed tissues
Easy to examine large numbers of cells
Rapid turnaround
DISADVANTAGES
Provides information only for locus of probe tested
Requires knowledge of chromosome anomaly or diagnosis

Other molecular cytogenetic methods[16] include comparative genomic hybridization (CGH), multiplex FISH (M-FISH), spectral karyotyping (SKY), and chromosomal microarray-based CGH[17] (aCGH). These specialized methods have been primarily the purview of research laboratories, but as technological advances occur, they are being brought on board in diagnostic laboratories. Conventional CGH uses a cocktail of tumor DNA and normal reference DNA, each labeled with a different fluorochrome. This cocktail is hybridized to normal metaphase chromosomes to detect regional genomic DNA gains and losses. This computer-based method screens the genome and allows analysis of tumor DNA when chromosomes cannot be obtained. Both SKY and M-FISH methods use multiple fluorochrome labels and computer software to "paint" each chromosome a different color. When the fluorochromes are hybridized to the abnormal tumor metaphase-cell chromosomes, computer analysis of the painted chromosomes can detect rearrangements and provide information about unidentified marker chromosomes and chromosome rearrangements that are not recognized by conventional banded cytogenetic analysis. Microarray CGH, still in its infancy, is a high-throughput and high-resolution method for the detection of microscopic and submicroscopic chromosomal imbalances. Microarrays are small, solid supports, usually glass slides, onto which thousands of different gene sequences are fixed. DNA from tumor cells and normal control cells is tagged with fluorescent molecules and hybridized to the microarray. A "reader" detects the fluorescent tags, and a computer program calculates the red-to-green fluorescence ratio to detect changes in the copy number of DNA sequences.

Cytogenetic Aberrations

Chromosomal aberrations in neoplasia can be grouped according to type. In the first type, no loss of genetic material occurs. Rearrangements of this type include reciprocal translocations and inversions that are known to relocate genes with resultant expression of altered gene products. The second type results in loss or gain of genetic material, and the pathogenic effect depends on which genes are gained or lost. Included in this type are nonreciprocal translocations, deletions, and duplications, as well as loss or gain of whole chromosomes. A third type of aberration results in amplification of genetic material from a specific gene or gene region. This is seen at the chromosome level as double minute chromosomes (small, paired, dot-like acentric chromosomes) or as homogeneously stained regions within a chromosome. Gene amplification, an uncommon aberration, is associated with specific neoplasias and most often correlated with aggressive disease, as, for example, in neuroblastoma.

The karyotype of a tumor may show single or multiple aberrations.[18] Some tumors demonstrate a single anomaly, such as a reciprocal translocation or a gain of an extra chromosome. Other tumors show many aberrations that may include reciprocal or nonreciprocal translocations, deletions, loss, or gain of chromosomes, and so forth. For some types of tumors, a complex karyotype indicates advanced or aggressive disease. The prognostic significance of a karyotype, however, depends on the specific aberrations present. Whereas some tumors have characteristic single anomalies, other tumors have patterns of multiple chromosome aberrations. An example of the former would be the reciprocal t(9;22) in poor-prognosis childhood acute lymphoblastic leukemia (ALL), and the latter example could be the favorable-prognosis hyperdiploid karyotype of childhood ALL that typically shows 53 or more chromosomes and extra copies of specific chromosomes, most commonly X, 4, 6, 10, 14, 17, 18, and 21.[19]

The utility of a cytogenetic analysis of tumor tissue depends on finding the abnormal population of cells that represents the neoplastic process. Cytogenetically, a clone is defined as present when two or more cells with the same chromosomal anomaly are found. A subclone is a second population of cells that contains the original chromosome anomaly and one or more additional anomalies in two or more cells. A subclone indicates clonal evolution and may portend a change to a more aggressive disease state. For instance, chronic-phase CML with the t(9;22) often shows clonal evolution when the disease transforms to the accelerated phase by the gain of an extra der(22) or "Ph" chromosome, trisomy 8, or an isochromosome 17q (Fig. 18-2).

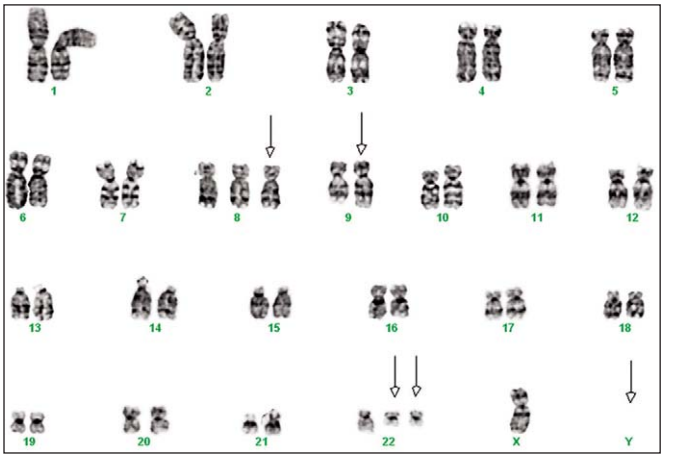

Figure 18-2 • Karyotype of clonal evolution in a male patient with chronic myeloid leukemia in blast crisis. The karyotype is 47,X,–Y,+8, t(9;22)(q34;q11.2),+der(22)t(9;22) (*arrows* to derivative chromosomes 9 and 22, extra chromosome 8, and missing sex chromosome).

Cytogenetic analysis is a valuable tool in the workup of a patient with a neoplastic process. In addition to defining the clonal chromosome abnormality of a tumor at diagnosis, conventional and molecular cytogenetic studies are indispensable for assessing disease status after therapy or transplantation and at disease relapse.

Chromosomal aberrations that provide diagnostic, prognostic, and patient management information are summarized in Tables 18-4, 18-5, and 18-6, and the genes known to be affected by the chromosomal aberrations are listed. Today the majority of these chromosomal aberrations and gene rearrangements can be detected by FISH methods. In some disorders, for example, CML, the genetic abnormality defines the disease process. In others, for example, AML with recurrent cytogenetic abnormalities, the aberrations define distinct entities within a heterogeneous disease. Cytogenetic aberrations within a disease category, for example, glial brain tumors, may provide critical information for therapy selection. No attempt is made in the tables to include all known chromosomal aberrations or their associations; only those with proven diagnostic or clinical significance are shown. Many of these aberrations are discussed in more detail in the discussion of specific tumors elsewhere in this book.

SUMMARY AND FUTURE DIRECTIONS

Cytogenetic analysis of tumor material provides an opportunity to visualize all genetic material in a cell as chromosomes. Almost all neoplasms have shown cytogenetic aberrations, and many of these are disease- and subtype-specific. In addition to providing diagnostic information, clonal chromosomal aberrations provide information vital to therapeutic management.

Cytogenetic information about tumor tissues has been accumulating since the 1960s. Today, cytogenetic studies are used to provide information about a patient's particular disease process, the best way to manage it, and the outcomes that can be expected. Not all tumors yield specific diagnostic or prognostic information, but sufficient valuable information is obtained to warrant cytogenetic study with or without FISH at the time of diagnosis for all childhood hematopoietic disorders and solid tumors, all adult hematopoietic disorders, sarcomas, central nervous system tumors, and select epithelial tumors.

Text continued on p. 262.

Table 18-4 Myeloid Disorders: Cytogenetic Aberrations with Diagnostic or Clinical Significance

Disease Entity	Chromosomal Aberration	FISH Genes Involved	Clinical Significance	References
Acute myelocytic leukemia	t(8;21)(q22;q22)	*RUNX1T1/RUNX1*	Favorable prognosis	Marcucci et al[a]; Schlenk et al[b]
	inv(16)/t(16;16)	*CBFB/MYH11*	Favorable prognosis; increased risk of CNS disease/relapse	Delaunay et al[c]
	t(15;17)(q22;q21)	*PML/RARA* and variants	Favorable prognosis; responsive to ATRA	Arber et al[d]
		ZBTB16/RARA and variants	Variant translocation—poor response to ATRA	Jaffe et al[e]
	t(11q23;v)	*MLL*	Short overall survival	Arber et al[d]; Ravindranath et al[f]
AML-M7	t(1;22)(p13;q13)	*RBM15/MKL1*	Defines infant AML-M7 subgroup	Dastague et al[g]
CEL, HES	del(4q12)	*FIP1L1/PDGFRA*	TKI responsive; *CHIC2* surrogate gene for testing purposes; unresponsive to TKI w/ non-activating *KIT* mutation (D816V)	Pardanani et al[h]; Cortes et al[i]
	Normal karyotype	*CEBPA* mutation	Increased survival; decreased relapse rate	Marcucci et al[j]; Jabbour et al[k]
		NPM1 mutation	Increased survival; must be present without *FLT3*-ITD/mutation	Mrozek et al[l]
		BAALC overexpression	Decreased survival; expression studies from peripheral blood	Jabbour et al[k]; Bloomfield et al[m]
		ERG overexpression	Shorter overall survival; expression studies from blood	Bloomfield et al[m]; Mrozek et al[l]
		FLT3 ITD/mutation	Decreased survival; increased relapse rate; worst prognosis with no or low *FLT3* wild type expression	Kottaridis et al[n]; Mrozek et al[l]
		MLL PTD	Increased relapse rate	Bloomfield et al[m]; Jabbour et al[k]
			Potential TKI responsive	Jabbour et al[k]; Kindler et al[o]
Systemic mastocytosis		*KIT* activating mutation	Less responsive with nonactivating KIT mutation D816V	Pardanani et al[h]; Droogendijk et al[p]
Myelodysplastic syndromes and AML	5q- sole abnormality		Longer survival; 5q- syndrome elderly w/ macrocytic anemia	Germing et al[q]; Giagounidis et al[r]
	–7		Poor outcome; short survival	Greenberg et al[s]; Frohling et al[t]; van der Holt et al[u]
	–5/5q-; –7/7q– together		Poor outcome; often in complex karyotype	Greenberg et al[s]; Frohling et al[t]; Giagounidis et al[r]
	+8 in noncomplex k-type		Intermediate <60 yrs; poor >60 yrs	Frohling et al[t]; Wolman et al[v]
	+11 in noncomplex k-type		Intermediate <60 yrs; poor >60 yrs	Frohling et al[t]
	t/del(11q)	*MLL*	Intermediate to poor prognosis	Greenberg et al[s]; Frohling et al[t]
	inv(3)(q21q26.2), t(3;21)	*RPN1* and *EVI1*	Poor outcome; short survival	Greenberg et al[s]; van der Holt et al[u]
	complex k-type (≥3 abn)		Poor outcome; short survival	Greenberg et al[s]; Chen et al[w]
	20q–, –Y		Good outcome; generally indolent course	Greenberg et al[s]; van der Holt et al[u]
CMML	t(5;12)(q31-q32;p13)	*PDGFRB/ETV6*	TKI responsive	Pardanani et al[h]; Apperley et al[x]
	t(5;17)(q31-q32;p13.2)	*PDGFRB/RABEP1*	TKI responsive	Pardanani et al[h]; Apperley et al[x]
Aplastic anemia	+6		Poor response to immunosuppressive therapy	Ohga et al[y]; Gupta et al[z]
Therapy-related AML/MDS	t(8;21), inv(16), t(15;17)	Same genes as de novo	t(8;21) longer survival than other 21q22 abnormalities	Shali et al[aa]; Schoch et al[bb]
	21q22 abnormalities	*RUNX1*	More common with topoisomerase II inhibitors	Shali et al[aa]
	11q23	*MLL*	More common with topoisomerase II inhibitors	Shali et al[aa]; Schoch et al[bb]; Mauritzon et al[cc]
	3q26.2 abnormalities	*EVI1*	Short overall survival	Shali et al[aa]; Schoch et al[bb]
	Chr 5 and 7 abnormalities		More common with alkylating or radiation therapy	Schoch et al[bb]; Mauritzon et al[cc]
	17p abnormalities	*TP53*	Short overall survival	Schoch et al[bb]

Table 18-5 Lymphoproliferative Disorders: Chromosome Aberrations with Diagnostic or Clinical Significance

Disease Entity	Chromosomal Aberration	FISH Genes Involved	Clinical Significance	References
Acute leukemia				
ALL				
B-precursor	t(9;22)(q34;q11.2)	*BCR/ABL1*	Very high risk disease; response to TKIs	Pui et al[a]; Jones et al[b]; Heerema et al[c]
	t(9;22)(q34;q11.2), –7, 7p–, 9p–	*BCR/ABL1, CDKN2A*	Worst outcome risk with high WBC	Heerema et al[c]
	t(4;11)(q21;q23)	*AF4/MLL*	High risk disease; often found in infants	Hilden et al[d]
	t(11q23) variants	*MLL*	>80% of infants with ALL	Hilden et al[d]
	t(12;21)(p13;q22)	*ETV6/RUNX1*	Low risk disease	Pui et al[e]; Al-Sweedan et al[f]; Stams et al[g]
	t(1;19)(q23;)(p13.3)	*TCF3/PBX1*	Favorable with intensified therapy	Pui et al[h]
	54–65 chr with +4, +10, +17	Chromosome enumeration	Low risk	Sutcliffe et al[i]
	<44 chr	Chromosome enumeration	High risk	Harrison et al[j]; Heerema et al[k]
	Near-haploid 23–29 chr	Chromosome enumeration	Very high risk	Harrison et al[j]; Heerema et al[k]
	Low hypodiploid 33–39 chr	Chromosome enumeration	Very high risk	Harrison et al[j]; Heerema et al[k]; Charrin et al[l]
	Near-tetraploidy	*ETV6/RUNXI*	Favorable; often associated with *ETV6/RUNX1*	Raimondi et al[m]
	der(21):*RUNX1* amplification	*RUNX1*	Unfavorable; older youth	Harewood et al[n]
B-cell	t(8;14)(q24.1;q32.3) or variants	*MYC/IGH@*	Improved outcome with lymphoma therapy	See below
T-cell	t(1p32) or del(1p32)	*TAL1*	Favorable prognosis	Van Grotel et al[o]; Graux et al[p]
	t(5;14)(q35;q32)	*TLX3*	?Favorable	Van Grotel et al[o]; Graux et al[p]; Cave et al[q]
	t(10;14)(q24;q11)	*TLX1*	Favorable	Van Grotel et al[o]; Graux et al[p]
	t(10;11)(p13;q14)	*PICALM/MLLT10*	Unfavorable	Van Grotel et al[o]; Graux et al[p]
	t(11;19)(q23;p13.3)	*MLL/MLLT1*	Favorable prognosis	Rubnitz et al[r]
	del(9p21)	*CDKN2A, CDKN2B*	?Favorable prognosis	Graux et al[s]
	t(9;9)(q34;34), *ABL1* amplification	*NUP214/ABL1*	Response to TKIs	Graux et al[p]
Chronic leukemia				
CLL, B-cell	+12		Intermediate prognosis	Dohner et al[t]; Byrd et al[u]; Dewald et al[v]
	del(13q14) or –13	D13S319 or *RB1* as surrogate FISH markers	Favorable as sole anomaly	Athanasiadou et al[w]
	del(11q21)	*ATM*	Shortened survival	Dohner et al[t]; Byrd et al[u]; Dewald et al[v]
	del(17p13)	*TP53*	Unfavorable	Dohner et al[t]; Byrd et al[u]; Dewald et al[v]
	t(14;19)(q32;q13)	*BCL3*	Often young adults	Michaux et al[x]

Continued

Table 18-5 Lymphoproliferative Disorders: Chromosome Aberrations with Diagnostic or Clinical Significance—cont'd

Disease Entity	Chromosomal Aberration	FISH Genes Involved	Clinical Significance	References
Plasma cell				
Multiple myeloma/ plasma cell leukemia	Hyperdiploid +3, 5, 7, 9, 11, 15, 19		Longer OS and EFS	Smadja et al[y]; Chng et al[z]
	Nonhyperdiploid		Unfavorable; <46, 46, and >81 chromosomes	Smadja et al[y]; Fonseca et al[aa]
	−13 or del(13q14)	*DBM/RB1*	Unfavorable	Chiecchio et al[bb]; Zhan et al[cc]
	del(17p13)	*TP53*	Unfavorable; common in PCL; CNS disease	Schilling et al[dd]
	t(11;14)(q13;q32)	*CCND1/IGH@*	Improved survival with intensive therapy	Fonseca et al[ee]; Soverini et al[ff]
	t(4;14)(p16;q32)	*FGFR3/IGH@*	Unfavorable; most common in PCL	Keats et al[gg]; Fonseca et al[hh]
	t(8;14) & variants	*MYC/IGH@*	Present in ~15% of MM	Avet-Loiseau et al[ii]
	t(14;16)(q32;q24)	*IGH@/MAF*	Unfavorable; most common in PCL	Fonseca et al[hh]
	t(14;20)(q32;q11.2)	*IGH@/MAFB*	Unfavorable	Boersma et al[jj]
Lymphoma				
Mature B-cell				
Follicular	t(14;18)(q32;q21)	*IGH@/BCL2*	Poor prognosis with *MYC* rearrangement	Kanungo et al[kk]
MZBCL MALT	t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21)	*API2/MALT1*, *BCL10/IGH@* *IGH@/MALT1*	Resistant to *Helicobacter pylori* therapy	Farinha et al[ll]
t(11;18) negative MALT	+3, +18, +18q21	3, 18, *MALT1*	Poor outcome, risk to transform to DLBCL	Streubel et al[mm]; Remstein et al[nn]
Mantle cell	t(11;14)(q13;q32)	*CCND1/IGH@*	Distinguish MCL from CLL; FISH best for dx	Bertoni et al[oo]; Belaud-Rotureau[pp]
Burkitt	t(8;14)(q24.1;q32.3)	*MYC/IGH@*	Favorable with aggressive therapy	Bociek et al[qq]; Lones et al[rr]; Dave et al[ss]
	t(8;22)(q24.1;q11.2)	*MYC/IGL@*	Favorable with aggressive therapy	Bociek et al[qq]; Lones et al[rr]
	t(2;8)(p11.2;q24.1)	*MYC/IGK@*	Favorable with aggressive therapy	Bociek et al[qq]; Lones et al[rr]
T-cell	t(14q11), t(7q35)	TCR sites	Most common rearrangements	Jaffe et al[tt]
Anaplastic large cell	t(2;5)(p23;q35) and variants	*ALK/NPM*	*ALK*+ tumors better survival	Jaffe et al[uu]

ALL, acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia; CNS, central nervous system; EFS, event free survival; FISH, fluorescence in situ hybridization; MALT, mucosa-associated lymphoid tissue; MZBCL, marginal zone B-cell lymphoma; OS, overall survival; TCR, T-cell receptor; TKIs, tyrosine kinase inhibitors; WBC, white blood count.

Table 18-6 Solid Tumors: Chromosome Aberrations with Diagnostic or Clinical Significance—cont'd

Disease Entity	Chromosomal Aberration	FISH Genes Involved	Clinical Significance	References
t(Xp11.2) RCC	t(X;1)(p11.2;q21.2)	*PRCC/TFE3*	Characterize pediatric papillary RCC	Ramphal et al[c]
	t(X;17)(p11.2;q25)	*ASPLCR1/TFE3*	Balanced translocation in RCC	Ramphal et al[c]
	t(X;17)(p11.2;q23)	*CLTC/TFE3*	Characterize pediatric papillary RCC	Ramphal et al[c]
	t(X;1)(p11.2;p34)	*PSF/TFE3*	Characterize pediatric papillary RCC	Ramphal et al[c]
t(6;11) RCC	t(6;11)(p21;q12)	*ALPHA/TFEB*	Subset of RCC, children, young adult	Argani et al[d]
Chromophobe RCC	Loss 1, 2, 6, 10, 13, 17, 21	Chromosome enumeration	Distinguish from oncocytoma	Hes et al[e]
Oncocytoma	1p–, t(11q13)	1p, *CCND1*	Distinguish from chromophobe	Jhang et al[f]
Rhabdoid	–22/22q–	*SMARCB1; BCR* as surrogate	Diagnostic	Biegel et al[g]
CMN	t(12;15)(p12;q25), +11, +17, +20	*ETV6/NTRK3*	Diagnostic	Sandberg et al[h]
Bladder, papillary	del(9)(p21)	*CDKN2A*	Homozygous deletion higher grade, stage	Wolff et al[i]
	8p–	8p, unknown gene	Higher recurrence rate, progression	Wolff et al[i]
	+7, +17	*FGFR3, TP53, MYC*	Genetic instability	Wolff et al[i]
Wilms' tumor	16q–, +1q, 1p–, –22, 17p–	1p, 1q, 16q, 17p, 22, *WT1*	Unfavorable histology; augmented chemotherapy if 1p–, 16q–	Perlman[j]
Prostate	+7q31, 8p22–, +8q24, 17p13–	7, *LPL, MYC, TP53*	High frequency in carcinoma	Qian et al[k]; Bastacky et al[l]
	17p13–, +8q24	*TP53, MYC*	Progression, higher Gleason score	Qian et al[k]
	10q–	*PTEN*	High grade PIN or carcinoma	Yoshimoto et al[m]
Gastrointestinal				
GIST	–14/14q–, –22/22q–	14, 22, *KIT* mutations	Distinguish from smooth muscle tumors	Sandberg et al[n]; Miettinsen et al[o]
			Response to TKIs	
Liver				
Hepatoblastoma	+20, +2, +8, t(1q12-q21)	Chr 2, 8, 20, 1q	Distinguish from HCC, HMH	Tomlinson et al[p]
HMH	t(11;19)(q13;q13.4), t(19q13.4)	19q	Distinguish from hemangioma or malignant tumor	Rakheja et al[q]
Salivary gland				
Pleomorphic adenoma	t(3;8)(p21;q12)	*PLAG1*	Diagnostic benign	Martins et al[r]
Mucoepidermoid cancer	t(11;19)(q21;p13)	*MECT1/MAML2*	Diagnostic malignant	Enlund et al[s]
Warthin's tumor	t(11;19)(q21;p13)	*MECT1/MAML2*	Benign tumor	Enlund et al[s]
Breast				
Invasive intraductal	dmin, hsr	*ERBB2* amp	Worst prognosis, response to TKIs, Mab	Tanner et al[t]; Geyer et al[u]
		ERRB2, TOP2A co-amp	Co-amplification, better response to FEC	Tanner et al[t]
Secretory breast	t(12;15)(p13;q25)	*ETV6/NTRK3*	Favorable; distinguish from IDC	Makretsov et al[v]
CNS				
Astrocytic tumors	+7, –10/10q–	*EGFR, PTEN*	Short survival, aggressive course	Fuller et al[w]
	9p21–	*CDKN2A*	Sensitive to antimetabolite therapy	Fuller et al[w]
	19q–	19q	Long-term survival	Fuller et al[w]

Table 18-6 Solid Tumors: Chromosome Aberrations with Diagnostic or Clinical Significance—cont'd

Disease Entity	Chromosomal Aberration	FISH Genes Involved	Clinical Significance	References
Glioblastoma	+7, 10q–, 9p–	*PTEN*, *EGFR*, *CDKN2A*	Short survival assoc w/ 10q-/*PTEN* loss	Ohgaki et al[x]
Oligodendroglial tumors				
Anaplastic	1p–, 19q–, der(1;19)(q10;p10)	1p36, 19q13.3	Longer survival, sensitive to therapy	Eoli et al[y]; Brandes et al[z]; Griffin et al[aa]
Mixed oligoastrocytoma	+7, –10/10q–, 15q–	*EGFR, PTEN*	High grade, progression	Koschny et al[bb]
Oligoastrocytoma	19q–	19q13.3	Favorable outcome	Fuller et al[w]
	1p–	1p36	Favorable outcome	Eoli et al[y]
Ependymoma				
Spinal	+7, –22q, 14q–	7, 14, 22q, *NF2*	Distinguish subtype	Mendrzyk et al[cc]
Intracranial	+1q, 6q–, +7, 9p–	1q25, p16, *EGFR*, *CDKN2A*	Pediatric, high risk	
Medulloblastoma	i(17q), 17p–, –10/10q–, +7	*MYCN, MYC*	Large cell/anaplastic morphology	Pan et al[dd]; Lamont et al[ee]; Gajjar et al[ff]
		ERBB2	High risk	
Supratentorial PNET	+1q, 16q–, 19p–	1q, 19p	Lacks i(17q), poor prognosis	Inda et al[gg]
AT/RT	–22 or del(22q11.23)	*SMARCB1; BCR* as surrogate	Distinguish from MB, PNET, CPC	Judkins et al[hh]; Biegel[ii]
Meningioma	–22 or del(22q11.2)	22q, *NF2*	Primary abnormality	Fuller et al[w]
	1p–, –14/14q–	1p, *IGH@*	Increased risk of recurrence, anaplastic	Espinosa et al[jj]
Choroid plexus tumors				
Carcinoma	Loss 2, 3, 4, 5, 6, 8, 10, 11, 13, 14, 15, 16, 17, 18, 19, 22	Chromosome enumeration	Distinguish from papilloma	Rickert et al[kk]; Bhattacharjee et al[ll]
Papilloma	Gain 7, 8, 9, 12, 14, 15, 17, 18, 19, 20	Chromosome enumeration	Distinguish from carcinoma	Rickert et al[kk]; Bhattacharjee et al[ll]
Small round cell tumors				
Alveolar RMS	t(2;13)(q37;q14)	*PAX3/FOXO1A*	Older youth, poorer outcome	Sorenson et al[mm]
	t(1;13)(p36;q14)	*PAX7/FOXO1A*	Younger, extremity location	Sorenson et al[mm]
	t(X;2)(q13;q35), t(2;2)(q35;p23)	*PAX3/AFX, PAX3/NCOA1*	Variant translocations	Nishio et al[nn]
		IGF1R amp	Disease progression	Bridge et al[oo]
Embryonal RMS	Gain 2, 7, 8, 11, 12, 13, 20	Chromosome enumeration	Distinguish from alveolar subtype	Bridge et al[oo]
	Loss 1p, 3p, 9q, 10q, 16q, 17p, 22	*IGF1R* amp	Gene amplification with anaplasia	Bridge et al[oo]
Neuroblastoma	del(1p), del(11q) w/o *MYCN* amp	1p, 11q, *MYCN*	Unfavorable in Stage I, II, IVS	Attiyeh et al[pp]; Spitz et al[qq]; Maris et al[rr]
	del(1p), +17q, *MYCN* amp	1p, 17q, *MYCN*	Unfavorable all stages	Janoueix-Lerosey et al[ss]; Spitz et al[qq]
	triploidy w/o above abn	Chromosome enumeration	Favorable	Maris et al[rr]
EWS/pPNET	t(11;22)(q24;q12) & variants	*FLI1/EWSR1*	Diagnostic, distinguish from other SRCTs	Bernstein et al[tt]
	t(21;22)(q22;q12)	*ERG/EWSR1*		Bernstein et al[tt]
	del(9p), 17p–, der(1;16)(q10;p10)	*CDKN2A, TP53*	Unfavorable prognostic factor	Bernstein et al[tt]

Continued

Table 18-6 Solid Tumors: Chromosome Aberrations with Diagnostic or Clinical Significance—cont'd

Disease Entity	Chromosomal Aberration	FISH Genes Involved	Clinical Significance	References
DSRCT	t(11;22)(p13;q12)	*WT1/EWSR1*	Distinguish from other SRCTs	Chang et al[uu]; Sandberg et al[vv]
Clear cell sarcoma	t(12;22)(q13;q12)	*ATF1/EWSR1*	Absent in cutaneous MM	Patel et al[ww]; Sandberg et al[xx]
Retinoblastoma	del(13q14), gain 1q, 6p	*RB1, DEK, E2F3*	Hallmark of retinoblastoma	Grasemann et al[yy]
Lymphomas	specific translocations		Distinguish from other SRCTs	See Table 18-5
Bone, soft tissue				
CFS/CMN	t(12;15)(p12;q25), +11, +17, +20	*ETV6/NTRK3*	Distinguish CFS from fibrosarcoma	Sandberg et al[h]
Synovial sarcoma	t(X;18)(p11.2;q11.2)	*SSX1/SS18*	Biphasic—most SYT/SSX1, unfavorable	Terry et al[zz]; Surace et al[aaa]
		SSX2/SS18	Monophasic-SYT/SSX1 or SYT/SSX2	Sandberg et al[bbb]; Ladanyi et al[ccc]
Lipoma	t(3;12)(q27–28;q14–15), variants	*HMGA2/LPP*	Distinguish from LPS	Sandberg[ddd]
Liposarcoma				
Myxoid, round cell	t(12;16)(q13;p11)	*FUS/DDIT3*	Diagnostic for myxoid LPS	Sandberg[eee]
Myxoid	t(12;22)(q13;q12) variant	*DDIT3/EWSR1*	Variant of t(12;16)	Sandberg[eee]
Well-differentiated	rings, markers, dmin	*MDM2, CDK4* amplification	Distinguish from lipoma	Sandberg[eee]
Leiomyoma	t(12;14)(q15;q24)	*HMGA2*	Distinguish from leiomyosarcoma	Sandberg[fff]; Sandberg[ggg]
ASPS	der(17)t(X;17)(p11.2;q25)	*ASPLCR1/TFE3*	Unbalanced translocation specific for ASPS	Sandberg et al[hhh]; Huang et al[iii]
EMC	t(9;22)(q22;q12)	*NR4A3/EWSR1*	Diagnostic, tumor specific	Sandberg et al[jjj]; Sandberg[kkk]
	t(9;17)(q22;q11.2)	*NR4A3/TAF15*	Variant translocation	Sandberg et al[jjj]; Sandberg[kkk]
	t(9;15)(q22;q21)	*NR4A3/TCF12*	Variant translocation	Sandberg et al[jjj]; Sandberg[kkk]
Dermal tumors				
DFSP	der(22)t(17;22)(q22;q13.1) or r(22)t(17;22)	*COL1A1/PDGFB*	Distinguish from atypical DF, MFH Response to TKIs	McArthur et al[lll]; Kaur et al[mmm] Sirvent et al[nnn]
GCF	t(17;22)(q22;q13.1)	*COL1A1/PDGFB*	Similar to DFSP	Sirvent et al[nnn]
Bednar tumor	der(22)t(17;22)(q22;q13.1) or r(22)t(17;22)	*COL1A1/PDGFB*	Similar to DFSP	Sirvent et al[nnn]
Hidradenoma	t(11;19)(q21;p13)	*MECT1/MAML2*	Same as Warthin's tumor	Behboudi et al[ooo]
Lung tumors				
NSCLC	3p-, +7, *EGFR* high copy number or amplification	*EGFR*	Response to TKIs	Cappuzzo et al[ppp]
Germ cell tumor				
Dysgerminoma, ovary	i(12p), 12p overrepresentation	12p	Distinguish from non-GCTs	Cossu-Rocca et al[qqq]
TGCTs, seminoma, NS	i(12p), 12p amplification	12p	Most common aberration, invasive disease	Zafarana et al[rrr]

ASPS, alveolar soft part sarcoma; AT/RT, atypical teratoid/rhabdoid tumor; CFS, congenital fibrosarcoma; CMN, congenital mesoblastic nephroma; CPC, choroid plexus carcinoma; DF, dermatofibroma; DFSP, dermatofibrosarcoma protuberans; DSRCT, desmoplastic small round cell tumor; EMC, extraskeletal myxoid chondrosarcoma; EWS, Ewing's sarcoma; FEC, fluorouracil, epirubicin, cyclophosphamide; GCF, giant cell fibroblastoma; GIST, gastrointestinal stromal tumor; HCC, hepatocellular carcinoma; HMH, hepatic mesenchymal hamartoma; IDC, intraductal carcinoma; Mab, monoclonal antibody; MFH, malignant fibrohistiocytoma; MM, malignant melanoma; NS, nonseminoma; NSCLC, non-small-cell lung cancer; PIN, prostate intraepithelial neoplasia; PNET, primitive neuroectodermal tumor; pPNET, peripheral primitive neuroectodermal tumor; RCC, renal cell carcinoma; RMS, rhabdomyosarcoma; TGCTs, testicular germ cell tumors; TKIs, tyrosine kinase inhibitors.

As technology and knowledge advance, cytogenetic laboratories will continue to provide the basic genetic picture of disease states using conventional cytogenetic analysis. FISH will play an expanding role in the diagnosis and management of neoplasias—for example by detection of molecular targets for therapeutic agents. FISH methods are evolving to accommodate tumor materials prepared, preserved, or stored in multiple ways. FISH commonly is used now to anchor a diagnosis or provide prognostic information, and is used as a post-therapy evaluation tool for residual disease for some tumors. Because FISH offers a more sensitive and specific method for residual disease detection than do histopathologic parameters,[20] it is likely to see increasing use for this purpose in the future. Combining FISH with other methods such as flow cytometry can provide an even better assessment of therapeutic response[21] As genomic information continues to be generated, new FISH probes and strategies will be developed to meet diagnostic needs. CGH, SKY, and M-FISH will continue to play a role in elucidation of genetic aberrations, and microarray-based CGH in particular appears to hold exciting potential for moving the field of molecular cytogenetics forward.

19 Molecular Diagnostics

Jeffrey A. Kant

SUMMARY OF KEY POINTS

Key Methods

- Polymerase chain reaction (PCR) amplification is a component of most molecular diagnostic applications.
- Automated and quantitative methods now exist that improve reproducibility and clinical application.
- Direct sequencing methods for acquired and germline mutations have a focused role.
- Interrogation and integration of data from multiple molecular targets is becoming more common.

Applications

Hematologic Malignancies

- Clonality is demonstrated using immunoglobulin and T-cell–receptor gene rearrangement assays.
- Tumor burden is quantitatively assessed targeting translocations that define many leukemias or lymphomas.
- *JAK2* V617F is used as a molecular marker for chronic myeloproliferative diseases.
- Identify markers are used in transplantation to match human leukocyte antigens and to assess engraftment and chimerism

Solid Tumors

- Identification of specific mutations facilitates diagnosis and management of de novo and hereditary cancers.
- Many soft tissue tumors can be diagnosed and classified based on specific translocations (see Chapter 97).
- Assays that indicate genetic instability have selected utility.

Assays in Development

- Profiles of gene or micro-RNA expression will play an increasing role in diagnosis and patient management.
- DNA methylation assays show promise for early diagnosis and classification of cancers.
- Pharmacogenetic assays will be coupled to existing and new drugs to optimize dosing.

INTRODUCTION

Characteristic markers involved in the molecular pathogenesis of cancer have been described with increasing regularity over the last three decades. "Molecular diagnostics" in the context of cancer generally refers to the analysis of nucleic acid (DNA or RNA) in patient samples to detect markers for purposes of diagnosis or prognosis. Most of these markers are acquired during cancer development and restricted to neoplastic cells. A subgroup of germline mutations found in all body cells that predispose to cancer at different ages is significant for the management and counseling of individuals and family members.

Sensitive detection technologies facilitate the use of molecular markers to track residual cancer, thus assisting with monitoring and adjusting therapy. Molecular tools can detect agents of etiologic interest (e.g., human T-cell leukemia virus, human herpesvirus) and also assist with the selection of therapeutic cell products (e.g., high-resolution histocompatibility typing for bone marrow transplantation). After transplantation, molecular methods are used to assess engraftment. The evolving potential of molecular diagnostic assays to yield information allowing individually tailored drug selection and dosage is commonly referred to as "personalized medicine." Because the functional manifestations of most nucleic acid changes are mediated through proteins produced (or not produced) from affected genes, the term *molecular diagnostics* also is used occasionally in the context of applications that involve the analysis of proteins (i.e., proteomics; see Chapter 20).

This chapter focuses on nucleic acid-based applications for which clinical validity and utility has been established. Molecular cytogenetic applications, including fluorescent in situ hybridization (FISH) and array comparative genome hybridization (CGH), are discussed in Chapter 19. Selective background is offered for a number of promising future molecular diagnostic applications currently under study. Clinicians in the United States should keep in mind that assays that yield information on which patient management is based must be performed in Clinical Laboratory Improvement Act (CLIA)-licensed laboratories.

METHODS

Specimens

Assays begin with extraction of target nucleic acid from a sample. Nucleic acid typically is obtained from the nucleus or cytoplasm of disrupted cells but may be derived from cell-free portions of the sample and even serum or plasma. Because nucleated cells are the primary source of DNA, paucicellular samples of bone marrow and blood or tumors following therapy may not reflect the state of a diagnostic sample. After taking tissue for histopathologic examination or other studies, it is crucial, if possible, to set aside a portion of the "diagnostic" specimen for nucleic acid preparation or storage, on which assays can be performed subsequently if desired. Blood, bone marrow, and body fluid samples must be anticoagulated adequately, because appreciable numbers of nucleated cells are lost in

Table 19-1 Sample Handling Tips for Molecular Diagnostic Testing

DO

- Submit samples for testing or nucleic acid preparation/storage at initial diagnosis, not only following therapy
- Send samples quickly to the clinical laboratory for processing
- Use EDTA or citrate-based anticoagulants for blood or bone marrow specimens; avoid heparin if possible
- Request re-analysis and comparison of material from prior diagnostic specimens against follow-up samples if you wish to evaluate possible clonal evolution.

DON'T

- Place an entire tissue sample or bone marrow sample in fixative unless necessary for pathologic examination; process the remaining portion appropriately.
- Freeze peripheral blood or bone marrow specimens for storage; refrigerate or place in satisfactory preservative.

clots. Ethylenediaminetetraacetic acid (EDTA) or citrate is preferable to heparin as an anticoagulant because heparin may bind nucleic acids or other reagents and potentially interfere with molecular assays. (Washing heparinized samples can help.) Heparin is the anticoagulant of choice for cytogenetic analysis, so it often is desirable to obtain two samples or split a sample when both assays are performed (Table 19-1). Tissue (at least 100–200 mg) can be frozen at −80°C or in liquid nitrogen and processed subsequently for nucleic acid or protein. DNA (and RNA) can be obtained from archival paraffin-embedded specimens, but typically there is appreciable fragmentation and/or degradation, and the preferred sample for molecular diagnostic analysis is a fresh sample. Assessment of molecular markers in cell-free samples (plasma or serum) has been demonstrated and may offer advantages; tumor-associated DNA and RNA presumably reside in cell-free domains protected from degradation.[1–4] Enrichment of tumor tissue from paraffin sections via manual or laser capture microdissection is increasingly useful in evaluating solid tumors.[5,6]

Samples should be submitted to the laboratory in a timely fashion, particularly if RNA is to be assayed. Collection tubes are available to immediately stabilize collected samples, although weekend blood or bone marrow samples from which nucleic acid is extracted often perform satisfactorily after several days at refrigerator (not freezer) temperatures. Usually, 4 to 6 μg of DNA is obtained per 1 million nucleated cells, so nucleic acid yield is problematic only in hypocellular samples, such as those derived from cerebrospinal fluid or bone marrow after treatment. In such cases, DNA may be insufficient to perform certain assays (e.g., Southern blotting).

Polymerase Chain Reaction

Polymerase chain reaction (PCR)[7] underlies the vast majority of molecular diagnostic assays. Isolated double-stranded DNA first is denatured to single strands, to which short single-stranded DNA oligonucleotide primers are bound, flanking the region of interest. Enzymatic extension from the primer copies the targeted region on each strand, effectively producing twice the amount of original nucleic acid target. Repeated cycles of denaturation, annealing, and extension amplify the targeted region many million-fold and facilitate the analysis of samples with low levels of target nucleic acid. One to as many as 10 to 15 assays generally can be performed for each microgram of DNA obtained.

For sensitive qualitative detection of unique DNA or RNA constructs such as chromosomal translocations, *nested PCR* can be per-

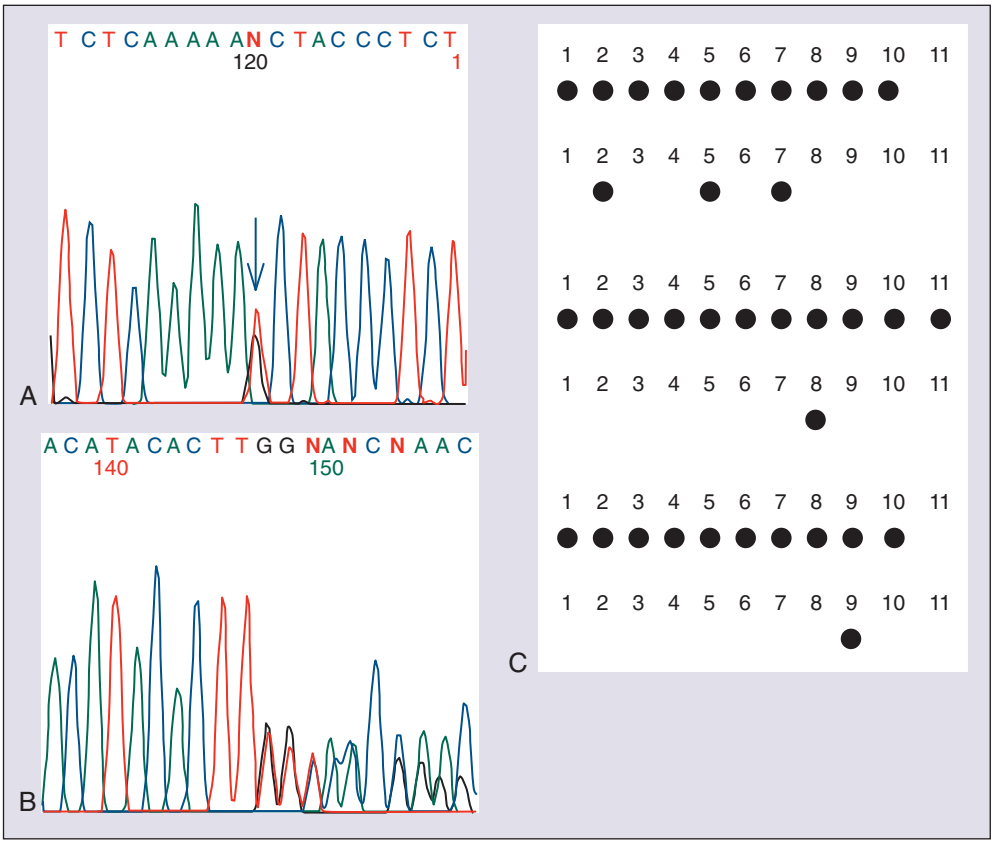

Figure 19-1 • Direct mutation detection. Forward-strand DNA sequences are shown for missense (p.Ile127Ser) **(A)** and frameshift (c.153_154insT) **(B)** mutations in the *SDHB* gene. **C,** Allele-specific hybridization for, *top* to *bottom, BRCA1* (185delAG, 5282insC) and *BRCA2* (6174delT) mutations. Specific probes for normal (WT) and mutant sequence are used on samples amplified together for BRCA1 exons 2 (*top*) and 20 (*middle*) and BRCA2 exon 11 (*bottom*). Patient samples tested in duplicate are 1,4, 2,5, 3,6. Heterozygous controls are samples 7, 8, 9. Sample 10 is a normal control. Sample 11 is a minus-DNA control (except 5382, where it is another normal control).

formed, in which an aliquot of the initial PCR reaction undergoes a second PCR series using a new primer set targeting sequences on both sides of the target but internal to the initial flanking primers. Nested PCR offers sensitivity with increased risks of contamination; increasingly, PCR is done on "real-time" platforms, which offer broad linear ranges and provide quantitative or qualitative results.[8,9] PCR assays can amplify DNA regions up to several kilobases. "Long distance" PCR,[10,11] which amplifies larger regions of DNA, is appealing for some applications but is not in widespread clinical use.

For PCR assays in which RNA is the starting material (RT-PCR), RNA first is incubated with the enzyme reverse transcriptase (RT) in the presence of either general or sequence-specific oligonucleotide primers. RT makes a DNA copy strand (cDNA) from the RNA template. The cDNA products then are subjected to standard PCR amplification.

DNA Sequencing

DNA sequencing typically is performed from primary PCR products.[12,13] Oligonucleotide primers bound to the "ends" of forward and reverse strands of PCR fragments are copied into single strands of varying lengths, allowing the DNA sequence to be read directly from capillary or gel-based laser systems (Fig. 19-1). This is accomplished by using a mixture of normal and fluorescently labeled dideoxynucleotides with termination of the copying reaction each time a dideoxynucleotide is inserted. Pyrosequencing, by contrast, determines DNA sequence over short stretches of nucleotides by measuring the amount of pyrophosphate generated after sequential addition of differing nucleotides.[14–16] Pyrosequencing in nanoliter chambers followed by software assembly of overlapping short sequences is the technical basis for high throughput sequencers capable of determining millions of nucleotides.[17]

Southern Blotting

Southern blotting is a venerable but increasingly less-used technique for assessing clonality or chromosomal translocations in hematologic or solid tumors (Fig. 19-2).[18] Restriction endonuclease-digested fragments of total sample DNA are separated in gels by size, then replica-transferred in denatured single-stranded form to a reinforced membrane where those fragments binding a labeled complementary probe can be visualized. Physical restructuring of a chromosomal region by translocation or physiologic elimination of DNA segments from immunoglobulin and T-cell receptor genes during lymphocyte development creates restriction fragments of new lengths characteristic of clonal cells that have expanded to form the cancer.

Southern blot assays have a number of disadvantages. They require moderate amounts of nucleic acid, typically several micrograms per lane evaluated. Southern blots also are labor-intensive, technically demanding, and typically take 5 to 7 days to deliver an answer.

Other DNA Assays

Numerous di-, tri-, and tetranucleotide sequences, known as *simple tandem repeats* (*STRs*) or *microsatellites* throughout the genome, demonstrate polymorphisms of varying lengths on maternally and paternally inherited alleles. Such markers are useful in segregation (or linkage) analysis to follow at-risk chromosomes passed within families, in the assessment of bone marrow engraftment, and in the comparison of the relative abundance of STRs in tumor and normal tissues to determine allelic loss (loss of heterozygosity [LOH]). The human genome also features large numbers of single-nucleotide polymorphisms (SNPs) that can be used to assess allelic loss as well as gain or loss of chromosomal regions.

Microarray "chips" composed of high-density assemblies of oligonucleotides or cDNA probes on glass or silica surfaces can be used to assess the array of transcripts or SNPs in normal or tumor DNA.[19,20] A particularly powerful application of chips is *expression profiling* of tumors to provide a relative assessment of RNA transcript levels from many genes in a tumor population. Powerful software analysis programs assemble such data into patterns that indicate the origin or behavioral profile of a tumor.[21,22]

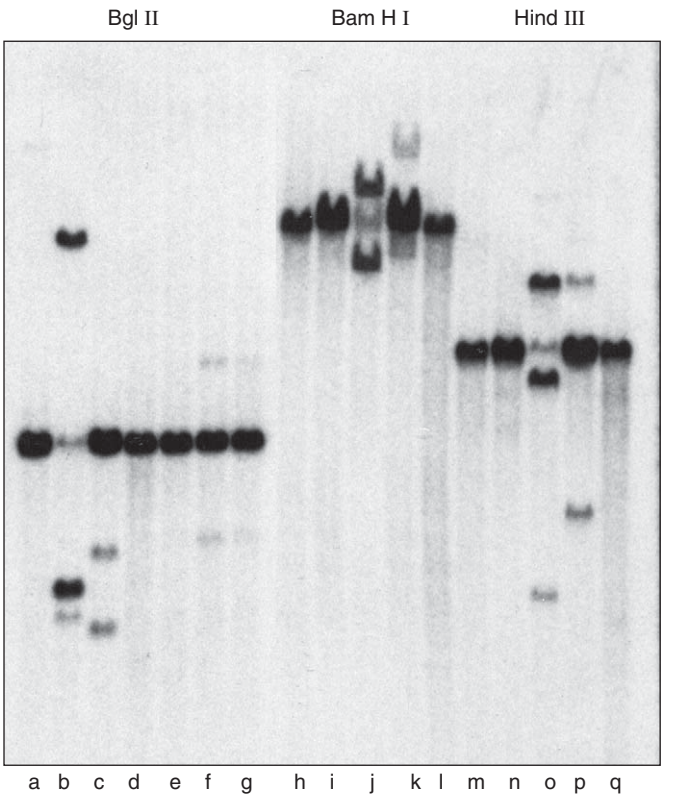

Figure 19-2 • Immunoglobulin heavy-chain gene assessment by Southern blot. Typical three-restriction enzyme analysis (using enzymes Bgl II, Bam HI, and Hind III) of five patient specimens (patient 1: lanes a, h, m; patient 2: lanes b, j, o; patient 3: lanes c, k, p; patient 4: lanes d, i, n; patient 5: lanes e, l, q). Note the different order of patients for Bgl II versus the other enzymes. A single germline band is seen in all enzyme digests for the normal control (patient 1). Lanes f and g are mixtures of 10% and 4% B-cell lymphoma DNA in normal DNA (note faint rearranged alleles above and below the germline band on the Bgl II digest); these serve as positive and sensitivity controls. Two rearranged alleles for both immunoglobulin heavy-chain genes are seen in patient samples 2 and 3. Patient 2 demonstrates an additional faint band, with enzymes Bgl II and Hind III supporting clonal evolution. Note also the reduced intensity of the germline allele for patient 2, indicating that this sample contains a high fraction of neoplastic cells. Patients 4 and 5 are normal for all enzyme digests.

APPLICATIONS

Clinical applications exist for (1) hematolymphoid neoplasms for which a large variety of molecular tests have evolved over two decades and (2) selected solid tumors. While molecular diagnostic assays that drive management of patients with solid tumors are still limited, with improved understanding of pathogenesis and related development of new therapies, they will be a major area of future growth.

Most molecular oncology assays are methods developed in individual laboratories. External proficiency surveys are available for some hematolymphoid and solid tumor assays, but standardization is limited. This lack of standardization results from a combination of factors, including low test volumes and limited incentive for commercial development, the tendency of academic laboratories to be early developers of new testing, and the fact that it is cheaper to perform laboratory-developed assays even when commercial assays are available.

Hematolymphoid Neoplasms

Molecular assays for hematolymphoid neoplasms are useful if the information provided by histology or immunophenotypic assessment is insufficient for diagnosis.[23] If the plan is to use a molecular marker to monitor disease following treatment, it is useful to confirm that that marker is present in diagnostic material, or store sample nucleic acid for future analysis. Molecular assay results typically are best evaluated in the broader context of clinical, histologic, immunophenotypic, and other information to arrive at the best picture of a patient's disease. Typically, this is done by a hematopathologist. Properly chosen assays can help in both the diagnosis and classification of neoplasms. *Clonality assays,* which are first-line tests for suspected hematolymphoid neoplasms, are directed at populations that demonstrate immunoglobulin heavy chain (IgH) or T-cell receptor (TcR) gene rearrangement or a specific chromosomal translocation.[24]

Gene Rearrangement Assays

Gene rearrangement assays look for a significant clonal B- or T-lymphoid population. Each tumor cell contains the same rearranged IgH or TcR gene, and Southern or PCR-based assays can detect down to 1% to 5% tumor cells. IgH gene rearrangement typically is assessed first for B cells, because this gene undergoes initial rearrangement during B lymphoid development. Light chain genes, particularly the kappa gene, also may be assessed. T-cell receptor beta or gamma chain genes commonly are examined for T-lymphoid cells. Southern blot testing is more common for beta genes, although PCR assays exist for both. Clinical assays for rearrangement of lambda light chain, T-cell receptor alpha, or T-cell receptor delta chain genes are uncommon.

Although Southern blot analysis is performed by a steadily diminishing number of laboratories, it is still the gold standard for B and T cell clonal assessment. In this technique, a labeled probe that recognizes the IgH or TcR gene is hybridized to restriction-endonuclease digested sample DNA. New hybridizing bands of different size indicate clones with rearranged IgH or TcR alleles (see Fig. 19-2). Rearrangement seen with two (or more) restriction enzymes for the sample is scored as positive.[25] Clonal evolution within a neoplasm sometimes may be observed as new hybridizing bands in the presence of previously demonstrated ones (see Fig. 19-2).

Increasingly, PCR assays alone (Fig. 19-3) are performed to look for clonal rearrangements of immunoglobulin and TcR genes. Rela-

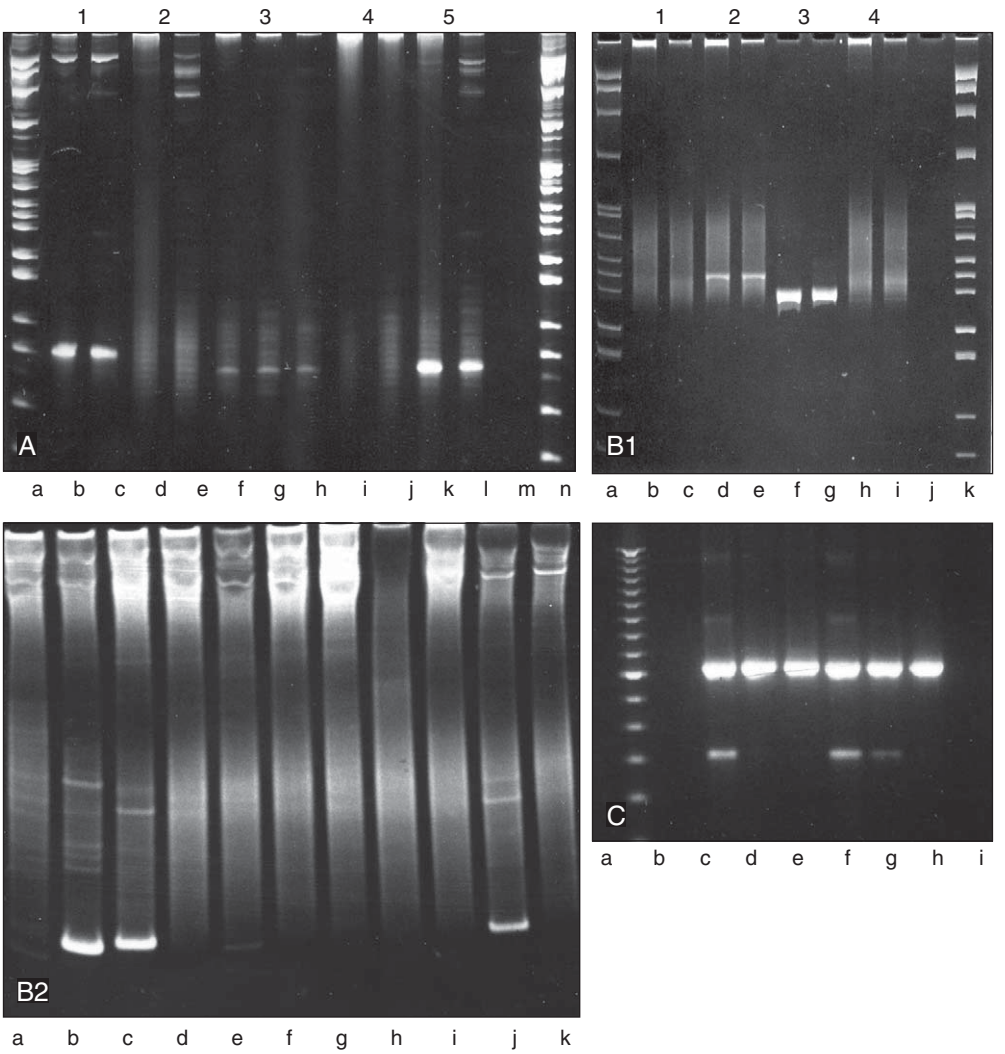

Figure 19-3 • Polymerase chain reaction (PCR) and reverse transcriptase (RT-PCR) analysis in hematolymphoid neoplasia. **A,** Immunoglobulin heavy chain gene PCR analysis. Testing is done at two or more different DNA concentrations for each of five patients. Lanes a and n are molecular size standards; lane m is a minus-DNA control to rule out potential PCR contamination. Patients 4 and 5 are known reactive (polyclonal) and lymphoma (monoclonal) samples, respectively. Patient 1 has a monoclonal process involving most cells in the specimen; patient 2 has a polyclonal process, and patient 3 has a subtle monoclonal process in a polyclonal background. **B1,** T-cell receptor gamma chain gene PCR analysis, straight electrophoresis. Patients 3 and 4 are known lymphoma and reactive samples. Patient 1 is polyclonal; patient 2 has a monoclonal process in a polyclonal background. **B2,** T-cell receptor gamma chain gene PCR analysis, homoduplex analysis. Samples are denatured following PCR amplification, allowed to renature and run on a polyacrylamide gel. Homoduplex bands at the "leading edge" of migration represent clearcut clonal specimens (lanes b,c); samples with polyclonal T-cell populations do not show distinct bands (lanes a,d,f,g,h,i). Lanes j (10% clonal + 90% polyclonal DNA) and k (100% polyclonal) are controls. A low-predominance clonal population in sample E is of uncertain clinical significance. **C,** Allele-specific amplification for *JAK2* V617F mutation. A common 3′ primer and two 5′ primers are used in a multiplex reaction; one primer amplifies all species in this area of the *JAK2* gene *(upper band),* whereas the other amplifies only species with the V617F nucleotide variant. Lane a is a molecular size ladder; lane b is empty; lanes c and f are positive patient samples; lanes d and e are negative patient samples; lane g is positive and sensitivity control with 2% JAK2 V617F in normal DNA; lane h is a normal patient; and lane i is a minus DNA control. *Note:* Size separations are shown on gels; capillary electrophoresis is an alternate analysis method.

tively conserved "framework" areas of variable (V) region gene segments serve as targets for upstream PCR primers; similarly conserved regions in joining (J) or adjacent sequences are targeted by downstream primers. Advances in PCR assay detection sensitivity and standardization have accompanied the European BIOMED-2 study, which developed and tested multiplexed groups of PCR primers that together detect the large majority of immunoglobulin and TcR gene rearrangements.[26] At this time, BIOMED-2 reagents are available in the United States only labeled as "research use only, not for use in diagnostic procedures."

The sensitivity of PCR assays typically is no more than 85% to 95% of those achieved with Southern blot.[26,27] Hematolymphoid neoplasms negative by PCR arise, presumably because PCR primers do not bind equally well to all V or J region gene segments that may participate in clonal rearrangement. The analytic sensitivity of PCR assays usually is modestly better and, in some specialized applications, markedly better than Southern assays. Samples can be analyzed rapidly if desired, and the low levels of DNA required for testing expand the range of evaluable samples, including, importantly, paraffin-embedded specimens. Immunoglobulin and T-cell receptor genes typically are tested for suspected B and T lymphoid proliferations, respectively. Immunoglobulin heavy chain gene-negative cases may show rearrangement of light chain genes or kappa-deleting elements.[26,27]

Low-level "clones" detected by PCR and Southern blot assays must be interpreted cautiously. These may represent low levels of neoplastic disease, but they also may be expansions of normal B or T cells responding to discrete antigens or other stimuli. The polyclonal ladder pattern seen in IgH PCR assays (see Fig. 19-3) is an example of this phenomenon. It is important to interpret low-predominance clonal populations in the broader context of a case. Conditions that enhance immune reactivity such as autoimmune disease may provide particular challenges. Important interpretive elements of clonality assays, and especially PCR assays, are given in Table 19-2.

Chromosomal Translocations

Molecular detection of a translocation confirms diagnosis and provides a sensitive marker for monitoring tumor burden. Molecular cytogenetic assays, such as FISH, usually are appropriate substitutes for DNA- or RNA-based assays to identify translocations in diagnostic samples. However, the ability of PCR methods to detect very low levels of tumor or minimal residual disease (MRD), makes molecular assays the standard of practice for monitoring disease (Table 19-3; Fig. 19-4). Either blood or bone marrow usually can be followed; bone marrow may have slight advantages.[28] Nested PCR/RT-PCR methods offer high detection sensitivity, but as endpoint assays cannot accurately determine levels of tumor. Most MRD assays employ real-time quantitative PCR or RT-PCR to follow the level of translocation relative to a reference transcript or gene found uni-

Table 19-2 Interpretive Cautions for Clinicians Ordering Hematolymphoid Clonality Assays

- Negative PCR results for IgH and TcR gene rearrangement or chromosomal translocation assays do not fully exclude the possibility of neoplasia, because the assay may not detect all rearrangements or translocations.
- If results are negative and a case is suggestive of neoplasia, make sure that laboratory reports indicate controls have been performed to exclude inhibitors of PCR amplification.
- Results described as "oligoclonal" or "indeterminate" for IgH or TcR gene rearrangement PCR assays should be interpreted conservatively. These may reflect self-limited reactive expansions of lymphocytes.
- Ultrasensitive qualitative "nested" PCR or RT-PCR assays for certain chromosomal translocations (e.g., BCL2/IgH, BCR/ABL) may be positive in normal individuals. It is uncommon to see such false-positive results using quantitative assays.

IgH, immunoglobulin heavy chain; PCR, polymerase chain reaction; RT, reverse transcriptase; TcR, T-cell receptor.

Table 19-3 Comparison of Methods for Minimal Residual Disease Assessment

Method	Sensitivity
Cytogenetics, conventional	1%–10%
Cytogenetics, FISH	0.2%–10%
Southern blot	1%–10%
Flow cytometry	$1/10^3$–$1/10^4$
PCR/RT-PCR, quantitative	$1/10^3$–10^5
PCR/RT-PCR, nested	$1/10^5$–10^6

FISH, fluorescence in site hybridization; PCR, polymerase chain reaction; RT, reverse transcriptase.

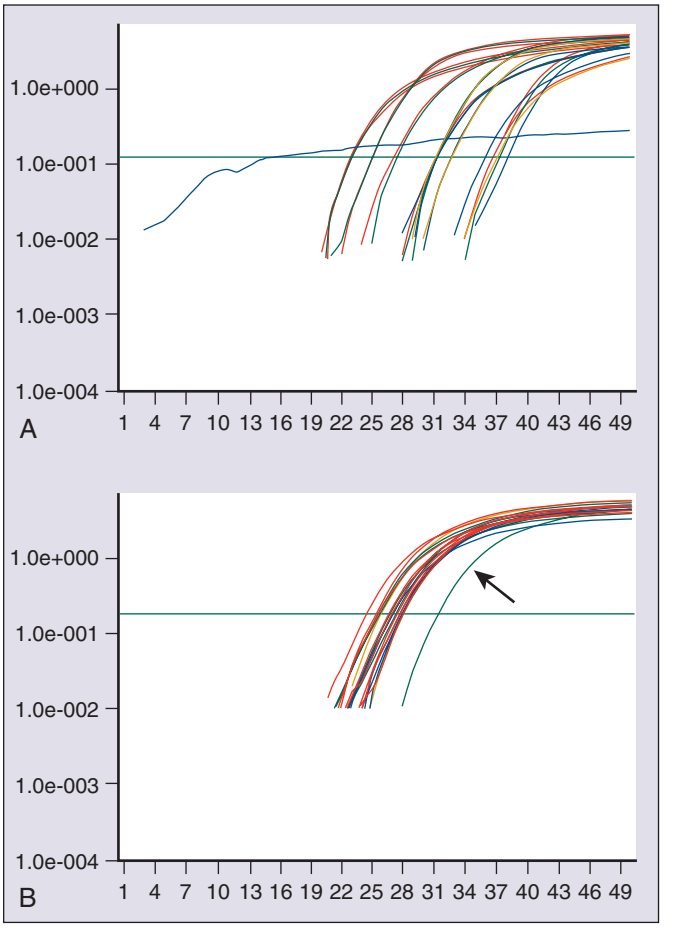

Figure 19-4 • **A,** *BCR/ABL1* transcript assessment by quantitative real-time RT-PCR. Numbers on the X axis indicate PCR amplification cycles. This panel shows amplification (the PCR cycle number at the rising curve crosses a threshold) for samples with high, 22–27 intermediate, 30–31 and lower 35–38 levels of *BCR/ABL1* major breakpoint transcript. **B,** Internal housekeeping transcript (*GUS,* beta glucuronidase) level in samples. Note that most are similar over a three-cycle range. One sample *(arrow)* is partially degraded. The ratio of *BCR/ABL1* to *GUS* transcript levels versus known standards is used as a relative quantitative measure of how much *BCR/ABL1* is present, and the logarithm reported of the fold reduction versus a baseline for patients with untreated CML.

formly in tumor and normal cells as a quality indicator.[29] Results often are provided as a $\log_{10}$ reduction or increase relative to a laboratory baseline for patients with full-blown disease.[30,31] Any value that increases or decreases by 1 log (less in some laboratories) over a prior sample is significant. Calibrators are being developed to standardize such assays among laboratories.

High-sensitivity PCR testing is not suitable to screen for disease. Low level false-positive results for *BCL2/IgH* and *BCR/ABL* translocations have been described in normal individuals and raise cautions for interpreting minimal residual disease.[32,33] Such results presumably indicate small populations of cells with a translocation that have not progressed through additional steps necessary to manifest neoplasia.

Assays in Bone Marrow Transplantation

The human leukocyte antigen (HLA) histocompatibility locus on human chromosome 6 is an exceptionally diverse region with well over 1000 alleles identified.[34,35] HLA matching of donors and recipients for bone marrow transplantation at class I and class II loci is a complex and important molecular diagnostic application in clinical oncology. Millions of potential donors have been pretyped through programs such as the National Marrow Donor Program in the United States.[36] Molecularly discrete alleles that share the same serologic (or antigenic) activity have been identified, and it is clear that high-resolution molecular typing to match donors and recipients offers benefits over low-resolution serologic typing for graft survival and graft-versus-host disease.[37] The best results with high-resolution typing are seen in those patients with the fewest class I or class II mismatches.[38] High-resolution DNA-based HLA typing is performed first with sequence-specific PCR primers or oligonucleotide probes, often followed by DNA sequencing when allele families are identified.

STR markers are used to assess engraftment and potential mixed chimerism following bone marrow transplantation.[39,40] These identity markers permit unambiguous determination of donor and recipient alleles and low levels of mixed chimerism down to a few percentage points. This information is useful in making decisions for pancytopenic patients regarding levels of immunosuppressive therapy as well as treatment for infection or recurrent disease.

Gene Mutations

Applications that target specific acquired mutations of selected genes are increasing in number. The *JAK2* V617F variant,[41] found in half or more of patients with chronic myeloproliferative disorders (CMPD), and rarely in other neoplastic myeloid disorders, has dramatically altered diagnostic approaches to patients suspected of CMPD.[42] It can be detected readily in blood; bone marrow specimens may offer increased sensitivity. Heterozygous versus homozygous status has not yet been convincingly shown to be clinically significant, but patients with polycythemia vera appear to have homozygous mutations more frequently. Should V617F become a therapeutic target,[43] quantitative assays for MRD assessment will likely follow.

Studies have revealed a range of interesting markers in patients with a normal karyotype who have AML.[44] More than one of these markers may occur in the same clone, and prognostic studies should be assessed with that knowledge. Duplications—and, to a lesser extent, point mutations[45] within the *FLT3* gene are associated with a poorer prognosis[46,47]; point mutations in selected regions of the *NPM1* gene are associated with either a normal or improved prognosis.[48–50] Expression levels of several other genes (*CEBPA, MLL, BAALC, ERG*) also have been reported to affect prognosis.[46,51–54] IgH gene variable region mutational status, perhaps combined with clinical stage, is among the most useful prognostic markers in chronic lymphocytic leukemia.[55,56] Patients with unmutated (<2% variation from consensus germline sequences) IgH genes in the chronic lymphocytic leukemia (CLL) clone do more poorly than those with mutated (>2% variation) genes.

Sequence analysis of the *ABL* kinase domain often is pursued to guide alternate therapies in patients who develop resistance to Gleevec.[57,58] RNA or protein-based assays that assess expression of drug resistance proteins such as multidrug resistance-associated P glycoprotein (*PGP*) or breast cancer resistance protein (*BCRP*) remain under investigation.[59,60]

Other Applications in Hematolymphoid Neoplasia

PCR is performed to look for viral agents associated with bone marrow failure or neoplasia—for example, parvovirus B19, human herpes virus types 6 and 8, human T-cell leukemia virus (HTLV), and Epstein-Barr virus (EBV). Quantitative levels of viruses are increasingly requested to distinguish between infection and rejection in immunocompromised patients following bone marrow transplantation. Some reports suggest that quantitative PCR assessment of EBV viral DNA levels may be a useful indicator to follow for possible emergence of post-transplant lymphoproliferative disease following solid organ transplantation.[61] Southern blot assessment of clonal or polyclonal integration of EBV viral DNA also may be useful in assessing potential cases of cases post-transplant lymphoproliferative disease for neoplastic risk. Microarray-based expression profiling applications are discussed in a following section.

SOLID TUMORS

Although useful applications of nucleic acid-based markers for diagnosis and management of patients with solid tumors have lagged behind their use for hematolymphoid neoplasia, there is recent significant growth. A range of molecular abnormalities can be detected, including chromosomal translocations, point mutations, allelic loss, gene amplification, microsatellite instability, epigenetic abnormalities such as methylation, and altered expression of single or multiple genes. Translocation, deletion, and amplification often can be detected by FISH as well as PCR or Southern blot methods for tumors with molecular abnormalities detectable by cytogenetic or molecular methods (see Table 1-6 in Chapter 18, Conventional and Molecular Cytogenetics of Neoplasia). A rich array of molecular diagnostic applications relating to sarcomas is discussed separately (see Chapter 97).

Hereditary Cancer Syndromes

Molecular genetic testing is important for a range of autosomal dominant familial cancer syndromes in patients with appropriate family history and/or clinical phenotypes. Testing usually is done on adults, but it may include children.[62] For common cancers, the nature of family history is crucial to decide whether testing a single gene makes sense.[63] Patients undergoing gene testing should receive pre- and post-test counseling and give written informed consent; they also should consider consulting a genetic counselor or geneticist.

Hereditary cancers with mendelian inheritance are a small subset (<5%) of solid tumors, but the detection of a disease-causing mutation is enormously beneficial to these patients and family members. Major syndromes include hereditary breast and ovarian cancer (*BRCA1, BRCA2, TP53,* and *CHEK2* genes), hereditary colorectal cancer with polyposis (*APC* gene), and hereditary non-polyposis colorectal carcinoma (*MSH2, MLH1* and other genes). Familial cases testing negative for mutations likely arise from undetected mutations (discussed in the following paragraphs) or complex inheritance due to abnormalities in several genes impacted by hormonal or environmental factors.

Hereditary cancers present a testing challenge because typically many mutations are spread over large areas of causative genes. This necessitates sequencing many or all exons to include exon–intron junctions or performing "mutation scanning" assays followed by sequencing regions with abnormalities. Scanning techniques such as single-strand conformation polymorphism (SSCP) analysis and denaturing high pressure liquid chromatography (DHPLC) reveal subtle physical differences caused by nucleotide changes and typically detect more than 95% of simple mutations. Guidelines exist for the functional interpretation of sequence variants,[64] which is crucial for counseling patients and family members. Previously described mutations

and neutral polymorphisms (i.e., nucleotide changes *not* associated with disease) often are available in disease-specific databases. Previously undescribed sequence variants that produce prematurely truncated proteins via nonsense, frameshift, and splice site mutations are likely to cause disease. New missense mutations that change single amino acids have uncertain functional consequences and often are reported as "variant of uncertain significance (VUS)." Segregation studies of a variant among family members may be helpful, and conversion analysis, a technology that separates and allows study in isolation of mutant patient alleles, facilitates functional resolution for many alleles that fall into the VUS category.[65] Major structural changes such as partial loss or duplication within a gene can be the basis for mutation in 15% to 20% of cases in hereditary cancers such as breast cancer due to *BRCA1*.[66] Sequencing and screening methods rarely detect major structural changes, because no unique DNA nucleotide changes result. Newer methods such as MLPA[67] permit comprehensive screening for duplications and deletions focused on changes in copy number of exons.[68–71]

Many other hereditary cancer syndromes can be sought clinically or on a research basis. A selected group with genes that can be analyzed focusing on fewer than 10 exons includes MEN-2; type 2 multiple endocrine neoplasia (*RET*)[72,73]; hereditary paraganglioma/pheochromocytoma (*SDHD, SDHB, SDHC*)[74,75]; Li-Fraumeni syndrome (*TP53*)[76]; von Hippel-Lindau syndrome (*VHL*)[77,78]; type 1 multiple endocrine neoplasia (*MEN1*)[79–81]; and Cowden syndrome (*PTEN*).[82,83]

Allele Imbalance and/or Copy Number Variation

The development of solid tumors commonly is accompanied by genetic instability leading to loss and, less commonly, amplification of small or larger regions of DNA from various chromosomes.[84,85] Such loss of heterozygosity (LOH) can be measured in two ways: (1) via PCR assays directed at microsatellite length polymorphisms that occur throughout genome, or (2) using single-nucleotide polymorphism (SNP) microarrays.[20,86] In the first, the ratio of different-sized alleles in the sample of interest can be compared to the ratio obtained from a normal (often adjacent) sample of the same individual. These ratios normally should be ~1.0. Because of connective tissue and vascular and inflammatory cells within a tumor, a marker may not be lost entirely, and conservative ratios (e.g., <0.66 or >1.50) typically are used to determine whether there is LOH for a marker. In a SNP array, hybridization levels of labeled sample DNA are compared to normal patterns at thousands of known normal and variant genomic sequences represented on the array.

Useful clinical applications of LOH analysis include evaluation of oligodendrogliomas, where LOH for markers on the short arm of chromosome 1 and the long arm of chromosome 19 are both diagnostic and prognostic[87,88]; to detect recurrence in bladder cancer[89]; and to discriminate, by comparing LOH patterns, de novo second primary tumors from metastatic spread of a single primary tumor.[90] Potential utility also has been demonstrated with cytologic bile duct brushing samples for pancreatic neoplasia, which can be combined with direct analysis for *KRAS* mutations.[91,92] Because STR analysis is a form of genetic identity testing, these sorts of sample screens also are useful to resolve the vexing question of whether a tissue "floater" from one specimen has somehow become included in the paraffin block of another.[93] High-resolution SNP arrays produce complex data that must be correlated clinically but show promise for revealing patterns in neoplastic or preneoplastic lesions.[94,95]

Gene Mutations

In addition to full gene or targeted sequencing in hereditary cancer syndromes, specific somatic sequence alterations have been described in various tumor specimens. Given the variability among studies, well-designed clinical trials are essential to establish the utility of individual biomarkers or panels in diagnosis, prognosis, selection of therapy, and population screening.

One useful application not directed at a specific gene or mutation is microsatellite instability (MSI) analysis.[96,97] In some tumors, additional, often minor, bands of different size are noted in addition to the bands corresponding to germline alleles seen in normal cells. MSI bands reflect genetic instability leading to insertions or deletions of nucleotides within an STR or single nucleotide repeat sequence; the additional alleles are believed to result from defects in mismatch repair (MMR) systems under control of genes such as *MSH2* and *MLH1*. MSI is useful as a screening assay for colon (Fig. 19-5) or other tumor tissue from patients suspected of the HNPCC syndrome. A positive MSI result typically triggers immunohistochemical testing of MMR gene expression and, based on those results, direct sequencing to identify potential germline mutations.[98] Whether MSI contributes to improved survival in colon cancer is controversial; disease-free but not overall survival may be improved.[99] A small percentage (~15%) of sporadic colorectal cancers also demonstrate MSI, and screening for the common *BRAF* mutation may allow their identification, thus saving workup for HNPCC.[100]

Mutations in the tyrosine kinase domain of the epidermal growth factor receptor (*EGFR*) gene identified in 10% to 20% of North American, and a higher percentage of Asian, non-small-cell lung cancers initially were thought to correlate with higher response rates to the EGFR-targeted agents gefitinib and erlotinib,[101] although a clear survival benefit has been difficult to demonstrate and results have varied among studies. *EGFR* mutations are more common in patients with adenocarcinomas, women, and individuals who have never smoked. Targeted sequencing of *BRAF*, *RET/PTC* and *RAS* genes for specific mutations may offer potentially useful information for prognosis and management in patients with papillary thyroid carcinoma,[102] although the frequency of their detection appears to be method-dependent.[103] Oncogenic mutations of *KIT* or platelet-derived growth factor receptor alpha (*PDGFRα*) are common and serve as useful therapeutic targets for tyrosine kinase inhibitors in gastrointestinal stromal tumors (GIST); as in CML, development of secondary mutations leads to resistance.[104] Mutations in the p53 (*TP53*) gene, a prominent feature of the hereditary Li-Fraumeni syndrome, occur in somatic form in half of all human cancers, with lower levels in leukemia and higher levels in colorectal and ovarian cancer. A number of studies suggest a role for this central mediator of cell death in tumor behavior and response to treatment, but its

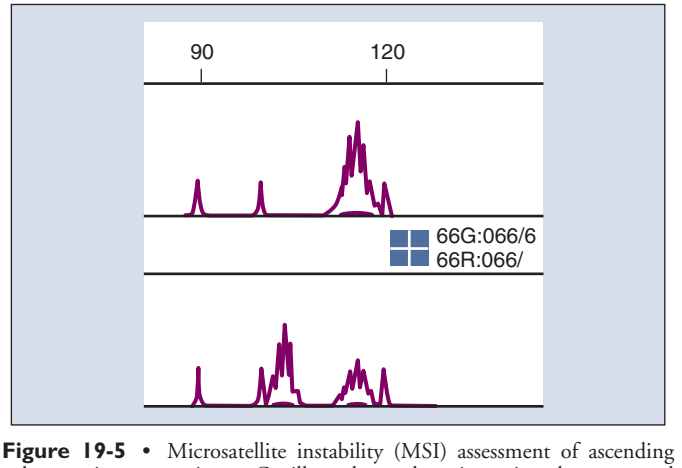

Figure 19-5 • Microsatellite instability (MSI) assessment of ascending colon carcinoma specimen. Capillary electrophoresis tracing shows normal *(upper)* and tumor *(lower)* analysis by STR (BAT26) analysis. The jagged peak in the upper tracing represents apparent homozygosity for a single allele. The jagged appearance arises from "stutter" during PCR amplification. Note the novel, smaller (left-shifted) allele in the tumor. This sample showed additional MSI using other markers; immunohistochemistry demonstrated MSH2 protein expression in normal colonic eithelium but not in tumor cells. (Courtesy of Antonia Sepulveda, MD.)

interactions are complex, and diagnostic, prognostic, or therapeutic utility requires much study.[105,106]

The potential to look for mutations from desquamated adenoma or carcinoma cells in stool as a screening approach for colonic cancer has been entertained for some time.[107] DNA seems to be stable for reasonable amounts of time as it traverses the colon and in collected stool. Studies targeting stool in large numbers of patients using multitarget assays that detect 15 to 21 mutations have performed better than fecal occult blood detection in detecting invasive cancers or adenomas with high-grade dysplasia; however, these assays still are not as good as colonoscopy.[108,109]

Extremely-high-throughput picoliter DNA sequencing platforms offer the potential to assess the full spectrum of simple nucleotide sequence mutations in cancers at very low levels and to follow changes over time.[110,111] Early studies indicate enormous breadth and complexity for investigators to probe and validate for clinical significance.

NEWER DIAGNOSTIC TECHNIQUES AND POTENTIAL APPLICATIONS

Epigenetic Markers

Another approach to detection of cancer-related alterations in a wide range of tumors[112] is the study of cytosine methylation status in upstream CpG islands; these show promise as early screening markers for cancer in relatively noninvasively obtained specimens such as saliva, sputum, pleural fluid, pancreatic juice, or even peripheral blood.[113–117] Silencing/inactivation has been associated with hypermethylation of tumor suppressor genes, DNA repair genes, or proto-oncogenes believed to be causal or linked to mutational changes in the development of cancer. Evidence also has been presented that as neoplasia develops, hypermethylation affects different gene groups progressively. Methylation markers may be useful for tumor diagnosis or subclassification.[118] The most extensively studied genes and tumors include *MSH2, MLH1,* and *CDKN2A*-p14 (colorectal, including patients with ulcerative colitis), *GSTP1* and *RASSF1A* (prostate), and *CDKN2A*-p16 (lung, esophagus, and pancreas). A number of other hypermethylated genes also have been described in lung and other cancers. For some genes (*KRAS, HRAS, MYC, FOS, BCL2*) hypomethylated status has been associated with neoplasia. Methylation status in some tumors correlates with their response to therapy,[119] and prognostic differences in leukemia or myeloma suggest possible therapeutic use of hypomethylating agents.

Pharmacogenetic Assays

The pharmacogenetic paradigm for personalized medicine in cancer is thiopurine-S-methyl transferase,[120] the homozygous absence of which in 1 of 300 individuals can lead to marrow aplasia following standard doses of 6-mercaptopurine or azathioprine in patients with acute leukemia or inflammatory bowel disease or post transplantation. An understanding of increasing numbers of common and rare gene polymorphisms associated with metabolism of anticancer drugs such as glucuronidation of irinotecan by *UGT1A1*[121,122] holds promise of developing a better dose schedule for effective treatment and fewer adverse reactions. Many pharmacogenetic relationships are complex, and clinicians understandably hesitate to use assays in the absence of validated algorithms. Genotyping by molecular methods offers distinct advantages, but may produce some false negative results.[123,124]

Microarrays

Microarray expression profiling for diagnosis, classification, and therapeutic selection in an assortment of leukemias and lymphomas has demonstrated impressive power in investigational studies.[125–132] Expression profiling also has been a powerful tool for biomarker discovery in the diagnosis and management of patients with solid tumors, and profiling studies of solid tumors have provided exciting results despite the seemingly greater challenge of analyzing samples with varying numbers of nonneoplastic vascular, stromal, and inflammatory cells. Initially dogged by reproducibility issues among laboratories, recent consortium studies indicate that commercially manufactured arrays are promising for clinical use.[133–135] The first cancer-directed microarray assay was approved by U.S. regulatory agencies in February 2007 for breast cancer assessment,[136] and other applications are in the pipeline, including those for assessment of metastatic tumor of unknown origin, leukemia, lymphoma, and colorectal cancer. Although clinical trials data are lacking, arrays theoretically offer platforms to predict response and aid selection of individualized therapies.[137] Because a modest number of targets (<100, or possibly even <10) may contain the bulk of useful information, targeted assays using quantitative RT-PCR or low-density-array platforms may be viable clinical platforms.[138–143] Prior studies and recent data suggest there may be overlapping or even distinct sets of genes that give comparable predictions.[144] Some assays may be done on paraffin-embedded tumor samples, but if array-based assays become more prevalent, pathologists and surgeons accustomed to placing biopsy specimens in fixative for morphologic and immunohistochemical analysis may need to adapt, because RNA from fresh tissues is likely to provide the highest-quality results. The use of microdissection (manual and laser-capture aided) to enrich with relevant regions for analysis is likely to increase.

Cancer-Specific Detection at Low Levels in Blood, Bone Marrow, and Tissue

For some time, investigators have probed the utility of tumor-specific molecular markers to identify metastatic carcinoma cells in sentinel or other lymph nodes or circulating in the blood with the hope of using such assays to determine patient prognosis and, in some cases, management.[145] Work has continued to detect cells by both molecular and nonmolecular methods.[146,147] Some groups have developed rapid PCR methods that would allow such markers to be used intraoperatively,[148] but these applications have remained resistant to clinical application in the absence of prospective trials. Difficulties have included false-positive results due to a lack of specific expression or expression from pseudogenes. False-positive results also have been noted in normal control samples. Advances in assays performed on cell-free circulating nucleic acids[149] offer alternate possibilities.

MicroRNAs

It has become increasingly clear that microRNAs (miRNAs), which are small RNA molecules of 19 to 24 nucleotides, play important roles in the regulation of normal gene expression. Accumulating evidence indicates that miRNAs, individually or in groups, act as tumor suppressors or oncogenes in hematolymphoid and solid tumors.[150–152] Assays that target or profile miRNAs are very likely to become available in the near future.

BUSINESS, REGULATORY, AND ETHICAL ISSUES IN MOLECULAR DIAGNOSTICS

Business and regulatory trends continue to affect molecular diagnostic testing in oncology. Oncologists probably will see package inserts recommending pharmacogenetic testing for increasing numbers of pharmaceuticals. As noted earlier in this chapter, interpretation of genotypes in the context of other medications and patient status probably will be complex.

Intellectual property positions on tumor markers, nucleic acid variations, techniques, and clinical applications are significant.[153,154] The *BRCA1* and *BRCA2* genes for hereditary breast and ovarian cancers are a well-known example. Patents to both genes are held by a single entity, and full gene analysis in the United States is restricted to a single laboratory. Exclusive licensing of patents also leads to single-provider situations. Conflicts have not yet emerged, but clini-

cians and laboratories remain concerned that panels of molecular markers in microarrays or other platforms may be delayed or difficult to offer because of multiple and conflicting patents.

There is continued government and public interest in oversight of molecular testing, particularly laboratory-developed tests. The Food and Drug Administration (FDA) has circulated revised guidelines for analyte-specific reagents, the basis for laboratory-developed tests. It appears that the FDA will require review and clearance of "special controls" for a new class of assays—in vitro diagnostic multi-analyte index assays—which process multiple laboratory results and, sometimes, clinical information to provide treatment recommendations via proprietary interpretive algorithms. Both developments may affect the types of complex assays available. Standards and calibrators should produce improved comparability of results among laboratories and methods. Beyond hereditary cancer syndromes, it is unclear whether establishing a genetic specialty area for laboratory accreditation, proposed by some, might affect molecular testing in oncology.

Payment for increasingly complex molecular assays continues to be a challenge. Reimbursement for molecular testing is governed largely by Current Procedural Terminology (CPT) codes, whose levels were undervalued initially and have gone largely unrevised for 15 years. Reimbursement levels typically are not sufficiently attractive to justify investment in oncology assay development at biotechnology companies, a situation that has prompted developers of complex assays to approach third-party payers directly to request payment under "miscellaneous" billing codes. Proposals have been advanced regarding improved payment for new technologies, but with political pressures for budget neutrality, the possibility of better reimbursement remains uncertain.

SUMMARY

Over the next two decades, molecular diagnostic assays will become increasingly important tools for the determination of tumor diagnosis, prognosis, and residual presence, as well as initial and follow-up therapy. Targeted individual molecular markers probably will remain useful, and may even be predominant for the near future. However, validated panels of markers or expression profiling of tumors using microarrays or proteomic methods show potential to dramatically supplement or replace single markers in determining diagnosis, prognosis, and whether available therapies will be beneficial. New understandings of molecular pathogenesis in cancer will develop from continuing research with microarrays and proteomic methods, leading, we hope, to targeted therapies and opportunities to monitor treatments with molecular assays. Intellectual property and regulatory actions may limit the rate at which clinical applications are developed because of licensing and cost considerations. There will be increasing demands on physicians to ensure that patients understand the impact molecular tests have on decisions for their management, and, with a plethora of possibilities, to choose wisely for cost-effectiveness.

20 Biomarkers for Cancer Diagnostics

Lori J. Sokoll and Daniel W. Chan

SUMMARY OF KEY POINTS

Serum Tumor Markers

Key Methods

- Radioimmunoassay and, more recently, enzyme and other immunoassays are cornerstones of cancer diagnostic methods.
- Monoclonal antibodies have been produced against a wide variety of secreted antigens.

Applications

Screening and Early Detection

- In most tumor systems, biomarkers do not have sufficient sensitivity and specificity for routine population screening, although combining them with other approaches can improve utility.
- In some high-prevalence situations tumor marker screening is appropriate (e.g., prostate-specific antigen [PSA] for prostate cancer).

Diagnosis

- Levels of particular markers are useful adjuncts to diagnosis in many tumor systems, including ovarian cancer, germ cell tumors, or neuroendocrine tumors.
- In some tumor systems, serum markers contribute to staging information and help direct therapy.

Monitoring

- Most serum tumor markers are useful to monitor treatment or progression of cancer.
- A decrease in tumor marker levels can be used as a means to assess the success of surgery or chemotherapy.
- An increase in a tumor marker can be a harbinger of relapse or disease progression.

INTRODUCTION

Tumor markers, also called *cancer markers, biomarkers*, and, in some instances, *cancer-associated antigens*, are substances present in or produced by a tumor itself or produced by the host in response to a tumor that can be measured in the blood or secretions and used to differentiate a tumor from normal tissue or to determine the presence of a tumor. Such substances can be found in cells, tissues, or body fluids. They can be measured qualitatively or quantitatively by chemical, immunologic, or molecular biologic methods to identify the presence of a cancer. A wide spectrum of molecules may be classified as tumor markers, including enzymes, hormones, oncofetal antigens, carbohydrate markers, blood group antigens, proteins, receptors, and genes or gene products.[1] Although, strictly speaking, tumor markers can be recovered from any tissue or fluid, this chapter is devoted largely to those that are secreted or shed and detectable in serum.

The first recognized tumor marker was the Bence-Jones protein, discovered in 1847 by precipitation of a protein in acidified boiled urine. This protein, the monoclonal light chain of immunoglobulins secreted by tumor plasma cells, still is used in the diagnosis of multiple myeloma. The first half of the twentieth century included the discovery of hormones, for example, human chorionic gonadotropin (hCG); enzymes, for example, acid phosphatase (for prostate cancer); and isoenzymes and proteins whose concentrations are altered in biologic fluids in malignancy. The discoveries of α-fetoprotein (AFP) and carcinoembryonic antigen (CEA) in the 1960s led to the use of tumor markers for monitoring and to the use of the term *oncodevelopmental markers*, coined because these markers were produced both in fetal development and in tumors.

An ideal tumor marker should be specific for a given type of cancer and undetectable in healthy people or in those with benign disease, as well as sensitive enough to detect small tumors for early diagnosis or during screening. Unfortunately, most known tumor markers are neither specific nor sensitive enough for these purposes. Other desirable characteristics include concentrations proportional to tumor volume; short half-lives to allow early assessment of response to therapy; predictable increases and decreases in concentration responding to cancer progression and regression; and ability to be measured in a standardized and reproducible fashion in easily accessible specimens. In practice, tumor markers are most useful in evaluating the progression of disease status after the initial therapy and in monitoring the effectiveness of subsequent treatment.[1–3]

Despite the numerous tumor markers that have been identified, relatively few are in routine clinical use. Practice guidelines and recommendations for the use of tumor markers in a range of cancers have been developed by groups of scientists and clinicians from the National Academy of Clinical Biochemistry[4,5] and the European Group on Tumor Markers,[6] although scientist and clinician viewpoints on the use of tumor markers do not always agree. The use of tumor markers is also included in *Practice Guidelines in Oncology* from the National Comprehensive Cancer Network,[7] and the American Society for Clinical Oncology has published recommendations for selected cancers.[8,9] Practice guidelines from these and other national and international organizations are summarized by Fleisher and colleagues[4] and Sturgeon.[10]

Tumor marker use in the United States is limited compared with that in other countries as a result of required approval by regulatory agencies such as the U.S. Food and Drug Administration (FDA), which influences reimbursement. In addition, the FDA typically

Table 20-1 FDA-Approved Tumor Markers

Analyte	Associated Cancer	Designated Indication
Serum, Plasma		
CA15-3, CA27.29	Breast	Monitoring; recurrence
HER-2	Breast	Monitoring
Circulating tumor cells (CellSearch; whole blood)	Breast	Prognosis in metastatic disease
CA125	Ovarian	Monitoring; second-look evaluation
CA19-9	Pancreatic	Monitoring
Total PSA, complexed PSA (cPSA)	Prostate	Detection in men aged ≥50 y in conjunction with DRE; monitoring; prognosis
Free PSA	Prostate	Aid in distinguishing prostate cancer from benign prostate conditions in men ≥50 y with a total PSA of 4–10 ng/mL and nonsuggestive DRE in conjunction with total PSA (% free PSA)
Prostatic acid phosphatase	Prostate	Monitoring
Carcinoembryonic antigen	Colorectal, breast, lung	Monitoring; prognosis
AFP	Nonseminomatous testicular	Monitoring
AFP-L3	Hepatocellular	Risk assessment
Des-γ-carboxy prothrombin	Hepatocellular	Risk assessment
Thyroglobulin	Thyroid	Monitoring (in patients without thyroglobulin autoantibodies)
Soluble mesothelin-related peptides	Mesothelioma	Monitoring
β-human chorionic gonadotropin	None	Detection of pregnancy (not approved as a tumor marker)
Urine		
BTA stat, BTA TRAK	Bladder	Management in conjunction with cystoscopy
NMP-22	Bladder	Diagnosis in symptomatic patients or those with risk factors; recurrence
Tumor cell markers (ImmunoCyt)	Bladder	Management in conjunction with urine cytology and cystoscopy
Tissue		
Estrogen and progesterone receptors	Breast	Assessing the likelihood of response to therapy; prognosis and management
HER-2	Breast	Identify patients eligible for trastuzumab (Herceptin) treatment
EGFR	Colorectal	Identify patients eligible for cetuximab treatment

AFP, α-fetoprotein; BTA, bladder tumor antigen; DRE, digital rectal examination; EGFR, epidermal growth factor receptor; FDA, Food and Drug Administration; NMP, nuclear matrix protein; PSA, prostate-specific antigen.

approves assays for specific clinical applications that may limit their use in other clinical settings. Currently approved markers and associated cancers and applications are listed in Table 20-1.

METHODS

A new era in the tumor marker field began with the introduction of radioimmunoassay in the 1960s. In the 1970s, the development of enzyme-linked immunosorbent assays (ELISAs) and the discovery of monoclonal antibodies led to improvements in marker measurement and discovery of new markers. Cell-surface antigens identified with the use of monoclonal antibodies, such as the carbohydrate antigens CA125 and CA15-3, demonstrate improved clinical sensitivity and specificity compared with the oncofetal antigens. Recently, studies of oncogenes and tumor-suppressor genes, as well as development of molecular techniques such as recombinant DNA technology, polymerase chain reaction (PCR), and automated sequencing, have resulted in the understanding and use of tumor markers at the molecular level.[1,2] New genomic and proteomic methods, such microarrays and matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry[11,12] will affect not only the discovery of new tumor markers, but also the way they are measured.

CLINICAL APPLICATIONS OF TUMOR MARKERS

Screening and Early Detection

Several factors must be taken into account when screening for a disease. The disease must be important, common, and the cause of substantial morbidity and mortality. An understanding of the natural history of the disease must ensure that early detection can affect the clinical course, and effective treatment must be available. The testing method also should be economical and noninvasive. When deciding to apply screening techniques, particularly if biochemical or immunochemical markers are used, an understanding of the analytic sensitivity (i.e., lowest detectable limit) and analytic specificity (i.e., extraneous interference) is essential. The precision of the assay (i.e., its ability to reproduce the results) also must be known and acceptable for use in large population studies. Clinical sensitivity and specificity, combined with the prevalence of the disease in the population, will affect the positive predictive value.[13]

Screening programs are most successful in regions or populations where specific cancers are highly prevalent. AFP concentrations have been used as a screening test for hepatocellular carcinoma in high-

incidence areas including China, Japan, Taiwan, Africa, and Alaska. With a cutoff in the range of 10 to 20 μg/L, AFP has been shown to have a sensitivity of between 60% and 90% and a corresponding specificity of 70% to 80%, although hepatitis and cirrhosis also may cause elevated values.[1,3] The American Cancer Society (ACS) has published specific recommendations for the early detection of breast, colorectal, prostate, and cervical cancers,[14] although among these cancers, the only serum tumor marker that is part of any screening algorithm is PSA.

Although controversy still exists on the value of early detection programs for prostate cancer, the ACS and the American Urological Association recommend PSA and digital rectal examination (DRE) annually beginning at age 50 for men with a life expectancy of at least 10 years.[14] It is recommended that prior to testing, men be offered information about the benefits and limitations of PSA testing so that they can make an informed decision with the assistance of their clinician. Other professional organizations, including the U.S. Preventive Services Task Force (USPSTF), American Academy of Family Physicians, and the American Medical Association advocate individualized testing decisions between patients and their clinicians, but do not recommend routine prostate cancer screening with either DRE or PSA. The USPSTF acknowledges that PSA testing is effective in identifying early prostate cancer, but did not find sufficient evidence that early detection improved health outcomes.[15]

Although PSA is for all intents and purposes organ specific, it is not cancer specific. PSA may be elevated (>4 ng/mL) in men with benign prostatic disease such as benign prostatic hyperplasia (BPH). PSA elevations also may occur with aging and with conditions such as prostatitis. Thus a number of methods have been proposed to increase the clinical utility of PSA for the early detection and diagnosis of prostate cancer, particularly in the diagnostic gray zone of 4 to 10 ng/mL, where there is significant overlap in PSA concentrations between prostate cancer and BPH. These approaches include age-specific reference ranges, PSA density, PSA velocity, and PSA molecular forms.[16,17] The premise behind age-specific references (0–2.5, 3.5, 4.5, and 6.5 ng/mL for age ranges 40–49, 50–59, 60–69, and 70–79 years, respectively) is that lowering the upper end of the reference range in younger men would potentially increase sensitivity and aid in detecting organ-confined tumors earlier when surgery may be curative, whereas extending the range in older men would increase specificity, taking into account small increases in prostate volume, and PSA production and secretion with aging. However, because extending the range in older men may miss significant cancers, the use of age-adjusted ranges is controversial.

Assessment of PSA density, the ratio of PSA to prostate volume determined by transrectal ultrasound, is another method to increase PSA specificity; this assessment attempts to adjust for the increased volume often found in BPH. Limitations to PSA density include inaccuracies in measurement of prostate size and reduced sensitivity of prostate cancer detection. PSA velocity, similar to an approach used with CA125 for ovarian cancer, is defined as the change in PSA concentrations over time. A velocity of 0.75 ng/mL per year or more is suggestive of cancer. At least three PSA measurements 12 to 18 months apart are needed to calculate velocity. The effectiveness of this approach may be diminished by interassay and interlaboratory variation.

The most successful approach to increase the clinical utility of PSA in the 4- to10-ng/mL range is assessment of the free and complexed forms of the PSA molecule. In the early 1990s, it was discovered that the majority of PSA measured in serum is complexed to protease inhibitors (~80% to 90%), with only a small portion in the free or unbound form. It also was discovered that men with prostate cancer, benign prostate disease, and no disease may differ in the proportions of free PSA and PSA bound to α_1-antichymotrypsin. Although the mechanism currently is unknown, patients with prostate cancer have a lower percentage of free PSA (free PSA/total PSA) compared with men with benign disease. By using a cutoff of 25% in men with a negative DRE, 95% of cancers can be detected while sparing 20% of unnecessary biopsies.[16]

In other tumor systems, in most cases individual tumor markers lack sufficient sensitivity and specificity for screening. For this reason, an approach to improve their utility is to combine analysis of the marker with other procedures. In ovarian cancer, for example, strategies have included combining CA125 with ultrasound or using a two-stage strategy in which ultrasonography is performed only if CA125 concentrations are elevated. In a study of 4000 women, the specificity of CA125 plus ultrasound was 99.9% compared with 98.3% for CA125 alone. Other strategies that have been proposed to improve the specificity of CA125 include the use of multiple markers, including OVX1 and M-CSF. However, requiring elevation of all markers, while increasing specificity, sacrifices sensitivity; similarly, when markers are complementary, if elevation of only one marker is used as an indicator of disease, then specificity is lost.[18,19]

Tumor Markers in Diagnosis

Lack of sensitivity and specificity limits the use of tumor markers for cancer diagnosis, although in contrast to screening of the general population, the prevalence of disease is likely to be higher in diagnostic situations. In most cases, histologic confirmation in tissue remains the gold standard for primary diagnosis, although tumor markers can still play a useful role, especially when combined with other methods, and may aid in differentiating benign and malignant disease or in identifying histologic tumor type.

For example, CA125, although still controversial as a screening marker, is more accepted as an adjunct in distinguishing benign from malignant disease in women, particularly in postmenopausal women with ovarian masses,[20] where elevated concentrations of CA125 greater than 95 U/mL in postmenopausal women can discriminate malignant from benign pelvic masses with a positive predictive value of 95%.[16] In premenopausal women, benign conditions resulting in elevated CA125 levels may be a confounding factor. The multiple markers approach has been applied to the preoperative discrimination of malignant and benign pelvic masses by using a number of analytic techniques.[21,22]

AFP and hCG can play a useful role in the classification of germ cell tumors. AFP is the major serum protein of the early fetus synthesized by the fetal gut, liver cells, and yolk sac. hCG is a glycoprotein consisting of two distinct subunits and is synthesized and secreted by the placental syncytiotrophoblast. In seminomas, AFP is not elevated, but hCG is present in 10% to 30% of cases. Either hCG or AFP or both are produced by 60% to 90% of nonseminomatous germ cell testicular tumors at the time of diagnosis. Both markers are elevated in embryonal carcinoma (hCG > 65%; AFP > 70%), but these markers are not useful in teratomas. AFP is elevated in yolk sac tumors, whereas hCG is elevated in choriocarcinomas, and therefore useful in gestational trophoblastic disease as well. Typical reference values for AFP are 10 to 15 μg/L, whereas 5 IU/L is often used as a cutoff for hCG in testicular cancer. Clinically, assays for total β-hCG, measuring both intact hCG and the free β-subunit, may be preferable because of the production of free β-subunits in cancer.[1]

Other tumor markers play a role in testicular cancers. Placental alkaline phosphatase, another oncodevelopmental marker, can be elevated in seminomas and in a number of other cancers. Sensitivity is increased when it is combined with the nonspecific enzyme marker lactate dehydrogenase (LDH). LDH concentrations further correlate with tumor burden and, therefore, with prognosis.[1,23]

Tumor markers also may play a role in the diagnosis of neuroendocrine tumors.[1,3,24] For example, the diagnosis of pheochromocytoma usually is established with an increase in the urinary excretion of catecholamines or catecholamine metabolites. Similarly, catecholamine metabolites vanillylmandelic acid (VMA) and homovanillic

acid (HVA) are useful markers for neuroblastoma. Calcitonin is used in medullary thyroid cancer, with increased diagnostic sensitivity resulting from stimulation of calcitonin release with pentagastrin, whereas urinary 5-hydroxyindoleacetic acid (5-HIAA) is the primary test for overproduction of serotonin in carcinoid tumors. Specific circulating serum tumor markers may aid in the diagnosis of pancreatic endocrine tumors (e.g., insulin in insulinomas, gastrin in gastrinomas, glucagon in glucagonomas, and somatostatin in somatostatinomas). It also has been suggested that neuron-specific enolase (NSE), an isoenzyme of the glycolytic enzyme enolase found predominantly in neurons and neuroendocrine cells and elevated in neuroendocrine tumors, may be helpful in the diagnosis of small cell lung cancer in the small percentage of cases in which it is not possible to establish a diagnosis by biopsy.

Prognosis and Prediction of Therapeutic Response

The clinical staging of cancer can be aided by tumor markers, because the serum level of the marker typically reflects tumor burden. The marker value at the time of diagnosis may be used as a prognostic indicator for disease progression and patient survival. Tumor markers may be included as staging criteria for some cancers, as, for example, with CEA and colorectal cancer,[25] LDH in lymphoma,[26] or LDH, hCG, and AFP in testicular germ cell tumors.[27] They also may be combined with other clinical parameters in staging nomograms, such as PSA with preoperative clinical stage and biopsy Gleason score to predict pathologic stage in men with prostate cancer.[28]

In contrast to serum tumor markers, a number of tissue markers play a significant role in predicting response to therapy, particularly in breast cancer, where estrogen and progesterone receptors are used as predictive indicators for response to hormonal treatment and measurement of *c-erb*B-2 (HER-2) overexpression is used to identify patients for whom treatment with trastuzumab (Herceptin) may be beneficial.

Monitoring Disease

Most serum tumor markers are used to monitor treatment and progression of cancer. Markers may be used to determine the success of the initial treatment (e.g., surgery or radiation), detect recurrences of cancer, and monitor the effectiveness of treatment.[1] If surgery is successful, a marker level that was elevated before surgery should decrease afterward. The expected rate of decrease is projected from the half-life of the marker. If the half-life after treatment is longer than the marker's known half-life, it can be assumed that the treatment has not been successful in removing the tumor. The magnitude of marker reduction may, however, reflect the degree of success of the treatment or the extent of disease involvement. PSA is particularly useful for determining the success of initial surgical or radiation treatment of prostate cancer. If the tumor was organ confined and all prostatic tissue was removed, after radical prostatectomy PSA concentrations should decrease to undetectable levels. After allowing for sufficient clearance of pretreatment PSA (total PSA half-life of 2 to 3 days), finding detectable post-treatment PSA suggests remaining prostate tissue or the presence of metastases.[18]

In recurrent cancer after a successful initial treatment, marker values may not appear within the normal half-life. They may decrease to a steady level that is higher than normal, or remain within the reference interval for healthy individuals. A subsequent increase in the marker values suggests recurrence of the cancer.[1] Serum tumor markers may detect "biochemical recurrence of disease" before clinical evidence. Ultrasensitive PSA assays allow earlier detection of prostate cancer after radical prostatectomy. In patients with breast cancer receiving adjuvant chemotherapy, elevation of the breast cancer marker CA27.29 has been shown to indicate recurrent disease before any clinical evidence appears. Early detection of cancer recurrence may be helpful if it makes it possible to initiate early treatment or change therapy, but it is useful only if effective treatment is available.[13]

Levels of most tumor markers correlate with the effectiveness of treatment and response to therapy. In breast cancer, the concentration of markers such as CA27.29 changes with the treatment and the clinical outcome of the patient, as does CEA in colorectal cancer, CA 19-9 in pancreatic cancer, and CA125 in ovarian cancer. Marker values usually increase with progressive disease, decrease with remission, and do not change significantly with stable disease. Tumor-marker kinetics are, in general, more important than individual values, although interpretation of kinetic changes may be complicated. For example, marker levels in response to treatment may show an initial delay before demonstrating the expected pattern of change.[29]

The Working Group on Tumor Marker Criteria of the International Society for Oncodevelopmental Biology and Medicine[30] has published the following criteria for the interpretation of changes in tumor marker values:

- "If no therapy is given, at least a linear increase in three consecutive samples (i.e., two time intervals) on a log scale should be registered to establish a recurrence. Usual intervals could be 3 months but are clinically determined. After a first increase, next samples should be taken after 2 to 4 weeks, irrespective of the absolute level." If therapy is given, the changes in marker values should reflect the clinical progression of the disease.
- "Progressive disease is defined by an increase in the marker level of at least 25%. Sampling should be repeated within 2 to 4 weeks for additional evidence. The sampling interval during therapy may depend on the type of tumor and should be related to clinical follow-up." A decrease in marker value of at least 50% is indicative of partial remission "with the concept that tumor load is related to the changes in serum tumor marker levels."
- The Working Group also provided a general statement that "a complete remission cannot be determined by tumor marker levels, but if tumor marker levels are elevated, the clinical decision of complete remission based on conventional methods should be considered incorrect unless an explanation for the presence of an elevated level is given."

ANALYTIC CONSIDERATIONS

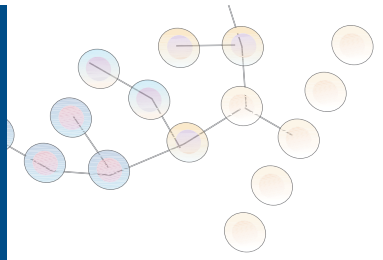
A number of clinical and analytic limitations should be considered in the interpretation and use of tumor markers.[29,31,32] Physiological influences to be considered include biologic variability, effects of aging and menopause, and half-life and route of elimination. Tumor markers can be elevated as result of renal failure, liver failure, and cholestasis, depending on whether the marker is eliminated through glomerular filtration or metabolized by the liver. For example, serum CEA concentrations may be elevated in patients with liver disease. A false-positive PSA, for example, may be seen with prostatitis, while inflammation of serous membranes or biliary ducts may falsely elevate CA125 or CA19-9, respectively.[31] Smokers have higher concentrations of CEA in comparison to nonsmokers, and reference ranges for CEA in lung cancer typically are stratified by smoking status. This underscores the importance of selection of cutoff values with respect to selection of reference groups. Knowledge of whether the reference group is based on healthy individuals or patients with benign diseases will influence interpretation.[29]

Knowledge of the tumor marker level before surgery is important for subsequent use in monitoring, because markers are not 100% sensitive, even in advanced disease. Tumors can be nonsecreting, or host genetic factors can affect the ability to detect an antigen. For example, CA 19-9, a sialylated derivative of the Lewis(a) blood group antigen, is not expressed in the estimated 3% to 5% of the population with the Lewis(a-b-) genotype.[1] Treatment also may influence marker concentrations, with increased release with chemo-

therapy or surgery, such as the spike observed in CA125 concentrations after abdominal surgery.[3] Tumor manipulation also can influence concentrations, as evidenced by the increased PSA concentrations observed after prostate biopsy, transurethral resection, prostate massage, or other procedures. Although the influence of DRE is thought to be minimal, it is recommended that blood for PSA measurements be drawn before the procedure or a minimum of 1 week after the DRE.[33]

One of the most critical analytic considerations in tumor-marker result interpretation is the fact that different assays, specifically immunoassays, may give different values for the same marker. Differing results among assays can be attributed to calibration differences resulting from different materials, value assignments, antibody types and specificities, assay designs and kinetics, variations in reference ranges or cutoffs, and assay robustness.[31,34,35] Therefore, values cannot be used interchangeably, and it is recommended that patients be followed up using the same laboratory method. Clinicians also should be informed when laboratories change tumor marker assay methods and should be offered a crossover period and an explanation of the association between the old and new assays.

Factors affecting assay robustness include the measuring range of the assay, encompassing the detection limit and upper limit where sample dilution is not required; accuracy and precision of dilutional linearity; high-dose hook or prozone effect leading to falsely low results; and interferences from endogenous antibodies. Endogenous antibodies include either anti-analyte antibodies such as thyroglobulin autoantibodies or anti-reagent antibodies such as heterophile and human anti-mouse antibodies (HAMA). HAMA, which may be produced as a result of treatment with monoclonal antibodies or immunoscintigraphy with antibodies similar to assay antibodies, can bind to reagent antibodies with resulting falsely high or low values, depending on assay design. HAMA can be minimized by using chimeric antibodies in vivo and at the assay level by choice of assay antibodies and inclusion of nonimmune animal serum as a blocking technique.[1,35]



FUTURE DIRECTIONS

With current advances in proteomic and genomic technology, the diagnosis of disease in the future will be based on a combination of methods, with classification based on molecular as opposed to morphologic features. Unique gene or protein profiles of multiple biomarkers, accounting for cancer heterogeneity, will be measured in tissue, cells, and body fluids. The analysis of panels of protein biomarkers may be performed by traditional immunoassay, antibody-based protein chips, or microarrays. Furthermore, many more diagnostic tests will be generated as the result of genomic and proteomic discoveries. For example, serum biomarkers for a number of cancers recently have been identified using mass spectrometry.[36,37] Integrated diagnostic tools that combine these methods with molecular imaging techniques will be used, and bioinformatics will play a key role. The rapid translation of tests from the laboratory to the bedside will elevate the importance of laboratory testing in cancer diagnosis and care of the cancer patient.

21 Imaging

Richard L. Wahl

SUMMARY OF KEY POINTS

- Noninvasive medical imaging often is essential to cancer management at multiple times in the course of the illness.
- Imaging currently is used for screening to detect cancer, characterizing lesions, performing locoregional and systemic staging, providing prognostic information, assessing response during and after therapy, restaging after treatment, performing follow-up of patients for recurrence, and precisely guiding therapies such as external beam radiation, brachytherapy, or thermal ablation.
- More invasive interventional radiologic procedures also can guide and monitor vascular or intraluminal delivery of treatments such as radioactive microspheres, embolic materials, radiofrequency or cryoablation, and therapeutic drugs.
- Imaging methods range from the traditional anatomic methods—x-ray, computed tomography (CT), and ultrasound—to the more functional methods of magnetic resonance imaging (MRI) and nuclear medicine methods, including positron emission tomography (PET) and single-photon-emission computed tomography (SPECT), and planar nuclear imaging. Optical imaging is promising, but limited by penetration of tissues to superficial structures in most cases.
- Plain films and mammography remain useful techniques, with mammography the only imaging method clearly proven effective when applied in the screening setting.
- CT remains the cornerstone technology for most oncologic imaging, and CT technology allowing for rapid-sequence angiography is finding new applications, as is three-dimensional reconstruction of CT data sets. Screening data with CT-colonography continues to improve, and in some studies it has been found to be comparable to traditional colonoscopy for colon cancer screening. CT scanning for lung cancer screening remains under evaluation and shows promise in high-risk populations.
- MRI is the imaging tool of choice for central nervous system, spinal, and musculoskeletal neoplasms, as well as in assessing vascular and some hepatobiliary and pelvic lesions. MRI also can be used to detect breast cancers, especially in women with dense breasts. Recent concerns regarding gadolinium-associated nephrogenic systemic fibrosis (NSF) have led to cautions in the use of MRI contrast medium in patients with impaired renal function.
- Bone scans using single-photon methods (^{99m}Tc methylene diphosphonate) remain the dominant procedure for detecting suspected bone metastases; however, this technology probably is less sensitive than MRI and PET techniques for detecting bone metastases of many tumors.
- PET and PET/CT technology using ^{18}fluorodeoxyglucose (FDG) continues to grow in a wide variety of applications and its use is becoming increasingly routine in the management of patients with cancer at varying states of the disease process. PET is used with increasing frequency in the staging and follow-up of lung, colorectal, and head and neck cancers, as well as lymphomas and other types of tumors, and is now a routine tool in lymphoma management at several points in the disease. PET with non-FDG tracers is a promising research area with growing clinical applications.
- The fusion of anatomic and functional images to create hybrid "anatomolecular images" with software or dedicated instruments such as PET/CT or SPECT/CT devices also is seeing rapid growth in applications in cancer imaging. Fully diagnostic CT scans coupled with PET imaging in the form of PET/CT often provide valuable composite imaging for cancer management.
- Imaging management for staging lung cancer and characterizing solitary pulmonary nodules often includes PET in addition to CT when the technology is available because PET has high accuracy in lung cancer assessments compared with CT.
- Imaging management of suspected recurrences of colorectal cancer, head and neck cancer, lymphoma, and several other cancers often now includes the use of PET in addition to CT. Use of PET at earlier stages in the workup is becoming increasingly common, as is the use of PET in early assessments of the efficacy of cancer therapies.
- In prostate cancer, available imaging methods remain suboptimal for detection of primary tumor and early determination of local or systemic tumor spread. MRI nodal contrast agents are promising but not yet routinely available, and MR spectroscopy has had only limited success in the prostate.
- Visceral angiography for diagnostic purposes is being supplanted by CT and MRI methods; however, it remains important as a tool for intravascular delivery of therapies such as chemotherapy, coils, or radioactive microspheres.
- CT, ultrasound, fluoroscopy, and innovative MRI systems can guide interventional procedures such as thermal and cryotherapeutic lesion ablations.

- Highly specific probe-reporter systems are being developed to allow for optical and radionuclide imaging of transfected gene biodistribution and function.
- Combined anatomic and functional information is being applied to allow for more precise planning of external beam radiation therapy, including IMRT and conformal therapy, methods that potentially allow for increasing dose escalation and minimization of toxicity to normal tissues.
- Emerging imaging methods are proving increasingly useful in providing information on the physiology and molecular characteristics of lesions, which means that a multiparametric biologic imaging phenotype for tumors can be obtained. This phenotype can more precisely guide individualized tumor treatment to yield a higher probability of success without excessive toxicity for treatment of the selected neoplastic process.

INTRODUCTION

Noninvasive imaging is of fundamental and increasing importance in the daily management of the patient with cancer. Although physical examination and laboratory diagnosis remain key for planning treatment, for solid tumor management, imaging tests represent a major objective metric of disease activity and may be used at different times during the course of the disease to monitor the efficacy (or lack of efficacy) of treatment. Imaging tumor size is an objective endpoint in disease management used to compare different types of cancer treatment and treatment across institutions. The use of imaging also is increasing in the drug development process and in developing new cancer therapies.

Specific clinical questions addressed by imaging include screening for the presence of cancer, characterizing anatomic lesions as malignant or benign, and staging a neoplasm—that is, determining the size and local extent of a primary lesion and determining whether it is localized or locoregionally or systemically metastatic. Such studies are essential for determining whether the patient is a candidate for surgical resection, identifying the extent of the field for radiation therapy, and determining whether systemic chemotherapy is appropriate. Initial staging of tumor size and extent also can provide important prognostic data. During the course of treatment, imaging is used to determine response of the cancer. Imaging also is used to follow patients for recurrence or development of second malignancies. Imaging is being used more often as a method to assist delivery of minimally invasive therapeutic procedures to ablate cancers and to guide the dosing of therapeutic drugs, including radiopharmaceuticals, more precisely.[1]

Imaging often is the best means of noninvasively identifying and assessing tumors. With information gleaned from imaging studies, the prognosis can be established and treatment decisions made with greater certainty. Before discussing the varying imaging methods available for cancer, this chapter considers some general principles that are applicable to all imaging tests.

Tasks for Imaging

The major roles of imaging in the current and evolving practice of cancer management are shown in Table 21-1.

GENERAL CONSIDERATIONS

Performance of Imaging Tests

Noninvasive imaging is used to perform a wide variety of important tasks. Although the best way to determine the medical utility of a diagnostic test can be argued, a few key concepts are required to understand and compare diagnostic tests. These can be applied to one of the most basic tasks (i.e., determining whether tumor is present) and also to the ability of imaging to predict resectability or response to treatment.

Sensitivity

Sensitivity describes how often the imaging test would give a "positive result" in a patient with cancer (i.e., true-positive [TP] finding). Ideally, the test precisely detects and locates one or multiple cancers in a given patient. Thus,

$$\% \text{ sensitivity} = 100 \times (\text{test positive/disease present}).$$

Sensitivity can be calculated on a per-patient basis or a per-malignant lesion basis. The per-patient basis most commonly is used in screening studies for early diagnosis, whereas the per-lesion basis may be used in patients expected to have multiple sites of tumor. Per-lesion detection analyses can be misleading because they can be heavily biased by a single patient's results if that patient has multiple tumor foci.

It can be difficult to judge how good a test is by reading the literature. Sensitivity is supposed to be substantially independent of

Table 21-1 Imaging in Cancer: Key Current Clinical Uses in Cancer Management

SCREENING
Lesion characterization: malignant or benign, size, local invasion
Tumor staging: locoregional, systemic, at initial presentation or on retreatment
Size and extent of tumor: to plan radiation or other local therapy
Prognostic information
Defining sites for biopsy and subsequent analysis by pathology
Guidance of interventional therapy
Assessment of response to treatment
Restaging tumor after treatment
Assessment of normal organ function or status before, during, and after treatment
Assessment for toxicity or complications of treatment
90% SENSITIVE AND SPECIFIC TEST
50% Prevalence of cancer in the population imaged
1000 Independent scans
50 False-positive findings in healthy patients (10% of 500)
450 True-positive findings in patients with disease (90% of 500)
Positive predictive value (disease positive/test positive): 450/500 (90%)
Possible conclusion: An excellent test!
90% SENSITIVE AND SPECIFIC TEST
10% Prevalence of cancer in the population imaged
1000 Independent scans
90 False-positive findings in healthy patients (10% of 900)
90 True-positive findings in patients with disease (10% of 900)
Positive predictive value (disease positive/test positive): 50/100 (50%)
Possible conclusion: A rather lousy test!
But these are the same test!

study composition, but as discussed in the next section, certain imaging tests may be insensitive for some very early-stage disease, but very, very sensitive for more advanced disease. Thus, the patient population and, very often, the tumor burden and average tumor size can make a difference in the sensitivity of a test. Virtually all noninvasive imaging tests are less sensitive for small-volume disease than for large-volume disease. For example, if an imaging test is used in a patient population in which patients have advanced disease before seeking medical attention (e.g., they are symptomatic at presentation), the imaging test may have far greater sensitivity than if it were used in patients with earlier-stage, smaller tumors. For example, positron emission tomography (PET) with ^{18}fluorodeoxyglucose (FDG) has been reported to be more than 90% sensitive for detecting metastatic melanoma, but it is less than 20% sensitive in detecting early (low tumor volume) nodal metastases of melanoma at initial surgical resection. A test with high sensitivity has a low number of false-negative results.[2] The false-negative fraction usually is expressed as 1 − sensitivity.[3]

Specificity

Specificity is the frequency with which a test result is negative if no disease is present, or the true-negative (TN) ratio. As a percentage, specificity is

$$100 \times (\text{test negative/disease negative}).$$

Again, specificity can be calculated on a per-patient basis or a per-lesion or per-region basis. The per-patient calculations commonly are performed in the screening setting. They also can be done per region of the body (e.g., Is the liver free of tumor? Are the draining lymph nodes free of tumor?). Specificity can be affected substantially if there is a population characteristic that can result in false-positive results for the imaging test. For example, inflammatory and infectious lung disease, such as active tuberculosis or sarcoidosis, if present in a patient population, can result in false-positive findings on PET or CT scans or other imaging methods. In this situation, the specificity of FDG-PET, and likely of CT, for staging the mediastinum for cancer would vary. Thus, the specificity of PET for assessing mediastinal lymph nodes may be much lower in areas of the world with endogenous TB than in developed areas without it. Therefore, an imaging test that is very useful in one part of the world may be far less useful in another part of the world. A highly specific test has a low frequency of false-positive results (i.e., a low frequency of a positive test results in the patient population that does not have the disease). The ideal imaging test has both high sensitivity and high specificity, although none of our current imaging tests have perfect sensitivity and specificity.[2]

Accuracy of Imaging

For detection of disease, a binary, yes-or-no answer as to whether disease is present or absent is desirable. When such binary answers can be provided, it is simple to mathematically provide an accuracy value for a diagnostic imaging test. Thus, accuracy is

$$100 * (TP + TN)/(TP + FP + TN + FN).$$

A highly accurate test is one with a low prevalence of false-positive and false-negative results.

Positive and Negative Predictive Values

Sensitivity and specificity define a test reasonably well, but its performance in a specific patient is affected by the characteristics of the population from which the patient is drawn. A physician normally wants to know whether an individual patient has cancer and whether the tumor is localized or metastatic. The correct answer is binary in most cases, but imaging does not always reveal the true status of the individual patient. Thus, the statistical likelihood of the accuracy of the result might be conveyed in the clinical imaging test report. This statistical likelihood will be related to the accuracy of the test as well as to the patient population characteristics. Thus, the positive predictive value often is of considerable clinical relevance. For example, the positive predictive value of a test with 90% sensitivity and 90% specificity will vary markedly, depending on the frequency of disease in the population. With these test performance characteristics, the clinician could reach two different conclusions regarding the same imaging test.

Thus, a test that is effective in a patient population with a high prevalence of a disease may be far less valuable in a patient population with a lower prevalence of the same disease, because there would be far too many false-positive results. The most effective use of imaging technology is in groups of patients in whom the imaging characteristics are expected to be robust enough to allow for predictions in individual patients. These challenges are particularly apparent when a test that was developed in a patient population with disease is used to evaluate individuals with a low prevalence of tumor (i.e., screening). In this situation, the number of false-positive findings may rise dramatically, sometimes nearly completely negating the value of the test.[4]

Receiver Operator Characteristic Curves

Cancer imaging tests are interpreted by imaging specialists, often radiologists. As with all of medicine, there is considerable science involved in image interpretation, but the human element, or "art," as it is referred to in some settings, also is involved. In developed countries, medical specialty boards have been established to ensure that practitioners have a basal level of training and knowledge, thereby providing some level of uniformity to image interpretations. However, even with board certification and extensive training, not all imaging specialists interpret a given imaging study in the same manner. Thus, although the goal of an imaging test often is a simple binary "yes, there is tumor" or "no, there is not tumor" answer, there are varying degrees of certainty in the interpretation of an image in most instances. Some readers read with high sensitivity, whereas others read with high specificity. Unless a test is very robust, it is hard to achieve both high sensitivity and high specificity.[5]

An example of a receiver operator characteristic (ROC) curve is shown in Figure 21-1. This set of curves reflects the performance of PET imaging in detecting axillary metastases in patients with newly diagnosed breast cancer. The axes of the curves are the true-positive fraction (sensitivity/100), which forms the y-axis, and the false-

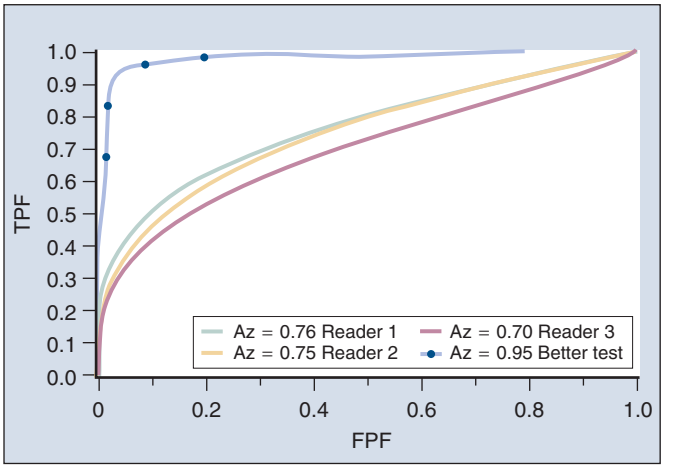

Figure 21-1 • Receiver operator characteristic (ROC) curves plotting the true-positive fraction (TPF) [sensitivity] vs. the false-positive fraction (FPF) [1 − specificity] for the three independent readers of the entire analysis data set. A hypothetical curve for the test if it had 95% accuracy also is shown. Az, estimated area under the ROC curve.

positive fraction (1 − specificity/100), which forms the x-axis, on a scale of 0 to 1. A perfect diagnostic test would yield no false-positive or false-negative results. The greater the area under an ROC curve, the greater the accuracy of the test. The results shown in the figure are from three readers who graded PET scans using a five-point certainty scale (i.e., not a simple yes/no, but a continuum from definitely abnormal to definitely normal). The three readers had similar ROC curves, indicating that they were of generally comparable accuracy. For the same test, however, two readers may be reading at different points on the ROC curve, meaning that one is more sensitive and one is more specific, but both are of equal accuracy. An excellent reader may have a greater area under the ROC curve than a less skilled reader, meaning that the more experienced (and more capable) reader is both more sensitive and more specific than a less experienced (and less capable) reader. Nonetheless, virtually none of our imaging tests is perfect, and varying "cut points" between disease and normalcy often are made, affecting the overall performance of the test. In this study, the area under the curve (AUC) of 0.7 to 0.76 was not viewed as sufficiently good for the task of nodal detection of metastatic cancer spread to the axilla. Despite this, a very high sensitivity or a very high specificity can be achieved depending on which part of the curve one operates in. A higher, hypothetical curve, with an AUC of 0.9, is shown for a more robust test, such as a higher-resolution PET system devoted to imaging the axilla. In practice, sentinel node sampling, often guided by imaging or a radionuclide-sensitive probe system, is assuming a very important role in this area of tumor staging.[6]

Other Approaches to Assessing the Value of Imaging

Although sensitivity, specificity, and accuracy commonly are used to characterize the tumor detection process, other metrics may be of greater importance. For example, some studies have focused on how often imaging substantially changes management. This kind of study is of great practical interest, but the optimal methods to assess such changes in treatment decisions are evolving. Ideally, one would like to show that the use of imaging, especially a new imaging technology, when applied randomly to half of the study population, provided a reduction in the number of adverse events in the imaged population or improved survival. As an example, a reduction in the number of "futile thoracotomies" has been used as a metric of success for PET vs. CT in planning the treatment of newly diagnosed lung cancer.[7] Ideally, randomization of patients to imaged versus not imaged groups can be shown to improve survival. However, performance of randomized trials in which half of the patients undergo imaging and the other patients do not (or they obtain different kinds of imaging), with an endpoint of survival, will be of great interest. Unfortunately, such studies are complex because management of patients after imaging may be altered markedly based on the imaging results. Thus, it can be difficult to separate the imaging study effect from the treatment effect. Ultimately, however, for some imaging studies to be adopted, such evaluations of survival will be needed. This point is particularly relevant to screening, as discussed later.

Screening Concepts and Challenges

Screening programs for cancer often have taken the form of laboratory tests such as the Papanicolaou (Pap) smear, or, more recently, blood tests for tumor markers. The success of the Pap smear in reducing societal mortality rates from cervical cancer is incontrovertible. The use of imaging in screening for cancer is an example of success and considerable interest, but also a source of considerable controversy. As discussed in detail in the chapter on breast cancer (see Chapter 95), screening mammography programs have been shown to be capable of saving lives in women older than 50 years of age. These programs also may save lives in women 40 to 50 years of age, but the data are less compelling.[8]

Studies have been initiated in which CT scanning is used in an attempt to detect early lung cancer.[9] Screening high risk populations with CT imaging has not yet been proven to affect mortality. However, the Early Lung Cancer Action Project (ELCAP), a large study screening patients at increased risk of lung cancer with low-dose CT, reported promising results in 1999.[10] Preliminary results from that trial showed that lung cancers are detected at a smaller size and that patients whose cancers are detected by screening live longer following diagnosis than patients whose tumors are not detected by screening. Whether this turns into longer-term survival for the screened population remains unclear. The ELCAP study further evaluated 31,567 asymptomatic persons at risk for lung cancer using low-dose CT from 1993 through 2005, and from 1994 through 2005; 27,456 repeated screenings were performed.[11] A diagnosis of lung cancer was made in 484 participants based on screening. Of particular note, 412 patients (85%) had clinical stage I lung cancer. Ten-year survival approached 90% in this group.[10,11] This study clearly demonstrated that annual spiral CT screening can detect lung cancer that is curable. Another large randomized trial of lung cancer screening currently is underway in which both CT scanning and chest x-ray screening are used. This trial has raised some controversies, because many small pulmonary nodules are identified that are not malignant, the costs of the trial as well as of the medical care for incidentally detected lesions are substantial, and a substantial radiation burden, which, in principle, could be carcinogenic, is delivered to patients receiving the screening. However, there is considerable hope that screening programs can achieve a reduction in lung cancer mortality. For example, as discussed later in this chapter, CT colonography holds excellent promise as a screening method for colon cancer, as an alternative to optical colonoscopy.

Other areas in which screening by noninvasive imaging has been performed include colorectal cancer, where virtual colonoscopy can be used to look for early colon cancers, and in the pelvis in women who are at risk for ovarian cancer. More recently, screening CT centers offering a virtual evaluation of the entire body have become available, and even more recently, MRI and PET screening have been offered in some locales. The growth of these centers has been driven emotionally and economically; these tests are not yet well-founded scientifically in the screening setting.

Screening carries challenges, risks, and costs that are beyond the scope of this overview chapter. However, several key points apply to all screening approaches, including those using noninvasive imaging. These points include (1) whether a screening program is reasonable to consider; (2) lead time bias; (3) length bias; and (4) the overall cost implications of screening, especially the costs of investigating false-positive results.

The requirements that a screening program must meet to be considered "reasonable" may differ substantially based on the specific society's values and a specific individual's perception of risk. However, in general, the following characteristics are important for cancer screening:

- The cancer must have a considerable public health effect.
- The disease must have an asymptomatic period in which detection by imaging is possible.
- A therapeutic intervention that can lead to better survival or quality of life must be available.
- The prevalence of the disease must be sufficient in the population being screened to justify screening (especially the cost).
- Medical, surgical or other treatment must be available for the early-stage cancer identified by screening.
- There must be a high likelihood that the patients in whom early cancer is identified by image-based screening will go on to have a suitable therapeutic intervention.

Further, the imaging test itself must be acceptable to patients (in terms of level of discomfort and cost), and it must be sufficiently sensitive to identify cancer often and sufficiently specific to minimize false-positive results. Finally, the costs of the screening process must be compatible with the society's or the individual's economic system,

and the screening procedure must pose little or no risk to the patient.[4]

Another important consideration in screening programs is lead time bias. This concept, simply stated, indicates that if the natural history of a disease is unchanged, but the diagnosis is made earlier in the course of the illness, the apparent survival will be improved. For example, let us assume that tumor X has a 6-year natural history from its beginning until the death of the patient, and that treatment was ineffective. The disease might become clinically detectable after 4 years and lead to death in 6 years, a 2-year survival after diagnosis. With screening, if the tumor is detected 3 years after the onset of disease and no improvement in treatment occurs, then the survival in the screened population would appear to increase from 2 to 3 years after diagnosis. This illusion of improved survival in the screened population is a considerable concern and can lead to inappropriate enthusiasm for screening programs.[4]

Another important consideration in screening is the possibility of length bias. This is a more complex concept, but it may be related to the types of cancer that can be detected by screening programs. A possibility is that very rapidly growing and presumably highly lethal cancers are less likely to be detected by annual screening programs, whereas more slowly growing cancers, which have an intrinsically better prognosis, may be detected more frequently by screening. In fact, some of the early cancer discovered may not be biologically relevant at all. If so, the patients with cancers identified in the screened population could appear to have a better survival than the patients with cancers identified in the unscreened population.

A third factor is the selection bias that is difficult to control for in observational studies. Selection bias occurs when there are unintended differences between the groups observed that, while they are associated with the variable used to sort the groups—for example, exposure in case-control studies and outcome in cohort studies—affect measurement of the study variable.[12] For instance, in a case control design on the effects on disease specific mortality of a particular screening program, investigators would look at patients who have died from the disease in question, versus those who have not, then determine the rates of the screening intervention in these two populations. However, it is possible that those likeliest to have sought screening were the ones at highest risk for the disease. Results for the screening's effect on mortality could be underestimated in such a scenario. Selection bias also can work in the opposite direction, where the high risk/poor prognosis individuals are less likely to seek screening. With the relative absence of large randomized prospective trials, as is the case when evaluating imaging as a screening tool, we may be tempted to base our conclusions on cohort or case control studies. However, the most accurate conclusions would be drawn from a randomized study design.

Collectively, lead time bias and length bias and, at times, selection bias, can make screening programs appear to improve the survival of patients with cancer. Because of these major biases intrinsic in screening, very large, randomized, studies are required to show that overall cancer-specific mortality (and ideally mortality from all causes) declines as a result of screening programs.

The advent of imaging and other screening tools that uncover a tumor long before it is symptomatic also brings up the need for biomarker discovery to help physicians to determine whether to treat what has been discovered through screening. The experience with prostate specific antigen (PSA) screening in prostate cancer serves to illustrate the point that not all cancers identified by screening eventually lead to death. Discovering and validating biomarkers that can help to distinguish reliably between lethal and nonlethal tumor types will be of great help in reducing unnecessary treatment in patients with less active disease.

Screening Costs

The determination of whether a screening program is valuable is based on its cost and benefit. The concept of quality-adjusted life-years (QALYs) often is applied. This concept is defined as the economic cost to society required to result in 1 additional year of quality life for a member of the society. In many western countries, a figure of $50,000 has been considered a useful guide, with QALYs lower than this amount considered cost-effective. Such a guideline, however, does not necessarily apply when individuals make their own determinations as to whether to pay for a screening test. For example, it is reasonable to expect that those with greater disposable income would be willing to pay more per QALY than those with less disposable income. Thus, it can be difficult to generalize about the cost efficacy of screening procedures.[13]

Even when people choose to undergo a screening test at their own expense, considerable costs can be transferred to society as a result of the screening program. For example, if a screening test has a high rate of false-positive results, a substantial number of follow-up biopsies or procedures will occur and can cost a great deal of money. Such costs can dramatically raise the total cost per QALY. Particularly invasive procedures also can increase the likelihood of morbidity or death as a result of additional investigations. To determine the true cost per QALY associated with screening, these additional costs and risks must be considered. Thus, screening remains an area of great promise, but also of considerable controversy. Screening beyond breast imaging must overcome major hurdles before it is likely to be accepted. It is quite possible, however, that in high-risk patient groups, such as those with a family history of cancer or major carcinogen exposure, with a high penetrance or of early onset, that screening may prove of greater value than in the general population.

Size of Detectable Lesions

Noninvasive imaging methods in humans cannot detect and localize a single malignant cell, although flow cytometric methods are very sensitive for finding a very few cancer cells in a patient's blood. Imaging methods are improving, however, and detection of a much smaller number of cells is possible in small animal models. However, it has been estimated that by the time a tumor reaches 3 to 5 mm in diameter, which is the lower limit in size for detection by the best current noninvasive methods in humans, the tumor has undergone more than 25 doublings and contains 0.1 to 1 billion cells, depending on their size.[1] In contrast, a cytologist, on a very good day, may be able to identify a single cell as malignant using a microscope.

Realistically, even for histologic assessment of malignancy, typically a group of tumor cells must be present before cancer is diagnosed. However, light microscopy and more sensitive techniques such as immunohistochemistry and polymerase chain reactions mean that pathologic techniques potentially will be more sensitive than imaging methods. One very important proviso is that for pathologic methods to be effective, actual examination of the malignant cells is required; the sample containing the tumor must be cut appropriately and viewed under a microscope. This task may be impossible, because the 8-μm sections that are used for pathologic examination typically are taken only from a small portion of a tumor or lymph node, whereas most of the tumor or node will be unexamined (e.g., to assess a 1-cm node using 8-μm-thick sections, approximately 125 sections would be required). This large number of sections is not typically obtained. Despite the markedly superior sensitivity of histologic methods over noninvasive imaging, there is a major sampling error issue, and, paradoxically, imaging in some diseases potentially may be more sensitive than histologic examination for cancer. This situation can arise in mammography, where small tumor foci can be seen on the mammogram but can be missed on cytological sampling, possibly due to sampling error. When tumors are imaged by noninvasive methods, the entire tumor is visualized, not just a small portion. So, paradoxically, imaging, despite limited resolution, can be more sensitive than cytology or pathology. However, if exhaustive and thorough sampling is performed, with microscopic examination of

tissue, there usually is greater sensitivity for tumor than there is with current noninvasive imaging techniques.

Stage Migration

One of the major goals of noninvasive imaging is to stage the tumor precisely to allow the clinician to best choose treatment and determine the prognosis. The evolving concepts of tumor staging are discussed elsewhere in this text, but improvements in detection technology can change the understanding of the natural history of a given stage of disease. Patients with small or microscopic metastases to the mediastinum are likely to do better than patients with bulky metastases, but both may have the same stage of disease. As the sensitivity for detecting small lesions improves, it becomes possible to identify more patients with small primary tumors and small metastases to the lymph nodes or systemic disease. Thus, when primary tumors are detected at ever earlier and less advanced stages as imaging methods improve, patients are assigned to a higher stage than was used historically. Their presence in the advanced-stage group appears to improve survival and outcome in that group. Moreover, the outcome of the lower-staged group also may improve because a subset of patients with now-detectable tumors has been removed from that group. The outcome of the overall group will not have changed. Thus, one has to be very cautious in extrapolating historical survival data based on an insensitive staging method with that seen with a more sensitive method.[4]

MAJOR IMAGING MODALITIES

Broadly stated, cancer imaging can be performed using anatomic or functional imaging methods.[1] The traditional imaging of the patient with cancer, and the most established methods, are based on anatomic imaging. However, interest is increasing in more functional methods in cancer imaging. Further, several anatomic imaging methods offer functional components that complement the anatomic method. Hybrid images, derived from and displaying both functional and anatomic data, also are becoming more widely available, often coming from the same hybrid imaging machine.[14,15] Imaging data are increasingly digital or digitized and suitable for postprocessing and image exchange. The major imaging modalities are discussed in the following section.

Plain Film X-Rays

The traditional x-ray remains an important part of cancer imaging. It commonly is used to detect bone tumors and can be used to detect lung cancers in the thorax. The method displays mainly water and calcium density and is affected by overlapping tissue in front of or behind the lesion. X-rays have become increasingly digitized in the last few years, with the introduction of film digitization and phosphor screen capture devices. X-rays offer exceptional resolution, but provide relatively little image contrast if there is not much calcium present. The radiation dose from a plain film x-ray depends on which portion of the body is being examined. In most centers, plain film radiographs for cancer management are being used less often, with CT scanning increasingly replacing radiographs in the abdomen and MRI in the brain and extremities.[16]

Mammography

Mammography is a specialized form of plain x-ray. Very high-resolution images of the breast are obtained using specialized devices optimized for breast cancer detection. Digital mammography is now available, and offers greater flexibility of image display because of the digital image format. A limitation of the digital format, however, is the field of view of the imaging phosphor, which may be too small to fully include some breast tissue. In the last several years, there has been a major shift toward digital mammography. The recent Digital Mammographic Imaging Screening Trial (DMIST), which included nearly 50,000 women, showed comparable overall accuracy between film screen and digital mammography in the overall study. A higher accuracy for cancer detection in women under 50, women with radiodense breasts, and pre- and perimenopausal women was seen with digital mammography as compared with film-screen mammography.[17] Despite this higher accuracy, the reported sensitivity for both techniques for cancers was only 41% with a positive predictive value of 12%, albeit with 98% specificity. This is far from ideal performance for a screening test. The move to digital mammography is in part to increase diagnostic accuracy but also to allow digital images to be viewed on picture archiving and communication system (PACS), as is the case with virtually all other diagnostic imaging methods in more and more imaging centers.[17,18] A newer technique, tomosynthesis, is under evaluation in which a number of "slices" of the breast are generated during a mammographic image acquisition. This approach offers considerable promise going forward, but is early in its evolution technically.

Computed Tomography

CT is now established as the dominant imaging technique for cancer detection and follow-up. Currently, tumor response and staging criteria very commonly are based on tumor size as measured on CT. CT scanners acquire images using an x-ray source and digital detector elements. The x-ray source rotates rapidly around the patient, commonly with a single scan level taken in 0.5 seconds or less. Faster and faster rotation speeds of the scanners, along with multiple simultaneous detectors capable of imaging multiple slice thicknesses in a rapid spiral motion, are being used. Scanners with 16 and 64 simultaneous slices are commonly in use, with scanners with 256 slices now in use in some devices. Large-field-of-view detectors may allow even more of the body to be evaluated nearly instantaneously. Current fast scanners can potentially evaluate the entire body in a fraction of a minute. Although such evaluations provide key information about lesion size, some lesions may elude detection unless contrast medium is given intravenously, orally, or both. With such devices, it also is possible to capture contrast in arteries or veins to provide superior visualization of these structures, which can then be displayed three-dimensionally or in a volume-rendered fashion. While more slices in a CT scanner make for faster CT scans, it is not clear that having more slices always results in a superior diagnostic quality scan. More slices and faster scans do mean that whole-body scans in a single breath hold can be obtained, which is advantageous, because it can reduce the frequency of breathing artifacts. A clear disadvantage of CT is its cost, both technically and in terms of the radiation dose. In the past several years, increased concern has developed regarding the total radiation dose being delivered by CT, particularly in children, due to the potential risks of carcinogenesis. Although CT is an exceptional technique, it remains a predominantly anatomic imaging method. While there is information in the timing of IV CT contrast enhancement, it is not easily extracted without a substantial radiation dose from repeated images. Thus, only a limited number of post-IV contrast images are obtained with CT, to limit radiation dose. All CT images are digital. A major challenge with CT is the large amount of image data generated for analysis, data that can take the radiologist a long time to interpret fully.[19]

Angiography

Historically, angiography has been performed after intravascular insertion of catheters into arteries, followed by rapid injection of iodinated contrast media, along with rapid-sequence filming of the images. The improving ability of rapid-sequence CT scanning to show the vascular anatomy (CT angiography) has caused it to rapidly replace angiography for diagnostic purposes. Angiography still can be used to produce the most precise maps of vascular anatomy before organ transplantation or radical cancer surgery. Most angiography

now is performed using digital image-capture devices, known as digital angiography.

Angiographic delivery of therapy is, however, an important area. This form of imaging can allow for therapeutic delivery of embolization materials such as coils, delivery of chemotherapeutic agents regionally, or delivery of radioactive microspheres, for example.

Angiography has high resolution, but typically delivers a high dose of radiation energy to the patient. The use of angiography remains essential for studies to evaluate GI bleeding, but with CT angiography continuing to improve in quality, the use of diagnostic angiography has become less frequent in routine clinical practice.[20]

Ultrasound

Ultrasound uses reflected beams of high-frequency sound rather than ionizing radiation to generate images. Ultrasound provides high resolution and some functional information, specifically about the presence and direction of blood flow in tissues. It also provides some information regarding tissue characterization properties, and is very effective in determining whether a tissue is cystic or solid. The method also is excellent for detecting vascular structures and determining extent of flow. Ultrasound provides real-time imaging capability to guide biopsies and procedures effectively. Ultrasound is less effective in the evaluation of deeper structures, and requires access to a sonographic window. Thus, it has only a modest role in evaluating deep abdominal structures. Ultrasound is used commonly in evaluations of the pelvis, neck (including the thyroid), and gallbladder and liver areas. Agents that can enhance the visualization of vessels or can be specifically retained in clots are under evaluation, suggesting that ultrasound can offer some functional information beyond the purely anatomic.[21]

Ultrasound contrast agents are being applied to a limited extent. Currently, these agents are mainly for intravascular use. High-energy focused ultrasound remains under development as a tool to ablate, or at least deliver thermal energy to, tumors with therapeutic intent. Ultrasound coupled with needle aspiration biopsy has been used in some settings as a minimally invasive procedure to characterize nodal metastases. Ultrasound combined with mammography also is being evaluated as a screening method for breast cancers, but results in high-risk patients have shown disappointingly low detection rates relative to MRI.[22]

Magnetic Resonance Imaging and Magnetic Resonance Spectroscopy

In many clinical settings, MRI, as applied in imaging for most cancers, is used predominantly as an anatomic imaging method that does not use ionizing radiation. MRI offers superb contrast resolution between tissues and excellent spatial resolution. MRI also offers a variety of forms of functional information. However, it does not offer the level of temporal resolution, in general, seen with ultrasound, fluoroscopy, or recent-generation, multiple-slice CT scanners. However, MRI technology has moved forward inexorably, and rapid-pulse sequences allowing gating of images now are available for several types of scanners. MR images can be of a variety of pulse sequences, allowing visualization of several parameters. However, visualization of hydrogen nuclei is the major approach with conventional 1.5T and 3T (Tesla) machines. Visualization of blood, especially with contrast materials such as gadolinium chelates, and of altered vascular permeability is routinely applied.[23]

MRI is the preferred procedure in evaluating neoplasms of the brain and spinal cord regions as well as musculoskeletal tumors. MRI also is being used with increasing frequency in the evaluation of tumors of the extremities, such as sarcomas. With gadolinium contrast enhancement, MRI also can be useful in locating tumors of the breast, which appear as areas of contrast enhancement. Such studies have shown the higher sensitivity of MRI versus mammography. However, there remain concerns that MRI may achieve this sensitivity with an accompanying relatively high false-positive rate, depending on the methods used for interpretation. Still, MRI probably is our most accurate technique for detecting and characterizing breast masses. MRI also can provide valuable information about tumors in close proximity to vascular structures as well as in the liver and upper abdomen. Tumors in the upper abdomen and liver can be degraded in their appearance on MRI because of respiratory motion artifacts. Therefore, this approach is applied less commonly than in other situations, such as in the lower pelvis, where there often is less respiratory motion artifact. Research currently is working on developing agents that can facilitate specific MRI contrast enhancement. More rapid whole-body MRI acquisition methods also are under evaluation, which may broaden the use of MRI.

In magnetic resonance spectroscopy (MRS), tissue characterization can be achieved by sampling its magnetic spectrum at 1.5T. Some devices now provide a 3T or higher field strength signal for evaluation, offering the possibility of more refined tissue characterization. Opportunities to detect increased content of choline (often increased in tumor foci) versus other substituents can be helpful in separating tumor from nonmalignant tissues in the brain and elsewhere. Spectroscopy also can provide information on lactate concentration and pH, among other parameters. A limitation of spectroscopy is resolution, which typically is not nearly as fine as that of MRI itself. Thus, spectroscopy has only limited application in most oncologic practice.[24]

Recently, diffusion MRI has shown promise in tumor response assessment. This depends on the freer movement of nuclei in areas of necrosis as compared with the motion of nuclei in fully viable tumors. This technique is demonstrating considerable potential for response assessment in brain tumors and recently has shown promise in tumors in the bones.[25]

Nephrogenic systemic fibrosis (NSF) recently has been linked to Gd-containing MRI contrast agents.[26] This condition has been described in patients with substantially impaired renal function who receive MRI contrast intravenously. "Black box" warning labels now appear on the product inserts for MRI, and we are seeing increased use of alternative imaging methods to MRI in patients with low creatinine clearance rates followed by sequential imaging studies. Gadolinium may be responsible in part for this process as it has been found in the skin of some of such affected patients.[27,28] In 2007, black box warning labels were added to the package inserts related to Gd-containing MRI contrast (Box 21-1).

Box 21-1. FDA BLACK-BOX WARNING REGARDING GADOLINIUM MRI CONTRAST MEDIUM

Warning: Nephrogenic Systemic Fibrosis

Gadolinium-based contrast agents increase the risk for nephrogenic systemic fibrosis (NSF) in patients with

- Acute or chronic severe renal insufficiency (glomerular filtration rate <30 mL/min/1.73 m^2)

OR

- Acute renal insufficiency of any severity due to the hepato-renal syndrome or in the perioperative liver transplantation period.

With these patients, avoid the use of gadolinium-based contrast agents unless the diagnostic information is essential and not available with noncontrast enhanced magnetic resonance imaging (MRI). NSF may result in fatal or debilitating systemic fibrosis affecting the skin, muscle, and internal organs. Screen all patients for renal dysfunction by obtaining a history and/or laboratory tests. When administering a gadolinium-based contrast agent, do not exceed the recommended dose and allow a sufficient period of time for elimination of the agent from the body prior to any readministration (See WARNINGS).

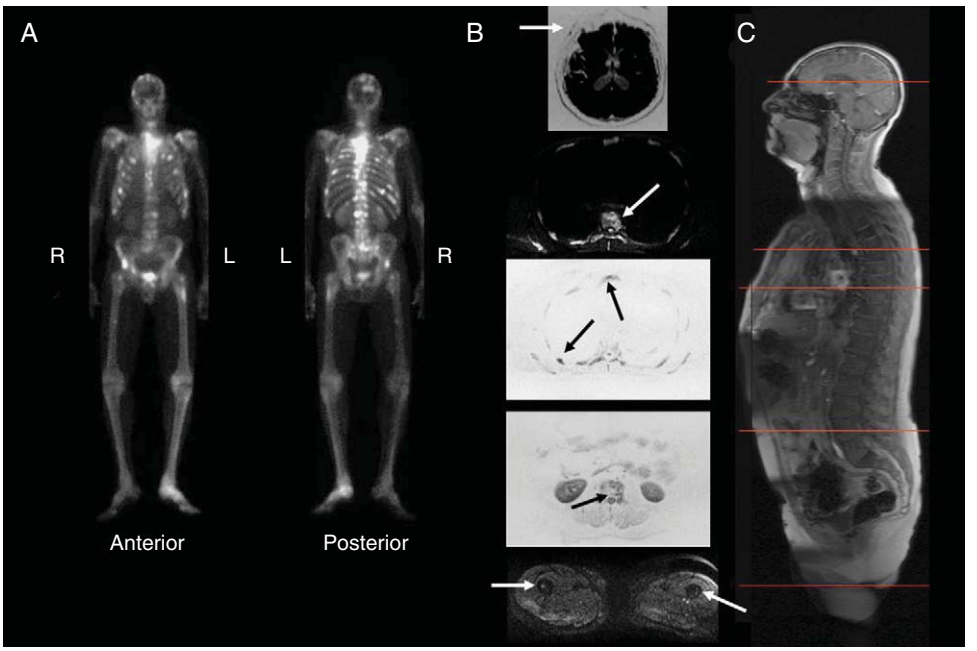

Figure 21-2 • Representative 64-year-old patient with metastatic disease. **A,** Tc99m MDP bone scan obtained after injection of the istotope 21 μCi. The bone scan demonstrates multiple areas of increased uptake in the calvarium, sternum, ribs, vertebra, pelvis, and femur. Degenerative and inflammation changes are noted in the left knee and left ankle (postfracture due to fall). **B,** Axial diffusion-weighted images (b = 300–600 s/mm^2) of corresponding areas of metastatic sites. Note that the sternum metastases are clearly seen, as are those in the rib and femur (*arrows*). **C,** Sagittal image showing whole-body coverage.

An exciting area of application of MRI technology is in the field of whole-body MRI. Such a test may begin to offer whole-body cancer surveys with no ionizing radiation delivered to the patient. Such applications to date have been less sensitive than whole-body PET imaging, but this area is emerging very rapidly[29] (Figs. 21-2 and 21-3).

Nuclear Medicine and Positron Emission Tomography

Radionuclide methods can provide a great deal of functional information, but the anatomic resolution often is limited. Broadly, there are single-photon and positron-emitting isotopes. Single-photon emitters typically have longer half-lives than positron emitters, and decay in a different fashion, emitting gamma rays. Depending on the ligand attached to the radioactive isotope, a wide variety of processes can be imaged. For single-photon imaging, the most common isotope is ^{99m}Tc, which can be used to image bone (bone scan with ^{99m}Tc methylene diphosphonate) or thyroid (technetium pertechnetate), for example. With positron emitters, the most commonly used tracer is F18, which is used as the radiolabel for FDG, an agent that images glycolysis in vivo. Because tumors have increased glycolytic metabolism in general, use of this agent in tumor imaging is increasing very rapidly, especially in lung and colorectal tumors and lymphomas.[30]

Both PET and SPECT have very high sensitivity for a small number of radioactive molecules in vivo as well as the ability to quantitate the radioactivity concentration precisely. Thus, these methods are important as both clinical and research tools. The intrin-

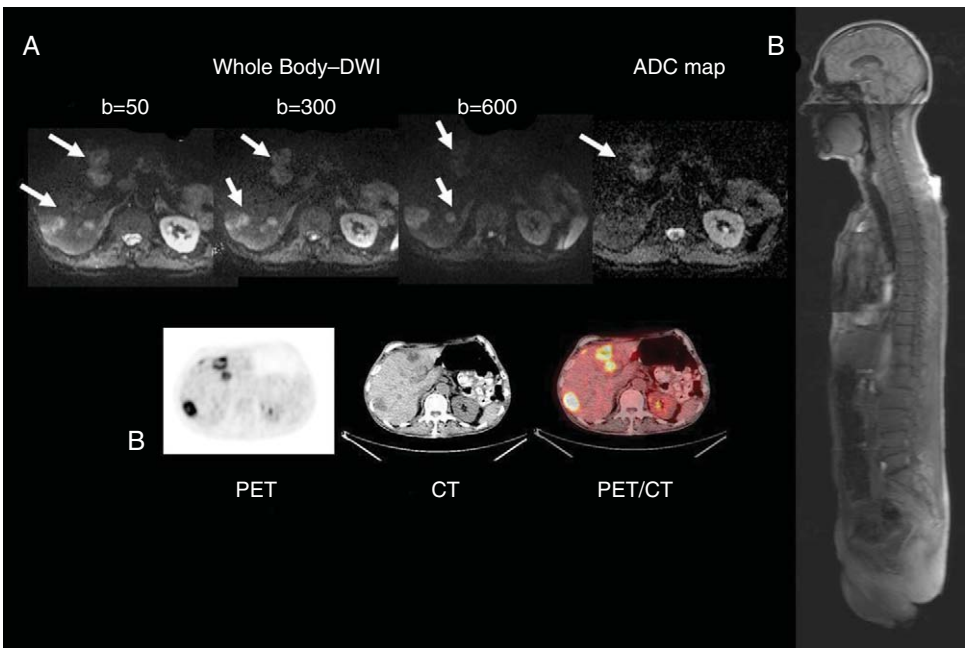

Figure 21-3 • This 72-year-old man had colorectal cancer and metastatic disease in the liver. **A,** Diffusion-weighted images of different b values in the liver. **B,** Corresponding PET, CT, and PET/CT images.

sic lack of anatomic resolution for PET and SPECT can be partly addressed by fusing the PET or SPECT images to CT using computer software. More recently, dedicated hybrid imaging devices, including both PET and CT or SPECT and CT in a single device, have been applied to the imaging practice of cancer.

Higher doses of radioactive isotopes also can be therapeutic. For example, ^{131}I is used for the treatment of thyroid cancer, as sodium iodide. The same isotope, conjugated to an anti-CD20 monoclonal antibody, has been approved by the U.S. Food and Drug Administration to treat low-grade and transformed B-cell non-Hodgkin's lymphoma that is considered refractory to standard treatments. The tracer doses are used to guide the treatment doses in such instances or at least to determine if the radioantibody has any unexpected targeting behavior.[31]

Optical Imaging Methods

Optical imaging methods are applied in a variety of ways. The external physical examination of a patient involves visual interrogation of reflected light. Infrared and transmitted light also are used to a limited extent in evaluating small parts of the body. Optical imaging has been limited in clinical deployment by the limited penetration depth of a variety of forms of light in the body. Thus, this type of approach may prove of greatest utility in evaluating small animals as part of experimental studies, or for superficial organs, such as the breast. Similarly, the technique may have greater utility in evaluating intraoperative procedures. The possibility of constructing light-emitting contrast media is a real one, and optical imaging has the potential to provide remarkable sensitivity and resolution in superficial structures. However, it is not routinely applied in cancer imaging, with the exception of visualization of the interior of the eye, visualization of the cervix, and endoscopy from above and below.[32] The strengths and weaknesses of the major imaging methods are contrasted in Table 21-2.

ANATOMIC VERSUS FUNCTIONAL IMAGING

Limitations of Anatomic Imaging of Cancer

Anatomic imaging has been the fundamental approach to cancer imaging for more than 100 years. These methods are quite robust, as is supported by their daily use in managing individual patients with cancer. Anatomic imaging normally detects a phenotypic alteration that is sometimes, but not invariably, associated with cancer—a mass. However, with anatomic imaging, we often do not know whether masses are the result of malignant or benign etiologies, as in solitary pulmonary nodules or borderline-size lymph nodes. Similarly, small cancers are undetectable with traditional anatomic methods, because they have not yet formed a mass. After surgery, it is even more difficult to assess for the presence of recurrent tumor with anatomic methods. Post-treatment scans are complicated by the need for comparisons with normal anatomy to detect altered morphologic findings as a result of cancer. Anatomic methods do not predict the response to treatment and do not quickly document tumors responding to therapy.[33] Despite these challenges, anatomic images remain routine in cancer management. PET, a functional imaging method, helps to address many of the limitations of anatomic imaging, and when combined with anatomic images in fusion images, is emerging as a particularly valuable tool, providing both anatomic precision and functional information in a single image set.[4]

Molecular and Functional Alterations in Cancer

The molecular bases of neoplasia are increasingly well defined. Mutations in genomic DNA precede the development of overt neoplasia.[34] With sufficient alterations in genotype, phenotypic changes occur. These genotypic and phenotypic changes in cancer antedate the development of a discrete mass lesion, and represent potential targets for innovative imaging agents. The concepts of altered "genome," "proteome," and "methylome" resulting in alterations in metabolism, consistent with an altered "metabolosome," are increasingly recognized as present in cancers. PET, because of its superb sensitivity to low signal levels, can detect signals from tracers, targeting such alterations that are preferentially present in cancer.

PET has led the growing field of molecular imaging to the clinic, in part because of the quantitative capabilities of PET and the sensitivity of electronic collimation, but also because of the choice of a proper radiotracer for cancer imaging. Although a wide variety of molecular, proteomic, and metabolic alterations occur in cancers, and many of these can or ultimately may be imaged with PET, the most useful target in the clinical practice of PET is the increased glucose metabolism present in most cancers. Other PET tracers, such as those targeting hypoxia, proliferation, amino acid transport, blood-brain barrier permeability, and protein synthesis, are discussed in the following sections. The challenge with all imaging modalities is how best to integrate them into clinical practice. The next section addresses these issues.

DISEASE-SPECIFIC IMAGING RECOMMENDATIONS

Brief discussions of the role and possible role of imaging in managing several common cancers follow. There is great variation in the imaging workup of specific types of tumors, depending on the type of therapy planned.

Table 21-2 Imaging Methods

Modality	Resolution	Sensitivity	Specificity	Functional Imaging Ability
Magnetic resonance imaging	1–2 mm	Moderate	Moderate	Moderate with spectroscopy
Computed tomography	1–2 mm	Moderate	Moderate	Low, except angiography
Radiographs	1–2 mm	Low	Moderate	Very little
Single-photon-emission computed tomography	1 cm	High	Moderate	Excellent
Positron emission tomography	5 mm	High	Relatively high	Excellent
Ultrasound	2 mm	Low	Low	Some, especially with contrast
Mammography	1–2 mm	Moderate	Relatively low	None
Angiography	1–2 mm	Moderate	Moderate	Low

Bragg DG, Rubin P, Hricak H: Imaging strategies for oncologic diagnosis and multidisciplinary treatment. In Bragg D, Rubin P, Hricak H (eds): Oncologic Imaging, 2nd ed. Philadelphia, WB Saunders, 2002, pp 3–20.

In general, the more aggressive and radical the planned treatment, the more critical the need is for accurate determination of the location of all foci of tumor through imaging. Similarly, the intensity and frequency of follow-up imaging examinations must be guided by the potential importance of the information gained. For example, if no effective salvage therapy is available, intensive surveillance for recurrent tumor makes little sense, except to provide reassurance to patients when test results are negative. This may seem self-evident, but it is surprising how practice patterns vary. The National Comprehensive Cancer Network recently has published recommendations on imaging approaches in specific cancers. In addition, the American College of Radiology has provided "appropriateness guidelines" for a variety of cancer therapies. These guidelines inherently lag behind developments in technology, but are based on careful analyses of the literature and expert opinion, and thus are worth consulting as they continue to be updated.

Lung Cancer

The initial diagnosis of lung cancer often is based on incidental detection of an abnormality on an imaging study, although more advanced lung cancer can cause hemoptysis, cough, weight loss, hoarseness, infection, or shortness of breath. There has been a great deal of interest in testing screening programs for lung cancer in high-risk groups such as heavy smokers. Both chest x-ray screening and CT screening have been evaluated. Chest x-ray screening has not been proven to be effective at reducing mortality from lung cancer. CT-based screening programs are of greater interest, and it is clear that these programs can detect lung cancers at an earlier stage, when they are smaller than lung cancers diagnosed by other methods. Patients with such cancers tend to live longer than patients with cancers diagnosed at a more advanced stage. However, detecting additional cancers is dependent upon detection of small lung nodules and many small lung nodules, and most of these are not of malignant etiology. The costs, both economic and in terms of risks from invasive diagnostic procedures, are considerable. In addition, concerns exist that the cancers detected by such an approach may be the more slowly growing cancers. Results from the National Lung Cancer Screening Trial are expected to be forthcoming to help assess this issue in the coming years.

The Fleischner Society has offered guidelines for dealing with small, incidentally detected pulmonary nodules, which involve imaging follow-up for lesions greater than 5 mm in size. Growing lesions require additional investigation.

Certainly, if a solitary pulmonary nodule 8 mm or larger in diameter is identified on a chest x-ray or on screening CT, the workup to determine whether it represents lung cancer can take a variety of forms. Comparison with old anatomic images is essential, but if none are available, a decision must be made whether to perform a biopsy or remove the tumor or follow the abnormality. A variety of factors can be considered, including patient age, smoking history, lesion size, and history of exposure to potential infectious agents.

The morphology of the nodule is investigated to determine whether it has characteristics that suggest malignancy or benignity. The margin and internal density of the lesion are examined. Smooth, well-defined margins suggest a benign nodule, but these also are seen in 21% of malignant nodules.[35] A lobulated margin suggests cells of different lines with uneven growth, but can be seen in 25% of benign nodules. A spiculated margin is highly suggestive of malignancy. Both benign and malignant nodules can be homogeneous and can cavitate. A cavity with a wall thickness of 4 mm or less is likely benign in 95% of cases, a wall thickness of 5 to 15 mm is indeterminate, and a wall thickness of more than 15 mm is likely malignant in 95% of cases.[35] If the lesion contains fat, it is specific for a hamartoma, and 50% of hamartomas have fat on CT.

Benign calcifications are central in the lesion, diffuse and solid, laminated, or popcorn-like. Calcification is seen in 6% of lung cancers on CT, and tends to be eccentric or amorphous.[35] Thus, calcification alone does not indicate benignity in a lung nodule. If contrast is administered and the lesion is monitored over 5 minutes, enhancement of less than 15 Hounsfield units (HU) suggests a benign lesion and enhancement of greater than 20 HU suggests a malignant lesion, with reported sensitivity of as high as 98%, specificity of 73%, and accuracy of 85%.[36] However, these CT criteria rely on very small changes in CT attenuation levels. These subtle changes may be insufficient to allow for reliable stratification of nodules as malignant or benign, because timing of the CT bolus also is an important consideration. The growth rate of the lesion also can be evaluated, but this is difficult for subcentimeter lesions. Computer programs for nodule detection are being developed that also provide lesion volume, and this may prove useful in follow-up.

However, for a significant number of patients, the risk of cancer remains intermediate. For such patients, FDG-PET imaging may be useful. PET has been reported to have sensitivity of approximately 96% for detecting cancer in solitary pulmonary nodules (predominantly ≥1 cm in diameter) in a retrospective meta-analysis,[37] with specificity of approximately 80%. However, some histologies are less well detected, such as those of bronchioloalveolar carcinomas. Nonetheless, the PET scan can help to determine which patients require immediate biopsy or excision of a nodule (i.e., a nodule with intense FDG uptake) versus those who can be observed (some of those with low or no tracer uptake). The use of PET varies widely, but it can be a valuable tool for helping to determine which patients need invasive procedures for pulmonary nodules. Because false-negative findings occur, however, patients who do not have surgery should be followed up regularly for up to 2 years to ensure that there has been no lesion growth. Figure 21-4A shows "hot" and "cold" nodules in the same patient.

Once lung cancer is diagnosed, an appropriate staging workup should be undertaken. The workup for non-small-cell lung cancer often is done to determine whether the patient is a candidate for surgery. Because FDG-PET imaging is at least 20% more accurate than CT imaging, PET is commonly recommended as a staging procedure for the mediastinum and for systemic evaluation for metastases.[38] In a prospective randomized trial, PET reduced the number of futile thoracotomies by half, from 41% to 21%, vs. algorithms in which PET was not performed.[39] This occurred, in part, because remote foci of metastatic disease that were not identified by standard staging methods were identified by PET. Consensus is developing on how PET should be used in staging non-small-cell lung cancer, but many centers routinely perform PET/CT before surgery, with the incremental benefit being most apparent (in terms of detecting additional remote disease from the primary lesion) in patients with larger primary lung cancers. It usually is considered prudent to perform a biopsy on FDG-avid tissues to prove that they represent cancer. Many would argue that mediastinoscopy is no longer essential for patients who have negative mediastinal PET and CT scans, although in some patients, cancer in nodes is detected only surgically. An example of a positive PET scan with ipsilateral and contralateral mediastinal tumor involvement is shown in Figure 21-4B. The role of PET/CT in lung cancer is to provide a thorough whole-body screening assessment.

For mediastinal nodes, a short-axis diameter of greater than 1 cm is considered abnormal on CT. Larger nodes can be reactive, and nodes smaller than 1 cm can contain tumor, leading to sensitivity of 40% to 67% and specificity of 79% to 86% for metastatic disease.[40]

The hybrid PET/CT technology is significantly superior to PET alone for the staging of lung cancer.[41] The best algorithm for staging the mediastinum is evolving, but PET and PET/CT are the most accurate noninvasive methods. Some argue that mediastinoscopy is necessary in each case, however, because PET may produce false-negative results in patients with a low tumor burden, although the negative predictive value of a negative PET scan and a negative CT scan is approximately 95%. Others, however, would argue that

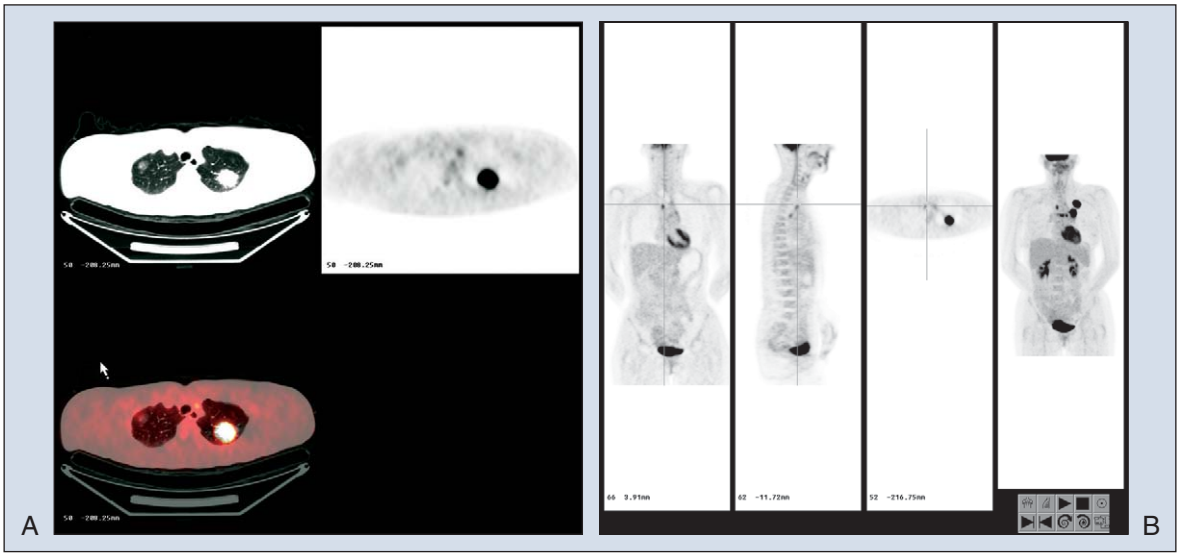

Figure 21-4 • **A,** Images obtained using positron emission tomography (PET) and CT. The upper left image is CT, the upper right image is PET, and the lower left image is a fusion of PET and CT data. The CT scan shows a smaller right apical nodule and a large left upper lung nodule. PET shows increased uptake of ^{18}fluorodeoxyglucose (FDG) in the left apical nodule, consistent with cancer, whereas only minimal uptake is seen in the right apical lesion, consistent with benign disease. Fused PET and CT images confirm the location of increased apical FDG uptake, as in the left lung nodule. **B,** Whole-body images from PET scans of the patient shown in part A. The images include coronal, sagittal, transverse, and "projection" whole-body views, from left to right. They show cancer in the left upper lung, mediastinal involvement, and a right paratracheal tumor focus. Normal uptake is seen in the heart, brain, and excretory system (bladder).

patients with a low tumor burden, below the level of detectability with PET and CT, may be suitable candidates for surgery without mediastinoscopy. Positive PET scans for metastases usually require tissue confirmation of the most advanced site of tumor to avoid false-positive imaging findings that indicate a tumor is not resectable. Figure 21-5 illustrates detection of lung cancer on CT and the use of reformatted virtual images.

MRI with contrast is recommended for imaging the brain. It usually is performed if patients have larger primary tumors or any symptoms that suggest central nervous system involvement, although in some centers, MRI with contrast is performed in every patient with lung cancer in whom resection for cure is planned. Evaluation for bone metastases currently is performed by bone scan. Any patient with bone pain or an elevated alkaline phosphatase level should undergo this study. In practice, where PET is available, bone scans are increasingly being replaced by PET scans. This area is evolving, and the bone scan remains the routine procedure in most centers when bone metastases are suspected, but FDG-PET can

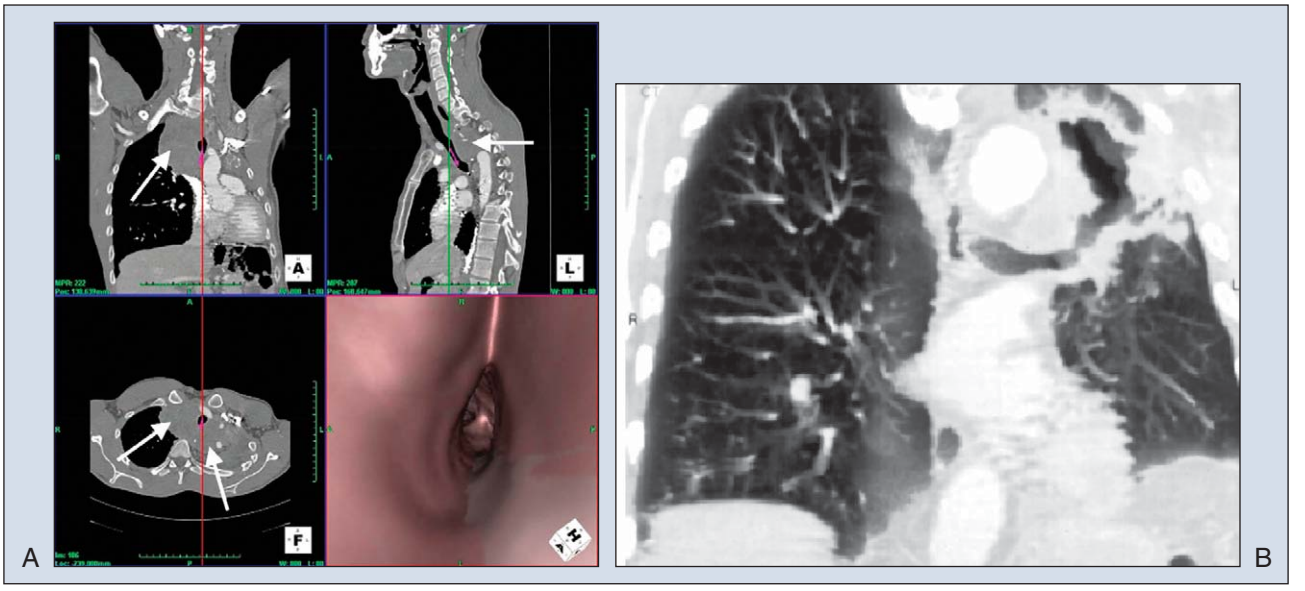

Figure 21-5 • Lung cancer. **A,** Axial CT image *(lower left)* shows a mediastinal mass *(arrows)* narrowing the airway. Figure 21-6 • Lung cancer. **A,** Axial CT scan of the chest with IV contrast shows a mass obstructing the right upper lobe bronchus. **B,** CT scan of the abdomen shows a metastatic hypodense lesion in the left lobe of the liver.

detect lung cancer metastases to bone that are not detected on CT alone.

In institutions where PET is not available, bone scan, MRI of the brain and CT of the chest and abdomen, to include the adrenals, are recommended. The abdominal CT should be performed with contrast to best evaluate the liver. Figure 21-6 shows extensive mediastinal disease and liver metastases on CT. In some centers, PET and diagnostic quality CT used together provide sufficient diagnostic information that no additional studies are required.

For small cell lung cancer, it must be determined whether the disease is extensive or localized before the form of therapy can be decided upon. CT is essential for the chest and upper abdomen. MRI of the brain typically is performed, and a bone scan is done to search for bone metastases. PET scans have been shown to upstage about 10% of patients with limited stage small cell lung cancer to extensive disease and to find lesions not identified by CT. FDG-PET identifies essentially all lesions detectable with CT.[42] Thus, many centers are using FDG-PET more routinely for this type of staging. PET also is useful in the evaluation of small cell lung cancers and mesotheliomas, although the data are evolving, and CT is the established method for this type of evaluation. For follow-up of lung cancer, the guidelines are more challenging because the available therapeutic options often are more limited. PET has a growing role because it can better separate residual scarring from viable tumor than can CT.

Evaluation of the Adrenal

Adrenal masses occur in approximately 9% of the population. These masses can be benign adenomas, metastatic disease from primary tumors such as lung cancer, or primary adrenal cortical carcinoma. CT and MRI are used to distinguish adenomas from malignant lesions in the adrenals. Adrenal adenomas have low attenuation on noncontrast CT as a result of elevated lipid content. If a threshold value of 0 HU is used, sensitivity is 47% and specificity is 100% for the diagnosis of adenoma.[43] If a threshold value of 10 HU is used, sensitivity is 71% and specificity is 98% for the diagnosis of adenoma.

Adenomas take up contrast material, but the washout of contrast material from an adenoma is faster than from a metastatic lesion. On 10-minute delayed images obtained after contrast injection, a decrease in the density of the lesion greater than 50% is specific for an adenoma.[43] If the lesion is atypical on CT, chemical shift imaging on MRI is used to determine whether it is an adenoma. An adenoma has both lipid and water content, and decreases in signal are seen on out-of-phase T1-weighted images. PET has a growing role in evaluating the adrenals, with accuracy of 90% and greater reported in some series. High FDG uptake typically is seen in metastases to the adrenal. Caution is in order, however, in that some adrenal adenomas can have moderately high FDG uptake. Figure 21-7 illustrates detection of adrenal and systemic metastases on CT and PET.

Breast Cancer

Mammography is the major imaging tool in breast cancer, allowing for early detection of tumors. When properly used, mammographic screening programs have been shown to save lives when compared with unscreened populations, and these programs are routinely implemented in many countries.[44]

Although mammography is a reasonably sensitive and specific procedure, the relatively low prevalence of cancer means that many

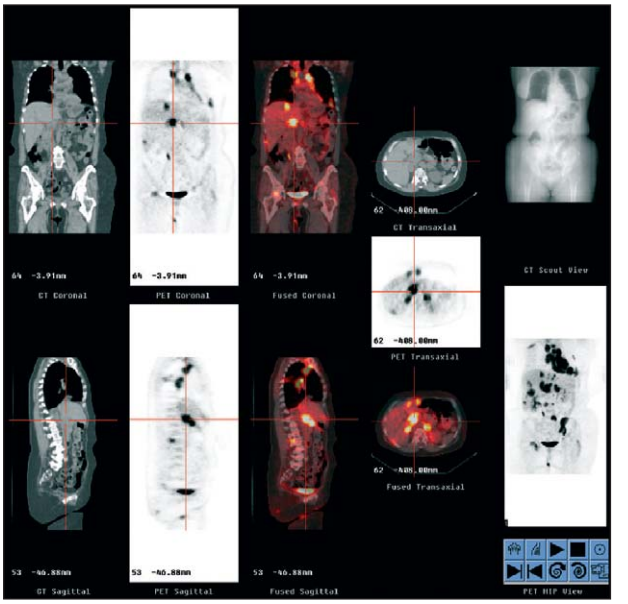

Figure 21-7 • PET and CT image panel shows a variety of PET, CT, and fused images that show diffusely metastatic lung carcinoma. Notable are adrenal metastases that are best seen on the transverse images, although many metastases are visible in a variety of locations. This figure also shows the multiple types of images available from a PET and CT system.

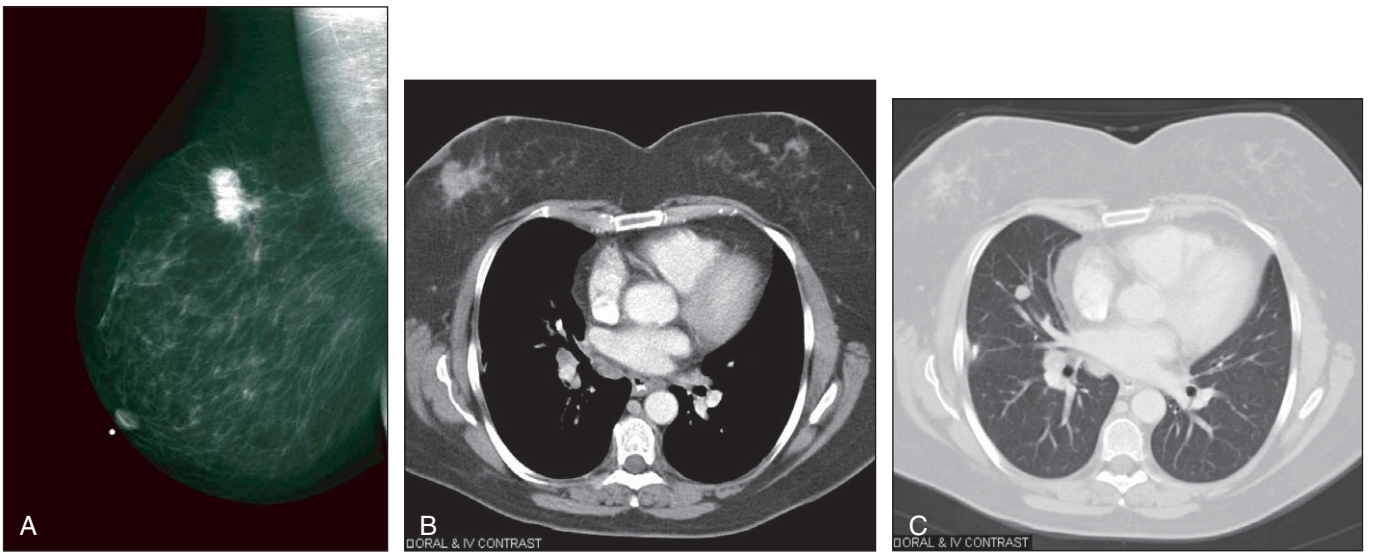

Figure 21-8 • Breast cancer. **A,** Mammogram of the right breast shows cancer. **B,** Axial CT image shows an irregular soft tissue primary mass in the right breast in a different patient. **C,** Axial CT image with a lung window shows a metastatic nodule in the right lung. (**A**, Courtesy of Dr. Nagi Khouri, Johns Hopkins University.)

image-directed biopsies show no tumor; thus, the results of the mammogram were falsely positive. Stereotactic biopsy devices have greatly facilitated nonsurgical breast biopsies. Although the sensitivity of mammography is generally considered "good," an overall sensitivity of less than 50% was seen for x-ray mammography in the Digital Mammography Imaging Screening Trial (DMIST). Even though this can be improved upon through the use of digital rather than film screen mammography, these results indicate clearly that mammography is far from perfect as a screening tool. Early efforts with tomosynthesis of the breasts, a mammographic method that provides a number of "slices" of the breast for analysis, are promising.[45] This approach can help remove overlying structures from the breast image, potentially improving lesion detection. It also is possible that use of IV contrast may enhance mammographic results.[46] Although other techniques can detect breast cancer, only ultrasound is used fairly commonly in most imaging centers to help to separate cystic from solid lesions or to help to locate and evaluate palpable but mammographically negative lesions. MRI with gadolinium contrast is used because it is a very sensitive technique and can help to determine whether disease is unifocal or multicentric. An example of a positive mammogram is shown in Figure 21-8A.

MRI has been evaluated as a tool for characterizing substantially abnormal mammograms or ultrasounds. The prospective multicenter NIH-sponsored trial of 821 patients referred for breast biopsy for American College of Radiology category 4 or 5 mammographic assessment or suspicious clinical or ultrasound findings were studied by MRI and showed an AUC of 0.88 in a population with 404 cancers present, with dichotomized data demonstrating sensitivity of 88% and a specificity of 68%. The positive predictive value was about 72%. The high sensitivity was still insufficient to obviate the need for biopsy in these patients, however.[47] Recently, MRI has been found to detect breast cancer in the contralateral breast of women with newly diagnosed primary breast cancers in approximately 3% to 4% of cases.[48] These additional cancers are found at a rate of about 25% in the lesions identified in this manner (i.e., 75% of the biopsies are negative). In addition, MRI has been used to screen high-risk women (e.g., those with the BRCA1 or 2 mutations) for breast cancer to some advantage. This higher sensitivity comes at the cost of more false-positive results and challenges in biopsy, which have limited deployment of the method. However, increased uniformity of reporting and greater similarities in technique are leading to more use of this methodology, which recently has been comprehensively reviewed.[49] PET methods occasionally are applied in the breast, but they are used for diagnosis infrequently due to the low sensitivity of whole-body PET scanners to small tumors. PET is used more commonly in disseminated disease.

Breast cancer often metastasizes first to locoregional lymph nodes. Current noninvasive imaging methods do not evaluate the axillary nodes effectively. However, imaging can help to define which lymph nodes should be resected for histologic sampling. Sentinel node imaging or detection using a radiation-sensitive probe system is becoming increasingly more important in axillary assessment of patients with breast cancer.[50] This procedure is discussed in more detail elsewhere in the text, but imaging is used, especially in European centers, to better localize the axillary nodes for intraoperative assessment and determine atypical routes of lymphatic drainage. Studies have shown sentinel node sampling procedures to be at least 90% sensitive—which is considered useful sensitivity—relative to axillary dissection, and they are virtually 100% specific.[51] FDG-PET is not sufficiently sensitive to detect small metastases and has an accuracy of only about 75% in axillary nodal staging.[52]

The extent of systemic imaging required in the initial workup of a patient with breast cancer depends on the size of the primary tumor and the status of the axillary nodes at biopsy. It can be argued that the likelihood of systemic metastatic disease is higher for patients with positive nodes; thus, more intensive evaluation may be more appropriate. Some would suggest a baseline bone scan and CT of the chest and abdomen at this time. The frequency of follow-up is debated, given the improbability of curing recurrent systemic disease, and some have advocated only limited biochemical follow-up. However, this area is controversial. Examples of primary and metastatic breast cancers imaged on CT are shown in Figure 21-8B and C. PET is a highly effective tool for evaluating soft tissue involvement and quickly assessing treatment response.[53] FDG-PET imaging can detect disseminated cancers; however, the optimal role of PET in imaging is evolving. PET is now approved for monitoring treatment response of breast cancer.

Prostate Cancer

The role of imaging in newly diagnosed prostate cancer is evolving. Although there is great interest in this area, currently available

imaging techniques are far from ideal and continue to evolve. The serum PSA test is controversial, but it has allowed the detection of smaller prostate cancers than generally are detectable clinically, along with opportunities for earlier interventions. In addition, mortality from prostate cancer has declined in the past 15 years. Many believe these two observations are not random associations, though this is discussed in more detail elsewhere in this book. However, this is an area of great controversy, though there is some evidence that early surgical resections are more closely associated with diminished mortality from prostate cancer than is watchful waiting. Thus, imaging in prostate cancer could play several roles: detecting cancer in the prostate; detecting the extent of tumor; and determining whether the tumor has spread beyond the prostate locally or systemically.

Evaluation of the Prostate

Unfortunately, intraprostate carcinoma is not detected particularly well by imaging with ultrasound or other methods. Although transrectal ultrasound has been used to guide biopsies, up to 40% of prostate cancers are isoechoic (and thus undetectable) by this method. Similarly, the positive predictive value of hypoechoic lesions of the prostate typically is well below 50%. Ultrasound can be used to detect abnormalities and guide biopsy of the entire prostate because it does an excellent job of defining the overall shape, size, and location of the prostate for purposes of systematic biopsy. A sextant approach often is used to sample the base, middle, and apex of the prostate bilaterally, in addition to taking biopsy samples of any suspicious areas. Although this technique is less than perfectly accurate for detecting prostate cancers, on ultrasound, tumors in the peripheral zone are more readily visible than tumors in the inner gland. The peripheral zone is echogenic, and tumors that are hypoechoic to it (approximately 60%) can be detected.[54] However, hypoechoic lesions also can be caused by inflammatory processes, and the positive predictive value of ultrasound is approximately 18% to 52%.[54] Contrast enhancement of the prostate on ultrasound has been used to some advantage to enhance detection rates and positive yields on biopsies of the prostate.[55] Similarly, on MRI, cancers that are hypointense on T2-weighted images are seen, but the findings are not specific for tumor. Extension of cancer beyond the prostate capsule is suggested on ultrasound when the capsule margin is irregular or the seminal vesicles are abnormal in morphology; however, sensitivity of as low as 20% has been reported. The sensitivity of MRI for extracapsular invasion is approximately 50%, and specificity is 95%.[54] Patients at intermediate risk for invasion, with a PSA level of 10 to 20 ng/mL and a Gleason score of 5 to 7, may benefit from MRI staging of local extension.[54] MRI methods are improving, especially with the use of spectroscopy.[54,56] However, spectroscopy is still applied mainly at a few centers with specialized expertise, so it is not yet a routine part of management of prostate cancer. Increased field strength for MRI is now being more systematically assessed and appears promising as a tool to separate benign from malignant prostate tissue by detecting tissue with increased ratios of choline/citrate.[57]

CT has no established role in evaluating the prostate itself or local invasion (25% sensitivity for capsular invasion), although tumors sometimes can be seen on CT (Fig. 21-9A). CT is used to detect bladder and rectal invasion, adenopathy, and distant metastases, and MRI is used to assess local extent. Similarly, the sensitivity for detecting nodal metastases has been reported to be as low as 30% with CT. Higher sensitivity can be achieved, but with lower specificity. Pathologic proof is desirable before it is concluded that a patient has metastatic disease to the lymph nodes, and if metastatic disease is demonstrated, radical prostatectomy is considered inappropriate. Large nodal metastases are easily detected on CT imaging, however (Fig. 21-9B).

It is not clear that MRI is better than CT; however, recent data on MRI using a node-specific paramagnetic contrast agent have shown very high sensitivity and accuracy in the detection of nodal metastases.[56] There is considerable hope for this method, but it has not yet been approved by the FDA.[58] Given the traditionally low sensitivity of CT and MRI to nodal metastases, it has been recommended that the serum PSA level be at least 20 ng/mL before CT is performed. If the CT findings are positive, then biopsy can be performed of the enlarged node or nodal sampling can be performed before radical prostatectomy. CT also is the test of choice for visceral metastases.

A bone scan is a sensitive technique relative to x-rays for bone metastases. The results of a bone scan can be positive when radiographs of bone are essentially normal. The current recommendation is that a radionuclide bone scan be performed only if the serum PSA level at presentation is greater than 10 ng/mL. Only very rarely is a bone scan positive for tumor at lower levels at the time of diagnosis. Some argue that for large primary tumors or very high Gleason scores a bone scan still may be appropriate at staging.

Thus, imaging is used selectively in patients with newly diagnosed prostate cancer. A bone scan commonly is used for recurrent prostate cancer whenever the PSA level begins to rise. New PET methods are promising in prostate cancer, but are not in widespread use in the United States. FDG-PET often is falsely negative in prostate cancer, especially for disease in the earliest stages.[46] Similarly, MRS has shown promise in evaluating the prostate gland and determining whether the tumor has spread beyond the prostate.

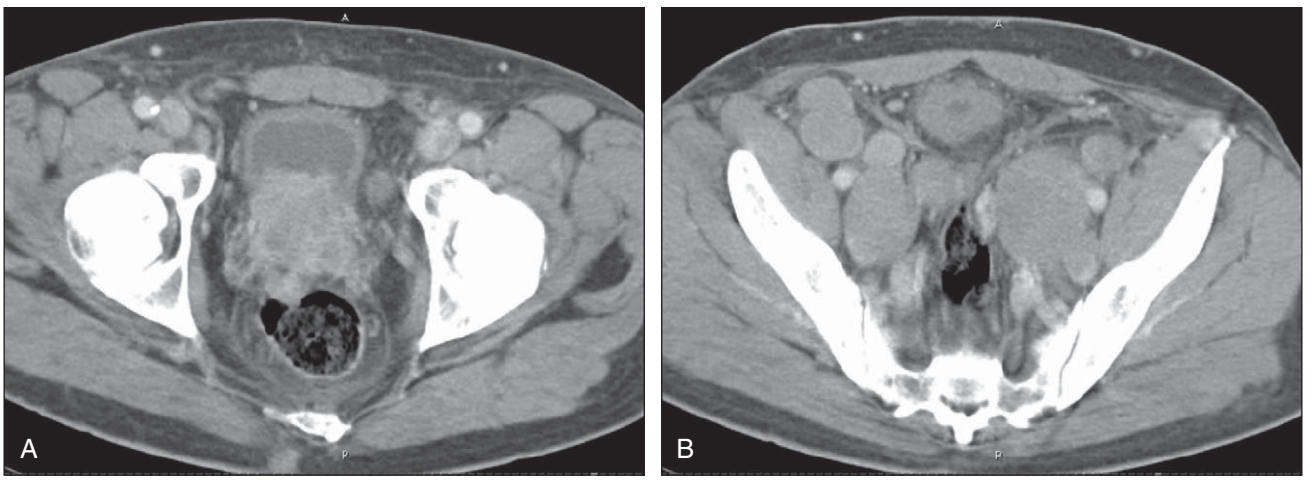

Figure 21-9 • Prostate cancer. **A,** Axial CT image shows an enlarged prostate with an enhancing mass and irregular margins. **B,** More superior image shows enlarged bilateral pelvic nodes from metastatic disease.

Much monitoring of prostate cancer now involves sequential blood tests to measure the PSA level. When the PSA level rises persistently, the tumor has recurred, but determining the site of recurrence often is problematic. Bone scans and CT often are used, with radioantibody imaging for anti-prostate membrane specific antigen antibodies used only infrequently because of limited diagnostic accuracy, although some promising results have been obtained by experienced groups.

Colon Cancer

The role of noninvasive imaging in the diagnosis of the primary lesion in colon cancer has changed over the last several decades. At one time, barium enema studies were used extensively to search for colorectal cancer. They have been replaced, in large measure, by fiberoptic colonoscopy. However, there is a growing level of interest in virtual colonoscopy, which is performed using CT scanning and per-rectum insufflation after thorough bowel preparation. This procedure is used to a limited extent for screening. The technique faces challenges because it requires bowel preparation and interpretation is quite time-consuming. Screening for colon cancer is an area of considerable opportunity for noninvasive imaging. Infrequently, these cancers can be detected by other methods such as ultrasound. The performance of virtual colonoscopy has been directly compared to that of optical colonoscopy in a study of over 6000 patients. Patients were randomized to either an optical or CT colonographic (CTC) group and were compared for the detection of advanced neoplasia and the total number of harvested polyps. Advanced neoplasia was confirmed in 100 of the 3120 patients in the CTC group (3.2%) and in 107 of the 3163 patients in the OC group (3.4%). There were seven colonic perforations in the OC group and none in the CTC group. Primary CTC and OC screening strategies resulted in similar detection rates for advanced neoplasia, although the numbers of polypectomies and complications were considerably smaller in the CTC group. CT colonography also was much less expensive than optical colonoscopy.[59]

Interestingly, the detection rate for polyps requiring biopsy was statistically identical between the two groups of patients. A large multicenter study is being performed in the United States to compare the two methods. A concern with the virtual colonoscopy method (CT colonography) is that it is highly interpreter-dependent. Before it can be recommended routinely, certainty of its performance across various medical centers will be highly desirable, though in expert hands it currently appears to be a viable alternative to colonoscopy and is considerably less expensive. It is probable that CT colonography methodology will assume a growing role in cancer screening in the coming years.

Regardless of means of detection, the extent of preoperative imaging performed before resection of primary colon cancer is variable, based on the institution. In general, the larger the primary tumor is, the more aggressive is the staging procedure required. In most instances, the primary tumor must be surgically resected for palliation (or cure), even if metastatic tumor is present. For staging, the most common studies include CT scan with contrast of the abdomen and pelvis, CT scan of the thorax (or chest radiograph), and bowel imaging to exclude the presence of a second primary colon cancer. In institutions in which PET imaging is available, PET is used somewhat more frequently at presentation; however, it is much more commonly applied in the setting of suspected recurrence.

For colorectal cancer, many advocate regular imaging studies after surgery for "cure," because isolated metastases or oligometastases of colorectal cancer can be resected from the liver or lungs; in some instances, the patient is disease-free for a long period. Thus, before such removal of a limited number of metastases is contemplated, a thorough imaging procedure is undertaken. This usually includes CT of the abdomen and pelvis with contrast and CT of the thorax without contrast. CT of the thorax may be replaced by a chest x-ray, but chest x-rays are less sensitive for pulmonary metastases.

PET is applied very often in this setting and in the setting of a rising carcinoembryonic antigen level after surgery. The precise timing of follow-up studies can be variable, but they often are done every 6 to 12 months in the early years after surgery. Considerable evidence supports the idea that PET can detect more metastatic foci than CT in the setting of a rising carcinoembryonic antigen level.[60] An example of a patient initially believed to have only a limited number of liver metastases is shown in Figure 21-10; however, more extensive disease was identified (Fig. 21-10B). PET/CT has been shown to offer higher accuracy than PET alone in recurrent colorectal cancer.[61]

Although immunoscintigraphy has been used, it has been rendered essentially obsolete due to the availability of FDG-PET. FDG-PET often does not detect small (<5 mm) tumors, however, and is

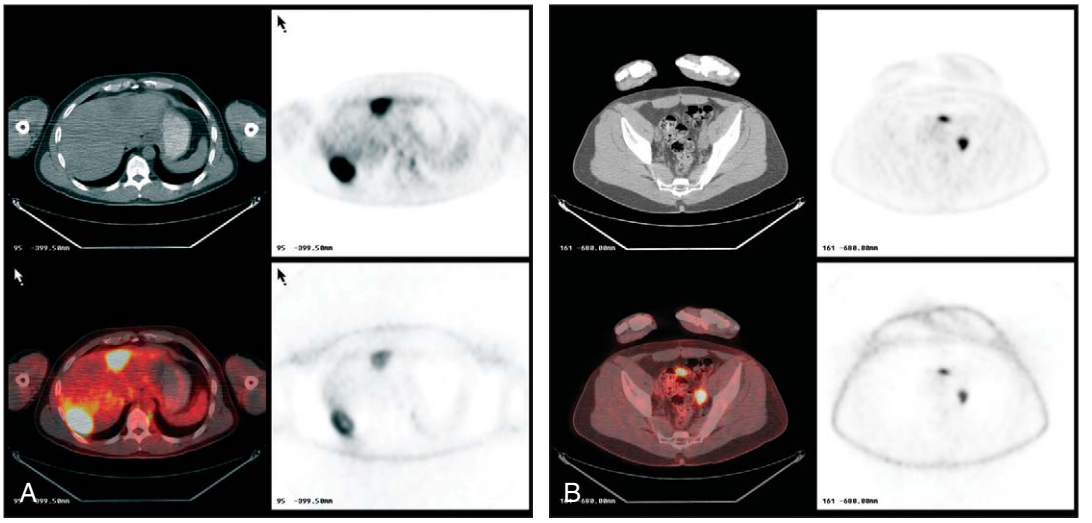

Figure 21-10 • Colon cancer. **A,** PET and CT image display of a patient with two ^{18}FDG-avid lesions in the liver. These are seen on the CT scan *(upper left)*, the attenuation-corrected PET scan *(upper right)*, the non–attenuation-corrected PET scan *(lower right),* and fused images *(lower left).* **B,** PET and CT images of the pelvis, oriented as in part A, show increased FDG uptake in a left external iliac lymph node metastasis.

known to be less sensitive for tumors of mucinous histology, so opportunities for improvement remain.

Ultrasound can detect many liver lesions, and is a very useful technique for guiding biopsies of the liver.[24] For liver metastases, CT is still the most commonly used procedure, but in a meta-analysis, PET was a more robust test to identify the presence and location of hepatic metastases of colorectal cancer compared with CT, MRI, or ultrasound methods.[62]

Gynecologic Neoplasms

Screening for gynecologic neoplasms usually is not performed by imaging, except for very limited programs that have evaluated the use of either transabdominal or, more commonly, transvaginal ultrasound of the pelvis to detect masses that may represent ovarian cancer. These programs have been combined with serum biomarkers. Such programs have not been proven cost-effective and are not widely applied, but they warrant further study, because this is a very important health problem. In women with high genetic risk of ovarian cancer, such as those with the BRCA mutation, screening may have greater value.

In cervical carcinoma, screening using the Pap smear has a large effect in terms of lowering mortality rates by detecting premalignant changes and early-stage disease. Although much of the staging of cervical carcinoma is performed by physical examination, for larger primary tumors, imaging has an important role. Both CT and MRI are used in the pelvis; however, the use of PET for tumor staging is increasing. As in other tumors, PET appears to be more sensitive than anatomic imaging methods. Emerging data show that PET provides better prognostic value than anatomic imaging in cervical cancer.[63–65]

In ovarian cancer, no technique is able to detect microscopic metastatic disease. Ultrasound is the main method by which ovarian tumors are identified at their earliest stages; however, the unfortunate fact is that these tumors are usually diagnosed at an advanced stage. Imaging can be used in an attempt to determine the extent of the surgical procedure that will be required. Both CT and MRI are used to assess the extent of ovarian cancer, with CT the preferred method (Fig. 21-11). PET is not sensitive to tumor foci smaller than 8 mm to 1 cm, but it is reasonably reliable in detecting larger tumor foci. For this reason, some advocate the use of PET to determine whether tumor debulking should be performed. PET has a role in the setting of a rising CA125 level in patients with normal CT findings.[66]

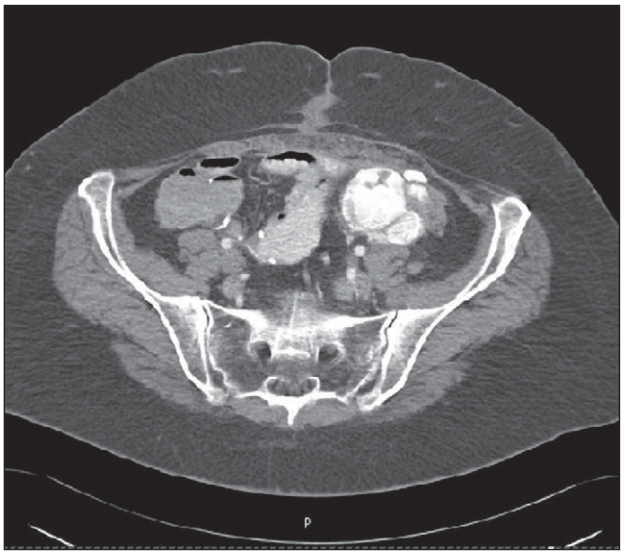

Figure 21-11 • Axial CT image shows a dense, calcified mass in the left pelvis, compatible with a metastatic implant from ovarian cancer.

The use of serum markers and imaging is recommended for surveillance after surgery for ovarian carcinoma. The aggressiveness of imaging follow-up depends on the treatments available. PET has an emerging role in this setting, although practice patterns vary widely. PET also has been shown to provide information related to treatment response in preliminary studies.[67,68]

Lymphoma

For both Hodgkin's and non-Hodgkin's lymphomas, accurate staging is important. For both types of lymphoma, accurate definition of the tumor burden is needed for effective treatment planning, especially treatment with external beam radiation. CT is the historically accepted method for noninvasive staging of lymphoma, with PET being used increasingly because many studies have shown it to be capable of locating more tumor foci than CT.[69] An example of CT imaging of abdominopelvic lymphoma is shown in Figure 21-12. In most lymphoma histologies, FDG-PET is more sensitive than CT, often detecting 20% more lesions than are seen on CT alone.[70] PET can detect disease in the bone marrow and spleen in some instances. In fact, marrow involvement seen on FDG-PET often is associated with a negative CT scan.[71]

CT is traditionally used for follow-up of lymphoma, and there are clear response criteria in place to follow lymphoma therapy. One of the challenges in lymphoma is that large masses often do not normalize in size after treatment, leading to questions in interpretation of a residual mass lesion. Determining whether these lesions contain a viable tumor is important, because it defines whether more treatment is needed. Data indicate that gallium (Ga)-67 scintigraphy can be effective for assessing the viability of residual Hodgkin's lymphoma and intermediate- and high-grade non-Hodgkin's lymphoma. However, multiple studies now have been published on FDG-PET in this setting, and this imaging modality has essentially replaced Ga-67 scintigraphy in assessing the viability of residual masses of lymphoma. If a residual mass of lymphoma shows increased FDG uptake, that usually is indicative of residual viable tumor; however, scans also can be falsely negative, because some tumor foci may be smaller than the resolution of PET imaging.[72] False-positive results have been described in patients with Hodgkin's lymphoma, however.[73]

Positive midtreatment Ga-67 and PET scans predict a poor outcome from therapy, and positive PET scans at the conclusion of a therapeutic regimen also indicate a poor prognosis. It is increasingly appreciated that PET findings soon after treatment is initiated can be highly predictive of ultimate outcome of the therapy.[74,75]

Challenges associated with PET include reactive lymph nodes and nodes involved with inflammatory processes such as sarcoidosis, which can be very FDG-avid. Similarly, uptake of FDG in brown fat in the neck and thymus can be confusing.[76]

Although anatomic imaging has been the key for lymphoma assessment, there is a growing trend to greater use of PET. PET imaging and PET/CT imaging, providing additional functional information, are of growing utility. A limitation of PET-only methods had been the lack of a standardized set of response criteria. Tracer activity in PET images generally decreases more rapidly than tumor shrinkage occurs (i.e., anatomic changes of treatment lag behind metabolic changes detectable by PET). For these reasons, PET scans may appear normal before CT scans do. A concern is that there is not strong evidence showing that a negative PET scan should be used to truncate the duration of lymphoma therapy. For example, if a PET scan became negative after two cycles of treatment, this would not justify, based on current data, discontinuing treatment. However, if a treatment involved a standard of four possible courses of treatment and PET became negative after these courses were completed, available data suggest that this portends a very good prognosis vs. a positive PET scan. Recently, new criteria for response including PET were developed for lymphoma. For FDG-avid lymphomas, a negative PET scan is required to determine a complete response.[77–79]

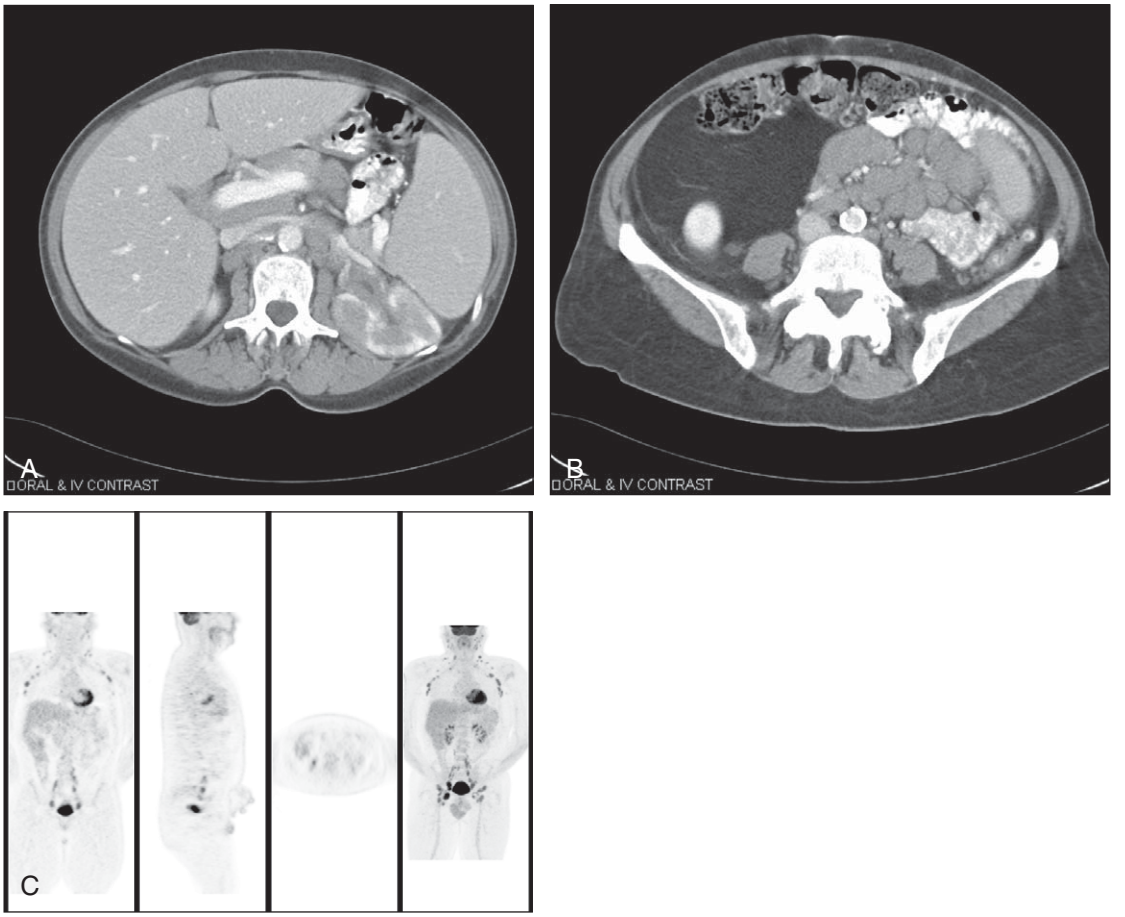

Figure 21-12 • **A,** Axial CT image with oral and IV contrast shows para-aortic adenopathy and infiltration of the left kidney by lymphoma. **B,** Image of the lower abdomen in the same patient shows enlarged mesenteric nodes. **C,** PET-only images (left to right: coronal, sagittal, transverse, and anterior projections) show focal areas of increased ^{18}FDG uptake in multiple lymph node groups, including the axillary, inguinal, and iliac regions, consistent with disseminated lymphoma.

It can be argued that PET is not essential in all patients with lymphoma. However, the use of PET and PET/CT is becoming increasingly the norm in centers where this technology is available. Because PET can find some lymphomatous tumors that cannot be detected by CT, this method is increasingly finding routine application in the care of patients with lymphoma (Fig. 21-12C).

An exciting new opportunity for the use of PET in non-Hodgkin's lymphoma is in the setting of a "response adaptive" approach. In such treatment approaches, patients who are poorly responding can be identified by PET performed soon after treatment is initiated. This approach can allow segregation of responding from non-responding patients. In the responding patients, standard treatment is given, whereas in the poorly responding patients, alternative approaches such as stem cell transplants are used. This approach currently is investigational, but it is an area of great promise because it allows the potential for tailoring the therapy to the individual patient's responsiveness to the treatment algorithm.[80] Recently, use of such an approach has been shown feasible in a clinical comparative trial on Hodgkin's lymphoma.[81]

Melanoma

The imaging management of melanoma varies based on the stage of disease. Radiologic imaging has no significant role in the diagnosis of primary melanomas. Lymphoscintigraphy—the injection of radiolabeled colloidal material, typically technetium ^{99m}Tc sulfur colloid, into the subcutaneous tissues or intradermally to locate lymphatic drainage routes, and thus lymph nodes with the potential for metastatic involvement—commonly is performed for primary melanomas of intermediate thickness. Although practice patterns vary, this method typically is used for melanomas that are more than 1 mm thick without other evidence of metastases. If the sentinel node identified by surgery (often using radionuclide guidance) is involved with tumor, additional staging procedures often are done.[82] These procedures most commonly include CT of the chest and abdomen, and of the pelvis as well if the melanoma affected the lower extremities. If there are systemic metastases, brain imaging is performed, using MRI with and without gadolinium contrast enhancement.

PET and PET/CT with FDG also are potent methods for detecting metastatic melanoma, often detecting more tumor foci than CT. PET can detect nodal metastases, but is not as sensitive as sentinel node imaging and is not a replacement for sentinel node imaging and removal. PET is particularly good for soft tissue metastases, but cannot detect microscopic disease. Thus, sentinel lymph node biopsy is used in preference to PET for detecting early metastases. There is some evidence that ultrasound can detect small nodal metastases of melanoma, but it is not widely applied and is also less sensitive than sentinel node imaging.[1] However, PET can detect most tumor foci larger than 6 mm and sometimes can detect smaller tumor foci. CT is a more robust technique for small pulmonary nodules than is PET.[83]

Melanoma metastases, especially if they are localized, can be resected surgically. However, identifying whether only one or two vs. many metastases are present is a major challenge. Aggressive surgical procedures are not appropriate if there are disseminated metastases. For these reasons, staging imaging procedures are performed aggressively before major surgery is undertaken to resect melanoma metastases. PET commonly is part of such a staging evaluation. For systemically metastatic melanoma, PET has been reported to have sensitivity well over 90%. Thus, although anatomic imaging dominates, PET has a growing role in melanoma assessment.[84] For bone metastases, radionuclide bone scanning also is an important diagnostic procedure. Recently, it has been shown that the performance of FDG-PET in melanoma is significantly enhanced if the CT scan portion of PET/CT is analyzed very carefully. This appears to increase both sensitivity and specificity of the method.[85]

Bladder Carcinoma

Bladder carcinoma often presents at an early stage, and no imaging evaluation is performed to determine whether there are locoregional or systemic metastases. However, ultrasound has been used to determine the depth of penetration of primary bladder carcinomas. An important consideration in bladder carcinomas is that uroepithelial tumors are often multicentric. Thus, intravenous pyelogram examinations to evaluate the entire genitourinary system commonly are performed early in the diagnostic algorithm. Although ultrasound can detect many bladder cancers 5 mm and larger, transurethral sonography is more sensitive; obviously, however, it is invasive. MRI is used more commonly than CT for assessing primary bladder lesions because of its superior soft tissue contrast characterization abilities.[86]

For larger primary tumors that are invasive, imaging evaluation is important to help to determine whether surgery is appropriate. Metastatic disease to locoregional nodes or systemic metastases indicates disease with a poorer prognosis, and tumor invading local structures or metastatic either to nodes or systemically often is considered unresectable. CT is used most commonly for local nodal staging, but MRI also can be used. Small nodal metastases usually are not detected using CT, because they have not enlarged the lymph nodes sufficiently to allow the tumor-involved nodes to be detectable. CT has a reported sensitivity of 60% to 70%. Biopsy commonly is used to determine whether an enlarged node seen on CT truly contains tumor. MRI probably is more sensitive than CT in detecting nodal metastases, and new contrast agents that accumulate in normal nodes are potentially important for enhancing the diagnostic accuracy of MRI in detecting nodal metastases.[87] Initial data with MRI contrast agents support the accuracy of this approach, but also point out that the interpreter's experience is important.[88] Such agents are not yet routinely available or FDA-approved.

FDG-PET has been used and is promising in bladder carcinoma; however, images of the pelvis can be degraded by intense F18 activity in the bladder. The use of PET in bladder cancer is enhanced by PET/CT and iterative reconstruction methods that make for better assessments of the pelvis with less degradation due to the bladder radiotracer activity. For bone metastases, radionuclide bone scan remains the procedure of choice, and MRI also can be sensitive. PET/CT is quite sensitive for metastatic disease beyond the pelvis and is being applied to a greater extent due to the availability of the CMS registry in the United States.[89]

Follow-up of bladder carcinoma usually involves the use of CT scans. Follow-up for new or recurrent bladder carcinoma within the bladder usually requires direct visualization of the bladder by cystoscopy.

Head and Neck Cancer

Head and neck cancers often are associated with cigarette smoking and alcohol use or abuse. Human papillomavirus also has been linked to head and neck cancers as well, especially in younger women. Most malignancies in the head and neck (except for lymphomas, as discussed earlier) are of squamous cell etiology. A key issue in these lesions is determining whether the disease is localized to the head and neck or whether metastatic disease or a second primary lesion is present. Thus, imaging of the lungs usually is done to exclude a primary or metastatic lung tumor. The physical examination is very important in assessing a primary lesion in the head and neck, but both CT and MRI are very potent methods. MRI typically is performed before and after gadolinium contrast is administered; CT scanning usually is performed after contrast enhancement (Fig. 21-13A). Because MRI is subject to respiratory and motion artifacts, CT is used somewhat more commonly in the initial staging of these tumors.[90]

CT and MRI can characterize the extent of primary tumors; however, CT is more effective than MRI in assessing the extent of involvement of cartilage or bone. For nodal metastases, current diagnostic schemes are based mainly on nodal size. Nodal size is an imperfect indicator of tumor involvement, however.

Increasingly, FDG-PET is being applied to the assessment of head and neck cancers. Although several studies have suggested that PET, MRI, and CT have similar sensitivity, more recent studies have suggested that PET is more accurate in staging (Fig. 21-13B and C). However, PET can detect increased glucose uptake in nonmalignantly involved inflamed nodes (false-positive findings). These can occur in patients with head and neck or gingival infection or the common cold. Defining the precise extent of tumor is important to determine whether surgery or radiation therapy should be performed, because more extensive tumors are less amenable to surgical resection.

Occasionally, head and neck cancers present as isolated nodal metastases without the location of the primary tumor being evident. Imaging has a role in such cases. Often MRI is performed as well as extensive inspection and biopsies; however, FDG-PET also has been applied. This method can detect as many as 15% to 30% of primary tumors.

For recurrent tumors, PET appears to be a more robust test than MRI or CT, especially when timed properly, probably because contrast enhancement can be seen in both postoperative changes (and postradiation tissue) and tumors. In general, FDG uptake is a more reliable predictor of tumor than the anatomic methods. PET is useful in surveillance for the recurrence of these tumors, but it is not yet considered the standard of care.

Thus, for head and neck cancers, MRI offers excellent contrast resolution for soft tissues, but can be degraded substantially by motion. For this reason, CT with contrast is much more commonly performed. FDG-PET is assuming a growing role in cancer management, especially for recurrence and for assessment of response to treatment. PET with CT is being used more often to stage and monitor these tumors during and after treatment, and may become the standard of care.[91] A recent comparison of PET/CT to MRI and PET alone showed superior accuracy of PET/CT versus the other methods.[92]

Pancreatic Carcinoma

The standard of care for the imaging diagnosis of pancreatic cancers is CT scanning. Although MRI can be useful, CT, including CT angiography, is the main method used for staging and assessing tumor invasion of vessels (Fig. 21-14). Some studies have shown FDG-PET to be somewhat more sensitive for detecting tumors and to have moderately high accuracy—approximately 85%—in characterizing pancreatic lesions as malignant or benign.[93–95] Ultrasound is used to assess cystic lesions. After treatment, salvage therapy is ineffective, and these patients often are less aggressively monitored than those with other, more treatable cancers. Neuroendocrine tumors of the pancreas often can be detected using 111n-pentetreotide (Octreoscan),

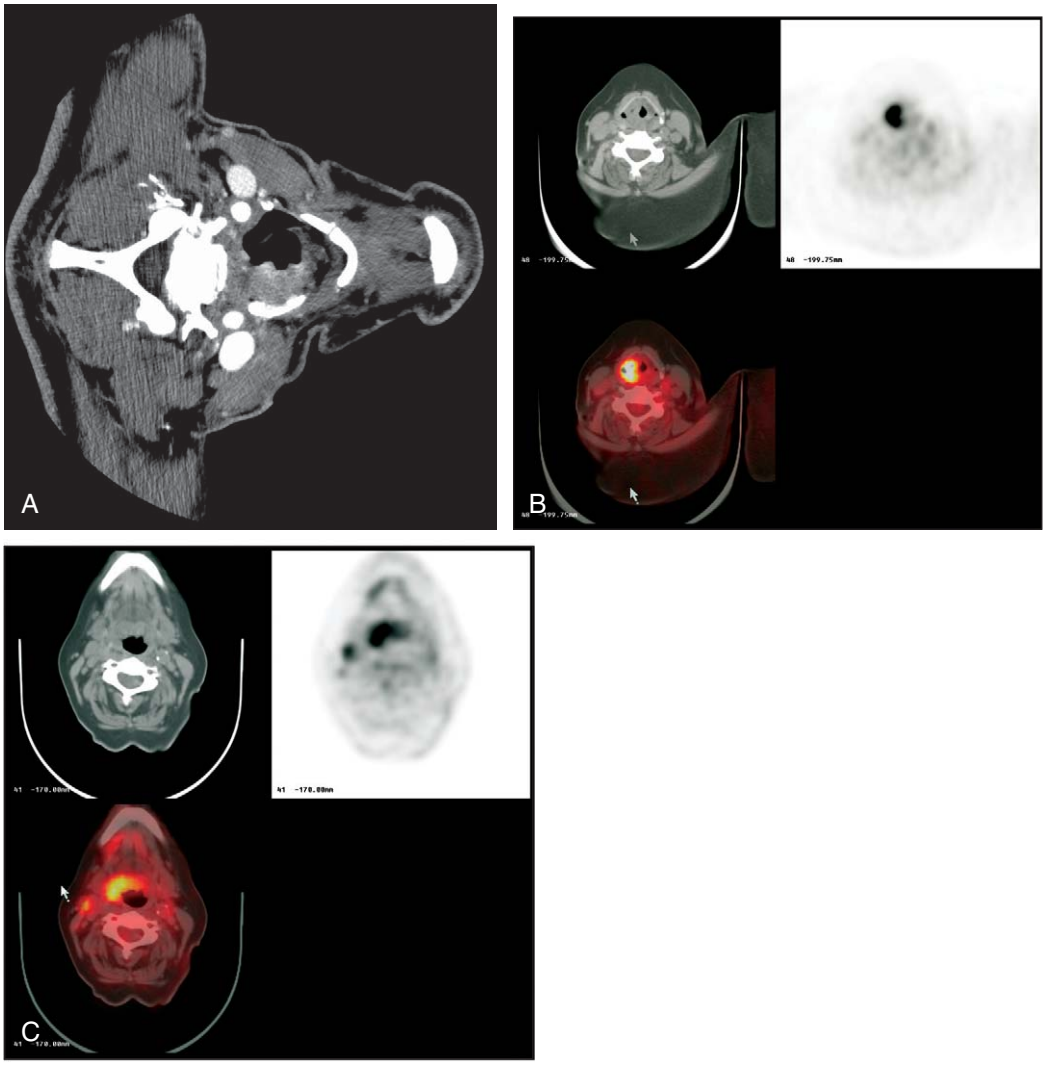

Figure 21-13 • Head and neck tumors. **A,** Axial CT image of the neck with IV contrast shows a mass in the left piriform sinus. **B,** PET and PET/CT images show right vocal cord cancer with intense tracer uptake. **C,** PET and PET/CT images from the lower level of the neck show nodal tracer uptake consistent with metastases. a SPECT procedure. Recently, positron emitter-labeled analogs of somatostatin have been developed and show encouraging biological characteristics compared with single photon agents.[96]

Liver Cancer

Hepatic malignancies, especially hepatomas, are common worldwide. Both CT and MRI can be very effective in detecting these lesions. They sometimes are challenging to assess, because the appearance of cirrhosis with regenerating nodules and tumors can overlap. Multiphase CT imaging, CT angiography, and MRI with and without gadolinium contrast are commonly used in hepatomas. PET is less reliable, because approximately half—and sometimes more—of hepatomas are not FDG-avid. There has been some use of alternative PET tracers such as C-11 acetate to image some pancreatic cancers, because some FDG-negative tumors are C-11 acetate avid.[97] Ultrasound also can be used to assess the liver and guide biopsies.

Metastatic lesions to the liver also are common, especially in the United States. For most tumors, CT is the initial method used for assessing whether tumor is present. However, FDG-PET is more sensitive than CT in detecting liver metastases in common cancers such as colorectal cancer.[60,62] Thus, PET is seeing greater application in assessing suspected liver metastases, although ultrasound, CT, and MRI also are important methods and still are more commonly applied in many centers (Fig. 21-15).

Kidney Cancer

In the past, renal cancers were detected by intravenous pyelograms; currently, however, the most common method for detection is CT. Renal cell cancer commonly is detected incidentally because of the widespread use of cross-sectional imaging. Between 25% and 50% of surgically treated renal cell cancers are discovered incidentally.[98] Renal lesions are classified as cysts or solid masses, depending on their characteristics as shown by imaging. Renal cysts are fluid-filled and appear anechoic with increased through-transmission on ultrasound. They show water density without enhancement on CT, and appear hyperintense on T2-weighted images, also without enhancement, on MRI. Renal masses typically are evaluated by CT because of its short examination times and ease of evaluation, even in patients with a large body habitus, which can make ultrasound difficult. MRI typically is used for problem-solving. Multiphasic scanning is performed

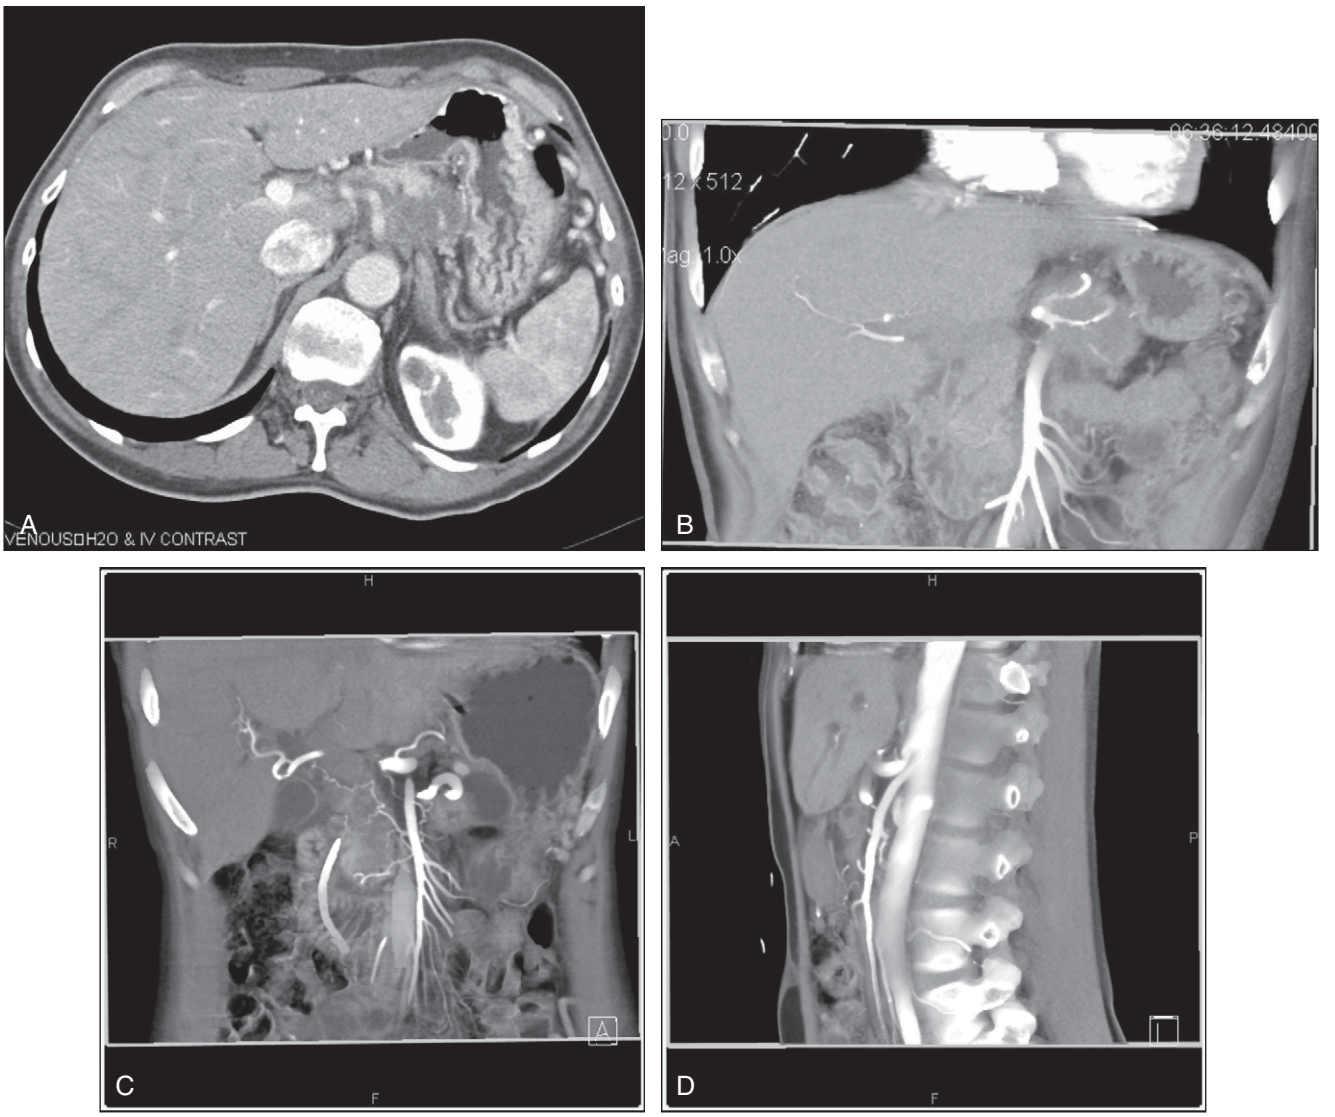

Figure 21-14 • Pancreatic cancer. **A,** Axial CT image shows a mass in the pancreatic body, encasing the splenic artery. **B,** Coronal volume-rendered three-dimensional CT image shows tumor encasing the splenic and left gastric arteries. **C,** Coronal volume-rendered maximum-intensity projection. **D,** Sagittal volume-rendered three-dimensional CT images show a mass in the pancreatic head without invasion of the superior mesenteric artery or vein. A common bile duct stent also is seen.

on CT to evaluate the density of lesions before contrast and as contrast filters from the cortex into the medulla and collecting system. An increase in density by greater than 20 HU corresponds to lesion enhancement and confirms the presence of a solid mass. CT is used to stage the tumor by determining the presence of renal vein invasion, adenopathy, local extension, and distant metastases. CT's accuracy for staging is 91%.[98] For resectable lesions, CT can provide information on whether the lesion is amenable to nephron-sparing surgery or partial nephrectomy. Lesions that are smaller than 4 cm, polar, and cortical, and do not involve the renal hilum or collecting system may be candidates for partial nephrectomy. Although CT, MRI, and ultrasound can all be used to assess renal lesions, CT with contrast is the dominant method (Fig. 21-16). PET is useful only when the tumor is FDG-avid. However, the normal excretion of FDG by the kidneys makes evaluation of the kidneys more challenging than other tissues, and some renal masses are not very FDG-avid. Thus, FDG-PET is not currently recommended for renal cancers, at least not for reliably characterizing renal masses as malignant or benign. Metastatic renal cancer is more accurately imaged on FDG-PET than is primary renal cancer.[99,100]

Endocrine Tumors

Imaging is used to study several types of endocrine tumors in a variety of locations. For adrenal tumors, CT is the procedure of choice, with metaiodobenzyl-guanidine ^{123}I (MIBG) scanning and MRI scanning also proving useful for lesion characterization.[100] MIBG accumulates selectively in pheochromocytomas. Adrenal masses with low HU values (<10 HU) typically are adenomas, which are lipid-rich. For the thyroid gland, radioiodine imaging commonly is used. For non–radioiodine-avid thyroid cancers, FDG-PET is very useful for lesion detection and is recommended in the setting of a rising serum thyroglobulin level with a normal ^{131}I or ^{23}I scan, particularly when recombinant TSH stimulation is used (Fig. 21-17).[101] For neuroendocrine tumors such as carcinoid tumors, CT and radiolabeled octreotide analogs are very useful. Several newer PET imaging agents

are under study for endocrine imaging, but are not yet widely available or widely applied.[96,102]

Brain Tumors

The dominant method for the assessment of brain tumors is the MRI scan, which is the preferred method for initial detection, assessment of extent of disease, and assessment of efficacy of therapy. The superior soft tissue contrast provided by MRI places it ahead of CT for lesion characterization (Fig. 21-18).

Unfortunately, even sophisticated MRI techniques, often relying on tumor enhancement using gadolinium, cannot detect microscopic disease. MRI findings, although fairly specific for tumor, are not completely specific. Thus, infarcts, infections, and foci of demyelination occasionally can mimic tumor foci on MRI. FDG-PET has a very limited role but can be useful in assessing residual tumor after radiation therapy and determining whether residual masses are caused by tumor or tumor necrosis. It is most accurate in highly aggressive tumors where brain tumor uptake of FDG is greater than that of normal brain tissue. Recently, other tracers, such as FDOPA and FLT, have shown results more promising than those for FDG.[103,104]

MRS also can be useful in evaluating this issue because tumors typically have high levels of choline and low levels of N-acetyl-aspartate. Angiography, although a historically useful method, is performed less frequently for diagnostic purposes in brain tumors. MRI, CT, and PET can guide biopsies. Further, MRI can be used intraoperatively to guide therapy.[105]

Pediatric Tumors

CT usually is the method of choice for evaluation of pediatric tumors. For tumors of the central nervous system and for sarcomas, MRI is preferred. FDG has a growing role, especially for lymphomas and sarcomas. MIBG scanning often is used in neuroblastomas. CT scanning should be performed with a reduced tube current and energy to minimize the radiation dose while preserving the quality of the diagnostic image. Multiphase CT should be avoided in children unless it is clearly indicated to minimize the radiation dose to the child.[106] PET/CT has shown broad utility in pediatric cancers, although the available literature is quite modest at present.

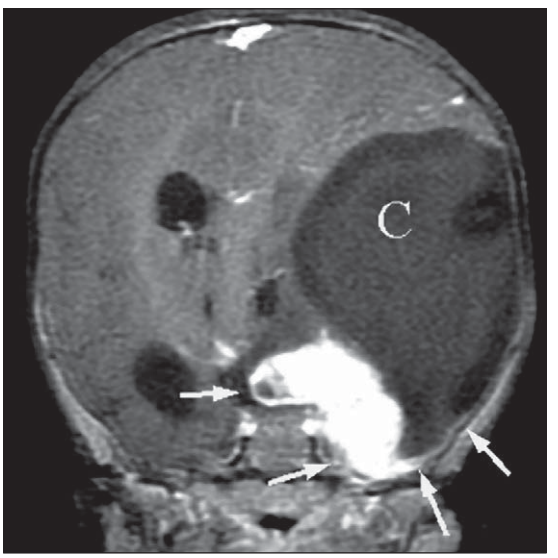

Figure 21-18 • Coronal MR image with gadolinium of the brain shows a mass with peripheral enhancement *(arrows)*, compatible with tumor, and a more hypointense necrotic area.

Esophageal and Gastric Cancer

CT scanning is the method of choice for initial staging of esophageal and gastric cancer. Endoscopic ultrasound is the most sensitive and accurate method for determining whether tumor has invaded the wall of the esophagus or involved the periesophageal nodes. PET scanning is very sensitive in determining whether stage IV disease is present, and typically is performed as part of the initial staging evaluation, at least for esophageal cancer, to identify patients who are clearly not candidates for surgery.[107] FDG-PET also is being used with increasing frequency to assess treatment response in patients with esophageal cancer, as early changes in glycolysis after treatment appear related to treatment efficacy.[108]

Sarcomas

MRI is the method of choice for detection and assessment of soft tissue sarcomas. Gadolinium contrast enhancement is commonly used as well. FDG-PET imaging has been useful in assessing primary sarcomas for aggressiveness and defining possible sites for biopsy as well as for defining prognosis and grade.[109,110] It also has been used to assess and predict the response of sarcomas to therapy.[111]

Gastrointestinal Stromal Tumors

GI stromal tumors are relatively infrequent, but have been studied extensively with both CT and PET imaging in the past few years. These tumors often are responsive to imatinib and other tyrosine kinase inhibitors, in part due to their constituitive overactivity of a mutated KIT oncogene. These tumors have been shown to be typically FDG-avid. FDG accumulation declines very rapidly with effective treatments, earlier than changes in tumor size. Of interest is that recently revised CT criteria may allow CT to assess response more quickly to treatment in such tumors, with changes in tumor HU one of the characteristic findings of response. Both PET and CT thus have a role in this somewhat uncommon tumor, especially for the early assessment of treatment response.[112]

DEFINING NORMAL ORGAN FUNCTION FOR CANCER THERAPY

Several tests are used to determine whether a patient is a suitable candidate for aggressive therapy. These tests include myocardial perfusion imaging at stress to determine whether ischemia is present, because if present it could increase the risk for a major surgical procedure. Echocardiography also is used for this purpose. Myocardial function often is evaluated before chemotherapy is given. This may be done using a myocardial blood pool study or, less commonly, an echocardiogram to determine chamber size and ejection fraction.

Pulmonary function usually is determined by pulmonary ventilatory function tests; however, split lung function and regional function may be determined by pulmonary perfusion imaging with ^{99m}Tc MAA (macro-aggregated albumin; i.e., a quantitative lung scan). Regional ventilation also can be assessed quantitatively. Such determinations help to predict the level of pulmonary function expected after surgery. Split assessment of renal function sometimes is performed before removal of a renal cancer to ensure that the remaining kidney will be functional.

Functional imaging can identify the location of eloquent brain activity and evaluate motor cortex function. It also can help to guide brain tumor surgery by avoiding key areas of the brain.

GUIDANCE OF RADIATION THERAPY

Radiation therapy can be palliative, or it may be performed with curative intent. In general, the goal is to deliver maximum radiation to the tumor while minimizing radiation delivery to normal tissues. This delicate balance is achieved through increasingly sophisticated

dose delivery systems. The anatomic location of a tumor most commonly is defined by treatment-planning CT. The CT data are used to define tumor and normal tissues with a therapy-planning system. The planning potentially can be enhanced by better definition of the gross tumor volume (or biologic tumor volume) versus anatomic tumor volume, which are not always the same. FDG-PET is beginning to be used to better define the biologic tumor volume, often with data from PET/CT. Although this procedure is hardly the norm, it is clear that imaging is key to the optimal planning of radiation therapy ports. Substantial potential exists to target areas of tumor that are not identified on CT (expand port size) or reduce ports to areas that are not involved with tumor, because the goal is to irradiate tumor while not irradiating normal tissues.[113] A substantial number of centers now include PET imaging as part of their radiation therapy planning in a broad range of diseases.[114] Treatment plans for radiation therapy are discussed in a separate chapter in this book.

INTERVENTIONAL PROCEDURES

Increasingly, imaging is being combined with a therapeutic procedure to provide minimally invasive therapeutics. Examples include the use of CT to guide thermal ablation of the liver or lung and the use of MRI to guide ablation of brain and prostate tumors (through heat and cold). The ability to locate tumors and follow, in near real time, the response to treatment is of tremendous potential.

Catheter-based delivery systems also are important. For example, angiographic catheters can be used to deliver regional chemotherapy, emboli, or radioactive or chemical microspheres to treat tumors. Radioactive microspheres also are assuming a growing role in interventional oncologic radiology.[115]

EMERGING OPPORTUNITIES IN IMAGING

Functional imaging methods such as PET and varying innovative MRI techniques are being used increasingly to assess treatment response early after treatment is begun.[25] Beyond this, a variety of imaging methods are being developed to image key aspects of tumor biology (Table 21-3). An exciting area for both MRI and PET is in detection of hypoxia, which is common in a broad range of malignancies and which represents a possible target for cancer treatments.[116]

Table 21-3 Emerging Uses of Imaging

INDIVIDUAL PATIENT MANAGEMENT DECISIONS
Screening
Phenotyping of the tumor and host
TUMOR
Viability, proliferation, extent of necrosis or apoptosis, hypoxia, prognosis, type of treatment most likely to be effective based on receptors or presence of imageable pathways
HOST
Individualized assessment of pharmacokinetics of the drug and of organ function and pharmacodynamics
DRUG DEVELOPMENT
Does the tumor have a relevant target?
Does the drug reach the target?
Is the target pathway affected by treatment?
Is the proper dose of drug being given?
Does alteration of the target pathway alter the tumor biology?

In addition to hypoxia, tumor perfusion can be imaged with a variety of approaches.

Even though the process is difficult, interest remains in gene therapeutic approaches, which has led to attempts to determine, through imaging, whether genes, when delivered, actually reach tumors and, more importantly, whether they express in vivo the desired levels of gene product expected to be required to achieve a therapeutic effect. For example, dopamine receptors have been transfected into cells and imaged with radioligands capable of binding to the D2 dopamine receptor. Similarly, genes have been transfected that express varying thymidine kinase activities. This agent is suitable for gene therapy and can be imaged with radiolabeled substrates such as FMAU.[117,118]

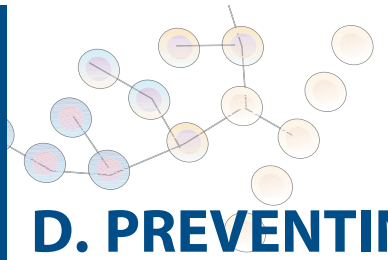
Similarly, a great deal of interest has been expressed in stem cell biology and the potential for stem cells to allow for regeneration of tissues. Tracking these stem cells in vivo and determining their biodistribution and ultimate proliferation are exceptional opportunities for imaging. These goals have been achieved with both nuclear medicine and MRI methods.

Small animal imaging devices of a variety of types are now being used to help in drug development. Small animal PET, SPECT, MRI, and CT scanners have been used to assess treatment response and aspects of tumor biology. Such methods are of critical importance for assessing the response of cancers to treatment with newer agents and understanding therapeutic effects. Even combined human PET/CT devices have been used for imaging and can provide useful information for drug development in cancer.

Some methods are of tremendous importance in preclinical studies, but will be more difficult to extend to human studies. One example is optical imaging. Such methods are capable of tremendous sensitivity and excellent resolution in vivo in small animals. A variety of approaches can be used, with emitted light, transmitted light, and reflected light. With bioluminescence approaches, a very small number of cancer cells can be identified in vivo in small animals. Such approaches, although very potent in vivo in small animals and capable of being combined with radionuclide and other methods, are not likely to be easily translated into humans, at least for broad applications, because of the limited penetration in tissue of light photons. However, in a broad range of detection issues the light can reach detectors, both intraoperatively and endoscopically for superficial structures, so this area is likely to be increasingly translated to practice. Thus, small animal imaging is a key element of progress allowing for proof of concept and refinement of tumor biological processes before translation to human use.

SUMMARY

Anatomic imaging of cancer using x-rays has been and remains extremely useful, and in the more modern form of CT is the dominant approach to imaging the patient with visceral cancer. Anatomic methods, although very potent, have clear limitations, but continue to improve, as evidenced by digital mammography and other techniques. Screening programs with mammography, CT of the thorax, and CT colonography are showing promise as methods to detect disease at earlier stages and potentially change outcomes. Anatomic methods can detect disease early, and such methods reliably show whether a mass is present. However, they provide limited information regarding the composition of the mass. In addition, they can be insensitive to small tumor foci, may be slow to change in response to therapy, are not predictive of response, and may be more challenging to apply in evaluating the postoperative patient. The functional information provided by MRI, including diffusion characteristics and, to a lesser extent, MR spectroscopy, adds to the anatomic signature of the lesions and continues to grow in application. Imaging additional phenotypic alterations of cancers with functional imaging methods such as PET adds information that often is clinically valuable for patient management in many common cancers.



Although many molecular alterations are present in cancer, the one that is by far most exploited in clinical practice and clinical research is the accelerated glucose metabolism present in most cancers. This process is well imaged with the radiotracer FDG. The ability to localize the molecular alterations of cancer spatially, through qualitative cognitive methods performed by the imaging specialist, computer fusion of image sets, or fused "anatomolecular" image sets using dedicated PET/CT, is key to optimal use of the imaging methods. Increasingly, the ability of PET imaging to quickly assess treatment response is allowing adaptation of treatments depending on the response of a specific patient's tumor to treatment. This response adaptive approach is expected to grow in the coming years. Functional imaging also is revising the approach to radiation therapy treatment planning. Functional "molecular" imaging methods such as PET, SPECT, and varying methods of MRI, in addition to optical and ultrasound imaging and technical improvements in CT and interventional techniques, are expected to enhance the care of the patient with cancer in the coming years and will likely continue to change the way oncology is practiced.

D. PREVENTING AND TREATING CANCER

22 Biostatistics and Bioinformatics in Clinical Trials

Steven Piantadosi and Jeanne Kowalski

SUMMARY OF KEY POINTS

Source of Uncertainty in Clinical Trials

- Uncertainty in trials can be classified as systematic error (bias) or random error.
- These types of errors can be controlled principally through the design of the medical study but not reliably through analysis alone.
- The strength of the evidence produced by a clinical trial depends on its design, primarily the amount and nature of the bias and random error that it controls.

Developmental Clinical Trials

- Clinical trials are designed primarily to meet specific developmental questions.
- An early developmental question is the relationship between dose and safety (phase I).
- These studies also address mechanistic questions such as pharmacokinetics and pharmacodynamics.
- The second major developmental step is providing evidence of safety and activity, usually in a disease specific cohort (phase II).
- These middle developmental trials provide evidence to support or discourage definitive, long-term, and expensive comparative trials.

Comparative Studies

- Comparative trials (phase III) often use randomization to remove treatment selection bias.
- Clinically definitive endpoints, such as disease progression and survival, are employed.
- Other systematic effects can be minimized by using masking.
- Random errors are minimized by employing sufficiently large sample sizes. These studies also require sophisticated infrastructures for data management, study monitoring, and multisite coordination.

Analysis

- The most appropriate methods to apply for analysis of a clinical trial depend strongly on the purpose and the design used for the study.
- All analyses begin with quality control data and sophisticated descriptive views of the data.
- Comparative studies require estimates of clinically relevant quantities such as risks or relative risks of the defined outcomes.
- Design flaws cannot be reliably corrected by sophisticated analyses.
- As a general principle, analyses unconditionally include all patients who meet the eligibility criteria and are based on treatment assignment.

Representation of Evidence

- The most clinically relevant summary of evidence from a trial is the estimate of the magnitude of treatment effect.
- In addition to magnitude, the precision with which an effect is estimated is often useful (e.g., 95% confidence interval).
- *P* values are deficient as measures of strength of evidence and should not be the primary currency of clinical trial results.

INTRODUCTION

The purpose of this chapter is to review biostatistical concepts that are helpful to clinicians in planning, conducting, and assessing clinical trials in oncology, and to provide some insight into the direction that future trials might take in light of the genomics era. For review, we describe areas where a statistical perspective can lead to improved design, execution, analysis, and interpretation of clinical studies. Several good texts and expository articles provide additional details regarding these concepts. These include history and policy,[1,2] general discussions,[3–12] cancer trials,[13–16] ethics,[17–19] prognostic factor analyses,[20,21] and reporting.[22–33]

Much of this chapter pertains to study design, because a well-designed and well-executed trial addressing an important therapeutic or management question will usually provide cogent evidence without an elaborate analysis. In fact, statistical analysis can do little to make the results of a poorly designed or executed trial compelling. This is not to trivialize analysis; an improper one can distort the findings of a well-designed and well-executed trial. To this end, our first topic is outlining some of the sources of uncertainty in inferences from clinical trials including dose-finding (phase I) studies, safety and activity (phase II) studies, and comparative (phase III) studies. Following this are discussed five areas of statistical activity that are important to the success of a program of studies in the management of oncologic disease: (1) formulation and refinement of an important therapeutic question through the use of developmental trials, (2) designing comparative trials, (3) implementing a trial and assuring quality control, (4) data analysis, and (5) describing results and preparing publications.

Later in this chapter, we discuss the future direction of cancer trials considering the combined roles of biostatistics and bioinformatics in cancer research, using vaccine trials as an example. Gene expression microarrays and gene expression databases provide new opportunities for the discovery of drug targets and for determining a drug's mode of action. Bioinformatics provides the computational tools by which to extract this information. Biostatistics provides the analytic tools to incorporate this information into clinical trial design and analysis. We later revisit concepts introduced at the begining of

this chapter within the context of cancer vaccine trials, because such trials represent a premier application of both fields with the development of immuno-based therapies designed to target discovered genes' function.

Many medical advances have been, and continue to be, made without conducting formal clinical trials. For example, when treatment effects are large, they usually become evident despite the variability and bias present in less formal methods of evaluation. However, many important treatment effects are characterized by natural variability of about the same magnitude as the treatment effect itself. In these circumstances, only careful design and conduct of clinical trials will separate treatment effect from bias and error reliably. Well-designed studies will estimate the magnitude of important clinical effects, quantify errors resulting from chance, reduce or eliminate bias, provide a high degree of credibility and reproducibility in results, and influence future clinical practice.

To meet these goals, investigators often conduct a variety of types of clinical studies. It is helpful to distinguish clinical trials from other types of medical investigations on the basis of who controls three essential components of design: treatment or exposure of the subjects, endpoint ascertainment (i.e., collection of outcome data), and analysis. True experiments place all three components under the control of the investigator. For example, a case report is relatively weak evidence, because it is a demonstration only that some event of clinical interest is possible. A case series is a demonstration of possibly related clinical events but is subject to large selection biases. In a database analysis, treatment is not determined by design but by patient or physician preference, permitting large biases. In an observational study the investigator takes advantage of natural exposures or treatment selection and chooses an appropriate comparison group by design. However, confounders may not be controlled adequately. In a clinical trial, treatment assignment is by design and endpoint ascertainment is actively performed on all subjects.

Using this type of hierarchy, one can see that the strength of evidence in medical studies is directly related to the amount of prospective design in the investigation. The more control exerted by the investigators over the essential components, the stronger will be the design and the more credible will be the results. See Byar[34] for a general discussion of this topic.

SOURCES OF UNCERTAINTY IN CLINICAL TRIALS

The most convincing clinical trials make use of methods to control and minimize relevant sources of uncertainty. Two types of uncertainty or errors can result when making inferences about treatment effects in medical studies: bias (systematic error) and random error. Both types of error can be controlled by using proper design. However, neither type of error can be reliably controlled by analysis alone.

Bias

There are numerous sources and types of bias in clinical trials; for example, see Sackett[35] or Chalmers.[36] All biases produce systematically high or low mis-estimates of the true treatment effect. Most of the time we do not know the direction of a particular bias, which means that it can either mimic a treatment effect or obscure it. Because, in human studies, we are often interested in treatment effects that are about the same magnitude as potential biases (and natural variation), control of systematic errors is critical. Consequently, we routinely attempt to eliminate bias through the appropriate use of design features such as eligibility criteria, randomization, objective endpoints, active ascertainment of outcomes, and treatment masking.

Patients who agree to participate in a clinical trial are usually not perfectly representative of the population with the disease (selection bias). Although this is often said to affect the external validity of the study, it is unlikely to affect the estimates of treatment differences. When the comparison group is subject to the same selection effect, as in randomized studies, relative treatment effects are estimated essentially without bias and are likely to generalize to individuals who do not meet the eligibility criteria. More clinically consequential biases arise from exclusion of patients after study entry, loss of data for reasons associated with outcome or prognosis, differential assessment of outcomes in treatment groups, and retrospective definitions or analyses. For example, it often seems clinically appropriate to exclude patients because of nonevaluability or nonadherence with the study protocol. However, such definitions are applied after registration or randomization and are therefore outcomes as well as potential predictors. One cannot reliably make exclusions based on such outcomes without the potential for bias.

Some data can be missing for reasons associated with outcome. For example, a recurrence (or death) event may not be observed because the patient has not returned to clinic for follow-up visits. Commonly used life table methods assume that such study subjects are censored at the time of last follow-up. Yet informative censoring results in an under-reporting of events and can only be corrected by actively ascertaining the status of all patients.

Random Errors

In later sections of this chapter we emphasize estimation of effects and confidence intervals as being the most clinically useful summary of data. However, because statistical hypothesis tests have had a prominent role in the design and analysis of trials and still provide a useful perspective on errors of inference, we discuss errors attributable to chance in these traditional terms. The two types of random error that can result from a formal hypothesis test are shown in Table 22-1. The type I error is a false-positive result and occurs if there is no treatment effect or difference but the investigators wrongly conclude that there is. The chance of making a type I error is frequently under the control of the investigator, even into the analysis stage of a clinical trial. This is true because the type I error can usually be controlled through the level of significance chosen for statistical tests.

The type I error must be carefully considered during the design of a clinical trial when multiple statistical tests are to be performed, a process that inflates the overall type I error. This happens, for example, when investigators intend to examine accumulating data and repeatedly perform statistical tests, as is done in sequential or group sequential interim monitoring of clinical trials. Failing to account properly for the effect of such repeated hypothesis tests can greatly increase the type I error rate. This point will be expanded later in a discussion of sequential methods.

The type II error is a false-negative result and occurs when we fail to detect a treatment effect or difference that is actually present. The power of a clinical trial is the chance of declaring a treatment effect of a specified size to be statistically significant (i.e., not making a type II error). The type II error can only be controlled by proper design, specifically a sufficiently large sample size, and not by procedures used in the analysis of the study.

A small study can yield a high power to detect a large treatment difference. However, as indicated previously, clinicians are usually

Table 22-1 Random Errors from Hypothesis Tests

	True State of Nature	
Result of Hypothesis Test	**H_0 True**	**H_0 False**
Reject H_0	Type I error	No error
Do not reject H_0	No error	Type II error

genuinely interested in modest-sized or small treatment effects. A small study will have low power to detect small differences. There is little sense in undertaking a complex expensive trial when the chance of missing a clinically important effect is larger than the chance of finding it.

A power calculation is hypothetical based on a specified, but as yet unobserved, treatment effect. Some observers of trials consider the power of a completed study against the observed difference, so-called post hoc power. When the observed treatment difference is smaller than anticipated, the post hoc power of the trial against that difference will be low, which seems to provide a cogent criticism. But after the study the treatment effect is no longer hypothetical, making a power calculation uninteresting unless someone intends to perform a new study in exactly the same circumstance. When a trial is finished, all of the information about the treatment effect is contained in the estimated value and its confidence interval; a post hoc power calculation adds nothing.

TYPES OF CLINICAL TRIALS

The use of clinical trials in oncology is similar to that in medical disciplines studying prevention, drugs, and devices. During the early developmental stages of new therapies, physicians evaluate evidence regarding related treatments and perform noncomparative clinical trials on the therapy under investigation. Statistical thinking is of great benefit in areas such as critical review of relevant literature, overviews of previous trial results, translational research studies, designing dose finding and toxicity studies, and designing studies to estimate treatment effects and feasibility.

Translational Trials

Only a small fraction of therapeutic ideas progress to developmental clinical trials. The transition from laboratory to clinic is guided by small targeted studies rather than large clinical trials. These small experiments, translational trials, may be the most common types of clinical trials performed. The methodology of translational clinical trials has not been fully formulated in the literature. This discussion is based on earlier work.[37] Nearly every new therapy depends on a transition from laboratory to clinic. Translational studies can sometimes be part of later developmental trials, provided that the subjects and the questions are compatible with it. The traditional dividing line between laboratory and clinical development is often said to be the phase I study (discussed later). In fact the interface between laboratory research and clinical development is formed by translational clinical trials.

The outcome in a translational trial is a biologic marker (target) that may require validation as part of the study. This is not a surrogate outcome, because it is not used to assess clinical benefit, although it might anticipate later questions of clinical benefit. The action of the treatment on the target defines the next experimental steps to be taken. In particular, the absence of a positive change is evidence of inactivity of the treatment.

A biologic outcome provides definitive evidence—an irrefutable signal—within the accepted paradigm of disease and treatment. The signal must be positive to support further clinical development. Good biologic signals might be based on a change in levels of a protein or gene expression, or the activity of some enzyme. As an example we consider a new drug for secondary prevention. The goal might require reducing the presence of biomarkers in the tissue. The absence of these effects would necessitate discarding or modifying the drug (or choosing a different target). Positive biomarker changes might suggest the need for preclinical improvements. Neither result would establish clinical efficacy. The basic characteristics of a translational trial are described in Table 22-2.

"A clinical trial where the primary outcome: (1) is a biological measurement (target) derived from a well established paradigm of disease, and (2) represents an irrefutable signal regarding the intended therapeutic effect. The design and purposes of the trial are to guide further experiments in the laboratory or clinic, inform treatment modifications, and validate the target, but not necessarily to provide reliable evidence regarding clinical outcomes."[37]

Table 22-2 Translational Trial: Basic Characteristics

The trial is predicated on promising preclinical evidence.
The treatment algorithm can be changed.
The treatment and target evaluation are fully specified in a protocol.
The evaluation relies on one or more biologic targets that provide definitive evidence of mechanistic effect.
The outcome is measurable with small uncertainty. Target validation may also be an objective, in which case imprecision in the outcome measurement could also represent a failure.
Large effects on the target are sought.
The protocol clearly defines "lack of effect" or failure to affect the target.
The protocol specifies the next experimental steps to be taken for any possible outcome of the trial.
The study is sized to guide additional experiments but not necessarily to yield strong statistical evidence.

Translational trials have continued experimentation as the primary context. The trial may provide evidence about the utility of more than one outcome. Many therapeutic ideas will prove useless during the laboratory-clinic iteration.

There are noteworthy deficiencies in these designs. One is the lack of proven clinical validity for the outcome. A second is the poor statistical properties of estimates. Not so obvious is that the translational trial paradigm confounds three effects: (1) the correctness of the disease paradigm, (2) the relevance of the biologic outcome, and (3) the action of the therapy. Errors in any of these can masquerade for either a positive or negative treatment effect. However, the correctness of the disease paradigm and the selection of a relevant outcome are usually based on strong evidence from earlier studies.

Dose Finding

Clinical trials that focus primarily on the relationship between dose and safety of new drugs or biologics are often termed phase I trials, particularly in oncology. Their purpose is to study drug distribution, metabolism, excretion, and toxicity and, in the case of cytotoxic drugs, to determine the dose associated with tolerable and reversible side effects. Until the last decade or so, statistical thinking contributed relatively little to the design of these studies. However, the relatively informal methods for dose finding have been steadily improved in recent years by statistical approaches. In oncology, dose-finding studies are often done in patients who have been previously treated with standard therapies. The features of classic phase I designs include (1) prior selection of a small set of drug doses to be tried, (2) treatment of a small number (e.g., three) patients at each dose with toxicity monitoring, (3) decision rules for stopping the trial based on clinical outcomes, (4) decision rules for escalating or de-escalating the dose in a subsequent cohort. Often a few additional patients are studied at the final dose, with the total number of patients treated being usually less than 25 to 30. This type of design alleviates certain practical and ethical problems in administering agents with unknown properties to humans. For example, it tends to minimize the number of patients treated at high (toxic) doses of the drug. It also tends to treat relatively larger numbers of patients at lower (ineffective) doses.

Such designs are inefficient. These properties tend to select conservative doses for later developmental testing.

Improved dose-finding designs have been suggested that correct such problems.[38,39] In some of these designs, doses are not prespecified but are determined from the current results and a mathematical model of the dose-toxicity curve. The final sample size of the trial is not fixed in advance but depends on the toxicities observed. The continual reassessment method is a prototypical design with these features. Some appropriate variant of the continual reassessment method has to be considered the design of choice for dose-finding trial of cytotoxic agents.

Safety and Activity

After determining the pharmacologic properties of a new drug and a clinically useful dose, trials focus on obtaining evidence of treatment safety and activity. These are conventionally termed phase II trials or safety and activity trials. The principal question to be addressed in this stage of development is whether or not the new treatment has enough promise to warrant testing against standard therapy in a large comparative trial—that is, a rigorous study with an internal control group. In this middle developmental step, the study design usually chosen to answer this question is a single cohort trial with an external control group. The control group comparison is usually based on the literature, prior investigator experience, or consensus opinion as to what constitutes a worthwhile level of activity in a given disease.

Such studies usually make use of surrogate clinical outcomes instead of definitive outcomes such as survival. Surrogate outcomes are chosen because ideally they are known soon after treatment, are easily and accurately measured, and are thought to be informative with respect to later definitive outcomes. Tumor shrinkage (response rate) is a classic surrogate outcome for activity in this setting, based on the cytotoxic model where it would imply tumor cell killing.

Unfortunately, tumor shrinkage is a poor surrogate for survival. Furthermore, some therapies would not be expected to produce tumor shrinkage in the usual cytotoxic model. An example might be cytostatic agents. Some caution has to be exercised when making developmental decisions on the basis of surrogate outcomes. For certain agents, safety and activity trials should make use of definitive outcomes such as survival (overall failure rate), making them somewhat larger and lengthier than conventional designs. For other agents, such as those based on vaccines, there has been much attention given to the potential use of molecular biomarkers based on gene discovery associations with cancer prognosis as surrogate outcomes; this is discussed further in the latter part of this chapter.

Two types of designs are commonly used in middle development: fixed sample size and staged. In fixed sample size trials, the number of study subjects is chosen in advance, for example to yield a specified precision in the estimated response rate. Staged designs use a treatment evaluation after groups of subjects have been entered, permitting early termination of accrual if high or low response rates are observed. Excellent working designs can be obtained from only two stages.[40] Numerous other statistical issues arise in the design and evaluation of phase II trials. Questions include patient selection, how to quantitatively evaluate response, patient exclusions, and the role of randomization. Space does not permit discussing these issues here. Reviews can be found in Buyse and colleagues.[13]

Sample Size for Middle Developmental Trials

There is a large literature concerning the quantitative design of middle developmental (phase II) trials. Here we consider some simple concepts to illustrate the connection between biologic outcomes and study size. Consider a phase II trial in which patients with esophageal cancer are treated with chemotherapy before surgical resection. A complete response is defined as the absence of macroscopic and microscopic tumor at the time of surgery. We suspect that this might occur 35% of the time and would like the 95% confdence interval of our estimate to be ±15%. Approximate 95% confidence intervals for a proportion, P, are

$$P - p \pm 1.96' \sqrt{[P(1-P)/n]}$$

where n is the number of patients tested and 1.96 is the quantile from the normal distribution corresponding to a two-sided probability of 5%. Substituting into this formula yields

$$0.15 = 1.96' \sqrt{[0.35(1-0.35)/n]}$$

or $n = 39$ patients required to meet the requirements for precision. Because 35% is just an estimate of the proportion and some patients may not complete the study, the actual sample size might be increased slightly. Expected accrual rates may be used to estimate the required duration of this study in a straightforward fashion.

A useful, but rough, rule of thumb for estimating sample sizes needed for proportions may be derived in the same way. Because $P(1 - P)$ is maximal for $P = 0.5$, an approximate and conservative relation between n, the sample size, and w, the width of the 95% confidence interval is $n = 1/w^2$. Thus, to achieve a precision of ±10% (.10) requires 100 patients, and a precision of ±20% (.20) requires 25 patients. This inverse-square relation demands large sample sizes for high precision. This rule of thumb is not valid for proportions that deviate greatly from .5. For example, for proportions less than about .2 or greater than about .8, exact binomial methods should be used to estimate precision and sample size.

Similarly, consider a middle developmental trial in which a definitive outcome such as reduction in the overall failure rate is required. On a log scale, the confidence interval for the hazard ratio is logD ± Z_a/D, where D is the hazard ratio, d is the total number of failures, and $Z_a = 1.96$ for a two-sided 95% interval. Like that for a response rate, this confidence interval can be made as small (precise) as necessary by observing more events.

Compared with a reference failure rate on standard therapy, a reduction of 33% on a new treatment (hazard = 0.2; ratio = 0.67) might be considered a useful improvement. If the reference failure rate is 0.3 per person-year (corresponding to median failure time of 2.3 years) and accrual proceeds at 75 subjects per year for 2 years with 1 additional year of follow-up, then we would expect to observe about 48 failures. This number of events would yield a precision of about ±0.06 (95% confidence interval) in the observed failure rate. Thus, such a study has to be larger and longer than a conventional safety and activity trial with a surrogate outcome.

COMPARATIVE STUDIES

Helping to design a comparative trial is a major responsibility for the biostatistician. The process involves detailed discussions with other investigators to resolve issues such as (1) what population should be studied, (2) are the treatment methods unambiguously defined, (3) how will patients be assigned to treatment groups, (4) how will outcomes be measured, and what can be done to assure that measurements will be obtained uniformly on all patients regardless of treatment assignment, and (5) what can be done to minimize loss to follow-up and to promote compliance to the treatment protocol.

In what follows, we outline some points of good design (Table 22-3) that are not intended to be taken chronologically. In fact, many of them must proceed simultaneously. However, attention to each of these items will probably result in a stronger trial.

Dual Roles of the Physician

Physicians who develop new treatments have two roles that are sometimes dissonant with each other. The first is as an advocate for the care and interests of the individual patient. The second is as a scientist representing the needs of others. The conduct of clinical trials is

Table 22-3 Ten Concepts in Comparative Trial Design

1. Review ethical issues and consent.
2. Quantify objectives.
3. Define the study population using eligibility and exclusion criteria.
4. Assess accrual resources.
5. Specify treatments.
6. Define endpoints and methods of assessment.
7. Calculate quantitative properties of the design.
8. Establish procedures for managing data.
9. Establish procedures for monitoring.
10. Control treatment allocation and bias.

one of many areas where these roles can, but do not necessarily, conflict. From a clinical trials perspective, physician advocacy for the individual patient is an ideal and not an exclusive standard of conduct. This ideal is not met in circumstances of triage, allocation of scarce and expensive technologies such as organ transplantation, training of new physicians, and vaccination. All of these circumstances knowingly place some patients at risk for the benefit of others.

Even if we accept the individual advocacy ideal, some patients will always receive an inferior treatment as a result of physician error. Failure to learn from such mistakes can hardly be considered ethical. It is incumbent upon the physician to learn quickly and convincingly from the inevitable use of less effective treatments so that their scope of application is minimized.

Controlled experiments in the proper clinical setting are the most reliable way to accomplish this. Conversely, we must learn about efficacious new therapies as quickly as possible so that they can be used broadly.

Although clinical trials are conducted worldwide, there are concerns voiced occasionally about the ethics of randomization. Although any medical technology can be used inappropriately in specific instances, there is nothing inherently unethical in the use of randomization when it is used because physicians lack knowledge about the superiority of treatments and to eliminate bias so that the best possible evidence can be gathered. There will always be circumstances of collective uncertainty in which randomized treatment comparisons are the most ethical course of action.

In some circumstances, evidence becomes available during the conduct of the trial that one treatment is superior. This can happen, for example, if one treatment is unexpectedly better or worse or has unacceptable side effects. Investigators are ethically bound to learn of such circumstances as early as possible by monitoring the accumulating data and closing the inferior treatment arm if necessary. The administrative and statistical plans to meet this contingency require planning during the design phase of the trial.

Quantification of Objectives

An important task in designing a clinical trial and drafting the study protocol is to convert clinical objectives into quantitative measurements of outcome variables. For example, we might be interested to know if a certain therapy "results in lower morbidity." However, the measurement of morbidity is not automatically well defined, particularly if the study involves more than one investigator. At least three aspects of morbidity must be defined. The first is a window of time during which adverse events can plausibly be attributed to the therapy. The second is a list of specific diagnoses or complications to be included. The third is a list of procedures required to establish each diagnosis definitively.

Definition of the Study Population Using Eligibility and Exclusion Criteria

Differences in eligibility criteria probably explain many of the discrepant results in the clinical literature from seemingly identical clinical trials. Even when several institutions use the same protocol, differences in interpretation of eligibility criteria and type of patients referred contribute to differences in outcomes. As a consequence, trials from different institutions and or periods of time may not be comparable even if the eligibility criteria are the same. This is one argument in favor of randomized concurrent controls.

To some extent, study results can be shaped by the eligibility and exclusion criteria. Consider how drug toxicity or operative morbidity can be reduced by the careful selection of patients. Age restrictions can reduce the number and severity of many chemotherapy toxicities, although such restrictions are seldom made explicit. Eligibility criteria can be used to define a more homogeneous study population, reducing the interpatient variability in outcomes. However, this will not necessarily reduce the size of a trial. For example, patients with poor prognosis may respond to treatment in the same way as those with good prognosis. If so, a trial excluding poor-prognosis patients would be needlessly prolonged.

In many instances endpoints may be evaluated more easily if certain complicating factors are prevented by patient exclusion. For example, if patients with recent nonpulmonary malignancies are excluded from a lung cancer trial, evaluation of tumor recurrences and second primaries might be made simpler.

Ethical considerations also suggest that patients who are unlikely to benefit from the treatment (e.g., because of organ system dysfunction) not be allowed to participate in the trial. Whenever possible, quantitative parameters such as laboratory values should be used to make these definitions rather than qualitative clinical assessments. Some studies in patients with advanced cancer call for a "life expectancy of at least 6 months." A more useful and reproducible criterion might be Karnofsky performance status greater than, say, 8.

Assessment of Accrual Resources

One unfortunate and preventable mistake made in clinical trials is to plan and initiate a study, only to have it terminate early because of low accrual. This situation can be avoided with some advance planning. First, investigators should be aware of the accrual rate required to complete a study in a certain fixed period of time. This is a best-case projection. Most researchers would like to see comparative treatment trials completed within 5 years and pilot or feasibility studies finished within a year or two. Disease prevention trials may take longer. In any case, the accrual rate required to complete a study within the time targeted can be estimated easily from the total sample size required.

Second, investigators must obtain realistic estimates of accrual rates. The raw number of patients with a specific diagnosis can often be determined easily from hospital or clinic records but is a large overestimate of potential study accrual. It must be reduced by the proportion of subjects likely to meet the eligibility criteria, and again by the proportion of those willing to participate in the trial (e.g., consenting to randomization). This latter proportion is usually less than half. Study duration can then be projected based on this potential accrual rate, which might be one fourth to half of the patient population.

Third, investigators can project trial duration based on a worst-case accrual. The study may still be feasible under such plans. If not, plans for terminating the trial because of low accrual are needed so as not to waste resources. In particular, accrual estimates from participating institutions other than the investigators' own are suspect. How long will the study take as a single-institution trial?

To estimate accrual more accurately, participants can be formally surveyed before accrual starts. As patients are seen over a period of time, a record can be kept to see if they match the eligibility criteria.

To estimate the proportion willing to give consent, one could briefly explain the proposed study and ask if they would hypothetically be willing to participate.

Treatment Specification

Control of treatments and their allocation is a defining characteristic of true experimental designs. In practical situations, explicit plans are needed for modifications in the treatment of individual patients. To satisfy scientific objectives, essential components of the therapy should be guided by the protocol, but modifications that are unlikely to affect the outcome should be left to the treating physician.

Physicians participating in trials are always obligated to replace protocol treatments with others when they feel that it is in the best interests of the patient. However, sufficient flexibility in the treatment specification, especially concerning complications, toxicity, or side effects, may permit most patients to continue following the protocol. This could contribute more information to the trial results and enhance the credibility of the study report.

Definition of Endpoints and Methods of Assessment

Selection of endpoints and the use of prospective methods of assessment greatly affect the strength of a trial. Important characteristics of the endpoint are that it correspond to the scientific objectives of the trial, as well as to be biologically meaningful within the context of the therapy or intervention under investigation; see further discussion on this point in the Design section. The method of assessing endpoints should be accurate and free of bias. This is helpful for both subjective endpoints and objective ones such as survival and recurrence time. Even when using well-defined event times, incomplete follow-up can create bias.

From a biostatistical perspective, there are three types of endpoints that are likely to be used widely in oncology trials: (1) continuously varying measurements, (2) dichotomous outcomes, and (3) event times. We will briefly discuss each of these.

Continuously Varying Measurements

Measurements that can theoretically vary continuously over some range are common and useful types of assessments. Examples include many laboratory values, blood or tissue levels, functional disability measures, or physical dimensions. In a study population these measurements have a distribution, often characterized by a mean or other location parameter, and variance or other dispersion parameter. Consequently, these outcomes will be most useful when the primary effect of a treatment is to raise or lower the average measure in a population. Typical statistical tests that can detect differences such as these include the *t*-test or a nonparametric analog and analyses of variance (for more than two groups). To control the effect of confounders or prognostic factors on these outcomes, linear regression models might be used.

Dichotomous Measures

Some assessments have only two possible values, for example, present or absent. Examples include some imprecise measurements such as tumor size, which might only be described as responding or not, and outcomes like infection, which is either present or not. Inaccuracy in measurement can make a continuous value ordinal or dichotomous. In the study population these outcomes will be frequently summarized as a proportion. Comparing proportions might lead to tests such as the chi-square or exact conditional tests. Another useful population summary is the odds or log-odds. The effect of prognostic factors or confounders on this outcome can often be modeled using logistic regression.

Event Times

Event times are common and useful outcome measurements in clinical trials. Survival time and disease-free or recurrence time are well-known examples. However, many other intervals might be of clinical importance, such as time to hospital discharge or time spent on a ventilator. The distinguishing feature of event time outcomes is the possibility of censoring. This means that some subjects under observation may not experience the event by the end of the study. Using the information in the censored observation time requires some special statistical procedures. In the study population, event time or "survival" distributions (e.g., life tables) might be used to summarize the data. Clinicians are also accustomed to seeing medians or fixed time proportions used to summarize these outcomes. Perhaps the most useful summary is the hazard, which can be thought of as a proportion adjusted for follow-up time. The effect of prognostic factors or confounders on hazard rates can often be modeled using survival regression models.

Other Endpoints

There are several other types of endpoints that are important for some medical studies but are not used frequently in oncology. These include counts, multiple-category outcomes, ordered categories, disease intensity measures, and repeated measurements. For example, units of blood used might be described as a count and chemotherapy toxicities are often described in ordered categories. As another example, cytogenetic responses are often recorded as categorical outcomes, and have received much attention for their use in assessing minimal residual disease (MRD) and in vaccine trials of chronic myeloid leukemia (CML). There has also been much discussion among clinical trial designers recently concerning the use of intermediate endpoints that become known early after treatment but are very reliably associated with definitive outcomes. Examples include premalignant lesions in cancer prevention studies and CD4 lymphocyte counts in acquired immunodeficiency syndrome (AIDS). Intermediate endpoints are probably not as relevant to oncologic studies as to these others areas of study. One notable exception is the use of prostate-specific antigen to monitor prostate cancer recurrence.

Control Treatment Allocation and Bias

Randomization

Randomization is one of the most effective means for reducing bias, because it guarantees that treatment assignment will not be based on patients' prognostic factors. The benefits derived from randomized treatment assignment are well known.[36,41] Following randomization, treatment differences can be attributed to the true treatment effect plus random variability.

One argument against randomization is that it is unnecessary because confounders can be controlled in the analysis by using statistical adjustment procedures. The extent to which this can be done relies upon two additional assumptions: (1) the investigators have measured the confounders in the experimental subjects, and (2) the assumptions of the statistical models or other adjustment procedures are known to be correct. Randomization is a more reliable method than adjustment, because it controls bias without these assumptions. Moreover, it controls the effects of confounders whether they are known to the investigator or not. Critics of randomization often overlook this last point, which provides randomized studies with their high degree of credibility.

Blinding or Masking

Masking (blinding) is another bias-reducing technique in which the patient (single-blind), physician (double-blind), and perhaps the monitors (triple-blind) in a clinical trial are unaware of the individual patient treatment assignments. As a result of blinding, treatment assessments can be made without prejudice, increasing the utility of both objective and subjective outcomes. Masking of drugs is often simple to implement, particularly with the assistance of a hospital pharmacy or pharmaceutical company. In oncology, treatment masking is frequently possible though sometimes logistically impractical.

Calculation of Quantitative Properties of the Design (Precision, Power, Duration)

Questions regarding the quantitative properties of clinical trial designs are among those most frequently asked by clinicians. It is not possible to specify a universally valid approach to answering such questions. Instead, we provide some basic ideas and examples. For a more statistically oriented review, see Donner.[42] Although computer software is available to perform many power and sample size calculations (e.g., Hintze[43]), most programs are written for a statistical user.

Two basic considerations in estimating precision and power are the purpose of the trial and its primary endpoint. For noncomparative designs, the goals of the study are often to estimate some useful clinical quantity with a specified precision. Examples of endpoints with clinical interest are average blood or tissue levels of a drug, the proportion of patients responding or meeting other predefined criteria, or population failure rates. A useful measure of precision is the confidence interval of the estimate. For example, narrow 95% confidence intervals indicate a higher degree of certainty about the location of a true effect than wide 95% confidence intervals do. Because confidence intervals depend on the number of subjects studied, targets for precision can often be translated into requirements for sample size.

Comparative clinical trials require more complicated methods to estimate sample size and power. Often, comparative studies are designed to yield statistical hypothesis tests with desirable properties, such as a high power to detect important clinical differences reliably. In trials with survival time as the primary endpoint, the power of the study depends on the number of events (e.g., recurrences or deaths). Confusion can arise over the number of patients placed on study versus the number of events required for the trial to have the intended statistical properties. As a test of equality between treatment groups, it is common to compare the ratio of hazard (or failure) rates (see following definition) versus 1.0. Under fairly flexible assumptions, the size of such a study should satisfy

$$d = [(Z_a + Z_b)^2(D + 1)^2]/(D - 1)^2$$

where d is the total number of events needed on the study, D is the ratio of hazards in the two treatment groups, and Z_a and Z_b are the normal quantiles for the type I and II error rates.[43]

For example, with this formula, to detect a hazard rate of 1.75 as being statistically significantly different from 1.0 by using a two-sided 0.05 α-level test with 90% power requires

$$[(1.96 + 1.282)^2(1.75 + 1)^2]/(1.75 - 1)2 = 141 \text{ events}$$

This is not the final sample size, as suggested by the safety and activity trial example discussed earlier. A sufficient number of patients must be placed in the study to yield 141 events in an interval of time appropriate for the trial. For example, if 50% of patients remain event-free (censored) at the end of the trial, 282 subjects are required. In general, the sample size, n, is $n = d/(1 - p)$, where p is the proportion censored.

TRIAL IMPLEMENTATION

Establishment of Procedures for Managing Data

All trials require certain minimal standards for collecting, quality controlling, and reporting data. Although many investigators use their own staff to perform such duties, sufficient skill is required to suggest that these activities be housed in groups dedicated to the purpose. Resources for this might exist on a departmental or institutional level. In other circumstances, an external or privately run coordinating center might be used. In no cases should this reduce access to the data or substitute for skilled translation of data elements from clinical and laboratory sources to study database.

There are at least five conceptual components to processing information from patients on a clinical trial: (1) eligibility check and registration/randomization, (2) data acquisition from the clinical record, (3) editing, error checking, building a database, and quality control, (4) interim reporting, and (5) analysis. Each of these, when properly performed, will reduce the frequency and severity of certain types of errors. Although one could write extensively about this subject, we summarize only a few important points about each component.

The eligibility check and registration is a simple but important quality control point. Even the knowledge that eligibility will be impartially checked causes many investigators to take entry criteria more seriously. Usually, a phone call requiring only a few moments is all that is needed. Using this opportunity, an identifying number can be assigned, a database record can be started, the pharmacy can be notified (if necessary), and other study bookkeeping can be initiated.

Data acquisition from the clinical record must be performed by an individual with sufficient clinical, protocol, and medical record knowledge. In some cases this requires the investigator's expertise, whereas in other circumstances a research nurse or data specialist can succeed. Unless studies are subject to external auditing, it is uncommon to catch errors made at this stage. Thus the principal investigator can have a major beneficial impact on the quality of data by being active here.

A simple and straightforward system for building and managing a database might begin with paper records or data forms that contain the information of clinical importance to the study. It is not necessary to record all the information needed for the care of the patient but rather only those items that correspond to the outcomes and objectives of the study. Ideally, one would not collect any items that do not need analysis. Information from these forms can be transcribed onto an appropriate computer database. Numerous quality control checks and edits are necessary to be certain that the database produced from paper records accurately represents the clinical record. For example, audits may compare the database with the chart. Within a single patient's record, computerized checks of bounds and internal consistency can be performed. When reviewed by a knowledgeable person, lists and summaries of the data can trap many errors.

Computer software has made some of these tasks more simple and reliable. Many investigators use spreadsheets to assist with these tasks in small studies, although database software is more powerful. When existing databases and human resources are available, investigators should attempt to use them rather than building a system for each study independently. In any case, the investigator should understand the flow of data from the clinical record through the final analysis. This flow of data, however, may involve metadata through the use of genomic information into clinical trials, in which case new technologies for storing, retrieving, and analyzing such information creates a challenge for medical informatics. Until recently, medical informatics has been an established field that pioneered the development and introduction of informatics methods in clinical medicine. With the increasing desire to transfer genomic results into medicine, bioinformatics has posed a challenge to the field of medical informatics for the development of novel clinically oriented methods to ensure success in such a transfer.[45,46] Indeed, the new era of genomics-based approaches to medicine, such as in defining and evaluating genome-related risk factors for various diseases, developing diagnostic tests, creating updated cancer cell classifications, or integrating genetic and medical data in clinical practice, will require support from both bioinformatics and medical informatics to address the collecting, quality controlling, and reporting data as part of clinical trials design, and prompts the need for new standards in such areas.[47]

Interim reporting serves several purposes. It provides an opportunity for the investigators to review accumulating data related to administrative aspects of the study such as accrual rates and delinquent observations. Complication and toxicity rates can be reviewed
