82 Cancer of the Rectum

Alfred M. Cohen, Michael C. Garofalo, Philip A. DeSimone, Nader N. Hanna, and William F. Regine

SUMMARY OF KEY POINTS

Incidence

- The incidence of rectal cancer in the United States is 44 cases per 100,000 population for a total number of new cases of approximately 34,000 annually.
- Since 1985, the incidence rate has been decreasing by 1.6% per year.
- The peak incidence of rectal cancer is during the fifth decade of life.
- Blacks have a 7% to 10% higher mortality rate from rectal cancer than whites.

Clinical Presentation

Numerous clinical features suggest the presence of rectal cancer:

- Located approximately 12 cm from the anal verge
- Rectal bleeding, often bright red and on the surface of the stool
- Subtle changes in bowel habits
- Decreased caliber of stool; mucus in stool
- Sensation of fullness and tenesmus
- Increased straining during defecation
- Synchronous colon cancer (in 2% to 9% of patients with rectal cancer)

Staging and Assessment

- Careful rectal examination yields 67% to 84% accuracy in staging (superficial, mobile, tethered, fixed) and should include pelvic examination for women and prostate examination in men.
- Rigid proctosigmoidoscopy provides the most accurate assessment of distance, size, and position as well as tethering to surrounding structures.
- Colonoscopy or double-contrast barium enema is used to assess for synchronous colon tumors.
- Endorectal ultrasound can assess the depth of invasion and nodal status. (Nodal assessment is less reliable.)
- Magnetic resonance imaging (MRI) with endorectal coil is equivalent to ultrasound, and both are more sensitive and accurate than computed tomography alone. MRI is used to assess locally advanced or recurrent local disease. Computed tomography should be performed on all patients to assess intra-abdominal spread. CT or chest x-ray is required to rule out synchronous lung metastases.
- The liver is the most frequent site of distant spread, followed by lung, retroperitoneum, ovary, and peritoneal cavity.
- Baseline carcinoembryonic antigen levels and prostate-specific antigen are assessed in men.

Differential Diagnosis

Differential diagnosis includes the following:

- Kaposi's sarcoma
- Inflammatory mass
- Developmental cysts
- Embryonic tumors (teratomas, chondromas, meningoceles)
- Sacral and presacral tumors (neurogenic tumors, liposarcomas, neurofibromatosis)
- Carcinoid tumors
- Gastrointestinal stromal tumors

Treatment

- Goals of treatment are cure, local control, and quality of life.
- All retrorectal tumors should be resected, and preoperative biopsy must be avoided.
- Full-thickness local excision is feasible for highly selected patients with T1 mucosal, submucosal, and early invasive cancer, particularly in patients with high-risk comorbidities.
- For T1–T3 rectal adenocarcinomas, surgical procedures are low anterior resection, low colorectal or coloanal anastomosis with J-pouch, and abdominoperineal resection, leaving at least 2 cm distal margin and clear lateral margins. With surgery, mortality rates are 1% to 7%, and morbidity rates are 13% to 46%. The survival rate at 5 years is 74% to 87%.
- The optimal therapy for T3 tumors is sharp mesorectal excision combined with total mesorectal excision.
- The majority of N0 patients are cured by surgery and, for some selected patients, adjuvant multimodal therapy. Combined therapy cures 50% of N1 patients; 25% of tethered or fixed rectal cancers treated by neoadjuvant chemoradiotherapy are subsequently resected and cured.
- Of patients who die of rectal cancer, 25% fail with pelvic disease only.

INTRODUCTION

Although the incidence of distal (rectal and lower sigmoid) cancers has declined, with a concurrent increase in more proximal colon cancers, approximately one quarter of colorectal cancers are located in the rectum. For many years, almost all patients with rectal cancer underwent abdominoperineal resection with a permanent colostomy. Today, this approach is rarely required. The successful treatment of patients with rectal cancer involves optimal surgical technique and frequently adjuvant chemoradiotherapy. This combined modality approach will maximize cure, minimize the risk of a subsequent symptomatic local or pelvic recurrence, and maintain quality of life. Such multimodality approaches are applicable to patients with rectal cancers at or below the peritoneal reflection. This designation

generally represents cancers below 12 cm from the anal verge. Tumors in the upper rectum or rectosigmoid are treated by surgical resection, and adjuvant therapy is based on the colon cancer paradigm.

EPIDEMIOLOGY

The incidence of rectal cancer in the United States is 44 cases per 100,000 population for a total number of new cases annually of approximately 34,000.[1] Since 1985, the incidence rate decreased by 1.6% per year through 1997. A decrease in colon and rectal cancer incidence rates has been observed in males and females and in all racial and ethnic groups. The incidence rate rises dramatically during the fifth decade of life. A study of 75,000 Medicare enrollees[2] observed that proximal colon cancers appear to be disproportionately high among elderly patients. Blacks have a higher mortality rate than whites for colorectal cancer, which holds true for both rectal and colon cancers. In a 25-year period,[1] 1974 to 1999, the gap between the survival rates of blacks and whites increased from a difference of 5% to 11% for colon cancer and from 7% to 10% for rectal cancer.

The anatomic subsites of colorectal cancer also changed in the same 25-year period. The cancer incidence by anatomic subtype has shown that the incidence of rectal cancer has decreased from 9.6 cases per 100,000 population to 7.6 cases per 100,000 population.[3] This same finding has been reported in Japan[4] in a report that shows an increasing percentage of right-sided colon cancers and a continuous decline in percentage of rectal cancers in both sexes and at all ages. Sharpe and colleagues[5] reported an observational study that showed a positive association between cigar smoking and cancer of the rectum. They also noted a weak positive association between cigarette smoking and cancer of the proximal colon. Several large cohort studies have shown that cigarette smoking is an independent risk factor for colorectal cancer.[6–11]

In a large cohort study of more than 22,000 healthy male physicians aged 40 to 84 years who were followed for more than 12 years, cigarette smoking was an independent risk factor for colorectal cancer incidence, the strongest risk being observed in current smokers of 20 cigarettes or more per day (relative risk: 2.14), Cumulative lifetime exposure and exposure during various periods of life also increased the risk of colorectal cancer.[12]

A recent study showed that the increased risk of colorectal cancer associated with cigarette smoking is dependent on the molecular characteristics of the tumor as defined by *APC* mutation and *hMLH1* expression status. The association between frequency of cigarette smoking (for a five-cigarette/day increment) and colorectal cancer was most apparent and stronger in tumors without a truncating APC mutation, while duration of smoking was associated with increased risk in *hMLH1*-deficient tumors.[13]

CLINICAL PRESENTATION, EVALUATION, AND STAGING

Patients with rectal cancer can have a broad range of clinical presentations. Early symptoms that suggest rectal carcinoma include rectal bleeding and subtle changes in bowel habits. Rectal bleeding is often mixed with stools or may coat the surface of the stool. It can be bright red and separate from the stools and therefore is often mistakenly attributed to hemorrhoids. Bright red blood only on the tissue paper may be evaluated in a young person with proctosigmoidoscopy. All other types of bleeding, including the presence of occult blood in the stools during a routine physical examination or presence of iron deficiency anemia, warrant a more complete endoscopic evaluation. Increased frequency of defecation, decreased caliber of the stools, mucus with stools, or mucous diarrhea (particularly associated with large villous adenomas) is quite common. Advanced tumors induce a permanent sense of fullness and tenesmus and increased straining during defecation. Sacral or deep pelvic pain, sometimes radiating down the perineum and thighs, occurs when the tumor invades the sacrum and the sacral plexus of nerves. Anal pain, initially on defecation and later continuous, may occur when low rectal cancer invades the anal canal. Incontinence supervenes when the anal sphincter is involved.

The importance of a detailed history and a thorough physical examination cannot be overstressed. Comorbid conditions and the patient's physical habitus may preclude major surgery and influence the decision of adjuvant therapy. Physical examination should always include a digital rectal examination to feel for a mass, assess its location and mobility, and feel for enlarged extrarectal lymph nodes (50% accuracy). Depth of invasion and whether the tumor is tethered or fixed can also be assessed during rectal examination with 67% to 84% accuracy.[14,15] A careful pelvic examination in women and a prostate assessment in men are essential. A rigid proctosigmoidoscopic examination of the rectum and the anus should follow. The distance of the tumor from the anal verge, anterior/posterior/lateral position, size, morphologic configuration, and extent of circumferential involvement are determined. Tumor mobility and tethering to surrounding structures are ascertained. If not obstructed, patients with rectal cancer should have a preoperative double-contrast barium enema or preferably a colonoscopy to assess for synchronous colon cancer (2% to 9%). Subjective and objective assessment of the patient's anal sphincter function is desirable. A weak or incompetent sphincter may favor a colostomy.

Endorectal ultrasound provides valuable preoperative staging (Fig. 82-1), including depth of tumor invasion into the rectal wall (89% to 92% accuracy,[16,17] 96% sensitivity, 90% specificity, 96% negative predictive value[18]) and nodal enlargement (79% sensitivity, 74% positive predictive value, 84% negative predictive value[19]), but confirmation of nodal metastasis with ultrasound-guided needle biopsy is less reliable (77% accuracy, 71% sensitivity, 89% specificity, 92% positive predictive value, and 62% negative predictive value[20]). Malignant nodes are differentiated from reactive nodes by being hypoechoic, hypervascular, and irregular.[21,22] Endorectal ultrasonography and magnetic resonance imaging (MRI) with endorectal coil exhibited similar accuracy and were superior to conventional computed tomographic (CT) scans in preoperative assessment of depth of invasion and adjacent organ invasion.[23] This improved diagnostic staging information is essential in considering local treatment for rectal cancer, deciding selective use of preoperative chemoradiotherapy in locally advanced tumors, and choosing between an abdominoperineal and low anterior resection.

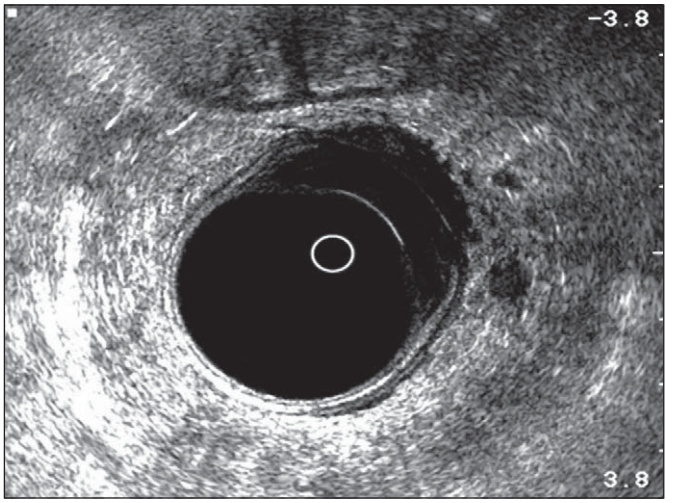

Figure 82-1 • Endorectal ultrasound of T3N1 rectal cancer. (Courtesy of Dr. W.D. Wong, Memorial Sloan-Kettering Cancer Center.)

The liver is the most frequent site of metastasis, followed by the lung, retroperitoneum, ovary, peritoneal cavity, and rarely the adrenal glands. Contrast-enhanced CT scan of the abdomen and the pelvis is recommended in all patients with rectal cancer, excluding the very elderly and those with very early cancer, such as cancer within a polyp or T1 rectal cancer. MRI is reserved for patients with locally advanced and recurrent rectal cancer requiring an exenterative procedure. A plain chest radiograph is useful and economical for screening for lung metastasis. Laboratory studies should be ordered as indicated by the patient's medical condition and anesthetic requirements. Measurement of the carcinoembryonic antigen (CEA) level in combination with imaging can refine the accuracy of preoperative assessment and overall prognosis and is useful if postoperative CEA monitoring is planned. Up to 95% of patients with advanced hepatic metastasis will have a CEA level above 20 ng/mL.[24] Normal preoperative CEA levels will identify patients who will not benefit from following CEA levels postoperatively. In men, a prostate-specific antigen level should be checked, particularly if the prostate gland is enlarged.

DIFFERENTIAL DIAGNOSIS

Kaposi's sarcoma of the rectum should be suspected in patients with acquired immunodeficiency syndrome who present with an unusual or atypical anorectal lesion. It is often associated with proctalgia (62%), hematochezia (50%), and diarrhea (50%).[25] Rectal carcinoids are often found incidentally during a screening colonoscopy or typically present with symptoms of bleeding, rectal pain, or constipation. They tend to be more indolent and less aggressive than colonic carcinoids, but as with most gastrointestinal carcinoids, tumor size correlates with the risk of metastasis and survival rates. Endoscopic resection is often adequate. Gastrointestinal stromal tumors of the rectum (Fig. 82-2) are uncommon and often present as source of lower gastrointestinal bleeding, rectal pain, or constipation. Because of their malignant potential and recent advances in the management of gastrointestinal stromal tumors with imatinib mesylate (Gleevec), it is imperative that these tumors be correctly diagnosed. Positive immunohistochemical staining with CD34 and CD117 confirms the diagnosis. For large or low-lying rectal gastrointestinal stromal tumors, neoadjuvant therapy with Gleevac can facilitate local and sphincter-preserving excision. Except for inflammatory masses, developmental cysts (such as dermoid, epidermoid, duplication, and tailgut cysts) and embryonic tumors (such as teratomas, chondromas, and meningoceles) are the most common retrorectal tumors. Other sacral and presacral tumors include neurogenic tumors, liposarcoma, and neurofibromatosis. Sacral pain and the sensation of fullness in the perirectal area are the most common symptoms of retrorectal lesions.[26] Digital rectal examination is the most important diagnostic maneuver. Posteroanterior and lateral radiographs of the sacrum and CT scanning are the preferred methods for characterization and differential diagnosis of retrorectal masses. MRI may also aid in planning the operative approach. Barium enema evaluation will confirm the presence of mass effect. Proctoscopy, although indicated, is usually normal. Most retrorectal lesions should be resected when diagnosed, even if they are asymptomatic and seem benign. Preoperative biopsy is generally not recommended, as it will not change the surgical need for resection and may contaminate the surgical field or lead to abscess formation. Biopsy is reserved for unresectable large retrorectal tumors.

SURGICAL TREATMENT OF RESECTABLE RECTAL CANCER

For most patients with early rectal cancer (T1 to T3), surgical resection is the primary treatment modality. Sound surgical techniques and adjuvant therapy can improve outcomes and maximize local and overall cure rates. Tumors in the upper third of the rectum have their lowermost edge 12 cm from the anal verge. Anterior resection or low anterior resection is the primary surgical procedure. Middle and lower third rectal cancers can be treated with restorative proctectomy with colorectal or coloanal anastomosis or abdominosacral resection with results similar to those that are achieved with abdominoperineal resection and permanent colostomy.[27] Overall surgical success depends on the ability to obtain a 2-cm distal margin; surgical expertise in obtaining clear lateral margins; the patient's body habitus, pelvic width, and prostate size; adequate collateral blood flow through the marginal artery; and whether or not there is associated colonic disease such as diverticulosis. Local approaches may be appropriate for patients with early rectal cancer within 8 cm from the anal verge or in patients with major medical contraindications to radical surgery.

Local Treatment

Selection Factors

Selection factors for full-thickness local excision are the same as or similar to those that are used for endocavitary radiation therapy (RT). This decision is therefore based largely on findings of digital rectal examination with increasing integration of use of transrectal ultrasound or MRI with endorectal coil.[20,23,28] Patients with T1 tumors without adverse pathologic features have a low incidence of local failure (5% to 10%) or lymph node involvement (<10%). With unfavorable pathologic features (lymphovascular invasion, high grade, deep submucosal invasion, signet ring cell, or colloid histology)[29–32] or evidence of tumor invasion into or through the muscularis propria,[30,33,34] the local recurrence rate is at least 17%, and the risk of regional lymph node involvement is at least 10% to 15%.[29] In an analysis by the Massachusetts General Hospital (MGH) of 40 patients who underwent local excision only, patients were categorized according to unfavorable clinical or pathologic features.[30] Among patients with T1 or T2 cancers following local excision, Blumberg and associates reported positive lymph nodes in 10% of T1 cancers and 17% of T2 cancers.[35] In addition, among the total group of 159 patients,

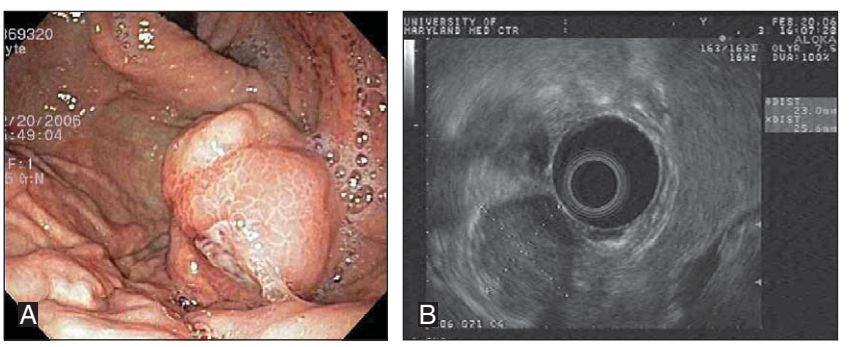

Figure 82-2 • Endoscopic (**A**) and TRUS (**B**) images of rectal gastrointestinal stromal tumors. (Courtesy of Dr. Nader Hanna, University of Maryland Medical Center.)

the incidence increased with the presence of lymphatic and vascular invasion (14% without versus 33% with). Even among the 42 patients with the most favorable features (negative lymphatic and vascular space involvement, well- or moderately differentiated T1 cancers), 7% were found to have lymph node involvement. The overall 5-year survival rate for the whole group was 65% with a locoregional recurrence rate of 27%. Hager and associates reported on a series of 20 patients with T2 rectal cancer for which local excision was performed and who were otherwise thought to be "low risk" (well to moderately differentiated, nonmucinous, no lymphovascular invasion, and negative margins), despite which the incidence of locoregional failure was still 17%.[33] Others have reported locoregional failure rates as high as 43% following either local or transanal excision in patients with T2 cancers.[36] There have been no randomized trials that compared transanal full-thickness local excision alone for T1/T2 with or without adjuvant chemoradiation to low anterior resection or abdominoperineal resection. Recent published results of local excision of T1/T2 rectal lesions without adjuvant therapy show local recurrence rates of 3.4% to 18% for T1 lesions and 27% to 67% for T2 lesions; these results are summarized in Table 82-1.

Local Approaches

Local approaches for treatment of early rectal cancer include transanal local excision, suprasphincteric posterior proctectomy (the Kraske procedure), transsphincteric posterior approaches (Bevan or York-Mason procedure), transanal endoscopic microsurgery (TEM), transanal fulguration, or local/contact radiation therapy (Papillon approach). TEM is a minimally invasive surgical technique that was introduced in 1984 by Buess. It incorporates a high-quality binocular operating system and pressure-regulated insufflation with continuous suction. Compared with conventional transanal resection, TEM provides superior intraoperative visualization and the ability to perform full-thickness excision of the tumor with clear margins, together with perirectal fat and adjacent lymph nodes[37,38] of tumors higher up in the rectum (4 to 18 cm from the anal verge). The technique is not yet generally established because of the high cost, the necessary special instrumentation and tools, and the unusual technical aspects of the approach.[38–46]

Treatment of cT2 rectal tumors with TEM combined with preoperative high-dose radiotherapy in 35 patients achieved survival rates similar to those of conventional open surgery.[47] Only minor postoperative complications occurred in five (14.3%) patients and included suture line dehiscence in three patients and stool incontinence in two patients. At a median follow-up period of 38 months, one patient presented with a local recurrence (2.85%) at 30 months of follow-up, and four patients developed systemic metastasis (11.4%). The survival and local recurrence rates that were reported in that study led to a prospective multicenter randomized trial (the so-called Urbino trial) to evaluate the efficacy of local excision in T2 tumors that were preoperatively treated by chemotherapy and high-dose radiotherapy versus standard open treatment (low anterior resection or abdominoperineal resection). At a median follow-up period of 56 months (range, 44 to 67 months), the local failure rate (5%) and distant metastasis rate (5%) were equal in the two groups.[48]

A recent review of the United Kingdom national TEM database from 21 centers since 1993 showed that of 454 rectal cancer patients, 69% underwent TEM with curative intent. The overall morbidity and mortality of TEM were 17.2% and 1.5%, respectively. Pathologic staging was as follows: pT0 (1.8%), pT1 (52.9%), pT2 (32.8%), pT3 (9.9%), and pTx (3.1%). Neoadjuvant therapy and adjuvant radiotherapy were administered in 8% and 18% of cases, respectively. Margin positivity (<1 mm) occurred in 20% of cases and was stage dependent. The 5-year disease-free survival rate was 77% for pT1, 74% for pT2, and 35% for pT3 with local recurrence rates of 20%, 25%, and 59%, respectively.[49]

Radical Resections

Sharp, total mesorectal excision (TME) with autonomic nerve preservation is the radical surgical technique of choice in conjunction with low anterior resection or abdominoperineal resection (APR). The mortality rate is 1% to 7%, and the morbidity rate (including genitourinary dysfunction, fecal incontinence, and permanent colostomy) is 13% to 46%. Locoregional recurrent disease is observed in 4% to 20% of cases, and the 5-year survival rate is 74% to 87%.[50–54]

Table 82-1 Local Excision of T1, T2 Lesions Without Adjuvant Therapy in Selected Series with More Than 50 Patients

Reference	No. of Patients (Per Stage)	Follow-up Time	LR	Survival Rate	Salvage Surgery for Isolated LR
Paty et al.*[223]	125 (T1 = 74, T2 = 51)	6.7 yr	T1 = 17% T2 = 26%	10-year OS: T1 = 74%, T2 = 72%	14/17
Mellgren et al.[224]	108 (T1 = 69, T2 = 39)	4.4 yr	T1 = 21% T2 = 47%	5-year OS: T1 = 72%, T2 = 65%	24/27
Garcia-Aguilar et al.[225]	83 (T1 = 55, T2 = 27)	54 mo	T1 = 18% T2 = 37%	5-year: T1 = 98%, T2 = 89%	17/20
Chakravarti et al.[176]	52 (T1 = 44, T2 = 8)	52 mo	28%	5-year DFS: 66	NS
Steele et al.[177]	59 (T1 = 59)	48 mo	T1 = 5%	6-year survival: 85	2/2
Kim and Madoff[226]	69 (T1 = 44, T2 = 25)	NS	T1 = 9% T2 = 28%	Cancer-specific 5-year survival: 88%	NS
Hager et al.[33]	59 (T1 = 39, T2 = 20)	33–40.5 mo	T1 = 8% T2 = 17%	5-year survival: T1 = 90%, T2 = 78%	NS

DFS, disease-free survival; LR, local recurrences; NS, not specified; OS, overall survival.

*In this series, 16 patients received postoperative radiotherapy and 15 additional patients received postoperative 5-FU and radiotherapy; however, local and overall recurrence rates were similar in both groups.

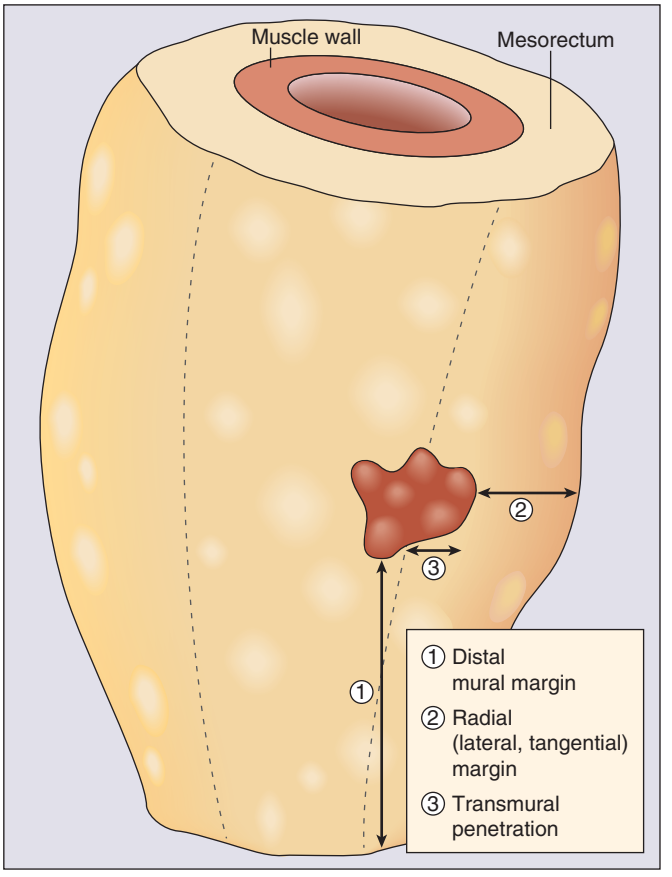

Figure 82-3 • Rectal cancer primary tumor margins.

Surgical Issues in Radical Resections

LATERAL CIRCUMFERENTIAL MARGINS AND TOTAL MESORECTAL EXCISION. The ability to obtain a negative lateral circumferential margin is associated with a decreased risk of local recurrence.[55–58] In a multivariate analysis, circumferential margin involvement was the most powerful predictor of local recurrence (hazard ratio: 12.2) and of overall cancer mortality (hazard ratio: 3.2; Fig. 82-3). Heald and colleagues have advocated TME in conjunction with low anterior resection or APR as the optimal surgical treatment for rectal cancer.[50] This technique involves removal of the entire rectal mesentery, including that distal to the tumor, as an intact unit. Complete distal TME is essential for clearance of any tumor deposits, which occur in 50% of T3 tumors with a maximal distal spread of 4 to 5 cm,[59] and is associated with increased frequency of local recurrence and decreased overall survival.[60,61]

Sharp mesorectal excision combined with TME provides the optimal surgical strategy. In contrast to conventional blunt dissection techniques, sharp mesorectal excision facilitates nerve preservation, enables complete hemostasis, and emphasizes gentle handling to avoid tearing or disruption of the smooth outer surface of the mesorectum. Sharp TME has been shown to achieve a negative circumferential margin in 93% of resected specimens. Although no randomized trial of TME has been performed, TME has been evaluated prospectively in Sweden, where it has been introduced via a formal preceptorship-based training program. A 5-year prospective audit reveals a local recurrence rate of 7% following the addition of TME compared to a historical control rate of 23%.

DISTAL MUCOSAL MARGIN. The ability to perform sphincter-preserving surgery is dictated by the requirements of a 2-cm distal margin rather than the traditional 5-cm margin.[62–66] Only 2.5% of patients (usually with poorly differentiated and node-positive rapidly disseminating disease) had disease spread greater than 2 cm.[27] There is no correlation between risk of local recurrence and the extent of distal margin in excess of 2 cm.[67–72]

PROXIMAL EXTENT OF LYMPH NODE DISSECTION. Proximal lymph node dissection should extend just distal to the origin of the left colic artery. No evidence indicates a relationship between local recurrence and survival and dissection of deep iliac lymph nodes[73] or high ligation of inferior mesenteric pedicle.[74,75] Patients with pathologically positive nodes along the inferior mesenteric artery have very low 5-year survival rates.[76,77]

Laparoscopic Surgery

Laparoscopic surgery for curable rectal cancer is controversial and still considered investigational. Laparoscopic anterior resection with curative intent generates considerably more reservations than does laparoscopic APR, which is technically much easier to perform. Data on the extent of lymphadenectomy, margins of resection, actuarial survival, and local recurrence rates have not been determined, and the current randomized trials of laparoscopic resection for colorectal cancer specifically exclude rectal cancer. The technique of laparoscopic TME is well described by Pikarsky and associates.[65] Reports suggest short-term gains of reduced pain, shortened hospital stay, accelerated activity, possible cost reduction, and improved cosmesis.[66] Hand-assisted laparoscopic surgery is a new technique that has the potential to overcome many of the existing limitations of pure laparoscopy.[78] A recent prospective nonrandomized single institution trial comparing open versus laparoscopic resection in 191 consecutive patients with low and midrectal cancer demonstrated a conversion rate of 18.4%. In the laparoscopic group, the mean time for complete patient mobilization was shorter (1.7 versus 3.3 days; $P < 0.001$), and patients were earlier in passing flatus (2.6 versus 3.9 days; $P < 0.001$) and stools (3.8 versus 4.7 days; $P < 0.01$) and in resuming oral intake (3.4 versus 4.8 days; $P < 0.001$). The mean hospital stay and overall morbidity and mortality rates were similar with no statistically significant differences. Laparoscopic patients had a higher rate of anastomotic fistulas (13.5% versus 5.1%) and reoperations (6.1% versus 3.2%), but the difference was statistically nonsignificant. Laparoscopic resection presented a significantly lower local recurrence rate (3.2% versus 12.6%; $P < 0.05$). Although the cumulative survival and disease-free rates at 5 years were nonsignificant between both groups (80% and 65.4% after laparoscopic surgery and 68.9% and 58.9% after open surgery), stage-by-stage comparison showed prolonged cumulative survival for stages III and IV cancer in the laparoscopic group (82.5% versus 40.5%; $P = 0.006$ and 15.8% versus 0%; $P = 0.013$, respectively) and a reduced rate of cancer-related death for stage III in the laparoscopic group (11.4% versus 51.9%; $P = 0.001$).[79]

The U.K. Medical Research Council (MRC) prospective multicenter, randomized, controlled trial of conventional versus laparoscopic-assisted surgery in colorectal cancer, included 128 rectal cancer patients in the open group and 253 patients with rectal cancer in the laparoscopy assisted group with intent to treat. (The actual treatment groups included 132 open and 160 laparoscopy-assisted surgeries). About 10% more patients underwent total mesorectal excision in the laparoscopy-assisted group than in the open surgery group. The rate of abdominoperineal resection was similar (27% in the open surgery group and 25% in the laparoscopic group). Lymph node yield was equally high in the two groups. The intraoperative conversion rate from laparoscopic to open was 34%. In the intent-to-treat population, there was no significant difference in the open versus laparoscopy-assisted group in regard to positive circumferential margin (14% versus 16%), overall intraoperative complications (14% versus 18%), overall morbidity (50% versus 59%), and mortality (5% versus 4%).While laparoscopic rectal resection did not adversely affect

bladder function, there was a trend toward worse male sexual function, which might be explained by the higher rate of TME in the laparoscopic rectal resection group.[80,81]

In a systematic review by the Cochrane group, it was noted that most reported laparoscopic surgery studies for rectal cancer are individual cohort studies, individual case-control studies, or case series with only one reported randomized controlled trial. Collectively, in 48 studies representing 4224 rectal cancer patients, there appear to be no significant differences in terms of disease-free survival rate, local recurrence rate, mortality, morbidity, anastomotic leakage, resection margins, or number of lymph nodes harvested. Laparoscopic approaches are generally associated with less blood loss, quicker return to normal diet, less pain, and less narcotic use but are also associated with longer operative time and higher costs, and no results of quality of life were reported.[82]

Patterns of Failure

Following potentially curative standard or conventional surgical resection for adenocarcinoma of the rectum, the incidence of locoregional or distant treatment failure is related to the extent of transmural disease and associated involvement of regional lymph nodes by metastases.[83–90] The incidence of locoregional failure is 8% to 21% in AJCC stage I disease (MAC stage A/B1), 29% to 44% in AJCC stage II disease (MAC stage B2/B3), and 50% to 61% in AJCC stage III disease (MAC stage C). The incidence of distant failure (as a component of failure) is up to 28% in AJCC stage I disease, 47% in AJCC stage II, and up to 74% in AJCC stage III disease. It has been claimed that when one compares these patterns of failures between multi-institutional trial settings versus single-institutional and predominantly single-operator (surgeon) series, great differences in results can be seen. These patterns of failures according to multi-institutional versus single-institutional/single-operator series are summarized in Table 82-2.[83–90] Although distant metastasis is most likely to be attributed as the cause of death in rectal cancer patients, the potential influence of locoregional failure as an antecedent event to the development of distant metastases is clinically important. Hence, decreasing locoregional failure is an important endpoint of treatment in rectal cancer. These data and rationale serve as the basis for consideration of adjuvant chemoradiotherapy in the management of rectal cancer and, in particular, as a standard for AJCC stage II (MAC stage B2/B3) and stage III disease (MAC stage C). It is important to note that limited retrospective data identify subsets of patients with stage I disease who may be considered for adjuvant therapy as well as subsets of patients with T3N0 disease who may not require adjuvant therapy.[91,92] Willett and associates identified a subset of patients with stage I disease who have an increased incidence of locoregional failure following an APR.[92] In an additional review of 117 patients with T3N0 disease, Marks and associates identified a favorable group of patients with moderately or well-differentiated cancers invading less than 2 mm into perirectal fat who had a 10-year actuarial locoregional failure rate of only 5% following surgery alone, compared to 29% in T3N0 patients without these favorable features.[93]

ADJUVANT THERAPY

Treatment Sequencing Issues

Preoperative versus Postoperative Therapy: Potential Advantages and Disadvantages

Table 82-3 summarizes the advantages and disadvantages of preoperative (typically chemoradiotherapy) versus postoperative adjuvant therapy. The major advantages of preoperative therapy are tumor

Table 82-3 Advantages of Preoperative versus Postoperative Adjuvant Therapy*

* Typically chemoradiation therapy.

downstaging with increased resectability and sphincter preservation as well as a reduced incidence of acute and chronic toxicity. Adequate doses of radiation (>4000 Gy) can sterilize peripheral margins of disease.[90] Marginally resectable and unresectable tumors can undergo tumor shrinkage, making them amenable to curative surgical resection, particularly within the confines of the ridged, funnel-shaped bony pelvis, which often limits the potential for adequate circumferential margins of resection.[55,58] Preoperative therapy also allows tumors to be resected with limited longitudinal surgical margins, thereby extending the level to which sphincter-sparing procedures can be performed safely in the distal rectum.[93] These advantages in turn are associated with the potential for a significant reduction in a source of tumor spillage associated with locoregional recurrence of disease as well as a reduction of the dissemination during surgery of viable tumor cells increasing the risk for developing distant metastatic foci. The potential therapeutic advantage of preoperative therapy (particularly radiation) with enhanced oxygenation prior to surgical disruption of tumor blood supply is well established.[94,95]

Preoperative therapy also has the potential advantage of reducing the risk of treatment of both chemotherapy- and radiation-related morbidity compared to that seen with postoperative therapy.[96–99] Following surgical resection, adhesions often develop and cause loops of bowel to be fixed within the pelvis. These fixed bowel loops often show enhanced tissue reaction with associated bacterial invasion, increasing the risk of severe treatment-related complications. In the preoperative therapy setting, the small bowel is less likely to be fixed within the treatment field and thereby is less prone to both acute and chronic treatment-related injury.

The major advantage of postoperative therapy is the ability to select patients who are at high risk for locoregional or distant disease recurrence based on pathologic staging of disease and operative findings. This also minimizes the potential of overtreating patients with either early disease (pathologic stage I) or radiographically occult metastatic disease found at time of surgery. Other potential advantages include the avoidance of possible wound-healing problems associated with preoperative therapy. Otherwise, studies have failed to demonstrate any increased potential for the development of disseminated disease during preoperative therapy and the subsequent waiting period prior to surgery.

Optimal Timing of Surgery Following Preoperative Therapy

Until the publication of the Lyon R90-01 randomized trial,[99] the optimal timing of surgery following preoperative therapy in rectal cancer was based on hypothesis or retrospective data. This study randomized 201 patients with stage T2/T3, NX, M0 into two treatment groups: (1) the short-interval group, in whom surgery was performed within 2 weeks of completion of preoperative radiation therapy (39 Gy and 13 fractions) versus (2) the long-interval group, in whom surgery was performed within 6 to 8 weeks after completion of preoperative radiation therapy. At a median follow-up time of 33 months, there was no difference in morbidity, local recurrence, or short-term survival between the two groups. These findings along with the previously demonstrated findings that rectal cancers undergo slow tumor shrinkage over several months after radiation[100] lend further support to the rationale that a longer delay before surgery, particularly in locally advanced tumors, might be desirable to allow for maximal tumor regression prior to surgery. Current randomized trials are systematically investigating the optimal timing of surgery out to as long as 12 weeks following completion of neoadjuvant therapy. In the most extreme example of delayed surgical intervention, Habr-Gama and colleagues have reported their continuing series of patients in whom they have delayed surgical intervention indefinitely following a clinical complete response (CR) that was assessed 8 weeks following neoadjuvant chemoradiation by clinical, endoscopic, and radiographic studies.[101,102] This approach is considered highly investigational; however, it is thought-provoking in terms of a treatment paradigm mirroring that for patients with cancers of the anal canal, in whom surgery is reserved for salvage of chemoradiation failures in patients who achieve a clinical CR to initial treatment.

Optimal Timing of Adjuvant Radiation Following Surgery

Lee and associates reported the results of a phase III study of postoperative adjuvant therapy in stage II and III rectal cancer that was designed to define the optimal sequencing of chemotherapy and RT.[103] In this study, 308 patients were randomized to early RT versus late RT. Patients received 45 Gy in 25 fractions of RT with eight monthly cycles of 5-fluorouracil (5-FU)/leucovorin chemotherapy. RT began with the start of chemotherapy in the early RT group versus with the start of the third cycle of chemotherapy in the late RT group. With a median active follow-up of 37 months, the disease-free survival rate was significantly improved in the early RT group compared to the late RT group (81% versus 71% at 4 years; $P = 0.043$). This finding was associated with an increase in both distant and locoregional disease recurrence in the late RT group and with an overall recurrence rate of 17% in the early RT group versus 27% in the late RT group ($P = 0.047$). Although overall survival was not significantly different between the treatment arms, these results suggest that the timing of adjuvant postoperative RT can have a significant impact on the outcome of patients with rectal cancer.

Radiation Treatment Planning

Preoperative Planning

Preoperative chemoradiation is the most common approach employed in the treatment of locally advanced rectal cancer treatment. The target tissues include the tumor, the perirectal lymphatics, the internal iliac lymph nodes (and the external iliac lymph nodes in T4 tumors or those with external iliac nodal involvement), and the presacral lymph nodes. Plans typically consist of three or four fields (left lateral, right lateral, posteroanterior, and/or anteroposterior). Every effort is made to exclude the small bowel from the field of treatment; therefore, small bowel contrast is utilized in the CT simulation of these patients so that the small bowel can be visualized well on the CT scan acquired for treatment planning. Typically, this consists of 100 mL of diluted barium by mouth at least 1 hour prior to the CT acquisition. In addition, it is preferable to position the patient prone on a modified "belly board" to allow for displacement of the small bowel up and out of the pelvis (Fig. 82-4). This displacement can be further maximized by giving patients explicit instructions to increase fluid intake to allow maximal distension of the bladder to further push the small bowel out of the pelvis during actual treatment. All patients should be simulated in a body mold for reproducible setup from day to day during treatment. It is also recommended that an anal verge marker be used as a reference point for CT-based planning. Typical preoperative treatment in the United States consists of 45 Gy in 1.8-Gy daily fractions to the pelvis followed by a 5.4- to 9-Gy boost.

Postoperative Planning

Treatment planning in the postoperative setting targets the postoperative bed and the draining lymphatics as described previously (and consideration can be given to including the inguinal lymphatics in patients with a rectal cancer that involves the anal canal). The risk of small bowel complications is higher in the postoperative treatment setting because the small bowel "falls" down into the virtual space in the pelvis that is consequent to the patient's surgical resection. It is of critical importance to delineate the small bowel on CT scans and pay careful attention to the dose that is delivered. As with the preoperative patients, a belly board should be utilized when possible to minimize small bowel dose.

For patients who have undergone an APR, the perineal scar should be marked and included within the radiation treatment fields with consideration of the addition of bolus depending on treatment distribution. For cancers arising in the mid- to proximal portion of the rectum, only the posterior half of the pelvis/presacral space needs to

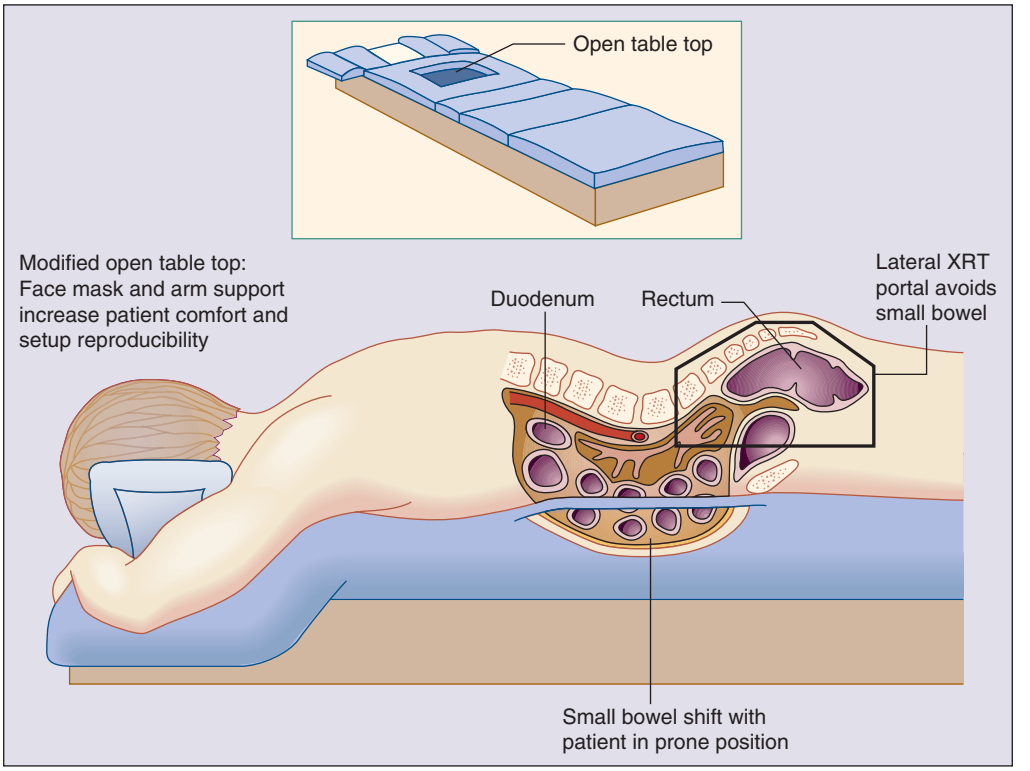

Figure 82-4 • The belly board or open tabletop device allows for maximal displacement of the small bowel (with bladder distension) during radiation treatment. An example of a lateral treatment portal is shown. The pubic bone is positioned just inferior to the edge of the opening. (From Mak AC, Marijnen CAM, Nagtegaal ID, et al: Late complications of postoperative radiation therapy for cancer of the rectum and rectosigmoid. Int J Rad Oncol Biol Phys 1994;28:597–603.)

be included within the treatment field with the anterior border posterior to the symphysis. However, for patients with very low-lying or distal rectal cancers, particularly those involving surrounding adjacent organs such as the prostate, bladder, uterus, and vagina, the anterior border should be placed anterior to the symphysis, in association with shaped alloyed blocks to maximize small bowel exclusion. Such technical considerations have been previously published in detail.[104–107] Typical postoperative treatment in the United States consists of 45 Gy in 1.8-Gy daily fractions to the pelvis followed by a 5.4- to 9-Gy boost in patients with negative surgical margins.

TREATMENT RELATED TOXICITY

Acute Toxicity

The acute complications generally include diarrhea with or without abdominal cramping, acute proctitis with or without tenesmus, bloody or mucous discharge, dysuria/cystitis, leukopenia, and thrombocytopenia. Although the addition of concurrent chemotherapy with radiation is associated with improved patient outcome, it also clearly increases the occurrences of these toxicities. Fortunately, these acute events are usually transient and resolve within a few weeks following the completion of therapy. The management of bowel-related toxicity usually involves the use of loperamide or diphenoxylate/atropine. Radiation proctitis can be treated with hydrocortisone foam or suppositories. Controlling bowel frequency will also help to control the symptoms of proctitis. The bowel mucosa typically recovers within 1 to 3 months following completion of therapy.

Cystitis is due to the effects of radiation on the transitional cells lining the bladder. Symptoms include dysuria, frequency, urgency, and nocturia. An infectious process must be ruled out, particularly if symptoms occur early in the course of therapy or if bladder catheterization was performed for treatment planning. Infection should be treated with an antibiotic based on urine culture and antibiotic sensitivity. Urinary analgesics, such as pyridium, are helpful for dysuria. Bladder spasms may require antispasmodics such as flavoxate.

Perineal dermatitis is more common in patients who are being treated postoperatively after APR in which the inferior border of the radiation fields is extended to cover the perineal scar and in patients with low-lying rectal tumors who are being treated preoperatively. Concurrent chemotherapy and bolus over the scar can often exacerbate the reaction. Treatment should be aimed at controlling the frequency of bowel movements, which tend to further exacerbate and irritate the perineal skin and reaction. Mild dermatitis can be treated with sitz baths and aloe wipes. More severe cases can be treated with nonmetallic skin creams.

Chronic Toxicity

Long-term complications include diarrhea, proctitis, small bowel obstruction, perforation or fistula, perineal and scrotal tenderness, urinary incontinence, and bladder atrophy/bleeding. In the MGH experience of 165 patients receiving 45 Gy postoperatively to the pelvis with a boost to the tumor bed to 50.4 Gy total, the incidence of long-term mild to moderate complications was 8% (4% transient and 4% persistent).[108] Persistent long-term complications were limited to proctitis (2%), delayed perineal wound healing (1%), and urinary incontinence (1%). The incidence of small bowel obstruction requiring surgery was essentially equal in the patients who received radiation (6%) and a historical control group of patients who were treated with surgery alone (5%).

Modern Radiation Therapy Techniques Toward Reducing Toxicity

When radiation is given concurrently with chemotherapy, the risk of radiation-related side effects increases owing to the radiosensitization

of tissues by the chemotherapy. Additionally, chemotherapy has its own side effects, some of which overlap with those associated with radiation therapy to the pelvis. Randomized trials have demonstrated that the grade 3 or 4 side effects of chemoradiation are less frequent when given preoperatively versus postoperatively.[98,109]

In the modern landscape of clinical trials in rectal cancer, many trials employ a second chemotherapy that is given concurrently with radiation therapy and 5-FU (or capecitabine). The most common dose-limiting toxicity associated with these novel approaches is gastrointestinal toxicity. In an effort to reduce the degree of gastrointestinal toxicity conveyed by the delivery of radiation therapy, newer radiation delivery techniques are being explored.[110–112] One of the most promising modern highly conformal radiation delivery techniques, intensity-modulated radiation therapy, may result in less gastrointestinal toxicity owing to reductions in small bowel dose. This technique will be the subject of an upcoming cooperative group trial (Radiation Therapy Oncology Group [RTOG] 0628). This trial will employ intensity-modulated radiation therapy planning and treatment in the neoadjuvant setting of locally advanced rectal cancer patients who are receiving concurrent capecitabine and oxaliplatin prior to a planned TME resection and adjuvant chemotherapy. The results will be compared with the identical arm of the RTOG 0247 trial, which employed conventional three-dimensional radiation planning.

Toxicity: Preoperative versus Postoperative Therapy

Despite the survival advantage in select patients receiving adjuvant postoperative chemoradiotherapy, such treatment is associated with substantial toxicity. In the previously discussed Gastrointestinal Tumor Study Group (GITSG) trial, the incidences of greater than grade 3 toxicity in patients who received adjuvant postoperative chemoradiotherapy was 35% for nonhematologic effects and 26% for hematologic effects.[83] In the North Central Cancer Treatment Group (NCCTG) trial, greater than grade 3 toxicity among patients receiving postoperative adjuvant radiation therapy alone was limited to a 5% rate of diarrhea.[113] In comparison, in the treatment group receiving combined adjuvant postoperative chemoradiotherapy, greater than grade 3 toxicity included a 41% rate of diarrhea and 33% rate of leukopenia. In both the GITSG and NCCTG trials, 35% of patients were unable to complete all planned cycles of chemotherapy owing to toxicity. Also, in the NCCTG trial, an additional 25% refused to complete their therapy.

As was discussed previously, preoperative treatment has the potential advantage of reducing the risk of treatment-related morbidity as compared to that seen with postoperative therapy.[96,97] In addition, it would appear that higher doses of chemotherapy can be delivered within the preoperative setting than in the postoperative setting. This is particularly evidenced in review of serial phase I studies of combined chemoradiotherapy performed at the Memorial Sloan-Kettering Cancer Center in both the postoperative and preoperative setting with similar design.[114,115] With the doses of leucovorin and radiation remaining constant, the maximally tolerated dose of 5-FU was higher for the preoperative radiation therapy regimen. Results from the German preoperative versus postoperative chemoradiotherapy study have reinforced that toxicity is greater when treating in the postoperative setting and treatment compliance is lower in the postoperative setting.[98] Grade 3 and 4 acute and chronic toxicity were 40% and 24% for the postoperative group versus 27% and 14% for the preoperative group. The Eastern Cooperative Oncology Group (ECOG) study recently reported by Bossett and colleagues lends further evidence to reduced chemotherapy compliance in the postoperative setting of patients receiving multimodality therapy.[116]

Use of preoperative radiation, particularly high-dose (>40 Gy) radiation, has raised some concerns about technical difficulty in surgical resection and delayed healing of abdominal and perineal wounds. As was previously discussed, in both the Swedish and MRC trials, the postoperative mortality rate was not increased with the use of preoperative radiation; and with use of the more conventionally fractionated preoperative MRC regimen (40 Gy at 2 Gy per fraction), there was no increase in postoperative or late complications.[117,118] Delay in wound healing has been implicated to be more likely associated with patients undergoing immediate surgical resection following preoperative radiation as compared to patients whose surgery was delayed 6 to 8 weeks. However, in the previously discussed Lyon R90-01 randomized trial of short-interval (2 weeks after completion of radiation therapy) versus long-interval (6 to 8 weeks after radiation therapy) time to resection, there did not appear to be a significant difference in perioperative morbidity and mortality rates.[99] It would appear that an increase in perioperative morbidity or a delay of wound healing is more likely associated with the use of a higher dose per fraction, similar to the intensive short course of 25 Gy given in five fractions.[119,120]

Sphincter and Bowel Function

Radiation therapy can affect sphincter function; however, systematic, prospective data inclusive of uniformly treated patients with pretreatment baseline sphincter assessment are lacking. Two such studies reporting on the impact of postoperative therapy on long-term sphincter function utilized nonrandomized, nonblinded, and retrospective telephone survey methods. The report from the Mayo Clinic evaluated the impact of postoperative chemoradiotherapy utilizing conventional doses and techniques of pelvic radiation combined with 5-FU-based chemotherapy in comparison to a matched group of patients undergoing surgery alone.[121] In comparison to the 59 patients who underwent surgery alone, the 41 patients who received chemoradiotherapy had a significant increase in bowel movements, incontinence, urgency, and the need to wear pads. Paty and associates reported on sphincter function in a series of 81 patients following coloanal anastomosis. The 40 patients who received preoperative or postoperative radiation therapy (with or without chemotherapy) following coloanal anastomosis had increased stool frequency and difficulty with evacuation compared with 41 patients who underwent surgery alone.[122]

In contrast to the preceding series, Birnbaum and colleagues have reported on the prospective evaluation of both the short-term and long-term impact of preoperative radiation on sphincter function.[123,124] All the patients were treated with conventional radiation techniques and doses and were assessed objectively with anal manometry with or without transrectal ultrasound. Radiation therapy had minimal effect on sphincter function in the 20 patients who were assessed for short-term results and the 10 patients who were assessed for long-term results.

POSTOPERATIVE THERAPY: RESULTS OF RANDOMIZED TRIALS

As was previously discussed, the major advantage of postoperative therapy in rectal cancer is to base treatment on operative/pathologic staging (Table 82-4). Early studies that were instrumental in defining the role of postoperative adjuvant therapy for rectal cancer included the GITSG and NCCTG studies.[83,107]

The GITSG study randomized 202 patients who had undergone "curative" surgical resection for adenocarcinoma of rectum to one of four treatment arms: (1) surgery alone, (2) surgery plus postoperative radiation (40 to 48 Gy over 4.5 to 5.5 weeks), (3) postoperative chemotherapy (5-FU plus methyl-CCNU), or (4) postoperative combined chemoradiotherapy.[83] At a median follow-up time of 94 months for all survivors, this study found a significant improvement in the long-term survival of patients receiving adjuvant postoperative chemoradiotherapy compared to surgery alone (59% versus 44%, $P = 0.005$).[107] This improvement was associated with a significant reduction of locoregional recurrence from 24% with surgery alone to 11% with postoperative adjuvant chemoradiotherapy. However, this was also associated with the increase in overall "severe or worse" toxicity associated with adjuvant postoperative chemoradiotherapy.

Table 82-4 Results of GITSG, NCCTG, and NSABP Studies Evaluating Postoperative Adjuvant Therapy for Rectal Cancer

	GITSG[83]		NCCTG[107]		NSABP R-02[127]

GITSG, Gastrointestinal Tumor Study Group; LR, locoregional recurrence; NCCTG, North Central Cancer Treatment Group; NSABP, National Surgical Adjuvant Breast and Bowel Project.

Subsequent to the GITSG study, the NCCTG study randomized 204 patients with pathologic high-risk rectal carcinoma to surgery and postoperative radiation (45 to 50.4 Gy in 5 to 5.5 weeks) versus surgery plus postoperative chemoradiotherapy utilizing 5-FU plus methyl-CCNU, which both preceded and followed combined chemoradiotherapy.[113] At a median follow-up time of over 7 years, there was a significant benefit in the adjuvant postoperative chemoradiotherapy group versus the postoperative radiation-alone group. This benefit was characterized by a significant reduction in locoregional recurrence rate, 25% versus 13% ($P = 0.036$); reduction in distant metastases, 46% versus 29% ($P = 0.011$); and improvement in overall 5-year survival rate, 57% versus 48% ($P = 0.0016$). These trials led to the 1990 NIH Consensus that recommended adjuvant therapy as the standard of care in the United States.[125]

An additional intergroup study evaluated the addition of biologic response modifiers, leucovorin and levamisole, as means of improving patient outcome; 1695 patients were entered on this three-arm phase III randomized trial, and at a median follow-up period of over 7 years, there was no advantage to leucovorin or levamisole regimens over bolus 5-FU in the postoperative adjuvant chemoradiotherapy treatment of high-risk rectal cancer.[126] Meanwhile, the NSABP R-02 trial was in part designed to evaluate the effect of radiation on overall survival in the postoperative adjuvant setting. It also evaluated the potential modulation of 5-FU by leucovorin. The study randomized 694 patients to receive either postoperative adjuvant chemotherapy alone ($N = 348$) or postoperative chemoradiotherapy ($N = 346$). In addition, all female patients received 5-FU plus leucovorin chemotherapy; male patients received either methyl-CCNU, vincristine, and 5-FU or 5-FU plus leucovorin. This latter aspect of the study design was related to the enigmatic findings of the prior NSABP postoperative rectal adjuvant trial showing differences in outcome related to gender.[85] With surviving patients on the R-02 study being followed on average over 7 years, adjuvant postoperative radiation resulted in no beneficial effect on overall survival ($P = 0.89$). The cumulative incidence of locoregional relapse among patients being treated with chemotherapy alone was 13% compared to 8% among those receiving postoperative adjuvant chemotherapy at 5 years ($P = 0.02$).[127] The results of the trials comparing preoperative chemoradiation versus postoperative chemoradiation are discussed in a separate section.

PREOPERATIVE RADIATION THERAPY: RESULTS OF CLINICAL TRIALS

Preoperative Radiation Plus Surgery versus Surgery Alone

In the early 1970s and 1980s, a number of studies evaluated preoperative radiation therapy (no chemotherapy) for rectal cancer that primarily utilized relatively low doses (<35 Gy; Table 82-5).[128–132] The interpretation of these trials within the context of contemporary management requires some consideration. Eligibility criteria in these studies generally allowed all patients to be entered, including those patients without imaging (e.g., CT scan or ultrasound) to rule out distant liver disease or those without transrectal ultrasound or MRI with endorectal coil to confirm extent of local transmural disease. In addition, there is great variance in the fraction size that was used. Nevertheless, although there appears to be some benefit in local control, there was no improvement in survival.

In Europe, the European Organization for Research and Treatment of Cancer (EORTC) completed a study of moderate-dose preoperative radiation, 34.5 Gy in 19 days at 230 cGy per fraction followed by immediate surgical resection compared to surgery alone.[84] The results of this study showed a significant improvement in locoregional control of disease with preoperative radiation (15% versus 35%; $P = 0.003$).

In a follow-up trial to their preoperative versus postoperative radiation trial, the Swedish group reported the results of a study evaluating 25 Gy in 5 days preoperatively (no adjuvant chemotherapy) versus surgery alone for resectable rectal cancer.[133] This trial is remarkable for being the first to demonstrate a survival benefit. After 5 years of follow-up and randomly assigning 1168 patients, the overall 5-year survival rate was 58% in the preoperative radiation plus surgery group versus 48% in the surgery-alone group ($P = 0.004$). This was associated with a local recurrence rate of 11% in the preoperative radiation group versus 27% in the surgery-alone group ($P < 0.001$). In addition, this benefit was seen for all stages of disease compared with surgery alone, suggesting that the initial clinical stage of rectal cancer may not be as important as previously considered.

The MRC rectal cancer working party staged a randomized trial of 40 Gy in 4 weeks preoperatively (no chemotherapy) versus surgery alone in only 279 patients with "potentially operable" locally advanced

RT, radiation therapy.

rectal cancer.[134] The results indicated a reduction in local recurrence ($P = 0.04$) and benefit in disease-free survival ($P = 0.02$) with use of preoperative radiation without a significant increase in overall survival ($P = 0.10$).

In the United States, several single-institution studies have examined the use of high-dose preoperative radiation (>40 Gy) and have reported lower recurrence rates with improved resectability and 5-year overall survival rates; some of these experiences are summarized in Table 82-6.[135–139] These results appear to be better than published results following surgery and postoperative adjuvant therapy. This benefit of preoperative radiation has been further substantiated by the results of a meta-analysis published by Camma and associates[133] (Fig. 82-5). This analysis involves 14 randomized controlled clinical trials of preoperative radiation (alone) followed by surgery versus surgery alone for "resectable" rectal cancers. It included a total of 6426 patients, 3081 of whom were treated with surgery alone. The meta-analysis found that the addition of preoperative radiation compared to surgery alone significantly reduced the 5-year overall mortality rate (odds ratio [OR]: 0.84; 95% confidence interval [CI]: 0.72 to 0.98; $P = 0.03$) and cancer-related mortality rate (OR: 0.71; 95% CI: 0.61 to 0.82; $P < 0.001$). This reduction was associated with a significant reduction in local recurrence rate (OR: 0.49; 95% CI: 0.38 to 0.62; $P < 0.001$) without a significant reduction in the observed occurrence of distant metastases.

Preoperative Radiation plus Total Mesorectal Excision versus Total Mesorectal Excision Alone

Between 1996 and 1999, the Dutch Colorectal Cancer Group randomly assigned 1861 patients with "resectable" rectal cancer to preoperative radiation (5 Gy for 5 days) prior to TME versus TME alone.[140] The trial used rigid quality control measures, training, and standardization as a requirement for selected surgeons, as well as pathologists, who met such requirements for study participation. At a median follow-up period of approximately 2 years for surviving patients, the overall 2-year survival rates for the two treatment groups were essentially identical at approximately 82%. However, with this relatively early follow-up, preoperative radiation was associated with a significant reduction in the relative risk at 2 years of local recurrence compared to TME alone: 2.4% in the preoperative radiation group

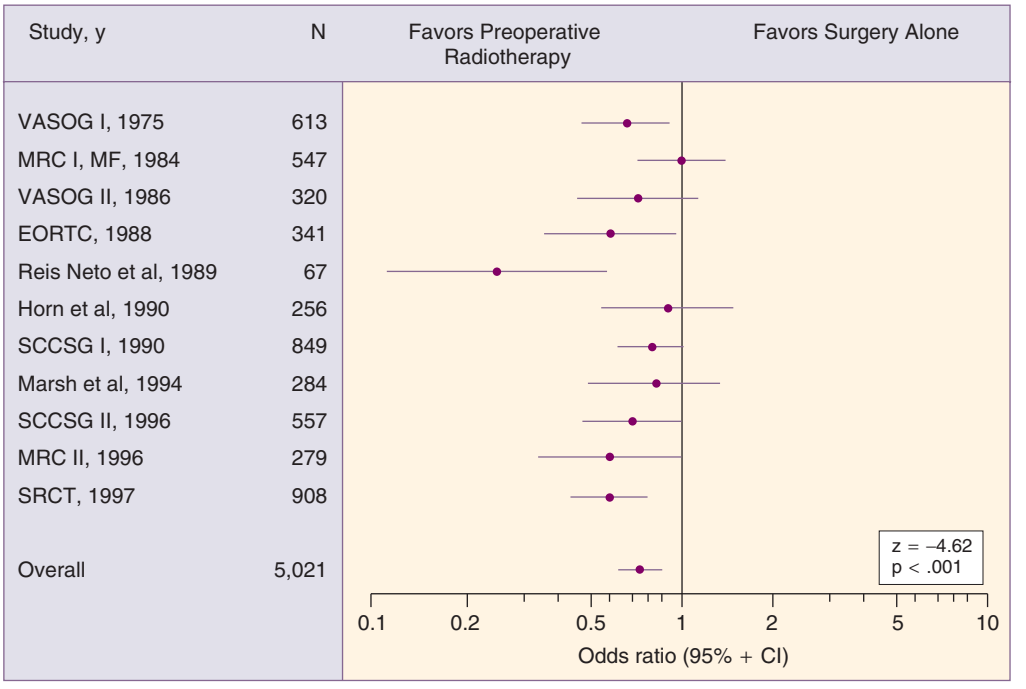

Figure 82-5 • Results of meta-analysis of 11 randomized trials of preoperative radiation versus surgery alone for "resectable" rectal cancer. The odds ratio and 95% confidence interval (CI) for treatment effect on 5-year cancer-related mortality rate are shown on a logarithmic scale. (From Camma C, Giunta M, Fiorica F, et al: Preoperative radiotherapy for resectable rectal cancer: A meta-analysis. JAMA 2000;284:1008–1015.)

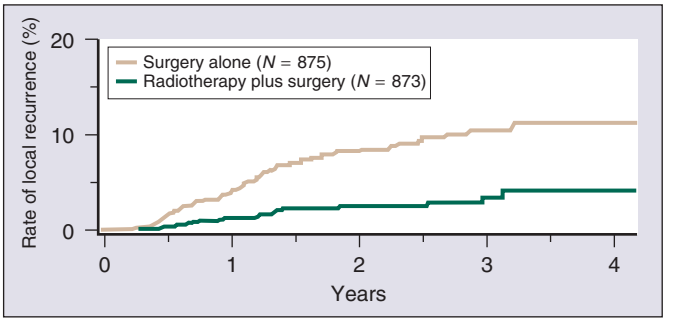

Figure 82-6 • Local recurrence rates from the Dutch Colorectal Cancer Group randomized trial of total mesorectal excision (TME; surgery alone) versus preoperative radiation plus TME. (From Kapiteijn E, Marijnen CAM, Nagtegaal ID, et al: Preoperative radiotherapy combined with total mesorectal excision for resectable rectal cancer. N Engl J Med 2001;345:638–646.)

versus 8.2% in the TME-alone group ($P < 0.001$); actuarial curves are shown in Figure 82-6. Actuarial analyses from the Dutch and Swedish groups utilizing TME without adjuvant therapy suggest that local failure rates in node-positive patients will likely remain in the 15% to 20% range at 5 years.

Whether the preoperative combined modality therapy as is currently used in this country with 5-FU-based chemotherapy is more effective than preoperative radiotherapy alone is unknown. This question is being addressed within an ongoing randomized EORTC trial. In the meantime, consideration of the use of pathologic response as a "surrogate" measure that would be predictive of long-term outcome in rectal cancer patients has been suggested by a number of series.[134,141–143] Such a surrogate marker for survival or outcome could expedite evaluation of rapidly evolving novel preoperative combined modality/chemoradiotherapy combinations. This strategy is being utilized nationally by the RTOG in a randomized phase II trial evaluating preoperative 5-FU and hyperfractionated radiation versus preoperative 5-FU and CPT-II with once-daily radiation in T3 and T4 rectal cancer patients and will be reviewed later. However, routine use of pathologic response following preoperative adjuvant therapy as a surrogate marker for outcome awaits further confirmation and long-term evaluation.[144]

Technical considerations in the preoperative setting are similar to those for postoperative radiation therapy. There is one major exception, however: the ability to dose escalate above 50 Gy (with its potential benefits),[145,146] particularly in the locally advanced setting, by way of once- or twice-daily hyperfractionated radiation.[146–148] Dose escalation is more feasible within the preoperative setting without an associated exponential increase in complication rates, as would be likely with similar attempts within the postoperative setting.[146–148]

Preoperative Radiation versus Postoperative Radiation

The evaluation of the advantages or disadvantage of preoperative versus postoperative radiation therapy alone in the setting of a randomized trial has been limited, including a failed attempt of such a study in the United States that was closed early owing to poor patient accrual (Intergroup Study R1023). In a Swedish multicenter trial[95] comparing preoperative versus postoperative radiation in rectal and rectosigmoid carcinoma, 471 patients were randomized to 25 Gy in 5 to 7 days preoperatively versus 60 Gy in 8 weeks after surgery. The local recurrence rate was statistically lower after preoperative radiation (12%) than after postoperative radiation (21%; $P = 0.02$). This improvement was observed despite the relatively modest dose of preoperative radiation (25 Gy) compared to the postoperative radiation dose (60 Gy). There was no difference in survival between the two groups (43% versus 40%), with a minimum follow-up period of 3 years and a mean follow-up period of 6 years.

Table 82-7 Rectal Cancer: Clinical Staging

Stage	Description	Location*
I	Mobile	A: >6 cm
	Free movement in all directions	
II	Partially fixed (tethered)	B: 3–6 cm
	Movable in at least one direction (cephalocaudad or lateral)	
III	Fixed	C: 0–3 cm
	Immovable in any direction due to fixation (not size) or perforated, obstructed, deeply ulcerated	
IV	Frozen pelvis	D: <0 cm (i.e., into anal canal)
	Invasion of pelvic sidewalls and/or sacrum—unresectable	

*Location as measured from the anorectal junction.

Preoperative or Postoperative Adjuvant Therapy Based on Clinical Staging

Parameters include tumor fixation, distance from the anorectal junction, and the consideration/feasibility of sphincter preservation. Such parameters, along with modern imaging techniques (e.g., CT scan, transrectal ultrasound, or MRI with endorectal coil), can be integrated into the use of a clinical staging system such as that previously published by Mohiuddin and Marks (Table 82-7).[149] Clinical staging systems have been proposed by others.[150] Such a staging system can then be used to determine an optimal treatment strategy (utilizing preoperative or postoperative therapy) for patients with rectal cancer.

PREOPERATIVE CHEMORADIATION: INCORPORATION OF NOVEL AGENTS

There are now seven drugs that the FDA has approved for the treatment of advanced metastatic disease in colorectal cancer: 5-FU, capecitabine,[151,152] oxaliplatin,[153] CPTII,[154] cetuximab,[155] bevacizumab,[156,157] and panitumumab.[158] The complete plus partial response rates varied from 35% to 50% in chemotherapy-naive patients when used in combination. Consequent to the use of these novel agents, the median survival of stage IV patients is approaching 2 years, and an increased median survival of 3 years is not out of reach.[159] A number of these agents are now being investigated in clinical trials in the treatment of nonmetastatic patients toward improved outcomes (Tables 82-8 through 82-10).

5-FU Plus Oxaliplatin Plus Radiation

The Lyon R04 trial is a prime example of the addition of one of these new chemotherapeutic agents.[160] The study had 40 patients T3/T4 N × M0 who received oxaliplatin at 130 mg/m^2 on day 1 followed by a 5-day continuous infusion of 5-FU 330 to 350 mg/m^2 and leucovorin 100 mg/m^2 given in two cycles with external beam radiation of 45 Gy in daily fractions of 1.8 Gy. Total mesorectal surgery was planned 5 weeks postradiation. The addition of oxaliplatin produced a complete plus partial response in 30 patients (75%).

- 5-FU 225 mg/m^2/day CVI
- 7 days/week beginning the day of the start of RT and ending the evening of the last dose of RT

Arm 2
- RT + chemotherapy*
- 4500 cGY (25 fractions)†
- Capecitabine 825 mg/m^2 PO bid throughout course of RT
- 7 days/week beginning the day of the start of RT and ending with the last dose of RT

*Epoetin-alfa 40,000 IU/SQ q wk (begin 7–10 days prior to starting RT/chemotherapy).
†+540 cGy boost for nonfixed tumors (3 fractions); 1080 cGy boost for fixed tumors 6 fractions.

Pathologic examination noted 6 (15%) patients with no residual tumor pT0N0. Sphincter-sparing surgery was performed in 26 patients. The minimal added toxicity of the oxaliplatin did not adversely affect any of the patients.

Complete sterilization of an operative specimen has been reported in other series to be between 5% and 32%[161–163] depending on tumor size, low stage, preoperative chemotherapy, and high-dose radiation therapy. Minsky[164] described 12 studies using oxaliplatin in varying doses with either 5 FU or capcitabiene. The CR rates in these phase I studies ranged from 14% to 58% and the maximum tolerated dose for oxaliplatin when given concurrently with 5-FU and radiation therapy has been established at 80 mg/m^2.

Chau, using an MRI criteria for poor-risk patients, studied the addition of oxaliplatin 130 mg/m^2 every 3 weeks to capecitabine 2 g/m^2 in divided doses times for 14 days with 7 days rest with radiation therapy and surgery.[165] The regimen was repeated four times. The radiation was delivered to a total of 45 Gy in 25 fractions of 1.8 Gy with a boost of 5.4 Gy to include the entire pelvis and pelvic lymph nodes. Capecitabine was given continuously without interruption with the radiation. All patients had a total mesorectal excision. Following surgery, capecitabine was given at 2.5 g/m^2 for 14 days with 7 days rest for 12 weeks. Seventy-seven patients were eligible for study; 67 underwent a total mesorectal excision. An R0 resection was noted in all but one patient. After undergoing neoadjuvant therapy, 88% of the patients were radiologic responders as defined as stable or better. After the chemoradiation therapy arm, 97% of the patients were noted to have stable disease or better following surgery. The CR rate of 24% was augmented by an additional 48% of the patients with only microscopic disease. MRI evaluation demonstrated a 76% downstaging of the primary tumor. Of the 26 patients in the pathologic T3 group, 16 were noted to have only microscopic disease. Thirteen patients were also noted to have downstaging. At the end of 1 year, the OS was 95%, and the 1-year disease-free survival rate was 87%. No comment could be made on the use of capecitabine in the postoperative adjuvant setting. It is one of the most important studies because of its neoadjuvant/adjuvant nature. It should set the bar for numerous protocols to come, as modern trials typically incorporate neoadjuvant chemoradiation therapy followed by surgery and further adjuvant chemotherapy.

Randomize into two treatment arms

Arm 1: CVI 5-FU (*225 mg/m^2/day, 7 days, 7 days/week, until completion of RT*)
+ Pelvic RT 45.6 Gy (*1.2 Gy bid, 6-h interval*)
+ Boost to tumor (*9.6 Gy for T3 and 14.4 Gy for fixed T4*)*
+ Surgery+ 4–10 weeks after completion of RT

Arm 2: CVI 5-FU (*225 mg/m^2 day, M-F, 120 hr/week, until completion of RT*) plus CTP-II (*50 mg/m^2, once weekly × 4 weeks*)
+ Pelvic RT 45 Gy (*1.8 Gy/day*)
+ Boost to tumor (*5.4 Gy for T3 and 9 Gy for fixed T4*)*
+ Surgery† 4–10 weeks after completion of RT

Maintenance chemotherapy is recommended for all patients after irradiation.
*Boost radiation may be delivered using conformal 3D techniques.
†IORT (optional) may be delivered to areas of tumor fixation at time of surgery.

5-FU Plus Irinotecan Plus Radiation

A phase I trial performed at Thomas Jefferson University Hospital defined the maximum tolerated dose of weekly CPT-II when combine with 5-FU and concomitant RT in rectal cancer.[166] Escalating doses of CPT-II (30 to 60 mg/m^2 over 90 minutes) on days 1, 8, 15, and 22 were combined with 5-FU during perioperative radiation treatments (45 Gy in 1.8-Gy daily fractions plus 5.4-Gy boost). All

patients went to a planned surgery and received adjuvant chemotherapy (5-FU and leucovorin). The maximum tolerated dose of CPT-II was established at 50 mg/m^2, and the dose-limiting toxicity was gastrointestinal. This study demonstrated a 24% pathologic CR rate.

Investigators at Stanford University performed a phase II trial incorporating CPT-II (50 mg/m^2 on days 1, 8, 15, and 22) with 5-FU (200 mg/m^2/day) and preoperative radiation (50.4 Gy) in patients with T3 rectal cancers.[167] This study demonstrated a 37.5% pathologic CR rate in the 37 patients who were enrolled. The major toxicity was gastrointestinal (28% grade 3 diarrhea).

A randomized cooperative group (RTOG 0012) phase II preoperative chemoradiation trial incorporating irinotecan for distal rectal tumors was reported by Mohiuddin and colleagues.[168] In this study, 106 patients were randomized to receive continuous infusion 5-FU (225 mg/m^2/day, 7 days per week until completion of RT) or the same 5-FU regimen plus CPT-II (50 mg/m^2 weekly for 4 weeks) during radiation. All patients went on to a planned surgery and adjuvant chemotherapy. The CR rate was similar in both arms (29% versus 31%). Tumor downstaging was equal in both arms, with an overall downstaging of 80%.

Capecitabine/Irinotecan/Radiation versus Capecitabine/Oxaliplatin/Radiation

Both irinotecan and oxaliplatin have shown promise in the preoperative setting when combined with standard 5-FU or capecitabine-based chemoradiation. Whether one is better than the other with respect to improving response rates and downstaging is the subject of an ongoing randomized phase II clinical trial being conducted by the RTOG (RTOG #0247), which accrued to completion in 2007. This study will provide a platform for future phase III preoperative chemoradiation studies.

PREOPERATIVE VERSUS POSTOPERATIVE CHEMORADIATION: RESULTS OF RANDOMIZED TRIALS

In patients with resectable locally advanced disease, adjuvant chemoradiotherapy has been demonstrated to significantly improve local control and overall survival when compared with surgery alone or surgery plus radiation.[169,170] After the results of the Krook trial were reported,[170] the 1990 NIH Consensus Conference established that standard postoperative treatment for locally advanced patients (T3/T4 or N+) in the United States was adjuvant chemoradiation.[171] Since that time, international debate has ensued as to whether neoadjuvant chemoradiation would offer advantages over adjuvant chemoradiation. Three prospective randomized trials have been conducted to assess the potential benefits of neoadjuvant chemoradiation over adjuvant chemoradiation in patients with resectable, locally advanced rectal cancers. The two U.S. trials (RTOG 94-01 and NSABP R-03) suffered from poor accrual and ultimately were closed prematurely and provided only preliminary information.[109] The third study, conducted by the German Rectal Cancer Study Group, was completed to full accrual, and the results were published in 2004.[98]

The landmark German study randomized 823 locally advanced patients (T3, T4, or N+) to either preoperative or postoperative chemoradiation. Chemoradiation consisted of 50.4 Gy of radiation in 1.8 Gy daily fractions concurrent with infusional 5-FU (1000 mg/m^2 daily during weeks 1 and 5 of radiotherapy). Radiotherapy was targeted at the tumor (or tumor bed) and draining pelvic lymphatics. Surgery consisted of a TME, and all patients received adjuvant chemotherapy consisting of four cycles of 5-FU (500 mg/m^2) given on days 1 through 5 of a 28-day cycle. The 5-year disease-free survival rate (68% versus 65%) and overall survival rate (76% versus 74%) were not statistically different for patients receiving preoperative versus postoperative therapy. Local control was statistically superior, with preoperative treatment (94%) versus postoperative treatment (87%). Additionally, there were threefold more protocol violations in the postoperative arm, indicating that compliance was higher when treating in the preoperative setting.

Considering the 194 patients in this study with "low-lying" tumors (those that were thought to require an APR on evaluation prior to randomization), patients in the preoperative chemoradiation arm were twice as likely to have a sphincter-sparing surgery (39% versus 19%) and threefold less likely to have an anastamotic stenosis (4% versus 12%) when compared with patients in the postoperative chemoradiation arm. In addition, grade 3 or 4 toxicities were significantly higher in the postoperative chemoradiation group than in the preoperative chemoradiation group (40% versus 27% for acute, 24% versus 14% for chronic). The results of this trial have helped to establish preoperative chemoradiation as the current preferred approach, particularly for patients with low-lying tumors.

ADJUVANT CHEMOTHERAPY FOLLOWING COMPLETION OF CHEMORADIATION AND SURGERY

The German trial established that preoperative chemoradiation was superior to postoperative chemoradiation, particularly for patients with low-lying tumors.[98] However, the trial did not address the potential added benefits of further adjuvant chemotherapy. The EORTC attempted to answer the question of the optimal timing of chemotherapy in relation to radiation therapy in clinically advanced T3 and T4 resectable rectal cancers[172] and sought to determine the potential additive value of adjuvant chemotherapy following preoperative treatment and surgery. The EORTC 22921 trial was a four-arm randomized study in which 1011 patients underwent randomization to either (1) preoperative radiation followed by surgery, (2) preoperative chemoradiation followed by surgery, (3) preoperative radiation followed by surgery and adjuvant chemotherapy, or (4) preoperative chemoradiation followed by surgery followed by adjuvant chemoradiation. The radiotherapy consisted of 45 Gy delivered to the posterior pelvic wall in 25 fractions of 1.8 Gy over a period of 5 weeks. The chemotherapy was similar in preoperative and postoperative treatment groups. There were two 5-day courses of 5-FU 350 mg/m^2 given IV bolus with 20 mg of leucovorin given in the first and fifth weeks of radiation therapy. Four 3-week cycles of postoperative chemotherapy were given. With a median follow-up of 5.4 years, there was no significant difference in overall survival between the groups that received chemotherapy preoperatively and those that received it postoperatively. The 5-year incidence rates for local recurrence were 8.7%, 9.6%, and 7.6% in the groups that received chemotherapy preoperatively, postoperatively, or both, respectively. The local recurrence rate in the group that did not receive chemotherapy was significantly higher at 17.1% ($P = 0.002$). As with the German trial, there was a higher degree of compliance with preoperative chemotherapy (82%) versus postoperative chemotherapy (42.9%). Preoperative chemoradiotherapy resulted in downsizing and downstaging of tumors, which were associated with an increase in local control but not overall survival.[116]

If we look specifically at the additive benefit of adjuvant chemotherapy, the 5-year overall survival was 63% in the groups that did not receive adjuvant chemotherapy and 67% in the groups that did receive adjuvant therapy. This 4% difference is similar to the 6.8% disease-free survival benefit of FOLFOX 4 seen for patients with stage III colon cancer as demonstrated in the MOSAIC trial.[173] The MOSAIC trial was designed to evaluate the efficacy of FOLFOX 4 compared with LV5FU2 in patients with stage II and III colon cancer. At 4 years, FOLFOX 4 significantly improved the disease-free survival rate when compared with LV5FU2 (75.9% versus 69.1%) in stage III patients but was not significant in the stage II patients. Wolmark and colleagues presented data from phase III of the C-07 trial, which randomized patients to either a FLOX or weekly 5-FU/high-dose leucovorin adjuvant regimen.[174] With a median follow-up of 24 months, preliminary results have been reported, and demon-

strate a 3-year disease-free survival benefit to FLOX (76.5% versus 71.6%), which is very similar in magnitude to the benefit seen in the MOSAIC trial.

ECOG trial E5204[175] is a recently initiated randomized phase III adjuvant study comparing oxaliplatin/5-FU/leucovorin with oxaliplatin/5-FU/leucovorin and bevacizumab in stage II and III patients who have received preoperative chemoradiation. This study was modified to incorporate patients who were put on the NSABP R-04 trial. The treatment schema is as follows: All patients will have received a minimum radiation dose of 40 Gy and not more than 54 Gy external beam radiation therapy (XRT) at 1.8 Gy per fraction per day for 28 fractions over a total of 5 1/2 weeks. Pelvic fields will receive 45 Gy in 25 fractions, followed by a boost of 5.4 Gy in 3 fractions. Intraoperative radiation therapy and/or brachytherapy are strictly prohibited. NSABP R-04 patients are exempt from meeting the minimum/maximum radiation therapy guidelines. Patients will have received concurrent radiation and chemotherapy, consisting of one of the following regimens. The radiation/capecitabine ± oxaliplatin regimens are open only to the patients who are enrolled on NSABP R-04. Physicians will report the chosen chemotherapy regimen at the same time of randomization. The allowed regimens are as follows:

- XRT + continuous infusion 5-FU
  5-FU 225 mg/m^2 over 24 hours 7 days per week during XRT
- XRT + 5-FU/leucovorin
  5-FU 400 mg/m^2 + leucovorin 20 mg/m^2 for 4 days during weeks 1 and 5 of XRT
- XRT + capecitabine ± oxaliplatin (allowed only for patients treated on NASBP Protocol R04)
  Capecitabine 825 mg/m^2 PO twice daily concurrently throughout course of XRT (beginning 2 hours before start of XRT and ending with the last dose of XRT 5 days per week)
  Oxaliplatin 50 mg/m^2 IV weekly for 5 weeks
- XRT + continuous infusion 5-FU ± oxaliplatin (allowed only for patients treated on NASBP Protocol R04)
  5-FU 225 mg/m^2/day by continuous IV infusion 5 days per week on days of planned RT (concurrent with XRT)
  Oxaliplatin 50 mg/m^2 IV (concurrent with XRT) weekly for 5 weeks

Surgery schedule: Surgical resection should occur 28 to 56 days (4 to 8 weeks) after the patient completes concurrent chemo/radiation therapy.

ECOG E5204 is a true adjuvant study aimed at defining the value of the biologic bevacizumab when added to FOLFOX chemotherapy in patients who have completed neoadjuvant chemoradiation and surgery. The NSABP R-04 study is significant in that it tries to answer the question "Is capecitabine as good as continuous infusion 5-FU and does oxaliplatin increase response rates when added to 5-FU or capecitabine?" The combined results of NSABP R-04 and ECOG E5204 will help to define optimal preoperative chemoradiation (5-FU versus capecitabine ± oxaliplatin) and adjuvant chemotherapy (FOLFOX ± bevacizumab).

ADJUVANT THERAPY FOLLOWING LOCAL EXCISION

Standard therapy for resectable rectal cancer has been radical or conventional surgical resection (inclusive of the possibility of TME) with increasing integration of preoperative or postoperative adjuvant therapy. In highly select patients, this approach has often been challenged by the use of more conservative local measures (see Table 82-1).

Table 82-11 summarizes the results of local excision with and without postoperative therapy.[176–181] It is important to note that most series are retrospective, single-institution studies, with varying degrees of integration of chemotherapy (typically 5-FU-based) and relatively limited follow-up.[177–181] Although these factors limit the degree with which results from these selective series can be reproduced within general practice and in the community, they at least suggest survival data that are comparable to those seen with radical or more conventional surgery alone for T1/T2, N0 rectal cancer.

Such results can now perhaps be considered to be reproducible in the general community setting with a greater degree of confidence given the results of the CALGB trial 8984. This trial was an intergroup trial and is the only multi-institutional prospective phase II trial evaluating the outcome of local excision in patients with T1/T2 rectal cancers.[177] Study entry criteria included T1/T2 adenocarcinomas that were more than 4 cm in diameter, encompassing less than 40% of the bowel wall circumference, being less than 10 cm from the dentate line, and having negative excisional margins. A total of 110 eligible patients were entered into the study. Of these patients, 59 had T1 adenocarcinoma and received no further therapy; 51 had T2 carcinomas and received external beam irradiation (54 Gy in 30 fractions at 5 days per week) and 5-FU (500 mg/m^2 IV days 1 to 3 and days 29 to 31) after full-thickness local excision. It is interesting that 51 additional patients were also entered into the study but were later (postsurgery) found to be ineligible, most commonly owing to (1) unclear/involved or uninterpretable surgical margins (49%; $N = 25$), (2) tumor stage above T2 (25%; $N = 13$), and (3) tumor diameter greater than 4 cm (24%; $N = 13$). Those who had excisions that were not thought to be "full thickness" were also considered ineligible (10%; $N = 5$). With a median follow-up period of 48 months, the local failure rate was 3%, the 6-year failure-free survival rate was 85%, and the overall survival rate was 87% among the T1 patients; among the T2 patients, the local failure rate was 14%, the 6-year failure-free survival rate was 71%, and the overall survival rate was 85%. Overall, five of the nine local-only recurrences were able to be surgically salvaged (by APR) without evidence of distant disease. However, local failure seen beyond 5 years of treatment has been reported and is not uncommon.[176] Careful follow-up and review of long-term results of this treatment strategy are clearly required.

Table 82-11 Local Excision for T1–T3 Rectal Cancer Plus Postoperative Adjuvant Therapy

Series	No. of Patients	5-FU (%)	T3 (%)	Follow-up Time	Survival Rates	Initial Local Control (Salvaged with APR/ Local Failures)
U. Florida[163]	45	4	2	2 yr (minimum)	88% 5-yr disease specific	89% (1/5)
Memorial Sloan-Kettering[164]	39	51	21	41 mo (median)	70% 5-yr actuarial	79% (5/8)
M.D. Anderson[27]	46	17	33	36 mo (median)	93% 3-yr overall	87% (–/4)
N.E. Deaconess[166]	48	54	10	41 mo (mean)	94% overall	92% (3/4)
CALGB[166]	51*	100	0	48 mo (median)	85% 6-yr actuarial	86% (4/7)
MGH[160]	47	55	0	51 mo (median)	74% 5-yr disease free	90% (5/9)

*Analysis is limited to the 51 of 110 patients with T2 disease who underwent a full-thickness local excision and received postoperative chemoradiotherapy.

SPECIFIC RECTAL CANCER MANAGEMENT ISSUES

Management of Medically Inoperable Patients: Results of Radiation and Chemoradiation

Outcomes of inoperable patients following treatment with radiation alone or radiation in combination with radiosensitizing chemotherapy are limited to phase I and II trials and retrospective institutional experiences. No phase III trials or randomized studies have been conducted in this population. Princess Margaret Hospital is credited with the largest retrospective series of medically inoperable patients treated with primary radical external beam radiation therapy. They have continued to add to this experience over recent decades.[182–184] In the most recent update, they report the long-term outcome of 271 patients who underwent primary radical external beam radiotherapy without prior or concurrent chemotherapy.[184] All patients received radiation doses of at least 40 Gy. On multivariate analysis, only tumor fixation was a significant predictor of CR. They reported outcome based on fixation. For patients with mobile, partially fixed, and completely fixed tumors, the overall 5-year survival rates were 48%, 26%, and 6% respectively. CR rates also varied with degree of fixation and were 49%, 22%, and 9% respectively. Acute and late grade 3 or higher toxicity was less than 2%, leading the authors to conclude that radical external beam radiotherapy represents a tolerable and potentially curative treatment option for rectal carcinoma patients without complete tumor fixation who are not surgical candidates or refuse surgery.

Local relapse following a CR to radical radiotherapy alone is high. In the previously cited Prince Margaret Hospital series, 78% of patients relapsed after initial CR, including 100% of patients with fixed tumors. Therefore, to improve local control (particularly for fixed tumors), dose escalation of radiation therapy and/or the addition of radiosensitizing chemotherapy is warranted. Overgaard and colleagues demonstrated a dose-response relationship between duration of CR and radiation dose in patients with inoperable rectal cancers.[185] Concurrent chemoradiotherapy should be strongly considered in patients whose performance status makes them able to tolerate a more aggressive regimen, particularly those with partially or completely fixed tumors.

Experiences of definitive chemoradiation in rectal cancer are limited. It has been demonstrated in randomized adjuvant studies that chemotherapy combined with radiation is superior to radiation alone. No such studies exist for medically inoperable patients. However, as was mentioned earlier in this chapter with respect to optimal timing of surgery after chemoradiation, there is a Brazilian experience that continues to be updated in which potentially operable patients who achieve a clinical CR to preoperative chemoradiation are not taken to surgery and rather are observed.[101,102] These data can be extrapolated to some degree to the medically inoperable patients with respect to expected outcomes with chemoradiation. In the 2006 update of this series, 122 patients had been included as having achieved a clinical CR at first assessment following completion of chemoradiation.[102] Reevaluation at 12 months revealed that 99 of the 122 patients (81%) who had achieved a clinical CR to chemoradiotherapy (consisting of 5-FU, LV, and RT to a total dose of 50.4 Gy) had sustained a complete clinical response. With a median follow-up of 5 years, overall and disease-free survival rates for these patients were an impressive 93% and 85%, respectively. The management of the medically inoperable patient or the patient who refuses surgery is always tailored to the patient's performance status and degree to which they can tolerate therapy. Aggressive management with dose-escalated chemoradiation is the preferred approach when feasible.

Management of Locally Advanced Rectal Cancer

Locally advanced rectal cancer is characterized by invasion through the muscle wall adherent to or invading surrounding structures yet confined to the pelvis. The accurate incidence of locally advanced rectal cancer is unknown and estimated at 5%.[186,187] Surgical resection within the context of a multimodality approach is essential for successful treatment outcome and control of symptoms. Surgery often involves TME with en bloc resection of contiguously involved structures to obtain negative margins of resection, which is essential to minimize risk of recurrence. At the time of surgery, thorough exploration to rule out metastatic disease is essential. The operative goal is complete resection with negative margins. Gross residual disease or microscopic margins have a negative impact on prognosis.[188] Adherent structures must be resected. Clinical distinction between benign adherence and malignant invasion is impossible, particularly if the patient received preoperative radiation. Approximately half of clinical attachments are inflammatory, not from tumor invasion. The most commonly resected organs are ovaries, uterus, vagina, and bladder, in that order.[189] Bladder preservation can be achieved with partial cystectomy with 2-cm margin. If the trigone is involved, total cystectomy with urinary diversion with ileal conduit or continent reservoir is required. The presence of positive bladder margins will adversely affect survival.[190]

Multimodality Approaches

Locally advanced patients are best managed with trimodality therapy, which typically includes neoadjuvant chemoradiation followed by surgical intervention and further adjuvant chemotherapy as suggested by the results of the recently reported trials by the EORTC and German Rectal Cancer Study Group.[98,191] Consideration can be given to more aggressive treatment during concomitant chemoradiation through either increased external beam boost dose or the use of intraoperative radiation therapy (IORT) as a boost strategy.

M.D. Anderson Hospital[192] has reported on its study of locally advanced tumors. Forty-five patients were evaluated. 5-FU was given at 300 mg/m^2 daily as a continuous infusion 5 days per week with radiation therapy. Radiation therapy was given as a concomitant boost using a three-field belly board technique. The boosts were given during the last week of therapy with a 6-hour intrafraction dose to the tumor plus 2- to 3-cm margin. The boost dose equaled 7.5 Gy per five fractions for a total dose of 52.5 Gy for 5 weeks to the primary tumor. Sphincter preservation was noted in 79% of the patients, and 31% of the patients achieved a pathologic CR rate. Tumor downstaging was pathologically confirmed in 86% of the patients.

The University of Kentucky reported in 1999 that preoperative chemoradiotherapy was effective in the control of fixed distal rectal cancers.[148] Two chemotherapy regimens were studied (5-FU at 1000 mg/m^2 on the first and fifth weeks of radiation days 1 to 4 and 28 to 32, and the continuous infusion 5-FU was 225 mg/m^2 for the duration of radiation). Two radiation arms were studied: 45 to 50 Gy and 55 Gy. Pathologic CRs were noted more often in a continuous infusion and in radiation therapy when given in doses above 55 Gy. The analysis showed that 10% of the patients who were given bolus 5-FU achieved a CR, while 67% achieved a CR with continuous infusion. With higher-dose radiation therapy, 67% achieved a CR with continuous infusion chemotherapy and none with the bolus 5-FU. Similar results were reported by Minsky and colleagues[193] in 1991 and by Rich and colleagues[194] in 1995. Rich and colleagues at that time had the largest number of patients studied: 77 to be treated with continuous infusion 5-FU, with a CR rate being reported at 29% and a local recurrence for T3 lesions at 9%.

SEER data review of surgically treated patients with locally advanced rectal cancer from January 1, 1988, through December 31, 2002, showed that younger age at diagnosis (<65 years) and female sex were positively and statistically significantly associated with multivisceral resection, whereas receipt of neoadjuvant radiation was inversely and statistically significantly associated with multivisceral resection. Compared with standard resection, multivisceral resection was associated with improved overall survival for patients with rectal

cancer (HR: 0.81, 95% CI: 0.70 to 0.94) with no associated increase in early mortality.[195]

A European trial randomly assigned 762 patients with locally advanced (T3/T4) rectal cancer within reach of DRE to radiotherapy alone (45 Gy over 5 weeks) or with concomitant bolus 5-FU (350 mg/m^2 per day) and leucovorin (20 mg/m^2 per day), each daily for 5 days during weeks 1 and 5. At a median 69-month follow-up, the combined modality group had a higher pathologic CR rate (11.7% versus 3.7%) and a significantly lower local failure rate (8% versus 16.5%), but the rate of sphincter-preserving surgery (52% versus 53%) and 5-year overall survival rates (67% versus 68%) were similar.[196]

In the randomized, controlled German rectal cancer study, 823 patients with clinically staged T3/T4 or node-positive rectal cancer were randomized to the same chemoradiotherapy regimen (50.4 Gy in 28 daily fractions to the tumor and pelvic lymph nodes concurrent with infusional 5-FU (1000 mg/m^2 daily for 5 days during the first and fifth weeks of RT) administered either preoperatively or postoperatively, with all patients having TME, and four additional cycles of adjuvant single agent 5-FU (500 mg/m^2 daily for 5 days every 4 weeks). The 5-year overall survival and disease-free survival rates were not significantly different between the neoadjuvant and adjuvant groups (76% versus 74%% and 68% versus 67%, respectively), However, the local recurrence rate was significantly less in the neoadjuvant treatment group (6% versus 13%, $P = 0.006$). Prognosis was related to final tumor stage in the surgical specimen (5-year disease-free rates of 86%, 95%, 81%, 65%, and 42% for T0, T1, T2, T3, and T4 tumors, respectively) and the presence of involved lymph nodes in the surgical specimen (5-year disease-free rates of 85%, 65%, and 18% for those with N0, N1, and N2 disease, respectively). The rate for sphincter preservation surgery was 39% in the neoadjuvant group and 19% in the adjuvant group.

A recent study compared 2-week versus 4- to 6-week intervals between radiation therapy and surgery. Significantly higher numbers of complete remissions (12% versus 0%) and tumor downstaging (55% versus 26%) and fewer lymph node metastases (22% versus 44%) were found in the group with the longer interval. No significant differences were found regarding operative data, short-term morbidity, local control, or long-term survival after a median follow-up of 34 months.[197]

Preoperative chemoradiation (5-FU infusional) with a hyperfractionated radiation boost to 61.8 Gy was evaluated in locally advanced rectal cancer with surgery performed 4 to 6 weeks later. All patients had either T4 or T3 and greater than 4 cm or 40% of the bowel circumference. RT consisted of 45 Gy to the pelvis (1.8 Gy per fraction) followed by 1.2 Gy twice daily (to the gross tumor volume) to a total RT dose of 61.8 Gy. Of the 20 patients who were evaluable for response, 10 (50%) had evidence of clinical downstaging, and 5 (25%) had more than 90% fibrosis in the resected specimen. With a median follow-up of 40 months, the 4-year actuarial rate for all patients ($N = 22$) of overall survival was 64%, that of disease-free survival was 62%, and that of local control was 84%. Three of 21 patients (14%) had positive margins; all of these patients developed a local failure ($P < 0.001$).[198]

Data from the MGH, the Mayo Clinic, and the Memorial Sloan-Kettering Cancer Center have suggested the beneficial effect of IORT (primarily, reducing the local recurrence rate to 10%) when combined with high-dose external beam radiation therapy and surgical resection in locally advanced primary rectal cancer. IORT is given in a single dose ranging from 10 to 20 Gy in patients who received preoperative external beam radiation therapy and 20 to 40 Gy when given alone. The 5-year actuarial local control and disease-specific survival rates in patients receiving IORT correlate with extent of residual cancer (Table 82-12).[199] In a retrospective analysis by Sadahiro and associates,[200] survival, disease-free survival, and local recurrence-free survival rates in the intraoperative radiotherapy group were significantly more favorable than those in the non-IORT group ($P = 0.01$, $P = 0.04$, and $P = 0.02$, respectively). Differences in survival were observed in stage II patients but not in stage I or stage III patients. There was no difference in the distant metastasis rate between the two groups. The results are less satisfactory for patients with recurrent rectal cancer, regardless of the extent of resection.[201]

Table 82-12 5-Year Actuarial Local Control and Disease-Specific Survival Rates*

Treatment	Local Control Rate (%)	Disease-Specific Survival Rate (%)
Complete resection	89	63
Microscopic residual disease	68	40
Macroscopic residual disease	57	14

*For patients with locally advanced primary rectal cancer, receiving adjuvant and intraoperative radiation therapy.

Pelvic exenteration and sacral resection for locally advanced primary rectal cancer have survival benefit if curative resection is possible. However, they are associated with high rates of morbidity. In a recent report by Yamada and coworkers,[202] the morbidity, reoperation, and mortality rates were 50%, 4.5%, and 0%, respectively. The overall 5-year survival rate for this group of patients was 74.1% for Dukes' B and 47.4% for Dukes' C (difference not statistically significant).

MANAGEMENT OF ISOLATED LOCAL AND PELVIC FAILURE

Typically, 55% to 80% of local recurrences present during the first 2 years after surgery. Several large reviews of outcome have identified an overall recurrence rate higher than 40% in rectal cancer, with pelvic recurrence the most common first site of relapse.[203] Among patients who relapse locally, half have isolated pelvic failure.[204,205] Two studies of patterns of recurrence in rectal cancer have demonstrated that local failure, without clinical evidence of distant metastases, accounts for about half of cancer-related deaths at 5 years. In a large series, reported by McDermott and associates,[206] 27% of rectal cancer deaths were attributable to isolated local relapse, and another 24% had combined local and systemic failure. In an autopsy series reported by Welch and Donaldson,[207] 25% of patients had only local disease at the time of death, 50% had both local and systemic disease, and only 25% died of systemic metastases alone. On average, two thirds of patients with pelvic relapse after simple local excision of their tumor are able to undergo curative reexcision, whereas for more radical primary surgery, complete reexcision is usually possible in only 30% of patients.[208]

Low anterior resection also appears to result in a small number of central, anastomotic recurrences that are easy to detect and treat. Unfortunately, these relatively favorable lesions account for only 25% of locoregional relapses after anterior resection.[208] Most appear to arise in the residual mesorectum and encroach on the lumen only secondarily, at a more advanced stage of their growth. APR, the most extensive of the standard operations for rectal cancer, is apt to relapse, with diffuse pelvic tumor or laterally situated masses invading the pelvic sidewall. Therefore, recurrence after APR has, in general, a poorer prognosis.[208,209]

PET scan can differentiate between recurrent tumors in the pelvis and scar. Bone scan to rule out osseous metastasis is indicated in the presence of musculoskeletal pain or if deep bony invasion in the pelvis is suspected. A positive bone scan, indicating that the tumor has penetrated the cortex of bone to invade the marrow, eliminates the possibility of curative resection. Pelvic MRI can be quite helpful to evaluate local encroachment of the tumor on adjacent vascular structures as well as pelvic bony destruction. Other clinical and radiologic criteria of unresectability include unilateral or bilateral hydronephrosis,[210] sciatic nerve pain,[211] frozen pelvis, and unilateral leg edema.[212]

Surgical Salvage of Pelvic Failures

Treatment of clinically apparent local recurrence is palliative rather than curative for most patients. Although systemic chemotherapy and radiation offer effective palliation, surgery, when possible, remains the treatment of choice. Radical surgical treatment of recurrent rectal cancer offers excellent pain relief, improved quality of life, and, in some cases, significant prolongation of life.[213]

In patients with posterior pelvic recurrence near or adherent to the sacrum, even more radical surgery is required. APR with in-continuity sacrectomy or pelvic exenteration with in-continuity sacrectomy (composite or sacropelvic exenteration) may help highly selected younger patients. The technical aspects of the procedure with the expected outcomes and potential complications should be thoroughly discussed with the patient. The impact of sacropelvic resection on all facets of a patient's life is tremendous. Sexual function is severely affected, the bladder is usually replaced by an ileal conduit, and a colostomy is required. Wanebo and colleagues have now reported on over 50 patients who underwent curative abdominosacral resection, with seemingly good palliation with excellent pain control and long-term survival in 31% of the patients.[214] These operative procedures have a formidable morbidity rate and a high mortality rate from hemorrhage or infection. Pearlman and associates[215] resected 21 patients with recurrent rectal cancer, 18 of whom had had prior radiation. Twelve patients had complete abdominosacral exenteration. Of the 16 patients who had potentially curative surgery, 8 were free of recurrence at 6 to 48 months after the procedure. If tumor is adherent only to the distal sacrum, then rather than full-thickness sacrectomy, the anterior cortex can be removed. This procedure is quite simple from S4 down. The use of argon beam coagulation provides additional tumor destruction along the periosteum without the need for sacrectomy. Finally, intraoperative radiation therapy may replace or add to the bone resections for posterior pelvic recurrence.

Multimodality Salvage of Patients Not Previously Irradiated

Patients with no history of prior radiation treatment can be considered for external beam radiation as a part of their salvage therapy, typically preoperatively in combination with chemotherapy. In addition, IORT has been utilized at select institutions in this setting. The Mayo Clinic has previously reported one of the largest IORT experiences in the literature: 123 patients (including 80 rectal cancer patients) who were treated with a combination of pelvic fractionated external beam radiation (45 Gy + 5.4 Gy) with or without 5-FU-based chemotherapy.[216] Maximal surgical resection was performed before or after radiation, and all patients received IORT with electrons to a dose of between 10 and 20 Gy. The 5-year local control and overall survival rates for the entire group were 63% and 20%, respectively. Patients who were able to undergo gross total resections had improved 5-year survival rates compared with those who were not (24% versus 18%). Single institutional analyses of the potential benefits of IORT in the setting of microscopically positive surgical salvage margins have demonstrated that IORT cannot compensate for incomplete resection. In a series of 41 patients with locally recurrent rectal cancer at MGH treated with external beam radiation, surgery, and IORT, the 5-year survival was 21% for those undergoing complete surgical resection versus 7 percent for those who were able to get only a partial resection.[217] Poorer outcomes in patients who were unable to get complete surgical resections (despite IORT) have held true across other institutional series of IORT use in this setting.[218,219] The relative paucity of institutions that are capable of delivering IORT and the lack of randomized data validating its potential benefits over conventional multimodality approaches continue to limit the utility of IORT in the recurrent setting.

Multimodality Salvage of Previously Irradiated Patients

Patients with local recurrences in previously radiated fields have traditionally not been considered for multimodality salvage approaches owing to concern over the late normal tissue complications that are anticipated; in most cases, these patients are relegated to palliative chemotherapy only. However, there is a growing experience demonstrating that reirradiation is a tolerable and potentially curative approach in these patients, including a recently reported phase II multicenter trial.[220–222] Mohiuddin and colleagues from the University of Kentucky reported a series of 103 patients treated with reirradiation to a median total dose of 85.8 Gy, with approximately one third of the patients going on to planned surgical salvage.[221] The 5-year survival rate was 22% for patients who were treated with reirradiation plus surgery versus 15% for those who received reirradiation alone. Grade 3 and 4 late toxicity occurred in approximately one fourth of the patients.

Valentini and colleagues reported the results of a phase II Italian multicenter trial of preoperative hyperfractionated chemoradiation for locally recurrent rectal cancer in patients who had previously been irradiated to the pelvis at a dose of ≤55 Gy.[222] Fifty-nine patients were treated with hyperfractionated radiation therapy (1.2 Gy twice daily) in a two-staged cone-down plan to a total of 40.8 Gy while receiving infusional 5-FU (225 mg/m^2). Thirty-nine patients were able to undergo surgery following chemotherapy and radiation. All patients received adjuvant chemotherapy with raltitrexed.

ISSUES FOR THE FUTURE

Optimal surgery combined with selected neoadjuvant therapy will continue to enhance the end results. Improved chemoradiotherapy regimens may lead to such high clinical response rates that the anal cancer paradigm could be adopted. At present, most patients with clinical CRs have microscopic residual tumor at resection. The biologic significance of these nests remains unclear. Because it is unlikely that patients will accept randomization between resection and observation, we should continue to capture data on a cohort of patients who decline radical surgery after neoadjuvant therapy. Correlative molecular markers and improved imaging (such as FDG-PET) may provide additional insight into which patients are likely to respond to neoadjuvant therapy or, if a complete clinical response is observed, which patients can be followed and could avoid radical surgery. Integration of targeted therapies, newer cytotoxic agents, and a more selective approach to the use of postoperative chemo-targeted therapy strategies will be defined.

Expanding the high-quality surgical initiatives into the community setting, combined with pathologic assessment of surgical quality indicators, remains a major challenge. It might be most appropriate to develop a rectal cancer treatment paradigm that encourages patients to seek treatment at specialty centers.

SUMMARY

The goals in the treatment of rectal cancer are cure, local control, and maintenance of quality of life. A small subset of patients with mucosal, submucosal, or early invasive cancer can be treated by local excision. Adjuvant chemoradiotherapy can improve the outcomes (particularly local control) in such patients. The majority of patients with invasive resectable rectal cancer require radical surgery. Optimal surgery for mid and low rectal cancer involves autonomic nerve-preserving sharp pelvic dissection, total mesorectal excision, and colorectal reconstruction. For many patients, restorative J-pouch colorectal or coloanal reconstruction will maximize the restorative reconstruction. Adjuvant chemoradiotherapy improves the local control and increases the overall cure, even with optimal surgery. For most patients who will be candidates for adjuvant chemoradiation therapy, the preoperative neoadjuvant strategy followed by surgery and then systemic chemotherapy will maximize local control and overall cure. Current clinical trials are exploring combinations of cytotoxic chemotherapy and targeted therapies concurrent with radiation and for an additional 4 to 6 months of treatment after operative resection.

83 Cancer of the Anal Canal

Uzma Malik and Mohammed Mohiuddin

SUMMARY OF KEY POINTS

- Cancer of the anal canal is an uncommon malignancy accounting for approximately 1.5% to 2% of all cancers of the lower alimentary tract in the United States. However, the risk has increased over the past 3 decades as a result of its association with human papillomavirus (HPV) and human immunodeficiency virus (HIV).
- The annual incidence of anal canal cancer in the United States is 1.3 per 100,000 in white men and 1.8 per 100,000 in white women.
- Anal cancer is considered one of the more curable cancers.
- Anal cancer is predominantly a locoregional disease with possible direct extension to surrounding tissues and lymphatic dissemination to inguinal and pelvic nodes. Hematogenous distant metastasis is relatively rare.
- The most common presenting manifestation is rectal bleeding, occurring in about 50% of patients.
- The treatment of anal canal cancer has changed from radical surgery to organ-sparing chemotherapy and radiotherapy and constitutes one of the success stories in recent oncologic management.

INTRODUCTION

Cancer of the anal canal is an uncommon malignancy, accounting for approximately 1.5% to 2% of all cancers of the lower alimentary tract in the United States.[1] The risk of anal canal cancer has increased over the past 30 years with its association with HPV and HIV, and although well over 4000 new cases per year are expected, it is still considered one of the more curable cancers. Significant advances have been made in the pathophysiology and treatment of anal cancer.[2] In the 1960s, anal canal cancer was routinely treated by abdominoperineal resection requiring a permanent colostomy.[3] Over the years, however, as a result of carefully designed studies, it is now possible to cure anal canal cancer in a majority of patients, with preservation of the anal sphincter.

ANATOMY

The anal canal is a 4-cm-long structure that passes downward and backward from the rectal ampulla (level of pelvic floor) to the anus (anal verge). The proximal border of the anal canal clinically corresponds to the anal sphincter at the level of the puborectalis muscle (palpable as the anorectal ring on digital rectal examination). This is where the rectum enters the puborectalis sling, made by fibers from both sides. The distal end of the anal canal is at the level of the anal verge, where the groove between the internal sphincter and the subcutaneous part of the external sphincter is palpable. This also is the level of the squamous-mucocutaneous junction and the perianal skin. At the dentate or pectinate line, which is a line that corresponds to the anal valves and anal sinuses, a zone of transitional mucosa is often present. This is defined as the zone interposed between uninterrupted colorectal-type mucosa above and uninterrupted squamous epithelium below.[4] Distal to the dentate line, the anal canal is lined by nonkeratinizing squamous epithelium, which merges with perianal skin (true epidermis). This junction has historically been called *anal verge* or *anal margin*. It follows that two distinct categories of tumors arise in the anal region. Tumors that develop from mucosa (columnar, transitional, or squamous) are true *anal canal cancers*, whereas tumors that arise from skin at or distal to the squamous-mucocutaneous junction are termed *anal margin tumors* (Fig. 83-1).

Lymphatic drainage of anal cancers depends on the location of the primary tumor. Tumors below the dentate line drain to superficial inguinal nodes, with some communication to femoral nodes and to the external iliac nodes. Tumors that originate above the dentate line drain to internal pudendal, hypogastric, and obturator nodes of the internal iliac system. The most proximal portion of the canal drains to perirectal and superior hemorrhoidal lymph nodes of the inferior mesenteric system.[5]

EPIDEMIOLOGY

The annual incidence of anal canal cancer in the United States is 1.3 per 100,000 in white men and 1.8 per 100,000 in white women.[6] More than 85% of cases diagnosed are in non-Hispanic whites. Approximately 4650 new cases of anal canal cancer are predicted this year.[7] Overall, the risk of anal cancer is increasing.[8] The median age at diagnosis is 62 years, although more cases are being seen in younger HIV-positive patients. Women more commonly have lesions above the dentate line, whereas distal anal canal cancers tend to be somewhat more common in men. Marked predominance is noted in females, and the preferential location is the posterior wall of the anal canal.[9] Anal canal incidence is higher in urban than in rural populations.[10]

ETIOLOGY AND RISK FACTORS

The incidence of anal cancer and its precursor lesions (such as anal intraepithelial neoplasia) is increasing in HIV-positive patients.[11] The absolute risk in persons with acquired immunodeficiency syndrome (AIDS) is 1 per 1000. Increased risk is found in young homosexual men, irrespective of HIV status. This suggests anal sexual activity as

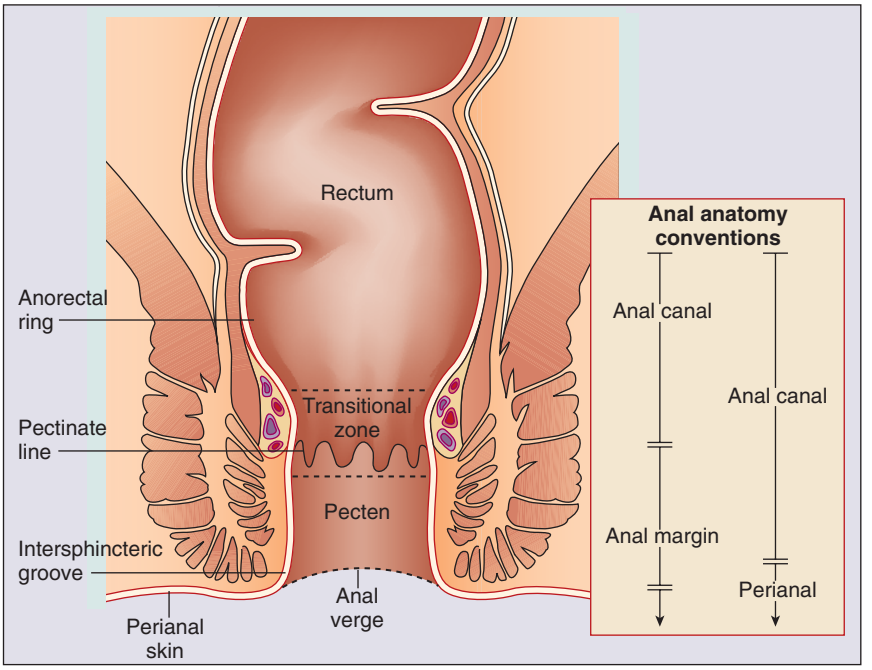

Figure 83-1 • Anatomy of the anal region.

an etiologic factor.[12] Association with HIV positivity may be the consequence of chronic immunosuppression, which in itself also has been associated with an increased risk of anal canal cancer and has been demonstrated also with vulvar cancer in renal transplant recipients.[13] HPV is a sexually transmitted agent that also has been implicated; among all of the known subtypes, HPV-16, -18, -31, -33, and -35 have been associated with malignancy or high-grade dysplasia.[14] The premalignant condition of cervical intraepithelial neoplasia (CIN) associated with HPV infection also occurs with HPV infections involving the anus (termed *anal squamous intraepithelial lesions* [ASILs]). As in CIN, ASILs can be morphologically low grade (LSILs) or high grade (HISLs).

HPV-6 and HPV-11 have been associated with benign genital condylomata. An association of other infectious agents with anal cancer has been suggested, such as syphilis and gonorrhea in men[15] and chlamydial infection and herpes simplex type 2 in both men and women.[16] It appears that cancers of the genital tract and anal cancer share some common etiologic factors.[17] An association between anal cancer and a higher number of sexual partners has been shown in women,[16] and anal cancer patients are more likely to have a prior diagnosis of CIN.[17]

Smoking and anal cancer have been associated in some studies, with a positive correlation with the number of cigarettes smoked per day and the duration for which a patient had been a smoker.[18] The possibility that the presence of benign conditions may lead to the development of anal cancer also has been suggested.[19] An association with anal fistulae, perianal abscesses, fissures, and hemorrhoids has been reported, which may be a result of the chronic inflammation and irritation associated with these conditions. This may not be a clear-cut association, however, because some evidence indicates that the risk of anal canal cancer is the highest during the first year after diagnosis of the benign condition, and this decreases after 5 years with an almost 10-fold reduction, suggesting that patients with benign conditions may actually have had undiagnosed anal malignancy as a cause of their symptoms.[20] Further studies showed little to no evidence that presence of these benign conditions leads to the development of anal cancer.[21,22] Molecular alterations also may play an important role in anal canal cancer causation. Alterations in the expression of wild-type p53 protein have been demonstrated.[23] As mentioned previously, cancers of the anus and cervix appear to have similar etiology, and approximately 80% of squamous cell cancers of the cervix contain a subtype of HPV, whereas most anal canal squamous cell cancers that lack HPV have a p53 mutation. Patients who have cervix cancer that contains HPV DNA tend to have a better prognosis,[23] perhaps because tumor DNA damaged by ionizing radiation is left unrepaired because of the absence of wild-type p53. Therefore, it is possible that anal cancers also are more susceptible to radiation if functional p53 protein is absent. This was shown in results from the Radiation Therapy Oncology Group (RTOG) 8704 study, which suggested that tumors with overexpression of p53 had a worse outcome than that for tumors with normal or absent expression. Overexpression of the c-*myc* oncogene also has been implicated in the pathogenesis of squamous cell cancers of the anal region.[24]

SCREENING, EARLY DETECTION, AND PREVENTION

Screening efforts in high-risk patients include physical examination, anal Papanicolaou (Pap) smear, and anoscopy if the Pap smear shows abnormalities. HSILs may be a precursor to invasive anal cancer, which may be detected by cytologic smears or anoscopy and biopsy, because the specificity of anal cytologic studies for the detection of HSIL is low.[25] This screening should not undermine efforts at prevention, which should include educating the general population about the risks associated with sexually transmitted infections, especially HPV infection, and anogenital cancers. Prevention efforts also may include development of a prophylactic vaccine, treatment of HPV infection with development of antiviral agents, delayed onset of sexual intercourse, and cessation of smoking. These are recommendations by the National Institutes of Health Consensus Panel of 1996.[26]

NATURAL HISTORY

Anal cancer is predominantly a locoregional disease, with possible direct extension to surrounding tissues and lymphatic dissemination to inguinal and pelvic nodes; hematogenous distant metastasis is a relatively rarer occurrence. Anal canal cancers constitute 75% of all

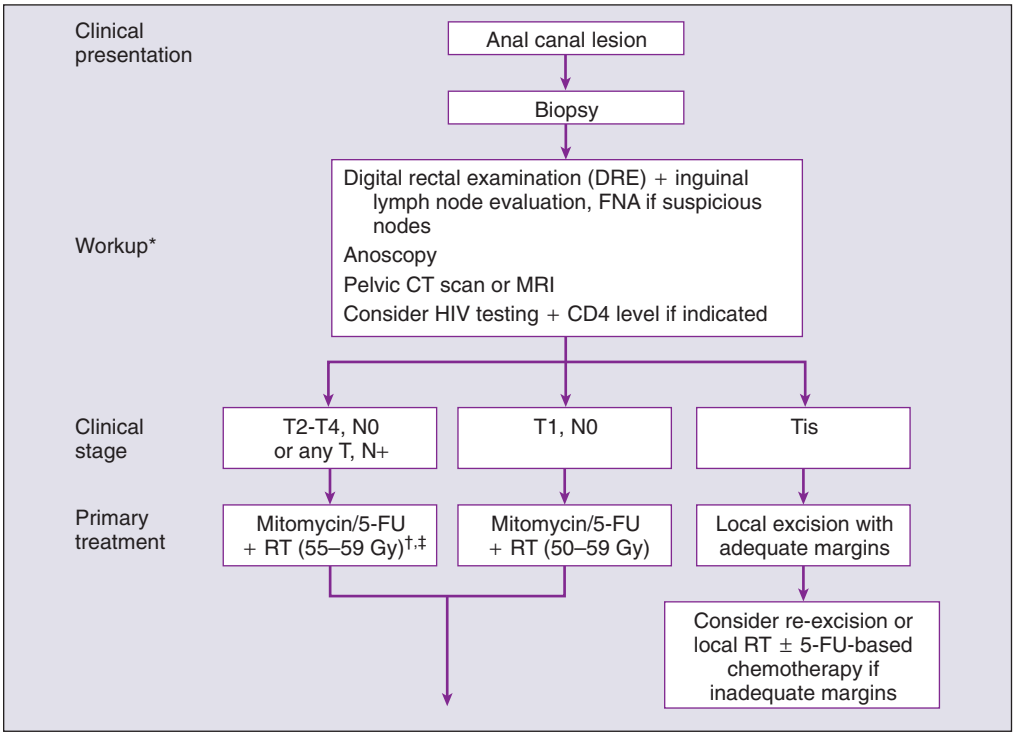

Figure 83-2 • Diagnostic algorithm for evaluating lesions of the anal canal and margin. CT, computed tomography; FNA, fine needle aspiration; 5-FU, 5-fluorouracil; MRI, magnetic resonance imaging; RT, radiotherapy. *Human papillomavirus (HPV) testing does not contribute to management. †Include bilateral inguinal/low pelvic nodal regions based on estimated risk of inguinal involvement. ‡Patients with anal cancer as the first manifestation of HIV/AIDS may be treated with the same regimen as non-HIV patients. Patients with active HIV/AIDS-related complications or a history of complications (e.g., malignancies, opportunistic infections) may not tolerate full-dose therapy and require dosage adjustment.

lesions, and only 25% are anal margin tumors. Local spread may be present in approximately 50% of cancers at diagnosis with involvement of the anal sphincter or surrounding soft tissues.[27] Extension to the rectum and perianal skin also may occur. Invasion of the vaginal septum is more common than invasion of the prostate gland because of the presence of Denonvillier's fascia in men, which acts as a barrier.[28]

Lymphatic drainage is dependent on the anatomic location of the primary tumor. Tumors that arise distal to the dentate line drain to inguinal lymph nodes (superficial and deep), and those above the dentate line spread primarily to the internal iliac system, and with more proximal lesions, spread occurs to the inferior mesenteric group. The regional nodes are considered to be inguinal (superficial and deep femoral), internal iliac, and perirectal (anorectal, perirectal, and lateral sacral). All other nodal groups represent sites of distant disease. The incidence of involvement of inguinal nodes is directly proportional to the size and extent of the primary tumor. Overall, this risk may be approximately 10% at diagnosis but may increase to 20% for tumors larger than 4 cm, and with T4 disease, this may be as high as 60%.[29] One report suggested that the risk of lymph node metastasis is not directly related to tumor size.[30] Distant metastasis may occur to any organ, but the liver and lungs are most frequently involved. Overall, distant metastases are relatively rare, because anal canal cancer tends to be a locoregional process. At diagnosis, only 5% to 10% of patients will be found to have distant disease. After curative treatment, the risk of distant disease varies, ranging between 10% and 30%, and depends on the initial tumor (T) stage.[31] The risk of distant metastasis also increases with the number of regional nodes involved.[27]

CLINICAL PRESENTATION AND DIAGNOSIS

Most patients with anal cancer are first seen with rectal bleeding. This occurs in approximately 50% of patients; 30% experience pain or the sensation of a rectal mass.[32] A common concern with most anal neoplasms is the frequent delay in diagnosis resulting from confusion with more common, benign conditions. Thus, the clinician must maintain a high index of suspicion when evaluating lesions of the anal canal and margin.[33]

An interval of 4 to 6 months may ensue between onset of symptoms and diagnosis in up to 50% of patients. A thorough evaluation of any patient with a lesion in the anal canal is therefore recommended (Figs. 83-2 and 83-3). This evaluation includes a digital rectal examination, palpation of inguinal nodes, and an anoscopic visual examination with biopsy of suggestive lesions, including enlarged lymph nodes, which may be caused by tumor or reactive hyperplasia in as many as 50% of palpable nodes (Box 83-1). The anal cancer need not be excised at the time of biopsy. Computed tomography (CT) scan or magnetic resonance imaging (MRI) is done to assess pelvic and suspicious inguinofemoral nodes. Rectal ultrasound examination is an accurate means of determining the depth of penetration of the tumor into the anal wall. It also serves to visualize local lymph nodes. CT scan of the abdomen and pelvis and chest radiography are recommended to assess locoregional and distant disease. Positron emission tomography (PET) scan also is recommended for staging. HIV testing also is suggested in patients with risk factors such as sexual history and drug abuse history. Carcinoembryonic antigen (CEA) level may be elevated in 20% of cases, but this study is rarely requested because no clinical benefit in patient management derives from obtaining this information.[34]

STAGING

Staging for anal canal cancers in based on the American Joint Committee on Cancer (AJCC) tumor-node-metastasis (TNM) staging system. The TNM classification for tumors is based on clinical or histopathologic findings, or both, as well as results of radiographic studies. The latter assesses local and locoregional extension. Surgical excision is infrequently done, so few tumors are staged histopathologically (Table 83-1). At initial presentation, approximately 50% to 60% of patients have T1 or T2 lesions, and 12% to 20% are node positive.

HISTOPATHOLOGIC CLASSIFICATION

The staging system applies to all carcinomas arising in the anal canal, including carcinomas that arise within anorectal fistulae. Melanomas,

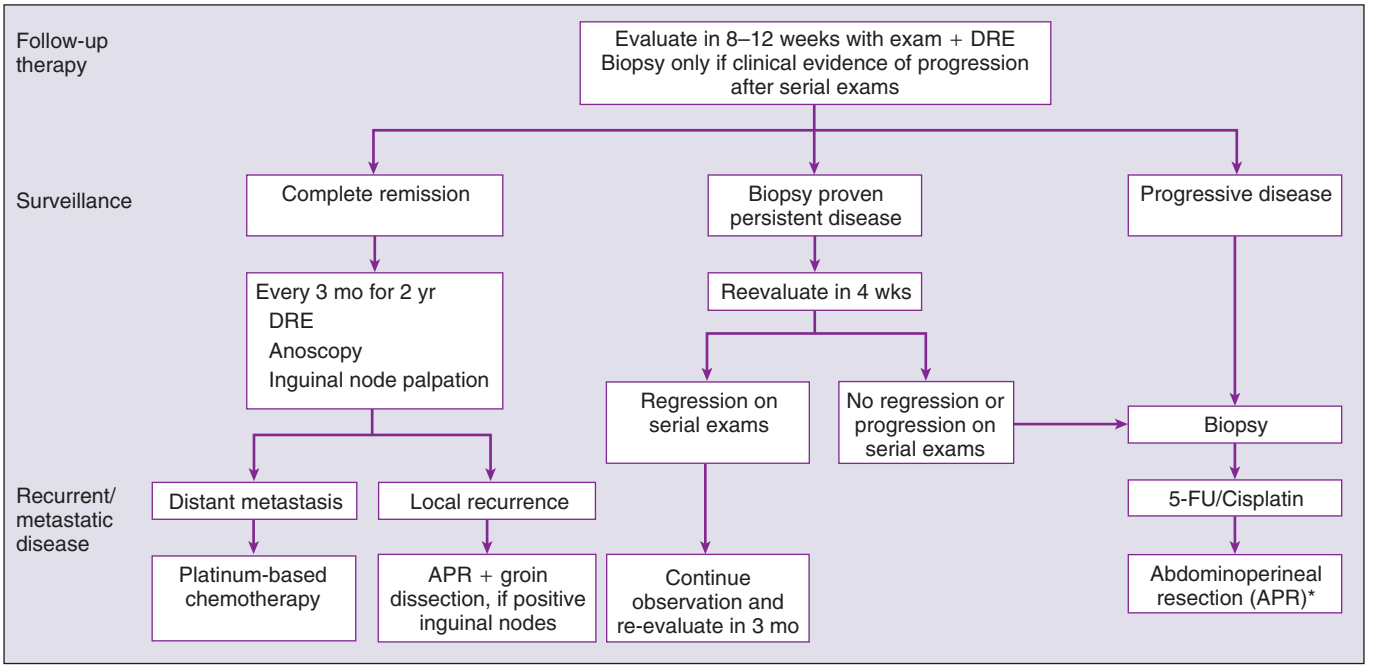

Figure 83-3 • Algorithm for treatment of anal cancer. APR, abdominoperineal resection; DRE, digital rectal examination; 5-FU, 5-fluorouracil. *Consider muscle flap reconstruction.

carcinoid tumors, and sarcomas are excluded from this staging system. Most carcinomas of the anal canal are squamous cell carcinomas. The World Health Organization (WHO) classification of the types and subtypes of carcinomas of the anal canal is presented in Box 83-2. The terms "transitional cell carcinoma"and "cloacogenic carcinoma" have been abandoned because these tumors are now recognized as nonkeratinizing types of squamous cell carcinoma.[35]

Box 83-1. DIAGNOSTIC WORKUP FOR CANCER OF THE ANAL CANAL

Essential Components of Evaluation

History
Physical examination
- Regional lymph nodes
- Adjacent organs for direct invasion
- Anogenital areas for concurrent malignancies

Proctoscopy
Biopsy of primary tumor
Fine-needle aspiration biopsy or simple excision of enlarged inguinal nodes
Chest radiograph
CT of abdomen and pelvis
Liver and renal chemistry
Complete blood cell count
HIV antibody assay, if risk factors are present

Useful Studies

Colonoscopy or air-contrast barium enema (to exclude other sources of lower gastrointestinal tract bleeding)
Bipedal lymphangiography

CT, computed tomography; HIV, human immunodeficiency virus.

TREATMENT

Carcinoma of the anal canal is a chemoradiotherapy-sensitive tumor and therefore is often a curable cancer, with anal sphincter preservation in 65% to 75% of patients. Significant advances have occurred over the past 30 years in its treatment. The treatment of anal canal cancer has changed from radical surgery to a combined approach of organ-sparing chemotherapy and radiotherapy and constitutes one of the success stories in recent oncologic management (Box 83-3). This principle also has served as a model for treatment of other types of malignancy.

Surgery

Surgical treatment was the primary therapy 20 to 35 years ago, but it has been replaced by sphincter-sparing therapy with combination chemoradiotherapy. Surgical therapy is now used most often as a method of salvage. Surgical treatment, when it was used as a primary therapy, required an abdominoperineal resection (APR). This con-

	Any T	N1	M0
	Any T	N2	M0
Stage IV	Any T	Any N	M1

MX, distant metastasis cannot be assessed; M0, no distant metastasis; M1, distant metastasis.

*Direct invasion of the rectal wall, perirectal skin, subcutaneous tissue, or the sphincter muscle(s) is not classified as T4.

sisted of wide local excision of the anus, to include the levator ani muscles and contents of the ischiorectal fossa. The operation results in a permanent colostomy, as well as loss of sexual function, in most patients. Overall, 5-year survival rates were approximately 50% after curative APR for anal canal cancer, with slightly better results of 55%

Box 83-3. COMBINED-MODALITY TREATMENT FOR SQUAMOUS CELL CANCER OF THE ANAL CANAL

Chemotherapy

5-Fluorouracil, 1000 mg/m^2 per 24 hours by continuous intravenous infusion for 96 hours, starting on days 1 and 28

Mitomycin C, 10 mg/m^2 by intravenous bolus on days 1 and 28

Radiation Therapy

45 Gy delivered in 25 fractions to pelvis ± boost to residual disease, to total dose of 54 to 59.6 Gy

to 71% in more recent series.[36–40] Despite reasonable survival rates, local recurrence continues to remain a significant cause of treatment failure. A review of 118 cases treated at the Mayo Clinic showed an overall survival rate of 70% and local recurrence rate of 40% (including patients with inguinal node recurrence). Local recurrence was a component of failure in more than 80% of patients who relapsed.[27] Frost and colleagues[37] reported an overall survival of 62%, with a 45% rate of failure in the pelvic and inguinal lymph nodes. Because of the high morbidity associated with inguinal lymph node dissection and the fact that the risks associated with the procedure outweigh its benefits, prophylactic groin dissection is not recommended. Surgery alone should be considered only for lesions of the anal margin in which the sphincter can be spared. The results of several major surgical series are summarized in Table 83-2. Tumor size, depth of invasion, and presence of inguinal or pelvic lymph nodes have been shown to have prognostic significance in terms of higher risk of local recurrence and worse survival.[27,36–39] A large series from the Memorial Sloan-Kettering Cancer Center demonstrated survivals of 63%, 55%, and 40% for T1, T2, and T3 lesions, respectively. The corresponding local recurrence rates were 16%, 35%, and 56%. Furthermore, patients with superficial invasion of the anal sphincter had a 79% survival rate, compared with 52% for those with deep muscle invasion.[38] Another review by Pintor and associates[39] demonstrated 60% survival for patients with T1 and T2 lesions, compared with 54% for patients with T3 and T4 disease. In a series from the Mayo Clinic, tumors confined to the anal epithelium and subepithelial connective tissues did not recur, whereas those invading the anal sphincter recurred in approximately one fourth of the cases, and those invading adjacent pelvic tissues recurred in almost half of the cases. Survival was affected by inguinal node metastases, with a 5-year survival rate of only 18%.[38]

APR is rarely used as initial therapy. It remains a useful procedure, however, for salvage after sphincter-preserving therapy and for management of complications related to conservative therapy.[40]

Radiotherapy

Radiotherapy has been used for treatment of anal cancers since the early 1900s, especially in Europe, whereas surgery was the treatment

of choice in the United States. Most series have demonstrated survival rates on the order of 45% to 65%. As with surgery, better outcomes have been seen with smaller tumors and in patients with disease-negative inguinal lymph nodes.[41–43] In a series from the Institut Curie between 1968 and 1979, the 5-year overall survival rate was 59% (70% for tumors less than 4 cm in diameter, 57% for those between 4 and 6 cm, and 33% for those greater than 6 cm). Correspondingly, anal-sphincter function was retained in 76% and 57% of cases, respectively, for tumors smaller than 4 cm and those from 4 to 6 cm in diameter. Likelihood of survival and local recurrence also depended on the extent of the tumor's circumferential involvement of the anal canal. For tumors with a circumferential involvement of 25% and 50%, survival rates of 71% and 61%, respectively, were demonstrated. Survival decreased to 19%, however, with 75% or more circumferential involvement. Local recurrence rates were 16%, 28%, and 100%, respectively.[41] Local control and survival rates from retrospective series of radiation alone are summarized in Table 83-3.

Complications of radiotherapy may result in the need for colostomy in 2% to 10% of patients.[41–47] Overall, results with a definitive course of radiotherapy are similar to if not better than results with surgery, especially for tumors smaller than 4 cm in diameter.[48] Radiotherapy allows sphincter preservation, thus making it a more preferred option compared with surgery. Excellent results also have been obtained with use of external beam and interstitial irradiation in combination. In their series of 222 patients with anal cancer, Papillon and Montbaron[47] used a treatment regimen consisting of external beam irradiation at a dose of 30 to 42 Gy, followed 2 months later with an interstitial implant using iridium (Ir) 192 to deliver 15 to 20 Gy. The 5-year survival rate was 65%. Patients with tumors smaller than 4 cm had a 76% survival rate, compared with 58% for patients with larger lesions. Sphincter preservation was achieved in 82% and 70%, respectively.[47]

Combined-Modality Treatment

Combined-modality therapy was described initially by Nigro and coworkers.[49] This was a preoperative regimen inspired by reports that 5-fluorouracil (5-FU) potentiated the effects of radiotherapy on gastrointestinal tumors.[50] This regimen consisted of delivering 30 Gy in 15 fractions to the primary tumor and pelvic lymph nodes with concurrent 5-FU (1000 mg/m^2 as a 4-day continuous infusion) and mitomycin C (MTC) (15 mg/m^2 bolus injection) chemotherapy, and APR 6 weeks after completion of the protocol.[52,53] Promising early results, however, suggested that surgery may not be necessary. The series of Nigro and colleagues[51] included 31 patients who underwent surgery and 73 who received chemoradiotherapy alone. Twenty-two of the 31 surgical specimens had no evidence of disease (NED) on histopathologic examination, and on long-term follow-up evaluation, an NED rate of 79% was found for the surgical patients, compared with 82% NED for patients receiving combined-modality treatment. Overall death rates were 6% in patients with tumors smaller than 4 cm and 26% for those larger than 4 cm.

Subsequent to the Wayne State protocol of Nigro and associates, Cummings and coworkers[53] performed a series of sequential prospective nonrandomized studies at Princess Margaret Hospital in Canada, evaluating radiation alone, radiation with 5-FU, and radiation with 5-FU and MTC. The best results were observed with both 5-FU and MTC along with radiation therapy. These investigators compared 30 patients treated with chemoradiation with 25 patients treated previously with similar doses and techniques of radiotherapy alone. The local control rate was 93% in the combined group, with no difference found between continuous and split-course regimens, and 60% in the radiotherapy-alone group. The overall survival rate was 70% in both groups. The RTOG confirmed these results in a phase II trial with the same chemotherapy regimen and a total radiation dose of 40.8 Gy at 1.8 Gy per fraction. Patients with smaller tumors (less than 3 cm in diameter) had a 2-year disease-free survival rate of 77%, compared with 53% for large tumors. Local control rate also was tumor size dependent: 84% for smaller lesions and 66% for larger tumors. Other investigators have suggested higher radiation doses for larger tumors.[54–57]

The rate of sphincter preservation also appears to be higher in patients who receive combined-modality therapy; rates of 85% to 100% were reported by several studies.[44,55,57,59] No definite evidence was found of a survival benefit with the combined-modality approach, but local control and colostomy-free survival are definitely improved

with the combination of chemotherapy and radiotherapy. The need for chemotherapy in addition to radiation has been established by two well-conducted randomized trials. Table 83-4 summarizes a number of series consisting of treatment with radiation therapy and chemotherapy, the latter using 5-FU and MTC, as initially described by Nigro and colleagues. Most of the series show good survival and local control rates in the range of 60% to 90%.

Following up a trial from Princess Margaret Hospital,[53] the EORTC (European Organization for Research and Treatment of Cancer) and the UKCCR (United Kingdom Coordinating Committee for Cancer Research) have done two randomized studies comparing radiation alone with combined radiation therapy and 5-FU–MTC chemotherapy.[60,61] Results of these two trials on follow-up evaluation at a median of 42 months are outlined in Table 83-5. In the EORTC trial, a locally advanced primary tumor (T3 or T4) or regional lymph node involvement was required for eligibility. Any stage of disease was eligible for the UKCCR trial. Initial radiotherapy consisted of 45 Gy to the pelvis in both trials but the boost was different. In the EORTC trial, a 20-Gy boost was delivered to partial responders 6 weeks after completion of therapy and complete responders received 15 Gy. In the UKCCR trial, a 15- to 25-Gy boost was given to patients who had a more than 50% response, and those who had a less than 50% response underwent surgery. The chemotherapy regimen consisted of 5-FU, 750 mg/m^2 per 24 hours on days 1 to 5 and 29 to 33, with a single 15-mg/m^2 dose of MTC on day 1, in the EORTC trial. In the UKCCR trial, 5-FU was given at a dosage of 1000 mg/m^2 per 24 hours on days 1 to 4 and on days 29 to 32 or 750 mg/m^2 per 24 hours on days 1 to 5 and 29 to 33, with a single

12-mg/m^2 dose of MTC. Complete response rates at 6 weeks after boost radiotherapy were 80% and 54%, respectively, favoring the combined-modality regimen in the EORTC trial. A trend toward a higher complete response rate also was reported in the UKCCR trial. This was measured 6 weeks after induction therapy, however, as opposed to 6 weeks after completion of all therapy, as was done in the EORTC trial. Although the local control rate was low in the UKCCR study at 39% at 3 years, it should be noted that the definition of failure in this study was less than 50% tumor reduction at 6 weeks after delivery of 45 Gy to the pelvis.

Local control was significantly better in both trials with the combination regimens, but no impact was seen on survival.[60,61] The need for MTC in combined-modality therapy of anal cancers was evaluated in a randomized U.S. RTOG–ECOG trial (RTOG 87–04/ECOG 1289). This was the first study comparing two methods of chemoradiotherapy in patients with anal cancer. One study arm used 5-FU alone with radiotherapy, and the other arm used 5-FU and MTC with radiotherapy.[62] (Results of this study are summarized in Table 83-6.). The addition of MTC was associated with fewer colostomies and higher rates of local control and disease-free survival, but with a significantly greater risk of grade 4 or 5 toxicity, seen in 26% of patients, compared with 7%. Survival was slightly higher with the MTC-containing regimen, but the difference was not statistically significant. The disease-free survival rate was 73% versus 51%, favoring the MTC-containing regimen. 5-FU was administered at 1000 mg/m^2 per day as a continuous infusion for 4 days beginning on days 1 and 28 of radiotherapy. MTC was administered at 10 mg/m^2 by intravenous bolus on day 1 of each 5-FU course. Two of the four treatment-related deaths in the MTC regimen group were believed to be due to failure to follow protocol dosage-reduction guidelines for the second MTC dose. The investigators concluded that despite the greater toxicity, the use of MTC in a definitive complete response regimen for anal cancer was justified.

Future Directions in Treatment

Chemotherapy regimens incorporating 5-FU and cisplatin have resulted in significant antitumor activity in patients with metastatic anal carcinoma.[63,64] Use of this combination has generated great interest, with a number of reports demonstrating response rates ranging from 55% to 82%. Table 83-7 summarizes the findings in some of these series. The RTOG study 98–11, which investigated use of such regimens for the management of metastatic disease, compared external beam radiotherapy (EBRT) with 5-FU plus MTC, given during weeks 1 and 5, and two courses of induction 5-FU and cisplatin, followed by concurrent EBRT plus 5-FU and cisplatin, with radiotherapy beginning on day 57. The study hypothesis was that induction chemotherapy may reduce tumor bulk before combined chemoradiation therapy and thereby provide better local control and colostomy-free survival; an additional two cycles of chemotherapy may positively affect the distant metastatic rate.[65] The trial enrolled 682 non–HIV-infected patients with squamous cell cancer of the anal canal. A preliminary report found no significant difference in rates of 5-year disease-free survival (48% and 56% for the experimental and control arms, respectively) or overall survival (69% in both groups), but the colostomy rate was significantly higher in the cisplatin treatment group (hazard ratio, 1.63).[65] Although hematologic toxicity was worse in the MTC group, nonhematologic toxicity and late radiotherapy-related toxicity rates were similar in the two groups. The investigators concluded that a 5-FU–cisplatin combination was not superior to the standard regimen of 5-FU plus MTC. Thus, 5-FU plus MTC remains the standard regimen for concur-rent chemoradiotherapy at most treatment centers and is included in published guidelines of the National Comprehensive Cancer Network.[66]

Radiotherapy Techniques

Photon energy of 6 MV or greater is indicated for irradiation of pelvic fields. In the past, large anteroposterior (AP) and posteroanterior (PA) fields were used for comprehensive coverage of the area of primary disease and inguinal nodes. Although this still is an appropriate technique, alternate-field arrangements also have been used. One such technique suggests that supplementary inguinal node radiation be given, preferably with electrons. In this alternate technique, initial pelvic fields include AP and PA fields to include the pelvis, anus, perineum, and inguinal lymph nodes. The lateral inguinal nodes should be irradiated using the AP field, but not the PA field, to minimize radiation dose to the femoral head and neck. The PA field should extend 2 cm lateral to the sciatic notch and should be designed to include the primary tumor and pelvic nodes. Electron fields are

Table 83-7 Response Rates with Cisplatin-Based Chemotherapy

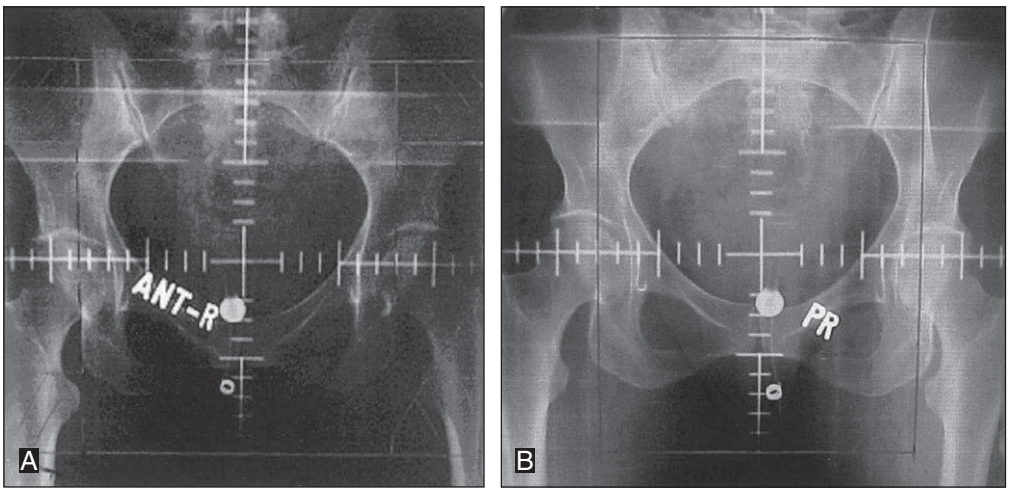

Figure 83-4 • A, Initial anterior photon fields *(solid line)* and supplementary electron fields to boost dose to lateral inguinal nodes *(dotted line)*. **B,** Initial pelvic posterior photon field.

designed to incorporate the lateral inguinal nodes not included in the posterior field (Fig. 83-4). The superior border of the initial pelvic fields starts at L_5-S_1 and is dropped to the level of the inferior border of the sacroiliac joints at 36 Gy (Fig. 83-5). The inferior border includes the anus, with at least a 2.5-cm margin. The initial dose is 36 Gy given at 1.8 Gy per fraction. This is calculated to midplane from the anterior and posterior pelvic fields. Dose to inguinal nodes is calculated, because these do not receive a contribution from the initial posterior pelvic field, which is not as wide as the anterior photon field. The remaining dose is supplemented with electrons to make up to 180 cGy per day (typically, inguinal nodes are situated at 3 cm). Another method of treatment uses a three-field technique as for rectal cancer, with one posterior and two lateral fields. The PA field is large enough to include the lateral inguinal nodes. The dose to the inguinal nodes is calculated and typically is approximately one third of the contribution from the PA field. The remaining dose is supplemented with inguinal electron fields.

Intensification of Radiation Dose

It is not yet known whether escalating radiation doses to more than 45 to 50 Gy in combined-modality therapy will result in greater benefit. Analysis of data from the Massachusetts General Hospital, the University of Kansas, the University of Maryland, and M.D. Anderson Cancer Center suggests a benefit in local control with higher radiation doses of 54 to 66 Gy.[67–71] A benefit with higher radiation dose also was suggested in the RTOG 8704–ECOG 1289 trial.[62] This issue was investigated recently in the RTOG 9811 study. After delivery of 45 Gy, use of an additional boost of 10 to 14 Gy was an option for residual disease.[65] A phase II RTOG study, RTOG 9208, unfortunately demonstrated a high incidence of colostomies of 23% with use of a radiation dose of 59.4 Gy with 5-FU and MTC.[72] This complication rate was thought to be related to absence of planned treatment break, and the investigators concluded that for higher doses to improve local control, radiation therapy may have been given in a continuous fashion, thereby increasing toxicity. A subsequent RTOG pilot trial, however, showed only an 11% colostomy rate with no treatment break.[73]

Side Effects and Radiation Complications

Anal sphincter function is maintained in 65% to 80% of patients after combined-modality treatment.[65] Late complications may result in loss of anal function, and colostomies may be needed in 2% to 10% of patients.[67] APR usually is done for disease recurrence. Acute toxicity may be significant with radiation and chemotherapy. The severity of toxicity may be influenced by fraction size and the type of chemotherapy. Fraction size was found to be a contributing factor by Cummings and associates[53] at Princess Margaret Hospital. The incidence of toxicity was decreased by approximately 50% when

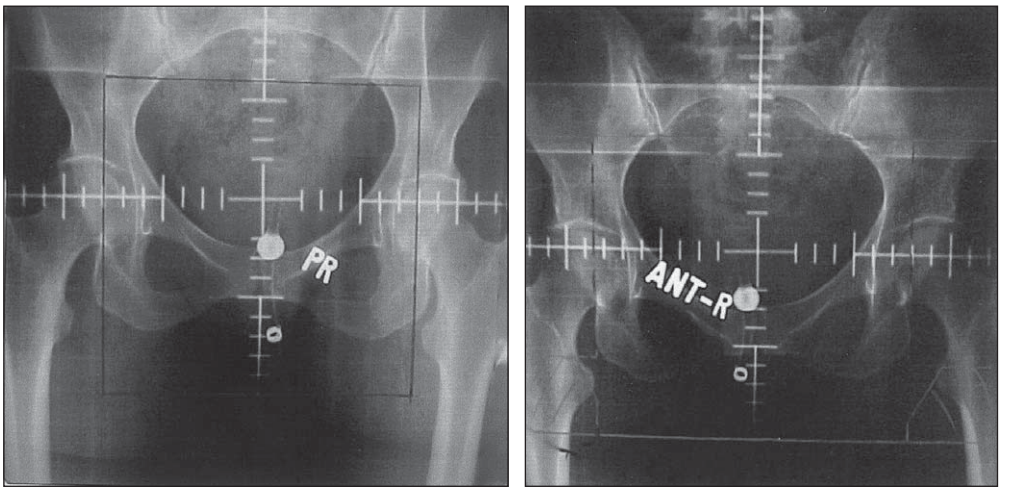

Figure 83-5 • A, Posterior pelvic field with its superior border at the level of the inferior sacroiliac joints. **B,** Anterior pelvic field reduction when the superior border is brought down to the inferior border of the sacroiliac joints.

fraction size was decreased from 250 cGy to 200 cGy, or when a planned treatment break was given. The type of chemotherapy in the RTOG-ECOG trial also determined the severity of toxicity. With 5-FU plus MTC, 26% of patients experienced grade 4 or 5 toxicity, compared with only 7% in the 5-FU-alone arm.[53] In the short term, most patients experience significant perineal skin reactions, often with confluent moist desquamation, such that a treatment break is necessary during most treatment courses. Other reactions may include fatigue, nausea, vomiting, diarrhea, dysuria, rectal and vaginal irritation, and possible bleeding secondary to proctitis, cystitis, and vaginitis.

Late complications may consist of perineal fibrosis, telangiectasia, and intermittent bleeding from the anorectal region or the bladder or vagina. Other late complications may include hyper- or hypopigmentation of the skin, pruritus, and atrophy of the skin. Edema of the genitals or lower extremities also may occur. A possibility exists for long-term alteration of bowel function, fecal incontinence, and fistula formation necessitating colostomy. Other rare complications may include painful nonhealing ulcers of the skin or anal mucosa, strictures of the anus or vagina, and osteoradionecrosis of the femoral head or neck. In patients with comorbid conditions that would compromise tolerance to combined therapy or specifically chemotherapy, treatment with radiation alone may be best. This strategy may be appropriate both in patients who may not be able tolerate chemotherapy and in HIV-positive patients with $CD4^+$ counts less than $200/cm^3$. In our experience, the usual combined-modality approach can be used effectively, without an increased risk of toxicity or complications, in patients with $CD4^+$ counts higher than $200/cm^3$ without any alteration in dose or chemotherapeutic agents.

Assessing Response to Primary Chemoradiotherapy and Persistent Disease

Prognosis is directly dependent on the size of the primary tumor and the likelihood of lymphatic spread of the cancer. Tumors 2 cm in diameter or smaller are cured in 80% of cases, whereas those 5 cm across or larger are cured in less than 50% of cases. Tumor regression after radiotherapy may be slow and may take up to 36 weeks, with a median time to tumor regression of 12 weeks from start of therapy. A majority of recurrences occur within 2 years of treatment.[53] Routine biopsy of regressing or clinically absent tumor is not recommended. Further radiation dose supplementation may be beneficial, but this is controversial, as illustrated in an RTOG trial at a planned biopsy 6 weeks after completion of therapy. Twenty-five of 310 patients were found to have residual disease after 45 days and two courses of 5-FU and MTC. Salvage therapy using irradiation at a dose of 9 Gy and cisplatin plus 5-FU resulted in a complete response in 55% of these patients 6 weeks later.[62] The supposed benefit of extra radiation dose as salvage therapy may be the result of continued slow tumor regression and may not necessarily be related to the increased radiation. This point is still not absolutely clear, however, and continues to be investigated. Biopsy may be considered after 12 weeks if evidence of progressive disease is found. Additional chemotherapy with 5-FU and cisplatin and APR may be considered for tumor persistence or recurrence.

Treatment of Metastatic Disease

The development of distant metastases is infrequent in patients with squamous cell carcinoma of the anal canal. In the UKCCR and EORTC trials, for example, distant metastases developed after combined-modality therapy in 10% and 17% of patients, respectively.[60,61] The liver is the most frequent site of distant metastases.[74–75] The only widely published active regimen for treatment for metastatic disease is cisplatin plus 5-FU[64,76–79]; single case reports describe activity for single-agent carboplatin,[80] doxirubicin,[81] and irinotecan.[82] No experience with newer agents, such as the taxanes and gemcitabine, in this setting has been reported.

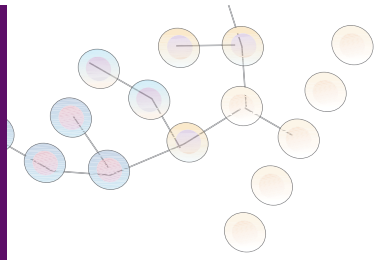
SUMMARY

In summary, squamous cell carcinoma of the anal canal is a disease best managed by a multidisciplinary approach. Optimal treatment is combined chemotherapy and radiotherapy. The recommended chemotherapeutic agents are 5-FU, delivered at a dose of 1000 mg/m^2 per 24 hours by continuous intravenous infusion for 96 hours, starting on days 1 and 28, and MTC, at a dose of 10 mg/m^2 given intravenously on days 1 and 28. It should be kept in mind that MTC can cause delayed thrombocytopenia, and platelet levels should be monitored before the second dose. Radiation therapy consists of 45 Gy delivered in 25 fractions to the pelvis over a 5-week period. The upper border of the field is reduced at a dose of 36 Gy. The issue of boost radiation for residual disease at the completion of the larger pelvic field is controversial. Some data suggest that local control is better with the addition of a boost. An increased risk of complications with a higher colostomy rate also has been reported, however. This issue currently is under investigation in the RTOG 9811 protocol, which is a phase III randomized study of 5-FU, MTC, and EBRT versus 5-FU, cisplatin, and radiotherapy.

This protocol permits a 10- to 14-Gy boost, at a dose of 2 Gy per fraction, to a reduced field after irradiation of the larger pelvic fields at 45 Gy in 25 fractions for T3 and T4 or node-positive lesions, as well as for T2 lesions with residual disease after 45 Gy. Clear evidence exists in the literature of poor local control with T3 and higher stage lesions of only 50%; accordingly, it is reasonable to prescribe a higher dose to lesions that are T3 or higher. Our recommendation as well as current practice is to treat more extensive disease with a dose of 59.6 Gy to a field 2.5 cm around the area of the anal canal malignancy. This field reduction is done after delivery of 45 Gy to the pelvis. Cisplatin currently is not a standard chemotherapeutic agent for the treatment of anal canal cancer. In the future, however, it may play a larger role. Cisplatin and 5-FU chemotherapy regimens have been used by a number of investigators. In their series of 21 patients, Rich and coworkers[71] used a treatment regimen consisting of 5-FU at a dose of 250 mg/m^2 per day and cisplatin 4 mg/m^2 per day. Both agents were delivered by intravenous infusion 5 days a week, along with radiotherapy at a dose of 54 to 55 Gy. Local control rate was 89%. In patients who received 5-FU alone, along with similar radiation dose, a local control rate of only 73% was achieved.[71]

Doci and colleagues[83] also reported the results of a phase II trial in 35 patients. Local recurrence rate with cisplatin treatment was 6%, versus 24% with the MTC-containing regimen. After investigation of its role in the management of anal cancer, however, cisplatin now is not recommended for treatment. It is, however, often considered for management of metastatic disease, for which further 5-FU and MTC or cisplatin may be used.[86] It also may be considered for patients whose medical conditions preclude the safe use of MTC. Patients with AIDS, for whom standard chemoradiotherapy doses may be too toxic, may tolerate 5-FU plus cisplatin as a safer alternative.[86,87] Patients who do not respond to chemoradiotherapy usually are offered an APR. Further chemotherapy consisting of 5-FU and cisplatin often is considered. Zelnick and colleagues[88] reported on 30 patients who underwent APR after chemoradiotherapy for recurrent or persistent anal canal cancer. Seventy-seven percent of tumors that were smaller than 5 cm with negative nodes were disease free 37 months after APR. However, none of the lesions larger than 5 cm was free of disease.[88]

Tumors of the anal margin or perianal region are treated much as for skin cancers.[89] Our treatment recommendation is local excision. If the tumor is large enough such that it requires an APR, we recommend treatment as for an anal canal cancer with combination chemoradiotherapy. Most of the lesions in this area, however, are small enough that a simple excision constitutes sufficient therapy. Adenocarcinoma of the anal canal also can occur, arising from anal ducts. This is a fairly uncommon entity. In general, such tumors are treated with preoperative chemoradiotherapy, followed by an APR.



The chemotherapy used in these instances is 5-FU, in a regimen appropriate for adenocarcinoma, with radiotherapy fields appropriate for anal canal cancer. Treatment is governed mainly by the cell type.

Anal canal cancer is a rare entity. Interest in tumors in this area has increased in the recent past because of increased incidence. It is a curable disease with combined chemoradiotherapy, in which significant advances recently have occurred in its management. The selection of therapy for each patient requires the cooperative effort of many physicians, including radiation oncologists, medical oncologists, surgeons, and gastroenterologists.

84 Liver and Bile Duct Cancer

Sharon Weber, William Jarnagin, Austin Duffy, Eileen M. O'Reilly, Ghassan K. Abou-Alfa, and Leslie Blumgart

SUMMARY OF KEY POINTS

Incidence
- Hepatocellular carcinoma (HCC) is one of the most common solid organ malignancies worldwide, with up to 1 million cases diagnosed per year.
- This high incidence relates to its common association with cirrhosis from either alcohol or hepatitis B or C.
- Cholangiocarcinoma and gallbladder cancer are less common hepatobiliary malignancies.

Etiology and Epidemiology
- The primary risk factor for hepatocellular cancer is underlying cirrhosis.
- Both the incidence of and the mortality rate for HCC and intrahepatic cholangiocarcinoma are increasing, primarily because of chronic infection with the hepatitis B and C viruses (HBV and HCV).
- Although several associated risk factors for gallbladder cancer and cholangiocarcinoma are recognized, most tumors arise as sporadic cancers.

Pathology and Tumor Biology
- These tumors are primarily adenocarcinomas.
- Because a majority of patients present with advanced disease, only a small proportion of these tumors are amenable to curative resection.
- Hilar cholangiocarcinoma has a propensity for local invasion, which makes definitive treatment challenging.

Clinical Findings
- Although patients with cholangiocarcinoma or gallbladder cancer may present with jaundice, a majority of patients with liver neoplasms are asymptomatic.
- Patients with cirrhosis often are incidentally discovered to have hepatocellular cancer because of an elevated serum alpha-fetoprotein (AFP) level or a liver mass found on routine screening.

Differential Diagnosis
- Considerations in the differential diagnosis include secondary hepatic malignancies and benign neoplasms such as focal nodular hyperplasia, hemangioma, or adenoma.

Primary Therapy and Salvage Therapy
- Primary treatment for liver and bile duct neoplasms consists of complete surgical resection.
- For patients with unresectable disease, few effective alternative treatments are available.
- Patients with nonresectable disease are candidates for experimental therapy, liver function and performance status permitting.

Prognosis
- The overall survival rate for all patients with these tumors is less than 5%.
- The 5-year survival rate for patients with *resectable* disease is approximately 30% to 50%.
- Unfortunately, even after complete resection, recurrence is seen in a majority of cases. Clearly, more effective adjuvant treatment is needed.

HEPATOCELLULAR CANCER

INTRODUCTION

HCC is a major worldwide public health problem. In the developing world, HCC has long been considered a priority oncologic problem, and in certain parts of the world, it is the most common solid organ tumor. In recent times, awareness of HCC also has increased in the developed world as a result of markedly rising incidence rates. A greater investigational energy has been focused on optimal management of this disease, and better systemic therapies are emerging. Nevertheless, the main therapeutic modality that can be considered curative is surgical resection.

Surgical resection is reliant on the remarkable regenerative powers of normal liver tissue. For Prometheus, strapped to a rock on the Caucasus mountains, a giant eagle returning daily to tear at his newly regenerated liver, this cycle of recovery was a cursed and unending punishment for giving the gift of fire to mortal beings. For modern patients and their physicians, the power of the liver to absorb, regenerate, grow, and function as a critical organ through the range of surgical and radiologic techniques, chemotherapy regimens, and emerging novel therapies, means that the myth of Prometheus has happier connotations as these strategies are integrated to better affect outcome.

EPIDEMIOLOGY

HCC is the fifth most common malignancy in the world.[1] Approximately half a million cases are diagnosed annually.[2,3] Wide geographic

and temporal variability has been recognized with regard to incidence rates, reflecting the different patterns of exposure to underlying risk factors for the development of the disease. Approximately 80% of cases worldwide arise in the developing world, where the major etiologic factor is exposure to HBV.[4] The highest-risk areas include eastern and southeastern Asia (median age-adjusted incidence rates [AAIRs] 35.5 and 18.3 per 100,000, respectively), middle Africa (median AAIR 24.2 per 100,000), eastern Africa (median AAIR 14.4 per 100,000), and parts of western Africa.[5] Even within these geographic areas, wide variations exist. Intermediate-risk areas include eastern and western Europe (median AAIR 5.8 per 100,000), northern Africa (AAIR 4.9 per 100,000), and South America (AAIR 4.8 per 100,000). The areas at lowest risk are northern Europe, Australia, New Zealand, and North America (AAIR 2.1 to 4.1 per 100,000). Temporal variations exist in the development of HCC, reflecting different patterns of exposure to etiologic factors. In high-risk areas, the age-specific incidence rates begin to increase after the age of 20 years, reflecting the importance of vertical transmission of HBV or acquisition of HBV infection in early childhood, and stabilizes at age 50 and above.[5] In low-risk areas, the incidence rate steadily increases with age, reflecting the later acquisition of viral infection or the impact of other factors such as alcohol-related cirrhosis. It also has been observed that in high-risk areas that have undergone development, the pattern of age-specific incidence rates resembles that in low-risk areas. In all populations, males are affected at a higher frequency than that for females.[6] The male-to-female ratio is further increased in high-risk areas.[5] The risk for migrants from high-risk areas remains high when compared with that for the host population into which they settle.[7] For instance, a 1.3- to 10.9-fold excess mortality from primary liver cancer (predominantly HCC) is reported among Asian migrants to North Ameica, Australia, or Europe.[7–9] Some studies have observed a diminution in risk in the descendants of migrants and in migrants living for a long time in the host country.[5,10] North America, although still categorized as a low-incidence region, has seen a dramatic increase in the incidence of HCC, owing primarily to an increasing incidence of HCV infection. El-Serag and coworkers reviewed records of 1605 patients diagnosed with HCC between 1993 and 1998 in 171 Veterans Affairs (VA) hospitals.[11] These workers noted a threefold increase in the age-adjusted rates for HCC associated with HCV, from 2.3 per 100,000 between 1993 and 1995 to 7.0 per 100,000 between 1996 and 1998.

ETIOLOGY AND PATHOGENESIS

An estimated 60% to 80% of patients present with HCC in the context of cirrhosis from liver parenchymal disease.[1] The risk factors for the development of HCC are therefore synonymous with those for the development of cirrhosis. The pattern of exposure to risk factors is age- and region-dependent. In broad terms, HCC occurring in developing countries generally is related to HBV infection in a younger population.[12] The impact of cofactors such as alcohol or tobacco use is less important than in the developed world, with the exception of aflatoxin contamination of food. The scale of the hepatitis B problem in the developing world is immense.[13] It is estimated that 360 million persons have chronic HBV infection.[14] Spread is predominantly by vertical transmission at the time of birth or by horizontal transmission in early childhood.[15] The probability of acquiring HCC increases with severity of liver disease. The annual risk of HCC is 0.5% for asymptomatic hepatitis B surface antigen carriers, whereas it rises 1000-fold in patients with HBV-associated cirrhosis.[16,17] In developed countries, the major etiologic factors consist of alcohol-induced cirrhosis and hepatitis C.[18] The annual incidence of HCC in the context of HCV-associated cirrhosis is 3% to 8%.[13,19] Nonalcoholic fatty liver disease (NAFLD) has emerged in recent times as an important cause of liver disease including HCC. This condition is associated with obesity, insulin resistance, and hyperlipidemia and commonly manfests with an asymptomatic elevation of liver enzymes. In a follow-up study of 129 patients with biopsy-proven NAFLD, HCC developed in 2.3% over a mean follow-up period of 13.7 years.[20] Other causes of HCC include hereditary hemachromatosis, Wilson's disease, and exposure to chemicals such as arsenic. An association between diabetes mellitus and HCC has been reported.[21] The relationship between tobacco use and HCC is unclear at present.

PATHOLOGY

HCC is an adenocarcinoma that may appear grossly as unifocal, multifocal, or diffusely infiltrative. With all patterns of HCC, a strong propensity for invasion of vascular channels is typical. Histologically, HCCs range from well-differentiated lesions that reproduce hepatocytes arranged in cords or small nests to poorly differentiated lesions. A distinctive clinicopathologic variant of HCC is fibrolamellar carcinoma, which occurs in young adults and has no association with cirrhosis or other risk factors.[22]

TUMOR BIOLOGY

HCC can metastasize to lung and bone late in its course, but for many patients, the tumor manifests as local-regional disease. Commonly, even after a complete and potentially curative resection, tumor recurs in the liver, owing to the common inciting event of chronic damage to the hepatocytes from hepatitis or cirrhosis.

CLINICAL PRESENTATION AND PATIENT EVALUATION

A majority of patients present with locoregional disease; however, in the later stages of HCC, metastases can develop. Recurrences after surgery are either intrahepatic or extrahepatic, with the most common sites of extrahepatic metastasis being lung, retroperitoneal lymph nodes, and bone. Most patients with HCC have few symptoms until late in the disease, when tumors are at an advanced stage. Clinical manifestations may include malaise, anorexia, abdominal pain, abdominal fullness due to ascites or mass effect, or weight loss. Because a majority of cases of HCC occur in patients with underlying cirrhosis, any worsening of hepatic function in a patient with previously diagnosed cirrhosis must prompt an evaluation for occult HCC. After a liver lesion is discovered, the patient should be asked about a history of hepatitis and risk factors for the acquisition of hepatitis (such as blood transfusion), ethanol abuse, or family history of metabolic diseases such as hemochromatosis or α_1-antitrypsin deficiency, all of which are risk factors for the development of HCC.

LABORATORY AND IMAGING STUDIES

Screening Tests

Measurement of serum AFP is the most widely employed screening test for HCC in an at-risk population. This test is recommended by the European Association for the Study of the Liver.[23] Unfortunately, its reported sensitivity ranges from only 25% to 65%,[24] prompting some authors to sound the death knell for serum AFP determination as a screening tool.[25] In a study of 1158 patients with HCC, it was found that serum AFP assay had a 54% sensitivity for a cut-off value of 20 ng/ml.[26] Only 18% of the patients had a serum AFP level in the diagnostic range (greater than 400 ng/ml). This study, however, in common with other AFP studies, had several methodologic flaws,[27] and properly conducted prospective studies are needed to address the issue of its utility in more definitive fashion.

One prospective study in an HBV carrier population randomized 5581 males to undergo either AFP testing every 6 months or no screening.[28] Although more HCCs (257 versus 117) and more early-stage cancers (28% versus 6%) were diagnosed in the screened population, overall survival was not different between the screened and unscreened populations.

The reported specificity in the literature ranges from 79% to 95%.[24] Elevated serum AFP does correlate with advanced tumor-node-metastasis (TNM) stage and other factors such as portal vein thrombosis and is associated with a poor outcome.[26,29] The role of other serologic tests such as assays for des-γ-carboxy prothrombin (DCP), *Lens culinaris* agglutinin-reactive fraction (AFP-L3), and insulin growth factor-1 (IGF-1) is unclear at present.[30]

Adjunctive screening with ultrasonography on an every 6-month basis also is recommended by published guidelines.[23] Of note, however, randomized controlled trials demonstrating a mortality reduction for this approach are lacking. The sensitivity and specificity of screening ultrasound in high-risk patients are 71% and 93%, respectively.[31] In one study in Taiwan with a high endemic hepatitis B infection rate, screening ultrasound examination in a selected at-risk population was found to decrease HCC-related mortality,[32] Ultrasound examination is cheap and safe but has low sensitivity for detection of small nodules, and its usefulness in this regard is particularly operator-dependent. Newer techniques such as helical computed tomography (CT) and contrast-enhanced magnetic resonance imaging (MRI) have a sensitivity exceeding 80%; however, their impact on mortality rates in at-risk populations needs to be evaluated prospectively before they are applied widely.

One randomized controlled trial has been performed using combined AFP testing and ultrasound examination ever 6 months in a defined "at risk" population. Nearly 19,000 people with HBV infection or a history of chronic hepatitis were randomized to undergo screening with ultrasound examination and AFP testing every 6 months or no screening. The study showed that screening reduced the HCC-related mortality rate by 37%.[33] Screening has not been proved to effect a mortality reduction in a Western population; however, it is unlikely that such proof in the form of a randomized controlled trial will be forthcoming, in view of the questionable ethics of randomizing at-risk persons to a control group.

In evaluating a potential screening test, it is vital to examine the effect on mortality rate, because any screening test has the potential to increase apparent median survival times by virtue of a lead-time bias. In addition, because of the global nature of this problem, any screening test should be cheap, relatively easy to perform, and reproducible.

Diagnostic Studies

All patients with suspected HCC also should undergo hepatitis serologic studies, including testing for hepatitis B surface antigen and hepatitis C polymerase chain reaction (PCR) assay. Depending on the degree of underlying liver damage from fibrosis, results on liver function testing and the prothrombin time may be abnormal. An assessment of liver function should be performed; the most commonly used assessment with the most widespread availability is the Child-Pugh score (Table 84-1). In cases in which an elevated AFP level and liver imaging findings suggest HCC, biopsy is unnecessary if the lesion is treatable with curative intent. In uncertain cases (normal AFP level or equivocal imaging findings, or both), biopsy may be indicated.

Table 84-1 Modified Child-Pugh Classification for Assessing Degree of Liver Impairment

Criterion	1 Point	2 Points	3 Points
Bilirubin	≤2	2–3	>3
Albumin	>3.5	2.8–3.5	<2.8
INR	<1.7	1.7–2.2	>2.2
Ascites	None	Mild	Moderate
Encephalopathy	None	Mild	Moderate

INR, international normalized ratio.

Adding the points for each patient's factors determines the Child-Pugh "class" as follows: A = 5–6 points, B = 7–9 points, C = 10–15 points.

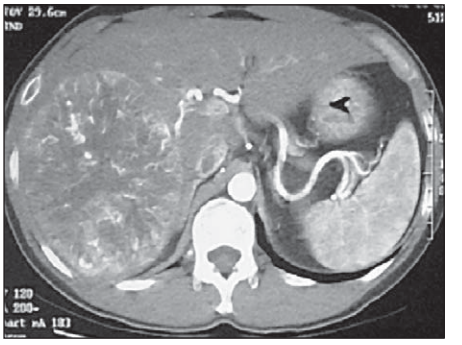

Figure 84-1 • Dynamic computed tomographic scan of a hypervascular right lobe hepatocellular cancer. (Courtesy of Spiros Hiotis, MD, New York University School of Medicine.)

Radiologic assessment in suspected HCC is extremely important in making the diagnosis and deciding which treatment modality is appropriate. Although ultrasound examination is widely available and therefore is often the first imaging study used to examine the liver in a patient suspected to have HCC, ultrasonography in fact is a poor test for characterizing liver lesions in patients with cirrhosis, in whom regenerating nodules often can be mistaken for tumor. On ultrasound scans, HCC typically will have a thin halo, lateral shadows, and posterior echo enhancement.

A more useful imaging test is dynamic CT. In the early phase, the tumor is seen as hyperdense because of its increased vascularity (Fig. 84-1). In the later phase, the tumor is seen as hypodense, as a result of washout of contrast from the more "porous" lesion. Magnetic resonance imaging (MRI) is becoming more frequently used as an imaging modality for evaluation of HCC. On MRI, HCC appears to be of low signal intensity on T_1-weighted images and of intermediate signal intensity on T_2-weighted images. MRI also can be useful in distinguishing HCC from benign lesions such as hemangiomas and regenerating nodules. Because of the propensity of this tumor type for extension into and along major vessels, contrast-enhanced CT or MRI is particularly useful for imaging the portal and hepatic veins. In addition, contrast-enhanced images provide critical information about multifocality, resectability, and presence of extrahepatic disease.

On imaging with CT or MRI, a common feature of HCC is its ability to invade vascular structures, such as the inferior vena cava (Fig. 84-2) or portal vein (Fig. 84-3). The tumor thrombus, which actually is an extension of the tumor itself into the vasculature, can be well seen on contrast-enhanced CT or MRI. The classic appearance is that of a mass within the vasculature, which fills and expands the lumen.

The angiographic appearance of HCC can be even more diagnostic because these tumors characteristically are hypervascular. Because angiography is invasive, it is difficult to recommend routine use of this study for diagnostic purposes. Angiography often is used, however, for therapeutic applications, such as tumor embolization with thrombotic agents with or without chemotherapy, and often detects small tumors not seen on other imaging modalities.

Although positron emission tomography (PET) using fluorine 18-labeled fluorodeoxyglucose (^{18}FDG) has been found to be useful to image a variety of tumors, its use in HCC has yielded disappointing results, with significantly lower standardized uptake value (SUV) for HCC compared with metastatic tumor or other primary liver tumors,[34] and an accuracy of 20% to 50%.[35–37] This is at least partly due to the marked difference in biologic behavior of these tumors, with high-grade tumors demonstrating increased SUV compared with lower-grade tumors.[37] Some investigators have found the SUV to be of prognostic value in those patients undergoing transplanta-

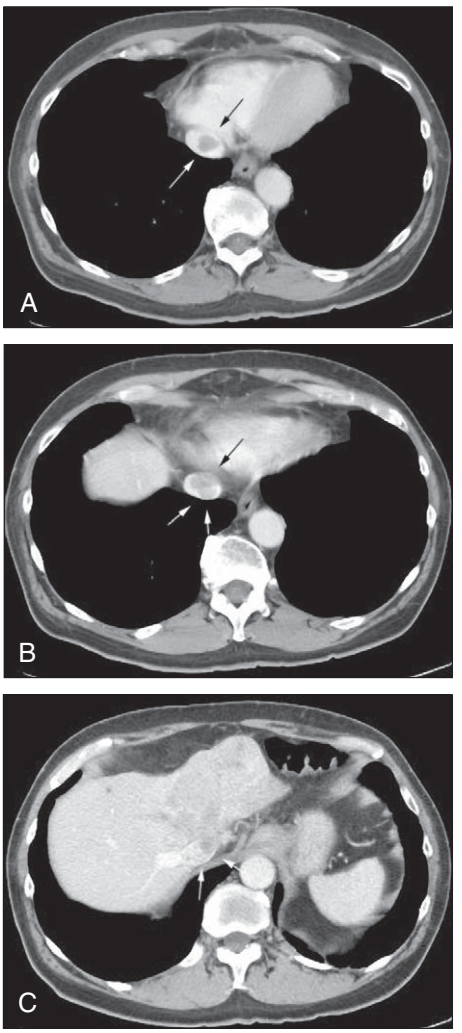

Figure 84-2 • **A–C**, Left lobe hepatocellular cancer with tumor invasion into the inferior vena cava *(arrows)*.

tion, although the practical significance of this variable is unclear.[37,38] The areas of greatest potential impact for FDG-PET appear to be in detecting extrahepatic disease before transplantation or resection and, in particular, in assessing response to therapy.[39,40] This latter role may be especially relevant in the era of novel therapeutics, which may result in metabolic changes in the tumor, rather than conventional response evaluation criteria in solid tumors (RECIST)-type dimensional changes.

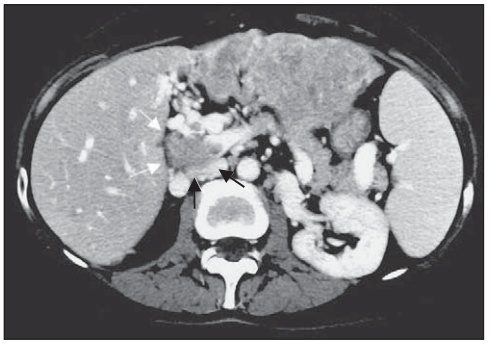

Figure 84-3 • Large left lobe hepatocellular carcinoma with vascular invasion into the portal vein, demonstrated by the classic finding of tumor thrombus filling and expanding the main portal vein *(arrows)*, with cavernous transformation of the portal vein.

STAGING CLASSIFICATION

The sixth edition of the American Joint Committee on Cancer (AJCC) staging classification uses size, presence of vascular invasion, lymph node status, and metastatic disease as prognosticators of outcome (Table 84-2). The main features of this revised system include the following: (1) all solitary tumors without vascular invasion, regardless of size, are classified as T1 because of similar prognosis; (2) all solitary tumors with vascular invasion, again independent of size, are combined with multiple tumors 5 cm or less in diameter and classified as T2 because of a similar prognosis; (3) multiple tumors larger than 5 cm and tumors with evidence of major vascular invasion are combined and classified as T3 because of a similarly poor prognosis; and (4) stage IV refers to metastatic disease only. The subcategories IVA and IVB have been eliminated.

The sixth edition classification has been validated by several investigators. Lei and colleagues applied the classification schemes from current and previous editions to a cohort of 440 patients who underwent curative resection for HCC and found that the current staging system accurately stratified patients into defined prognostic groups.[41]

Table 84-2 American Joint Commission on Cancer Staging System* for Hepatocellular Carcinoma Including Intra-Hepatic Bile Ducts: Tumor-Node-Metastasis (TNM) Classification

Stage	Grouping		
I	T1	N0	M0
II	T2	N0	M0
III-A	T3	N0	M0
III-B	T4	N0	M0
III-C	Any T	N1	M0
IV	Any T	Any N	M1

DEFINITIONS

Primary tumor (T)

TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor.
T1	Solitary tumor without vascular invasion.
T2	Solitary tumor with vascular invasion; or multiple tumors, none more than 5 cm.
T3	Multiple tumors >5 cm, or tumor involving a major branch of the portal or hepatic vein(s)
T4	Tumor(s) with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum.

Regional lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

Distant metastasis (M)

MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

PROGNOSIS

HCC is unique among other gastrointestinal cancers in that it frequently occurs in the setting of an already diseased organ. The prognosis therefore depends not only on an anatomic assessment of the tumor, as reflected by the TNM system, but also on the extent of underlying liver damage. Scoring systems that evaluate only tumor characteristics (e.g., TNM) or only liver function (e.g., Child-Pugh) are deficient. A number of prognostic scoring systems have attempted to incorporate non-tumor-related factors to better define prognosis. The Barcelona Clinic Liver Cancer (BCLC) staging classification divides cases into four categories of differing severity.[42] The Cancer of the Liver Italian Program (CLIP) looks at Child-Pugh class, tumor morphology (number of nodules and volume), AFP level, and presence of portal vein thrombosis.[43] This scoring system has been externally validated by a number of studies[43,44] and has been recommended by the American Hepato-Pancreatic-Biliary Association/American Joint Commission on Cancer Consensus Conference on Staging of Hepatocellular Carcinoma.[45] Because of differing prognoses for patients with HCC stemming from ethnic diversity and variation in viral etiology (e.g., either HBV- or HCV-related), it is unlikely that one scoring system will suffice for all populations. For example, the Chinese University Prognostic Index (CUPI) was developed in a cohort of patients with predominantly HBV-related HCC and may be more applicable to that population.[46]

Outcome

Overall survival after liver resection or transplantation has been reported from numerous investigators (Tables 84-3 to 84-5). In patients with unresectable disease, the survival rate is dismal, with a median survival time shorter than 12 months even with chemotherapy.[47,48]

Patterns of Recurrence

At 5 years after resection of HCC, the recurrence rate has been reported to be between 30% and 60%.[49–51] Cirrhotic patients experience recurrence at a much greater rate than that observed for noncirrhotic patients. The liver is the first site of recurrence in up to 90% of these patients.[49,52,53] Other common sites of recurrence include lung, peritoneum, bone, and brain.[54,55] It is uncommon for patients to present with isolated extrahepatic recurrences.[54] The median time to

recurrence is approximately 24 months, although the range is highly variable.[55]

The most well-accepted risk factors for recurrence include tumor size, multifocal disease, vascular invasion, and high preoperative AFP level.[50,53,56–59] Other risk factors include tumor differentiation,[58] tumor rupture,[57] and cirrhosis,[53,57,60] particularly when tumors are stratified according to size.[50] Of interest, multifocal HCC has been found to be a risk factor for recurrence in few studies.[61,62] Some evidence also suggests that outcome after resection is improved in patients with HCC associated with hepatitis B compared with that in patients with hepatitis C-associated HCC.[63]

PRIMARY TREATMENT

Resection

Partial Hepatectomy

Surgical excision by partial or total hepatectomy represents the only potentially curative therapy for HCC. Resectability for any hepatic tumor, including HCC, is dependent on the patient's ability to withstand a major surgical intervention, absence of extrahepatic disease, and favorable anatomic criteria. The results of surgical resection are influenced greatly by the preoperative liver functional status. Cirrhosis adversely influences surgical outcome in many ways and often is the only determinant that results in an unresectable status. Because the liver parenchyma in cirrhotic patients is fibrotic and firm, retraction and isolation of intraparenchymal vessels are hazardous surgical maneuvers that are associated with increased risk of hemorrhage during resection of HCC. Patients with cirrhosis also are likely to have thrombocytopenia related to portal hypertension, further exacerbating the potential for hemorrhage. Indeed, portal hypertension, even in the face of relatively well preserved hepatic synthetic function, is an ominous finding and generally excludes resection as a treatment option. Finally, cirrhosis is associated with decreased regenerative capacity, increasing the risk of liver failure after partial resections. For these reasons, hepatic resection in patients with cirrhosis carries a significantly higher operative risk than that associated with resection in noncirrhotic patients, and patients with cirrhosis and HCC typically are better served with transplantation if indications regarding tumor size and number are present.

Outcome after resection in noncirrhotic patients is excellent; partial hepatic resection can be performed with a less than 5% operative mortality rate and is associated with a 5-year survival rate in excess of 30% (see Table 84-3). For noncirrhotic patients with resectable tumors, therefore, surgical resection represents the treatment of choice. The adverse influence of cirrhosis on surgical outcome, however, is well documented by clinical data: The operative mortality rate is greater than 10% even at large-volume centers (see Table 84-3). Nevertheless, cirrhotic patients who survive the operation have a 5-year survival rate of approximately 30% (see Table 84-3).

Thus, patient selection for surgery depends primarily on hepatic function. Over the years, many complex methods of evaluating liver function have been tested to assist in patient selection. Assessment by Child-Pugh classification (see Table 84-1) remains the most useful and most widely used in western series, although the indocyanine green (ICG) retention rate commonly is used in Asia. Few surgeons are willing to perform hepatic resection for patients with Child-Pugh C liver status, and the operative mortality rate may be as high as 30% for patients with Child-Pugh B cirrhosis. These patients clearly are better served with transplantation if they meet accepted criteria. Therefore, most surgeons will consider resection only for patients with Child A, or in some cases, Child B, liver function. In patients with cirrhosis but with preserved liver function, no difference in long-term survival has been observed even when a larger tumor size required extended hepatectomy, rather than more limited resection.[64,65]

HCC has a great propensity for vascular extension, and the presence of tumor thrombus within the main portal vein or vena cava (see Figs. 84-2 and 84-3) is an ominous sign that should be regarded as a contraindication to resection. Liver resections accompanied by portal venous tumor thrombectomies are unlikely to yield long-term survival. Multiple lesions do not preclude surgical resection or ablation (or both),[50,60,66] because, in the highly selected patients whose tumor is amenable to complete resection or ablation, 5-year survival rates can still be expected to be between 20% and 30%.[50,60]

Total Hepatectomy and Transplantation

Total hepatectomy and liver transplantation is an attractive option for the patient with cirrhosis and cancer, because it may potentially cure both the underlying liver disease and the tumor. Generally well-accepted indications for liver transplantation (Milan criteria) include Child-Pugh B or C status in patients with a single HCC less than 5 cm in size, or fewer than three tumors all less than 3 cm in diameter. Using these criteria, the most recent series have found a 5-year survival rate of approximately 70%, with a 15% chance for recurrence (see Table 84-4). In comparing the results of transplantation with those of resection, it is important to recognize the inherent selection bias of choosing not only those patients with small HCC, associated with a better prognosis, but additionally the bias of performing transplantation only in those patients whose disease has not progressed while they are waiting for an organ. Thus, the patients who receive liver transplants are those whose tumors have a less aggressive natural history. This point is demonstrated by a recent intention-to-treat analysis that found "drop-out from waiting list" to be the sole survival predictor.[41] This study noted that the 2-year survival rate of patients evaluated for transplantation was reduced from 84% to 54% during two separate time periods in which the waiting time increased markedly, so that more patients were excluded from transplantation as a result of progression of disease. Survival was significantly worse for patients on the transplant list than for patients who were the best candidates for resection.[67]

In addition, two recent papers have evaluated the outcomes in patients undergoing liver resection with tumors that fit the Milan criteria (see Table 84-5). In this select group of patients, the overall survival rate at 5 years was 70%, similar in outcome to that for liver transplantation.[59,68] As expected, the risk of intrahepatic recurrence in patients undergoing resection was higher than after liver transplantation. To address this problem, the authors suggested a strategy of salvage transplantation for those patients whose tumor recurs after hepatectomy.

In practice, many obstacles exist to limit the applicability of transplantation to a large number of patients worldwide. The greatest obstacle is the lack of available organs for transplantation. Some U.S. centers report long waiting times, with nearly equal numbers of patients being excluded from transplantation while on the waiting

list due to progression of disease and of those who receive transplants.[69] In Asian countries, where the need for donor organs is greater, and social and cultural obstacles to organ donation are the norm, livers are in even greater shortage than in the United States. In addition, because of organ scarcity, it is vital that a thorough cost-effectiveness analysis be performed to compare results after liver transplantation for benign versus malignant disease.

The cost associated with the transplantation procedure is also a major obstacle. Although perioperative morbidity and mortality rates are declining, in most centers, the mortality rate is still substantial. Table 84-4 summarizes some of the published data to date, including only relatively recent trials with more than 50 patients. It is clear that operative mortality rates can be as high as 10% to 20%,[70,71] and recurrence rates, as high as 50%,[72] in these series.[61] Nevertheless, for patients with liver dysfunction, total hepatectomy with liver transplantation represents the only potentially curative option, because few of these patients can tolerate major hepatectomy. To demonstrate this point, in noncirrhotic HCC, survival is similar after hepatectomy or transplantation, whereas in patients with cirrhotic HCC, survival was significantly improved after transplantation compared with hepatectomy at each TNM stage.[73]

Long term results of HCC treated by transplantation also are related to extent of original liver involvement, with the best results reported in patients with small HCCs discovered incidentally during transplantation performed for cirrhosis.[74] Clearly, large tumor size and the presence of vascular invasion are associated with a higher risk for recurrence after transplantation.[61,75,76]

Recently, several authors have reported the results of living related donor liver transplantation (LDLT) for HCC. Because this procedure requires a right hepatectomy in a healthy donor, concerns have arisen about the safety and ethical implications of this procedure. In addition, sporadic reports of deaths in donors from the United States and elsewhere have intensified these concerns. In one of the largest series reporting the results of LDLT in 71 patients, with approximately 40% due to HCC, the mean waiting time to transplantation was markedly reduced from 414 (for cadaveric organ transplants) to 83 days (for living related donor transplants), with a recurrence rate of 15%.[77]

To summarize, patients with HCC without liver dysfunction should be considered for resection, whereas patients with HCC arising in the setting of Child-Pugh B or C cirrhosis, and with disease extent meeting the Milan criteria, should be referred for transplantation.

Cryosurgery

Cryoablation is becoming an increasingly popular method for treating HCC. In this modality, probes that are cooled by liquid nitrogen or argon are introduced into tumors, followed by freezing under ultrasound guidance until an adequate volume of tumor plus a 1-cm margin has been treated (Fig. 84-4). Cryosurgery has great theoretical advantage in the treatment of tumors in cirrhotic patients in that very little nonmalignant parenchyma is damaged; thus, patients with cirrhosis often are still candidates for the procedure. In addition, this technique is useful for treating bilobar tumors, whether with cryosurgery alone or with cryosurgery plus resection.[78]

The major disadvantage is the need for general anesthesia and laparotomy, because this technique generally is not performed percutaneously. In addition, some tumors are not treatable with cryosurgery, primarily owing to size, because it is clear that complications increase as more tumor volume is destroyed. A number of series have been published clearly demonstrating safety of such an ablative approach in experienced hands.[78,79]

Radiofrequency Ablation

Radiofrequency ablation (RFA) is an excellent alternative to cryosurgery and offers the advantage of percutaneous as well as intraoperative application (Fig. 84-5). Some authors have suggested that both the complication rate and the recurrence rate after RFA is lower than after cryosurgery.[79] No true prospective comparative trials, however, have been conducted. The disadvantage of RFA is that it is difficult to monitor under real-time ultrasound guidance, unlike in cryosurgical ablation, because no distinct demarcation between viable tissue and RF-ablated tissue can be seen. In a comparison of ethanol injection and percutaneous RFA, data from a randomized trial showed improved 4-year survival after RFA (74%, versus 57% after ethanol injection).[80]

In the largest study on the use of RFA in patients with cirrhosis and HCC, 194 patients underwent RFA of their tumor.[81] The complication rate was 12%, with local recurrence in only 5% after a median follow-up period of 35 months, although recurrent disease developed at other sites within the liver in a large number of patients. Of note, one of the additional advantages of RFA is that it is useful for treatment of recurrent disease.[82]

Microwave Ablation

Ablation of liver tumors using percutaneous microwave coagulation is a relatively new technique that will require further prospective trials before the technique can be widely adapted to treatment for HCC. The advantages of this technique are the higher temperatures it can achieve in a shorter time and the capability for use of multiple probes. In a preliminary study, survival rates for patients with primary disease and recurrent HCC were 47% (5-year) and 50% (4-year), respectively.[83]

Ethanol Injection

Percutaneous ethanol injection is a highly effective treatment for small HCC, with a 3-year survival rate of 60%[84] and a 5-year survival rate of 45%.[85] In this technique, absolute alcohol is injected into liver tumors percutaneously under CT or ultrasound guidance, which results in tissue necrosis[86] (Fig. 84-6). Tumors that are amenable to ethanol injection include those less than 4 cm in diameter, and usually fewer than 4 in number. This method may be curative for small lesions, but trials comparing this technique with other methods of ablation are needed.

In one of the only studies comparing ethanol injection with RFA for patients with small HCC, effective tumor necrosis occurred using either technique, but RFA required fewer treatments to achieve this effect (1.2 sessions for RFA versus 4.8 sessions for ethanol). More complications, however, occurred in the patients undergoing RFA.[87] Thus, treatment decisions for these patients should be individualized.

Hepatic Artery Embolization

Because a large majority of patients present with liver-only disease, which is technically unresectable owing to the presence of multiple, bilateral tumors or underlying hepatic dysfunction, other forms of therapy are acutely needed for HCC. These tumors are intensely vascular and are fed primarily by the hepatic artery; accordingly, embolization of the feeding arterial vessels has been shown to be one possible treatment option for these patients. A recent randomized controlled trial (RCT) compared patients with Child A or B cirrhosis with unresectable HCC who were randomized to receive treatment by chemoembolization or embolization or conservative treatment. The trial was stopped early because of the finding of a survival advantage for chemoembolization, with a 2-year survival rate of 63%, compared with 27% for control and 50% for embolization.[88] In addition, in a prior RCT performed by the same investigators, no difference was noted in survival for embolization compared with conservative treatment.[89] Lee and colleagues assessed the benefits of transcatheter arterial chemoembolization compared with standard hepatic resection in an Asian population of 182 patients. Both groups received initial chemoembolization performed using lipiodol CT. Ninety-one patients who subsequently underwent surgery and 91 who refused surgery were allocated to receive serial chemoembolizations. These investigators observed that chemoembolization appeared to be as effective as resection in the population of patients with locally

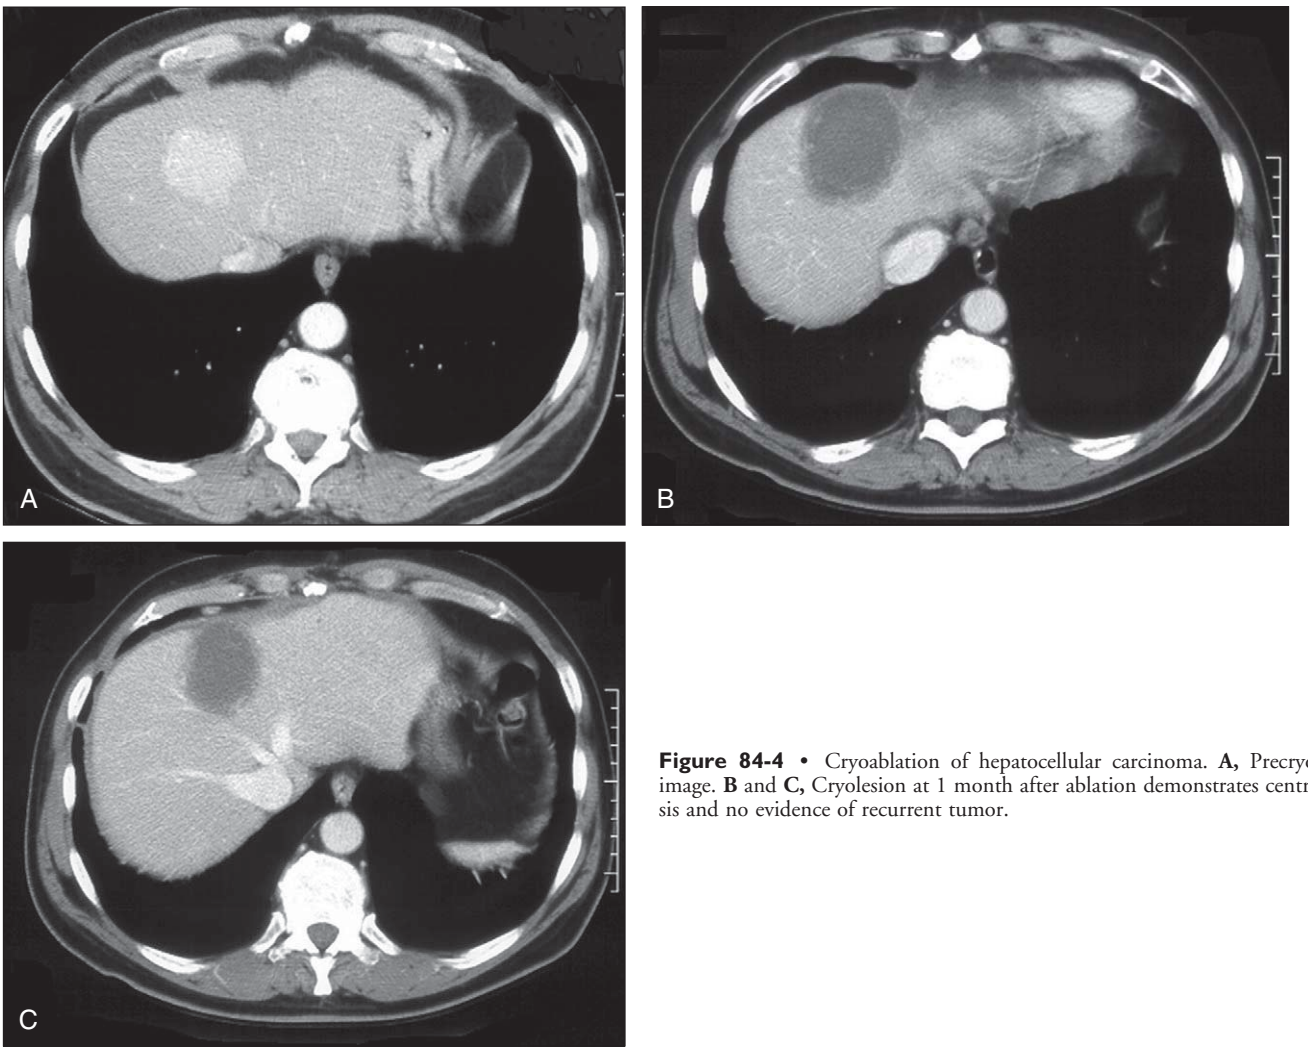

Figure 84-4 • Cryoablation of hepatocellular carcinoma. **A,** Precryoablation image. **B** and **C,** Cryolesion at 1 month after ablation demonstrates central necrosis and no evidence of recurrent tumor.

advanced liver tumors with adequate liver function. Thus, chemoembolization appears to be a potentially viable treatment option for patients with either unresectable or resectable disease, and additionally, it may have an advantage over conservative treatment.

Chemotherapy

It is a fair summation of more than 20 years of investigational work that systemic chemotherapy has had a disappointingly low level of impact on this disease.[90] This limitation is related mainly to the inherent insensitivity of HCC to chemotherapeutics.[91] HCCs express the multidrug-resistant gene *MDR1*,[92] and the underlying hepatic dysfunction that often accompanies HCC precludes or limits aggressive systemic therapies. The most well-studied agent has been doxorubicin.[90] In two recent phase III studies in which doxorubicin therapy served as the control treatment, response rates of 4% and 10.5% were observed for single-agent doxorubicin, with median survival times of 31 weeks and 6.8 months respectively.[93,94] A range of other chemotherapeutic agents, including cisplatin, gemcitabine, capecitabine, paclitaxel, irinotecan, etoposide, and fludarabine, have been investigated and found to have minimal activity.[95–101]

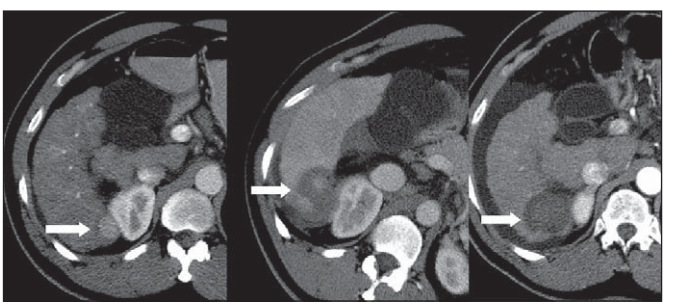

Figure 84-5 • Percutaneous radiofrequency ablation of hepatocellular carcinoma *(arrow)* in a high-risk patient with advanced cirrhosis. *Left panel*, Preablation image; *middle and right panels*, postablation images.

Combination chemotherapy is associated with modestly improved response rates at the expense of greater toxicity. No clear standard has emerged. One of the more promising but toxic combinations is a regimen of cisplatin (Platinol), interferon-α-2b, doxorubicin (Adriamycin), and 5-fluorouracil (5-FU) (PIAF), initially published by Leung and coworkers.[102] The initial phase II report was provocative, noting a high partial response rate of 26%, and of the patients with a baseline elevation of AFP level, 42% demonstrated a greater than 50% decline in AFP level with treatment. Additionally, nine patients were able to undergo surgery, and in four, no evidence of viable tumor was noted at the time of surgery. Of concern was the high rate of myelosuppression and mucositis, and two treatment-related deaths occurred in the context of neutropenic infection. Poor prognostic factors predictably included high Okuda stage, presence of cirrhosis, and vascular involvement.

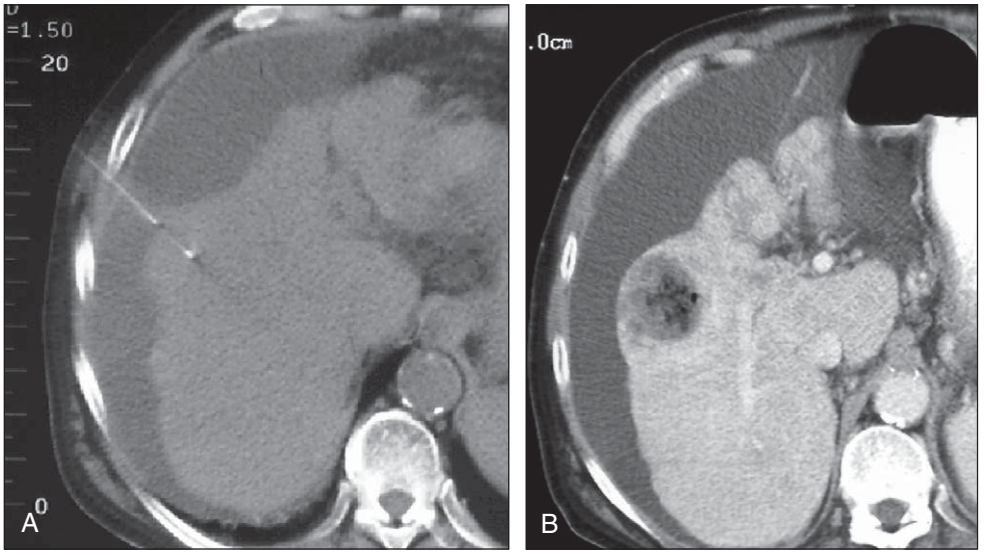

Figure 84-6 • **A,** Percutaneous needle placement under noncontrast computed tomography (CT) guidance for alcohol ablation of small hepatocellular carcinoma in a cirrhotic patient with ascites. **B,** Post-ablation contrast-enhanced CT scan.

Subsequently, Yeo and associates reported a randomized phase III study of 188 patients comparing PIAF with doxorubicin as a single agent.[94] No statistically significant difference in median survival times was found. The combination of gemcitabine and oxaliplatin has been investigated by Taieb and colleagues in a small trial (comprising 21 patients) using two different schedules.[103] Overall response rate was 19%, with disease stabilization in 48% and a median survival time of 12 months.

Novel Therapies

The poor efficacy of chemotherapy in this tumor type probably means that merely combining cytotoxics in different regimens is a strategy unlikely to result in dramatic advances in the way this disease is treated. It is likely that the combination of chemotherapy with so-called biologic therapies—that is to say, therapies that are targeted to a particular known aspect of tumor biology—offer the best hope for more effective therapies in the intermediate-term future.

HCC is a vascular tumor. As in other diseases, high levels of circulating vascular endothelial growth factor (VEGF) have correlated with a poor prognosis.[104,105] The proof of the therapeutic principle of anti-VEGF therapy has been demonstrated in colorectal, breast, and lung cancer with bevacizumab,[106] a humanized monoclonal antibody that targets VEGF. Sorafenib is an oral multikinase inhibitor that targets VEGF receptor (VEGFR) (−2/−3), in addition to RAF kinase and PDGFR-β tyrosine kinases.[107] Abou-Alfa and colleagues performed a large phase II study examining the use of single-agent oral sorafenib in 137 patients with inoperable HCC and Child-Pugh A or B status, with no prior systemic treatment.[108] Median time to disease progression was 4.2 months, and median overall survival time was 9.2 months. Although objective partial response rate was 2.2%, 33.6% achieved stable disease. At the ASCO 2007 annual meeting, data were presented from a large phase III placebo-controlled trial of sorafenib for the first-line treatment of HCC.[109] In this important study, 602 patients with well-preserved liver function (Child-Pugh A status in greater than 95%) were randomized to receive either placebo or sorafenib 400 mg twice daily. Median overall survival, the primary endpoint of the study, was significantly better for the sorafenib arm (10.7 vs. 7.9 months; hazard ratio, 0.69; 95% CI, 0.55 to 0.87; $P = 0.0006$), and the study was closed early because of the improved efficacy based on a preplanned stopping rule. This is the first study to demonstrate a statistically improved survival for any agent in patients with advanced HCC.

With regard to other antiangiogenic agents, bevacizumab has demonstrated only modest single-agent activity[110] in HCC phase I studies. This finding mirrors the experience in other diseases, in which the best results were obtained in combination with chemotherapy. Zhu and associates performed a phase II trial of bevacizumab with a gemcitabine-oxaliplatin combination,[111] obtaining a relative risk of 20%, with stable disease in 27%, median progression-free survival time of 5.3 months, and median overall survival time of 9.6 months. Ligand binding of epidermal growth factor receptor (EGFR) can lead to activation of the Ras/Raf/Erk/MAPK cascade, which is believed to be of major importance in HCC carcinogenesis.[112] EGFR can be inhibited extracellularly by antibody binding or intracellularly through inhibition of its tyrosine kinase. Cetuximab is a chimeric monoclonal IgG1 antibody directed against the EGFR. It has been shown to arrest cell growth in HCC cell lines.[113] A phase II study however showed no activity in 30 patients with advanced HCC.[114] Erlotinib is an oral EGFR tyrosine kinase inhibitor. Two phase II studies have demonstrated modest efficacy in HCC.[115,116] The relative tolerability of erlotinib and its oral formulation makes it an attractive consideration for investigation in chemoprevention and in the adjuvant setting. The combination of erlotinib and bevacizumab also has been explored, with early evidence of activity for this combination in a phase II single-arm study that showed a 22% response rate and 55% progression-free survival at 16 weeks.[117]

Intra-arterial Chemotherapy

The regional administration of chemotherapy using the hepatic artery has the attraction of achieving high concentrations of drug in the liver and minimizing systemic exposure, particularly if drugs are used that undergo a high degree of first-pass metabolism. The usual coexistence of cirrhosis complicates the local delivery of drugs however, and possible arteriovenous shunting may result in unwanted systemic exposure.[118] Numerous small phase II studies have examined various combinations, the most common components being floxuridine (FUDR), mitomycin, doxorubicin, and cisplatin.[118–121] The optimal drug combination to be administered intra-arterially is not known. In a study of 116 patients with HCC and portal venous invasion (an adverse prognostic sign), Obi and colleagues administered thrice-weekly intramuscular interferon with alternate-week intra-arterial 5-FU. Nineteen patients (16%) achieved a complete response, and 42 patients (36%) had a partial response.[122]

ADJUVANT THERAPY

A compelling rationale exists for use of adjuvant therapy for HCC based on the high rate of intrahepatic and extrahepatic recurrence

after potentially curative resections, as well as the development of second primary tumors within the diseased liver. Unfortunately, no adjuvant strategy has been shown to be effective in prospective controlled studies.

In a prospective randomized controlled trial, 64 patients who underwent orthopic liver transplantation for HCC were randomized to receive doxorubicin or no adjuvant treatment.[123] No difference was observed in outcomes for the two arms. Schwartz and associates conducted a larger meta-analysis of 13 randomized trials, 3 involving systemic adjuvant therapy, 4 assessing the role of HA chemoembolization, and 6 assessing a variety of other therapeutic agents.[124] The overall conclusion was similar in that neither systemic or intra-arterial-based chemotherapy nor chemoembolization has been shown to improve overall or disease-free survival after resection, in comparison with that observed with no treatment. Reservations with regard to the quality of the data included small size of trials in patients with heterogeneous underlying liver function and a lack of documented effect for many of the agents tested in a setting of more advanced disease.

One provocative study from Hong Kong assessed a single-dose treatment of intra-arterial iodine 131-labeled lipiodol as adjuvant therapy compared with observation for patients with hepatitis B-related HCC.[125] The study was terminated early after 43 patients were enrolled when an interim analysis demonstrated a marked difference in survival for patients in the treatment group: 57.2 versus 13.6 months. The 3-year survival rates were 86.4% for the treatment group and 46.3% for the control group. Additional larger, randomized trials of this agent are needed in broader patient groups with HCC to investigate its utility.

Early invasion of tumor into the portal venous system is believed to be an important factor underlying postresectional tumor recurrence.[126] This potential mechanism for recurrence forms the basis for considering direct intraportal chemotherapy as an adjuvant strategy. In a small study, Chau and colleagues demonstrated that this approach using a combination of 5-FU, cisplatin, and doxorubicin was safe and feasible. When compared with case-matched control subjects, patients with early-stage disease who received this regimen demonstrated an improvement in disease-free and overall survival[127] (Box 84-1; Fig. 84-7).

OUTCOME AFTER TREATMENT OF RECURRENCE

Because recurrent HCC may be amenable to potentially curative resection, early detection of such recurrences is extremely important. Multiple series have shown that 5-year survival rates between 20% and 82% are possible in patients with recurrent HCC that is resectable.[52,128–131] In addition, repeated liver resection in this group is safe, as demonstrated by one study that found no difference in blood loss, operative time, and incidence of complications when comparing repeated liver resections with first-time resections.[128] Therefore, in patients found to be medically fit for surgery, with adequate liver reserve and technically resectable tumors, repeat hepatic resection is the therapy of choice. In patients who are not candidates for repeat resection but have isolated liver recurrence, liver transplantation may be possible. In patients who are not candidates for any surgical intervention, percutaneous RFA, microwave ablation, and ethanol injection are effective methods to treat recurrent liver disease.[82,83,85] In addition, transcatheter arterial embolization often is an option to treat recurrent HCC. One final option for treating unresectable disease is intra-arterial administration of yttrium 90 particles, although efficacy data are limited.[132]

TREATMENT COMPLICATIONS

After resection, postoperative morbidity occurs in approximately 40% of patients, consisting primarily of transient hepatic insufficiency, intra-abdominal abscess or biloma, gastrointestinal bleeding, and cardiopulmonary complications.[50] Postoperative mortality rates range from 3% to 12% in most series (see Tables 84-3 and 84-4). After transplantation, the 90-day mortality rate is approximately 15% (see Table 84-5).

Box 84-1. TREATMENT OF HEPATOCELLULAR CARCINOMA

Patients with tumors suspicious for HCC based on known risk factors (hepatitis or alcohol) and/or preoperative contrast-enhanced imaging undergo serologic testing for AFP. In patients with elevated AFP and surgically resectable lesions, definitive treatment is then performed (see Fig. 84-7). In patients with known risk factors and a new liver lesion found on axial imaging, we pursue definitive treatment without biopsy. Only in patients in which both the diagnostic imaging is not classic for HCC and the AFP is normal would we consider biopsy of these lesions. This is for two main reasons: (1) suspicious lesions must be dealt with surgically regardless of biopsy results, and (2) the small but real risk of needle-tract seeding.[1,2]

Evaluation of liver functional reserve uses the Child-Pugh classification. Preoperative staging evaluation is performed using abdomen and pelvis contrast-enhanced biphasic CT with thin sections (5 mm) of the liver. Patients with disease limited to the liver undergo treatment according to the following algorithm shown in Figure 84-7.

Patients are not considered surgical candidates if they have high medical risk that precludes surgery. Select patients with bilobar tumors may be treated either with multiple segmental resections or a combination of resection and ablation; however, recurrence in this setting is extremely high, and ablative modalities are probably more appropriate. Select patients with isolated portal vein involvement may be considered candidates for hepatectomy with concomitant portal vein resection.

Patients with unresectable disease not amenable to alcohol injection or percutaneous RFA are first considered for embolization. In patients who are not candidates for embolization, we attempt to place these patients on a clinical trial, particularly since the response to traditional systemic chemotherapy is so poor.

FOLLOW-UP PROGRAM

After surgical treatment of HCC, scheduled follow-up evaluations are extremely important to look for recurrent disease, which can occur in up to two thirds of patients after potentially curative resection. Many patients with recurrent disease actually have metachronous second primaries, which develop in the setting of cirrhosis owing to the fact that the entire liver is diseased and therefore susceptible. These recurrent or new hepatomas can be treated effectively only if discovered early.

Associated Medical Conditions

The follow-up program also must aim to prevent and treat complications of associated parenchymal disease, which is common in this patient population. Patients may need treatment for alcoholism, and patients with hemochromatosis should be treated for iron overload. Of greatest importance is adequate treatment to prevent the complications of portal hypertension, because it is estimated that up to one quarter of patients who die after diagnosis of liver cancer succumb to gastrointestinal bleeding from portal hypertension.[133]

Recommended Follow-up Program

Routine follow-up evaluation after resection of HCC should include an office visit 2 to 3 weeks after hospital discharge. Liver transaminases, as well as tumor markers, are assessed. For classic HCC, the tumor marker is AFP[134]; for the fibrolamellar variant of HCC, levels of neurotensin or other markers[135,136] may be elevated in the serum

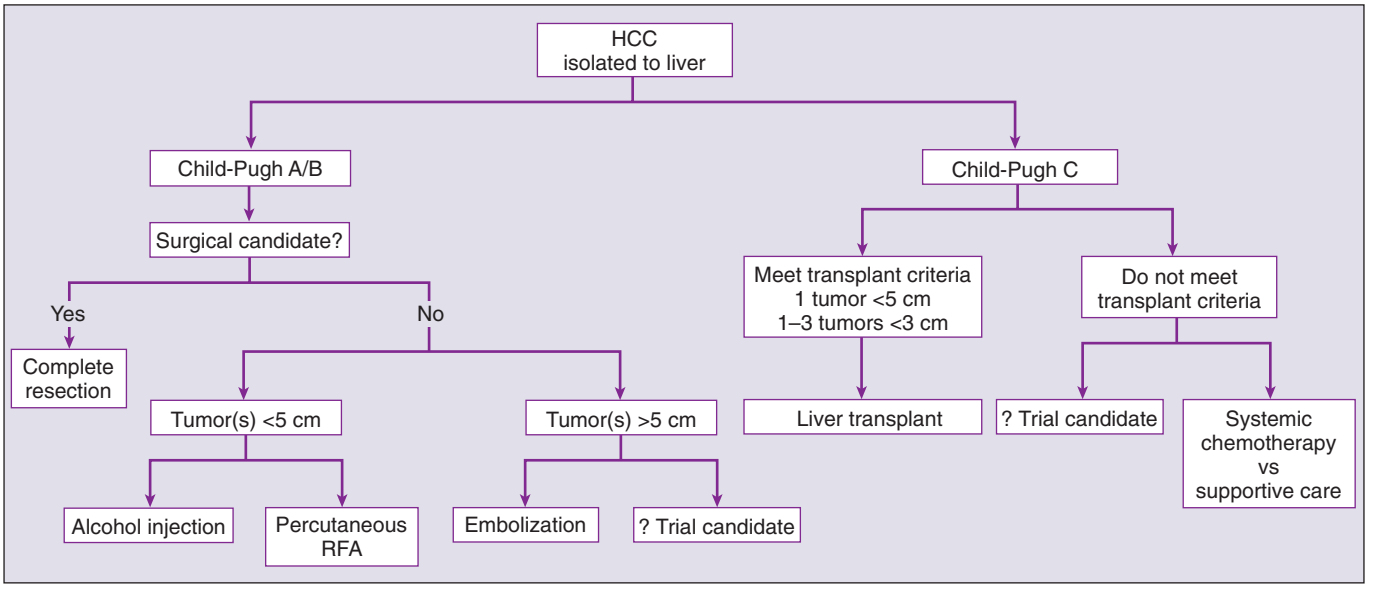

Figure 84-7 • Treatment algorithm for hepatocellular carcinoma (HCC). RFA, radiofrequency ablation.

before resection. A return of tumor markers to normal levels postoperatively should dictate a routine follow-up approach.

The routine follow-up program generally consists of office visits every 3 to 6 months with history and physical examination and measurement of liver function tests and tumor markers. Patients should be asked about symptoms of worsening portal hypertension or liver failure and symptoms of biliary obstruction, including itching or changes in stool or urine color, primarily because a significant proportion of patients die from liver failure, not HCC.[137] New-onset right upper quadrant pain or bone pain should prompt investigation by appropriate radiologic examinations. Physical examination should evaluate for new masses, worsening ascites, and jaundice. The follow-up program also should include contrast-enhanced abdominal CT every 6 months, with a chest radiograph obtained yearly. Five years after resection, office visits should be reduced to every 6 months.

ISSUES FOR THE FUTURE

Because the incidence of hepatocellular cancer is rising, it is imperative to develop improved screening tests that increase the sensitivity and specificity for detecting HCC. Some authors have suggested that a more sensitive means to detect recurrence may be evaluating the serum for the presence of AFP messenger RNA (mRNA) by reverse transcription polymerase chain reaction (PCR) assay. In this study, the postoperative presence of AFP mRNA was an independent prognostic factor for HCC.[138] Molecular studies to assess for genes associated with a high risk of recurrence have shown promise in preliminary studies but require further evaluation.[139–141] Clearly, it would be helpful if the molecular characterization of specific genes associated with an increased risk for developing HCC also could help with either early detection or prevention of the disease.[142]

GALLBLADDER CANCER

INTRODUCTION

Because tumors arising in the gallbladder often are asymptomatic until late in the course of the disease, they frequently manifest at an advanced, often unresectable, stage. Gallbladder cancer is a rare malignancy with a dismal outlook owing to its insidious onset, propensity for local invasion, and rapid disease progression. Gallbladder cancer also frequently manifests as an incidental finding during laparoscopic surgery for ostensibly benign disease. The argument for further definitive therapy in this context has been convincingly made for surgery and less so for systemic therapy and radiotherapy, but in all cases the rarity of the disease has resulted in a dearth of prospective randomized phase III studies to guide therapy at critical decision points. The available data are from small, single-institution and often retrospective studies. Although surgery remains the only curative option, most series report a less than 5% overall 5-year survival rate, probably owing to the fact that 40% of patients present with advanced disease.[143]

EPIDEMIOLOGY

Only 6000 to 7000 new cases of gallbladder cancer are diagnosed in the United States each year.[144] Gallbladder cancer is more common in women than in men in all populations, and in some geographic areas the rates are three times higher for women. Incidence increases with age in all populations.[143,145] Certain geographic areas are characterized by a high incidence of gallbladder cancer, including South America and India. A high incidence also has been documented in North American Native Americans and Mexican Americans, but the highest incidence of gallbladder cancer is in women from La Paz, Bolivia (15.5 cases per 100,000 population).[145] The geographic variability clearly correlates with populations that have a higher rate of gallstone formation.[145] To further strengthen this association, the mortality rate from gallbladder cancer has been inversely correlated with cholecystectomy rates in Chile, a high incidence region.[146]

ETIOLOGY AND PATHOGENESIS

Although an increased risk of gallbladder cancer with cholelithiasis is recognized, gallbladder cancer subsequently develops in less than 0.5% of patients with gallstones.[147] Nevertheless, up to 85% of patients with gallbladder cancer are found to have gallstones.[148,149] The association of gallstones with carcinoma probably is related to chronic inflammation. Larger stones, greater than 3 cm in greatest dimension, are associated with a 10-fold increased risk of cancer.[150]

Besides gallstones, the other main associated risk factors include chronic infections of the gallbladder and environmental exposure to specific chemicals such as Thorotrast, a preparation of colloidal thorium dioxide. Thorotrast is a radiologic contrast medium that emits alpha particles, thus causing chronic exposure to internal alpha-particle radiation when administered systemically. A study conducted in Sweden found that the incidence rates for cancer at all sites was increased 3 times over that in the general population, with the largest increase in primary liver and gallbladder cancers.[151] Because of this increased risk, Thorotrast is no longer used.

Patients with choledochal cysts have an increased risk for the development of carcinoma anywhere in the biliary tree. The incidence is higher in the gallbladder (12%), however, than in the biliary tree (5%).[152] The risk of carcinogenesis increases with age; accordingly, complete surgical resection is recommended for all patients with choledochal cysts at the time of diagnosis. In addition, anomalous pancreaticobiliary junction has been found to be associated with gallbladder cancer, occurring in up to 65% of cases.[153,154]

Because of the strong association of gallbladder cancer with gallstone disease, the question has been raised as to whether all patients with gallstones should undergo elective cholecystectomy. Several arguments have been made against elective cholecystectomy as a means to prevent gallbladder cancer. First, the historical practice of performing cholecystectomy only in symptomatic patients, thus leaving the gallbladder in place in patients with asymptomatic gallstones, has not led to an increase in the prevalence of gallbladder cancer over time. Second, epidemiologic studies have found the 20-year risk of developing cancer in patients with gallstones is less than 0.5% for the overall population and 1.5% for high-risk groups.[147] Thus, routine cholecystectomy for asymptomatic gallstones due to concern for future increased risk of gallbladder cancer does not appear to be warranted.

One higher-risk subset of patients with gallbladder disease is the population with "porcelain gallbladder," a calcified gallbladder wall. Historically, it was thought that the incidence of gallbladder cancer in patients with porcelain gallbladder was as high as 25% to 60% (Fig. 84-8). Because of this, it was standard surgical practice that all patients with calcification of the gallbladder wall should undergo open cholecystectomy, even if asymptomatic. More recently, however, this association has been challenged by the finding that less than 20% of patients with diffuse calcified gallbladder wall are found to have cancer.[149] Of interest, Stephen and Berger recently reported a retrospective analysis of over 25,000 gallbladder specimens and subdivided those patients with calcified gallbladders into two types: those with complete intramural calcification and those with selective mucosal calcification. Although a significant increase was observed in the incidence of gallbladder cancer in patients with focal mucosal wall calcification (7%; odds ratio, 13.89), no patients with diffuse intramural calcification were found to have cancer.[155] Finally, another recent retrospective review found 15 porcelain gallbladders among over 10,000 specimens examined, and none of the patients had gallbladder cancer.[156] The results of these studies indicate that the risk of gallbladder cancer in patients with porcelain gallbladder appears to have been greatly overestimated; therefore, cholecystectomy should be performed only in patients with either selective calcification of the gallbladder wall or other findings on preoperative studies suggestive of carcinoma.

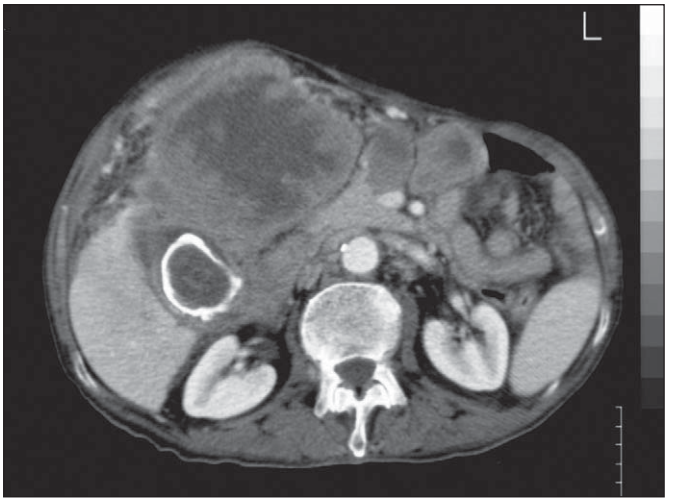

Figure 84-8 • Porcelain gallbladder demonstrated on computed tomographic scan with concentric calcification of the gallbladder wall. A large gallbladder cancer also is present.

PATHOLOGY

More than 80% of gallbladder cancers are adenocarcinomas; several histologic subtypes, including papillary, nodular, and tubular, are recognized. Papillary tumors, which grow predominantly into the gallbladder lumen, have an improved prognosis compared with the other subtypes.[143] Poor prognostic signs in gallbladder cancer include grade[143,157] and vascular invasion.[143] The most important prognostic sign is lymph node involvement,[158] although 5-year survivors with nodal involvement have been documented.[159] Less than 5% of cases are squamous cell carcinomas, with the remaining 10% being anaplastic lesions including small cell carcinoma, which has a particularly virulent course but may be responsive to cisplatin-based chemotherapy.

Limited information exists regarding the genetic changes in gallbladder cancer. The most widely reported gene abnormalities associated with gallbladder cancer include p53,[160] K-ras,[160,161] and CDKN2 (9p21) mutations.[161,162] The finding of a greater frequency of K-ras mutations in patients with an anomalous pancreaticobiliary junction has led investigators to believe that reflux of pancreatic enzymes into the biliary tree may contribute to the development of cancer.[161] Because of current limited knowledge of the sequence of molecular changes, no detectors of early disease or of risk assessment have been identified. Clearly, this is an aspect of investigation that needs improvement, particularly in endemic areas.

TUMOR BIOLOGY

Gallbladder cancer spreads by means of the lymphatic and venous drainage system. Due to drainage of the cholecystic veins directly into the adjacent liver, these tumors often involve hepatic parenchyma, most often portions of segments IV and V that directly abut the gallbladder fossa. The rapid spread of gallbladder cancer has been thought to be due partly to its thin wall and discontinuous muscle layer. In addition, the portion of the gallbladder that is in direct contact with the liver has no serosa; thus, direct liver invasion is common. Lymphatic spread is first to the cystic duct (Calot's) node, then to pericholedochal and hilar nodes, and finally to peripancreatic, duodenal, periportal, celiac, and superior mesenteric artery nodes. Nodal disease in the porta hepatis can cause common bile duct obstruction with resultant jaundice, which is the first clinical symptom in 30% of patients. Jaundice also may be caused by tumors arising in the gallbladder infundibulum, which may spread directly to the cystic duct and common hepatic duct. Although peritoneal metastases are frequent, distant extraperitoneal metastases are not.

CLINICAL PRESENTATION AND PATIENT EVALUATION

In patients with signs or symptoms, abdominal pain, sometimes consistent with biliary colic or acute cholecystitis, is the most common symptom, followed by jaundice.[163] A majority of patients are found

to have gallbladder cancer during evaluation for possible cholelithiasis or choledocholithiasis. Patients also may present with weight loss, anorexia, or an increase in abdominal girth secondary to ascites. Physical findings include right upper quadrant tenderness or a palpable mass, hepatomegaly, and ascites. Owing to its nonspecific presentation, gallbladder cancer is not diagnosed preoperatively in more than half of the cases. Of patients presenting with jaundice in the setting of gallbladder cancer, a majority will have advanced disease.[164]

LABORATORY AND IMAGING STUDIES

Results of laboratory tests usually are normal except in patients with jaundice who have elevated liver enzymes, consistent with biliary obstruction. No reliable screening tests are available to evaluate patients at increased risk for gallbladder cancer.

Imaging evaluation often reveals an asymmetrically thickened gallbladder wall (Fig. 84-9) or a mass within or replacing the gallbladder on ultrasound examination. Because polyps and carcinoma can have an echogenicity similar to that of the gallbladder wall, these lesions often are difficult to distinguish. The diagnostic difficulty increases when inflammation is present from gallstones. At times, ultrasound examination can visualize invasion of the liver, adjacent adenopathy, and a dilated biliary tree. The capability of ultrasound examination to differentiate benign from neoplastic disease is enhanced with use of endoscopic ultrasound techniques, and this modality may be more specific than CT or MRI.[165–167]

A dynamic contrast-enhanced CT scan may identify a gallbladder mass or invasion into the liver parenchyma or adjacent organs. The classic finding in a patient with gallbladder cancer is asymmetrical thickening of the gallbladder wall (see Fig. 84-9). The sensitivity and specificity of contrast-enhanced CT in diagnosing neoplastic lesions are close to 90%.[168] Staging of gallbladder carcinoma using CT, however, is limited by poor sensitivity in identifying nodal spread.[169]

In patients who are jaundiced, direct cholangiography may be useful to delineate extent of biliary involvement, as well as to relieve symptoms of biliary obstruction. A mid-bile duct obstruction not due to gallstones represents gallbladder cancer until proven otherwise. More recently, with the improvements in MRI technology, magnetic resonance cholangiopancreatography (MRCP) has evolved into a single noninvasive imaging modality that allows complete assessment of biliary, vascular, hepatic parenchymal, and nodal involvement, as well as involvement of adjacent organs; thus, this modality may be helpful in select cases.[170–172]

STAGING CLASSIFICATION

The American Joint Committee on Cancer's (AJCC) TNM staging system (Table 84-6) reflects prognostic characteristics of tumor depth, regional nodal disease, or distant spread. Gallbladder cancers frequently spread to the liver, which is involved in 70% of patients at the time of surgical evaluation. The gallbladder differs histologically from the rest of the gastrointestinal tract in that it lacks a muscularis mucosa and submucosa. Thus the gallbladder wall is composed of (1) a single layer of columnar cells, the mucosa, and lamina propria, (2) a fibromuscular layer, (3) a perimuscular, subserosal layer containing lymphatics and neurovascular structures, and (4) a serosal surface, except where the gallbladder is embedded in the liver.[173] Because lymphatics are present in the subserosal layer only, tumors invading less than the full thickness of the muscular layer have minimal risk of nodal spread.

Several changes have recently been incorporated into the AJCC staging system (i.e., the sixth edition of the staging manual, published in 2002)—specifically, the T and N classifications have been simplified in an attempt to separate locally invasiv e tumors into potentially resectable (T3) and unresectable (T4) lesions. The distinction between T3 and T4 based on depth has been abolished. Lymph node metastasis is now classified as stage IIB, and stage IIA refers to resectable tumors with no lymph node involvement. In line with other pancreaticobiliary malignancies, the stage III grouping refers to

Table 84-6 American Joint Commission on Cancer Staging System for Gallbladder Carcinoma: Tumor-Node-Metastasis (TNM) Classification

Stage	Grouping		
0	Tis	N0	M0
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T3	N0	M0
IIB	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
III	T4	Any N	M0
IV	Any T	Any N	M1

DEFINITIONS

Primary tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades the lamina propria or muscle layer
T1a	Tumor invades the lamina propria
T1b	Tumor invades the muscle layer
T2	Tumor invades the perimuscular connective tissue; no extension beyond the serosa or into the liver
T3	Tumor perforates the serosa (visceral peritoneum) and/ or directly invades the liver and/or one other adjacent organ or structure, e.g., stomach, duodenum, colon, pancreas, omentum or extrahepatic bile ducts
T4	Tumor invades main portal vein or hepatic artery or invades multiple extrahepatic organs or structures

Regional lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

Distant metastasis (M)

MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Figure 84-9 • Computed tomographic scan demonstrating asymmetrical thickening of the gallbladder wall, a classic finding in gallbladder carcinoma.

locally advanced, unresectable disease, and stage IV indicates metastatic disease. Stage I includes tumors invading into but not through the muscular layer of the gallbladder. Stage II disease is characterized by invasion into the perimuscular, subserosal layer, without spread to the liver and without nodal disease. Stage III and stage IV disease are as previously defined.

PROGNOSIS

The 5-year survival rate for all patients with gallbladder cancer is less than 5% in most series, with a median survival time of 6 months.[174,175] This dismal outlook results primarily from the fact that most patients present with unresectable disease. For those patients undergoing resection, survival is dependent on depth of penetration and nodal status. In large series, the overall 5-year survival rate after resection is 40%.[174] Nearly 100% survival is reported after simple cholecystectomy for T1 disease; patients with T2 and T3 tumors without nodal disease have a 5-year survival rate greater than 50%.[158,159,176–179] Node positivity and presentation with jaundice are ominous findings, with few 5-year survivors among patients with these features.[159,180]

Figure 84-10 • Intraoperative photograph during staging laparoscopy demonstrating occult peritoneal metastases on the inferior surface of the right diaphragm.

PRIMARY TREATMENT

The only curative option in patients with gallbladder cancer is complete surgical resection. In a study of 5836 patients with gallbladder cancer, the 5-year survival rate for patients who had surgery with curative intent was 17% but less than 1% for those with unresectable disease.[147] In a review of data for 10,301 patients with gallbladder cancer from the SEER database, those who underwent surgery had a significantly longer median survival than those who did not.[181] Recognizing the inherent bias of these retrospective analyses, and also the fact that patients who undergo surgery are selected by virtue of a number of factors, including good performance staus, lack of precluding medical comorbid conditions, less advanced stage of disease, and possibly more favorable disease biology, these data nevertheless support the role of surgery as the primary therapeutic modality. Unfortunately, however, resection is possible in only 25% of patients at presentation because of the advanced nature of the disease.[147]

It is essential for optimal patient care that patients with gallbladder cancer be identified before laparoscopic cholecystectomy is performed, owing to the risk of port site seeding and bile spillage with potential tumor spill.[163,179]

Role of Staging Laparoscopy

Because a large percentage of patients have been found to have occult unresectable disease at the time of exploration, several investigators have studied the use of initial staging laparoscopy for this disease.[175,182–184] Gallbladder cancer has a marked propensity to spread intra-abdominally, so patients with this tumor are ideal candidates for detection of intra-abdominal metastases with laparoscopy. Support for this application of staging laparoscopy comes from the fact that up to 50% of patients are found to have unresectable disease at the time of laparoscopy[175] (Fig. 84-10). Patients who are detected to have unresectable disease at laparoscopy can begin other forms of therapy earlier and may undergo the procedure on an outpatient basis. Particularly because patients with unresectable disease have a median survival of only 6 months, the importance of quality of life and time out of the hospital cannot be overemphasized.

Cholecystectomy with or Without Partial Hepatectomy

Gallbladder cancer results in rapid local progression and death unless it can be curatively resected. In a collected review of 5836 patients with gallbladder cancer, the overall mean survival time was between 2 and 5 months, with a 5-year survival rate of 4%.[174] The 5-year survival rate for patients undergoing resection with curative intent was 17%. Of the 2115 patients with unresectable tumors, only a single 5-year survivor was described.[147] Although surgical resection represents the treatment of choice and the only potentially curative therapy available, resection is possible in only 25% of patients at presentation owing to the advanced nature of the disease.[147]

The operation of choice must be tailored to the depth of penetration of the tumor. For tumors limited to the muscular layer of the gallbladder (T1), simple cholecystectomy is adequate.[159,185–187] T1 tumors have not yet invaded the subserosal layer, which contains lymphatics, so lymphadenectomy is not required. Attesting to the fact that early gallbladder carcinoma is completely curable, simple cholecystectomy has resulted in nearly 100% survival when early cancer is an incidental finding after elective cholecystectomy.[188]

Difficulty can arise at the time of surgery in identifying polypoid lesions of the gallbladder as either benign or early gallbladder cancer. Although it appears that frozen section diagnosis is fairly reliable in determining whether lesions are malignant or benign (95% accurate), the accuracy in correctly assessing depth of invasion is only 70%.[189] Thus, it may be difficult at the time of surgery to determine the extent of resection. Accordingly, pursuing a more aggressive resection if the depth of invasion is in doubt is important for adequate clearance of disease.[190]

The extent of surgical resection for T2 or greater tumors has been controversial, with recommendations ranging from simple cholecystectomy to radical excision including hepatectomy. Although it is clear that major hepatic resection can be performed safely, with a mortality rate of less than 5%[158,159,174,186,187] (Table 84-7), the ability to achieve a complete resection of cancer must be balanced with the morbidity of the procedure. Because the gallbladder is not surrounded by serosa at its attachment to the liver in the gallbladder fossa, even T2 tumors (full-thickness invasion of the muscular layer into the perimuscular connective tissue, but not into the serosa) may invade the normal plane of dissection in the gallbladder fossa during simple cholecystectomy. Therefore, T2 tumors cannot be completely removed with cholecystectomy alone, and a radical cholecystectomy, with resection of a 1- to 2-cm rim of normal liver around the gallbladder fossa, is the minimum resection that is required. Many investigators, however, have found that resection of segments 4b and 5 of the liver, which abut the gallbladder fossa, results in a more anatomically controlled dissection with less blood loss.[191] An additional component of the definitive surgical treatment is regional lymphadenectomy, because approximately half of the patients with T2 tumors are found to have nodal spread after resection.[158] Dissection of lymph nodes should include all tissue from the bifurcation of the hepatic ducts to the distal common bile duct. Proponents of this approach advocate liver resection on the basis that it is the only way to obtain

Table 84-7 Results after Radical Resection for Gallbladder Cancer

†Dixon E, Vollmer CM Jr, Sahajpal A, et al: An aggressive surgical approach leads to improved survival in patients with gallbladder cancer: a 12-year study at a North American Center. Ann Surg 2005;241:385–394.

an adequate margin on the hepatic side of the gallbladder, and that resection of the regional nodes allows the best chance for complete tumor clearance. For all of these reasons, simple cholecystectomy is inadequate for T2 or greater tumors. When segment 4b-5 resections have been performed in patients with T2 tumors, the 5-year survival has increased from a range of 25% to 40% after simple cholecystectomy to 70% to 100% after radical resection.[158,159,177,185,186,188]

For T3 and T4 lesions, a high likelihood exists for intraperitoneal and hematogenous spread and significant morbidity associated with the radical procedures that often are necessary for excision of local disease. In patients with disease limited to the gallbladder, however, recent series support an aggressive approach to resection (see Table 84-7). For large tumors with liver invasion, segment 4b-5 resection or extended right hepatectomy is warranted to completely clear the hepatic bed of tumor.

Surgical exploration should be performed in all patients with no medical contraindications. If a T1 tumor is suspected, a cholecystectomy and biopsy of regional nodes should be performed after thorough examination of the abdominal cavity for any signs of tumor dissemination. The pathology and depth of penetration should be confirmed by frozen section, and the procedure terminated if a T1 tumor with disease-negative margins is confirmed. For T2 lesions, either a radical cholecystectomy (wedge resection of the hepatic bed) or a segment 4b-5 resection with lymphadenectomy should be performed.[158] For T3 or T4 lesions, a segment 4b-5 resection or extended right hepatectomy is performed as needed for complete tumor clearance.

Location of the tumor is important in determining the extent of resection. If the tumor arises in the gallbladder infundibulum, the common bile duct is often involved with tumor, either by direct extension or external invasion of the hepatoduodenal ligament. In this case, an extended liver resection and excision of the common bile duct should be performed. In addition, all patients who present with jaundice will require resection of the common bile duct to clear the tumor. Reconstruction is then performed by Roux-en-Y hepaticojejunostomy. Tumor arising in the fundus of the gallbladder, however, can be treated with limited hepatic resection without excision of the common bile duct. In order to clear the lymph nodes in the porta hepatis, complete lymphadenectomy should be performed skeletonizing the common bile duct, hepatic artery, and portal vein.

Incidentally and Laparoscopically Discovered Gallbladder Cancer

Gallbladder cancer often is discovered during histopathologic examination after cholecystectomy for presumed benign gallstone disease. As a result of the popularization of laparoscopic cholecystectomy in the past decade, an increasing number of patients with gallbladder cancer are found incidentally. Particularly in patients with bile spillage at the time of surgery, laparoscopic resection in patients with unknown gallbladder cancer may convert potentially curable early gallbladder cancer into incurable disease.[179] Because radical resection remains the only possibility for cure, however, patients with T2 or greater tumors without signs of distant disease should be offered a second resection to eradicate all disease. At the time of surgery, excision of laparoscopic port sites also should be performed owing to the well-documented possibility of port site seeding even if they appear grossly normal.[163,188,192,193]

At reoperation, patients presenting with incidentally discovered gallbladder cancer during laparoscopic cholecystectomy present multiple technical challenges. A common finding is postoperative inflammation in the right upper quadrant, which hinders distinction of tumor from normal tissue. Determination of gross ductal or nodal involvement by tumor is always difficult at the time of reoperation. In addition, postoperative fibrosis often encases the right hepatic artery, which crosses behind the bile duct in most patients. For all of these reasons, a second operation for incidentally discovered gallbladder cancer often requires an extended right hepatectomy along with excision of the extrahepatic biliary tree and periductal lymphatic tissues. This resection allows adequate excision of the lymphatic tissues at the confluence of the bile ducts, with a greater likelihood of achieving disease-negative margin on the bile duct, and limits the need for biliary reconstruction to only one side of the liver. The disadvantage is that a large portion of normal liver parenchyma is sacrificed, and consequently, transient postoperative liver dysfunction is common. Although curative resection of incidentally discovered gallbladder cancer may be more difficult to perform, no difference in overall survival has been found between patients who initially undergo noncurative resection and are then re-explored for definitive resection and those patients undergoing initial curative resection.[174]

When a patient presents with T1 gallbladder cancer discovered after simple cholecystectomy, the pathologic findings must be reviewed to determine if the entire gallbladder has been removed and if the cystic duct margin is clear of tumor. If the cystic duct margin is positive for disease, the patient requires local bile duct excision at a minimum. If all margins are disease-negative, no further therapy is warranted. If the tumor is proved to be T2 or greater, however, the patient should undergo a radical resection if evidence of extrahepatic disease is absent. Patients with a known or suspected early gallbladder carcinoma should not undergo laparoscopic cholecystectomy. Rather, open exploration and cholecystectomy should be performed.

ADJUVANT THERAPY AND TREATMENT OF ADVANCED GALLBLADDER CANCER

Adjuvant Therapy

Adjuvant therapy for biliary tract malignancies (gallbladder and cholangiocarcinoma) remains a controversial and largely unproven consideration. Very few randomized trials have been conducted, and those that have are notable for (1) small patient numbers and (2) inclusion of patients with several malignancies (e.g., gallbladder and cholangiocarcinoma, ampullary, and sometimes pancreatic malignancies), thus limiting the statistical power and validity of the conclu-

sions. In view of the relative rarity of these malignancies in the United States, large-scale randomized trials are feasible only in the context of a multi-institutional or cooperative group setting.

One prospective randomized phase III trial by Takada and associates of adjuvant chemotherapy with 5-fluorouracil and mitomycin versus surgery alone for resected patients with pancreaticobiliary malignancies offers some interesting results.[194] A total of 508 patients were accrued from 31 centers over a 6-year period, including 140 with gallbladder cancer. In 112 evaluable gallbladder cancer patients, the 5-year survival rate of 26% for the adjuvant treatment group was significantly better than that for the control group at 14% (P = 0.0367). Similarly, the 5-year disease-free survival rate favored the adjuvant treatment group at 20.3%, versus 11.6% (P = 0.021). Significantly improved body weight also was observed in the adjuvant treatment group. For the other malignancies assessed in this trial, pancreas, bile duct, and ampulla of Vater cancers, no benefits with regard to disease-free and overall survival were observed.[195] This trial suggests that adjuvant chemotherapy may offer benefit for patients with resected gallbladder cancer; however, replication in a larger-scale setting is required before definitive conclusions can be drawn.

A majority of gallbladder cancers recur with both local and systemic disease, so a logical approach is to consider combined chemoradiation therapy in the adjuvant setting. Kresl and coworkers[196] recently reported on the Mayo Clinic retrospective experience with adjuvant 5-FU chemotherapy and external beam irradiation in patients with resected gallbladder cancer. Patients with completely resected gallbladder cancer (i.e., with disease-negative margins) who received adjuvant chemoradiotherapy had a 5-year survival rate of 64%, suggesting a favorable outcome compared with historical data for complete resection without additional treatment (approximately 33%). Again, large-scale prospective trials of postoperative adjuvant chemoradiation therapy are needed to determine the true merits of such an approach. Investigational issues with regard to adjuvant therapy include incorporating drugs with greater systemic activity than that of the fluoropyrimidines (e.g., gemcitabine) into an upfront adjuvant setting, as well as trying to delineate the role of local radiation modalities (e.g., brachytherapy) in the adjuvant context.

Metastatic Disease

A majority of studies assessing the role of chemotherapy in gallbladder cancer also have included patients with cholangiocarcinoma. Many phase II studies have demonstrated feasibility and some degree of efficacy, but the impact of chemotherapy in terms of overall survival and quality of life is unclear. With use of older drugs such as 5-FU, a single-agent response rate of approximately 10% has been reported.[197] Capecitabine, an oral tumor-activated fluoropyrimidine, has shown activity on its own and in combination with platinum agents.[96,198,199] Gemcitabine is a nucleoside analog prodrug that is activated by intracellular phosphorylation. It is a U.S. Food and Drug Administration (FDA)-approved agent for treatment of locally advanced and metastatic pancreatic adenocarcinoma. Many studies have evaluated gemcitabine both as a single agent and in combination with other agents, and it probably has become a first-line drug of choice for a majority of oncologists.[200–205]

Novel Therapies

It is clear that currently available medical therapies for biliary tract malignancies are woefully inadequate. The key to identifying new agents for treatment of this disease lies in developing a greater understanding of the genetics and molecular pathogenesis of gallbladder cancer. Such an approach may lead to the identification of novel targets, as well as paving the way for a more sophisticated approach to identifying persons at risk for developing this cancer and ultimately to screening and early detection, which is likely to represent one of the few strategies that may affect the long-term outcome with this cancer. Along the signal transduction pathway, therapeutic targets are abundant, but their potential has not been verified. Epidermal growth factor receptor (EGFR) and c-Erb-B2 expression has been observed in gallbladder carcinoma.[206] Erlotinib, an EGFR oral tyrosine kinase inhibitor, has some activity. In one study of 42 patients with advanced biliary cancer, a majority of whom had received prior chemotherapy, partial responses occurred in 3 patients, and 7 additional patients remained free of disease progession at 6 months.[207] Cyclooxygenase-2 (COX-2) appears to play an important role in VEGF-mediated angiogenesis, pointing to the potential use of COX-2 inhibitors in conjunction with chemotherapy or as a chemopreventive strategy.[208]

TREATMENT COMPLICATIONS

Larger series of patients with gallbladder carcinoma treated with definitive surgical resection have shown complication rates from 28% and mortality rates of zero to 4%.[163,174,176] The most common postoperative complications include intra-abdominal abscess or biloma and other infectious complications such as pneumonia or wound complications.[163]

FOLLOW-UP EVALUATION AFTER RESECTION FOR GALLBLADDER CANCER

The most common forms of recurrence after resection of gallbladder cancer include carcinomatosis, intrahepatic metastases, and nodal recurrence in the retroperitoneum. Jaundice is a common sign, but patients with recurrence also may present with ascites due to carcinomatosis. For most tumors, local recurrence is found synchronously with diffuse intra-abdominal spread. Therefore, surgical treatment of recurrence has little potential for cure. If recurrent disease is found after resection, prognosis is exceedingly poor, with death occurring secondary to biliary sepsis or liver failure within months of diagnosis.

The main goal of the follow-up program after resection of gallbladder cancer is to provide palliation for symptomatic recurrences. The main symptoms and signs associated with recurrence requiring palliation are pruritus or cholangitis associated with jaundice and bowel obstruction associated with carcinomatosis. Additional goals of the follow-up program are to detect benign complications of surgical treatment such as biliary stricture. When jaundice or cholangitis is the presenting symptom of possible recurrence, a nonsurgical palliative approach using percutaneous transhepatic cholangiography (PTC) and stenting usually is favored unless a benign postsurgical stricture is suspected. Because of the rapid growth of tumor in patients with recurrence, the hospitalization and recovery time from a surgical bypass usually are not justified for recurrences resulting in biliary obstruction.

Routine follow-up evaluation of a patient after resection of gallbladder cancer includes office visits every 3 months with physical examination and measurement. Although CA19-9 may be elevated in patients with gallbladder cancer, the sensitivity and specificity are poor,[209] so this marker should not be used for screening patients for recurrence. Because only limited treatment options are available for patients with asymptomatic recurrence of gallbladder cancer, overaggressive use of imaging studies is not warranted. Therefore, the use of imaging studies should be individualized.

ISSUES FOR THE FUTURE

Clearly, improving the ability to recognize early gallbladder cancer in high-risk geographic areas would have an important impact on outcome in these patients. Such advances probably will require elucidation of the sequential molecular changes associated with gallbladder cancer. Other improvements in screening programs in high-risk areas, potentially resulting in prophylactic cholecystectomy, are likely to be beneficial.[145]

BILE DUCT CARCINOMA

INTRODUCTION

One of the most technically difficult surgical resections is in patients with bile duct tumors arising in the hepatic hilus, named Klatskin tumors, or hilar cholangiocarcinoma. Bile duct cancers can arise at other sites, including within the liver (intrahepatic cholangiocarcinoma) and below the biliary bifurcation but above the pancreas (mid-bile duct cholangiocarcinoma). Distal cholangiocarcinoma involves that portion of the bile duct within the pancreas, which requires pancreaticoduodenectomy and is discussed in Chapter 85. The location of the tumor affects prognosis, as well as the potential for curative resection.

Resection of biliary neoplasms, particularly hilar cholangiocarcinoma, often requires radical resections and complex biliary reconstructions that have only recently become safe in routine practice. Surgery also may offer effective palliation for these cancers by providing biliary bypass for jaundiced patients with unresectable tumors. Because patients often are diagnosed late in the disease course and because complex operative techniques are required for potentially curative resection, these tumors represent one of the greatest challenges for definitive treatment. Adding to this challenge is the lack of proven effective options for adjuvant treatment.

EPIDEMIOLOGY AND PATHOGENESIS

The overall incidence of hilar cholangiocarcinoma in the United States is 1.0 per 100,000 per year, although other geographic regions such as Israel and Japan have higher rates.[210] The incidence of intrahepatic cholangiocarcinoma in the United States is approximately 0.7 per 100,000, with a similar mortality rate. During the last 30 years, it appears that both incidence and mortality in the United States are increasing.[211]

Cholangiocarcinoma is a rare cancer that arises from the biliary epithelium and is diagnosed in fewer than 4500 patients in the United States each year.[212] Cholangiocarcinomas arise slightly more often in males,[213] with a male-to-female ratio of 1.3:1, with a predisposition to affect those between 50 and 70 years of age. Risk factors for this disease include primary sclerosing cholangitis, ulcerative colitis, choledochal cysts, and biliary tract infection, either with *Clonorchis* or in chronic typhoid carriers.[214] Management of patients with cholangiocarcinoma arising from one of these underlying conditions is challenging.[215] Some industrial chemicals such as nitrosamines, dioxin, asbestos, and polychlorinated biphenyls also have been implicated in the pathogenesis of cholangiocarcinoma.[210] Although some evidence suggests an increased risk of cholangiocarcinoma after transduodenal sphincteroplasty,[216] it is difficult to distinguish whether the tumor was secondary to the surgical intervention or whether the underlying disease led to sphincteroplasty.

PATHOLOGY

Similar to gallbladder cancer, hilar cholangiocarcinoma tends to invade locally. More than 95% of these tumors are adenocarcinomas. They are morphologically described as nodular (which is the most common), scirrhous, diffusely infiltrating, or papillary. Histologic subtypes include acinar, ductular, trabecular, alveolar, and papillary. Perineural invasion clearly is a poor prognostic sign.[217] Papillary tumors (Fig. 84-11) appear to be associated with a more favorable outcome[218] and to be similar to intraductal papillary mucinous neoplasms of the pancreas.[219] Much less frequent bile duct tumors include cystadenocarcinomas, hemangioendotheliomas, and mucoepidermoid carcinomas.

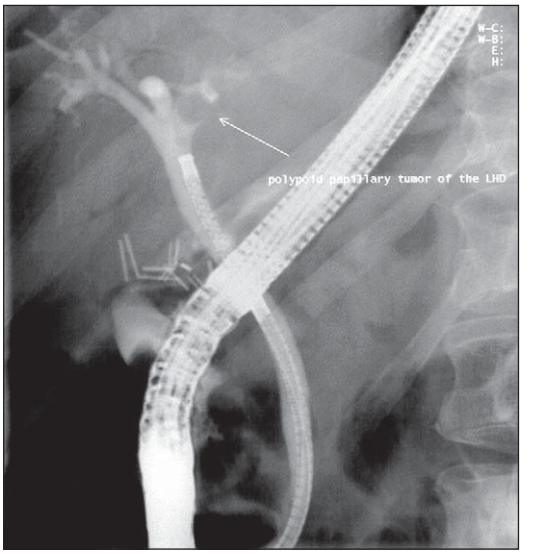

Figure 84-11 • Endoscopic retrograde cholangiopancreatography. The filling defect in the left bile duct proved at biopsy and subsequent examination to be papillary cholangiocarcinoma.

In patients with intrahepatic cholangiocarcinoma, negative prognostic signs include vascular invasion, multiple tumors, disease-positive tumor margins, large size, and lymph node metastases.[220] These tumors can be either sclerotic, mass-like lesions (Fig. 84-12) or cystic lesions[221–223] (Fig. 84-13).

Historically, cholangiocarcinomas have been classified according to their location in the upper (60%), middle (15% to 20%), or lower third (15% to 20%) of the bile duct. Middle third lesions arise between the cystic duct and the superior border of the duodenum. Lower third lesions are found below the superior border of the duodenum but above the ampulla. The problem with this classification is that the anatomic landmarks are somewhat arbitary and not clinically useful. In addition, many mid-bile duct obstructions due to malignancy are from gallbladder cancer, and even when the obstruction is truly secondary to a mid-bile duct cholangiocarcinoma, very few of these tumors are amenable to treatment by local excision of the bile duct. A more useful classification may be to divide these lesions into upper-half and lower-half tumors, based on the location of the cystic duct as it enters the common duct in the case of normal anatomy. The usefulness of this classification scheme is that it allows

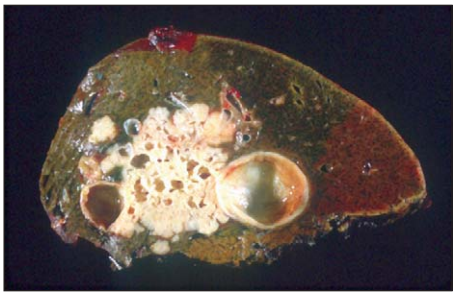

Figure 84-12 • Gross image of resected intrahepatic cholangicarcinoma reveals solid and cystic components of the tumor.

the surgeon to determine whether a hepatic or pancreatic resection will be required for clearance of tumor.

TUMOR BIOLOGY

Because hilar cholangiocarcinomas arise in the bile duct, which is in close approximation to the portal vein, the tumor often causes portal vein occlusion as it enlarges. This results in lobar atrophy on the ipsilateral side. In addition to local invasion, nodal metastases occur frequently. Intrahepatic cholangiocarcinoma, unless arising in a location near the hilum, less commonly results in local invasion.

CLINICAL PRESENTATION AND PATIENT EVALUATION

The vast majority of patients with hilar cholangiocarcinoma present with painless jaundice, although mild right upper quadrant pain, pruritus, anorexia, malaise and weight loss also may be reported. Cholangitis is the presenting symptom in 10% to 30% of patients. Some patients have their cancer discovered on evaluation for otherwise asymptomatic elevations of alkaline phosphatase and gamma-glutamyl transferase.

Patients with intrahepatic cholangiocarcinoma usually are asymptomatic. Many patients are found incidentally to have a liver tumor present on cross-sectional imaging performed for other reasons. Many of these patients present to a surgeon with biopsy evidence of adenocarcinoma without a known primary. The standard evaluation in these patients should include assays for tumor markers to rule out an elevated CA19-9, carcinoembryonic antigen (CEA), or AFP; upper and lower endoscopy to evaluate for a primary gastrointestinal source; CT scan to assess for a primary tumor in the gastrointestinal tract or pancreas and to rule out other metastases; and, in women, a mammogram. If no site of primary disease is found, the diagnosis in a majority of patients will be intrahepatic cholangiocarcinoma.

LABORATORY AND IMAGING STUDIES

Laboratory evaluation usually reveals elevated bilirubin or alkaline phosphatase and gamma-glutamyl transferase consistent with biliary obstruction in patients with hilar cholangiocarcinoma or a mid-bile duct lesion. Results of other laboratory tests typically are normal. In patients with intrahepatic cholangiocarcinoma, findings on laboratory evaluation usually are normal.

A variety of imaging tests are available to assess patients with hilar cholangiocarcinoma. Abdominal ultrasound examination is noninvasive, easily available, and inexpensive and thus is commonly used as a first imaging modality. The advantage of ultrasonography is that it can quickly establish the level of biliary obstruction. Cross-sectional imaging with intravenous contrast-enhanced CT scan probably is the most readily accessible technology and provides the moststaging information. CT scans frequently reveal dilated intrahepatic biliary ducts with a normal, collapsed gallbladder and, depending on the level of the tumor, a nondilated or partially dilated extrahepatic biliary tree. In addition, the presence of hilar adenopathy can be assessed. Portal vein patency can be determined with ultrasound examination or helical CT. In addition, signs of hepatic lobar atrophy should be sought (Fig. 84-14), because this fnding is associated with a high incidence of ipsilateral portal vein involvement by tumor. Magnetic resonance cholangiopancreatography (MRCP) offers the potential for evaluating parenchymal, vascular, biliary, and nodal involvement with a single noninvasive examination.[170–172] Frequently, it is possible to visualize the tumor itself with MRI .

In many centers, direct cholangiography is used to evaluate the extent of biliary involvement and provide palliation for jaundice. Endoscopic retrograde cholangiopancreatography (ERCP) has little role to play in high biliary obstruction because opacification, absolutely essential for assessing resectability, is difficult to accomplish in the proximal biliary tree. ERCP can be effectively used to image more distal lesions, however. At the time cholangiography is performed,

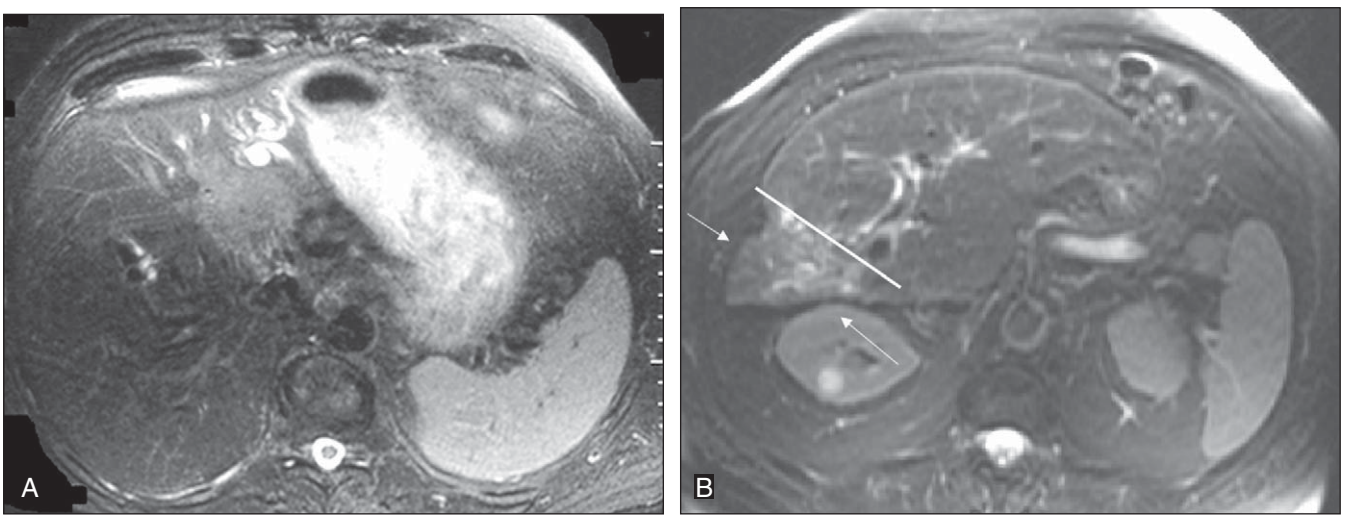

Figure 84-14 • Lobar atrophy in the liver due to portal venous invasion by cholangiocarcinoma. Magnetic resonance image demonstrates left lobar atrophy (**A**) and right lobe atrophy (**B,** *arrows*; *line* marks delineation between right and left lobes).

some authors advocate the routine preoperative placement of biliary drainage catheters to aid in intraoperative identification of the bile ducts.[224,225] Others have found a higher incidence of infectious complications[226] and greater mortality[227] and a longer hospital stay[228] after preoperative placement of biliary drainage catheters. The difficulty in making the decision regarding preoperative stenting is that many patients are severely symptomatic as a result of jaundice and pruritus and thus require palliation. Accordingly, a delay in operative intervention may necessitate biliary stent placement.

In many cases, it is difficult to obtain histopathologic confirmation of cholangiocarcinoma except in very advanced cases, even with the use of biliary brushings and cytologic specimens obtained at the time of direct cholangiography. In a majority of cases, patients are offered surgical therapy based on clinical suspicion and radiographic appearance.

In patients with intrahepatic cholangiocarcinoma, cross-sectional imaging with CT scan usually is sufficient. Tumors may be mass-like or may demonstrate cystic areas (see Figs. 84-12 and 84-13).

STAGING CLASSIFICATION

The AJCC TNM staging system for bile duct cancers is described in Table 84-8. In the 2002 AJCC TNM staging classification for extrahepatic bile duct cancer, several changes have been incorporated. The T and N classifications have been simplified. T1 is now classified as invasion of the subepithelial fibromuscular connective tissue. T2 is defined as invasion beyond the wall of the bile duct. Involvement of branches of the portal vein, hepatic artery, or liver is termed T3. Invasion of the main portal vein, common hepatic artery, or regional organs is now termed T4. In line with other hepatobiliary tract malignancies, stage III now signifies locally advanced, unresectable disease, and stage IV denotes metastatic disease.

In order to attempt to incorporate clinically important indicators of resectability, preoperative staging systems have been advocated that incorporate imaging features consistent with advanced disease, such as hepatic lobe atrophy or portal vein involvement[229] (Table 84-9). Of greatest importance, with the increasing acceptance of major hepatic resection for these tumors, these systems attempt to define whether ipsilateral involvement alone is present, because tumors with bilateral extension, to either the secondary biliary radicles or the portal vein, are not resectable.

Table 84-8 American Joint Commission on Cancer Staging System for Extrahepatic Bile Duct Carcinoma: Tumor-Node-Metastasis (TNM) Classification

Stage	Grouping		
0	Tis	N0	M0
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T3	N0	M0
IIB	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
III	T4	Any N	M0
IV	Any T	Any N	M1

DEFINITIONS

Primary tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor confined to bile duct histologically
T2	Tumor invades beyond the wall of the bile duct
T3	Tumor invades the liver, gallbladder, pancreas, and/ or unilateral branches of the portal vein or hepatic artery
T4	Tumor invades any of the following: main portal vein or branches, common hepatic artery, or other adjacent structures, e.g., colon, stomach, duodenum, abdominal wall.

Regional lymph nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

Distant metastasis (M)

MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Table 84-9 Revised Preoperative Tumor Staging System for Patients with Hilar Cholangiocarcinoma*

Tumor Stage	Description
1	Tumor involving *biliary confluence ± unilateral extension to second-order biliary radicles*
	No liver atrophy or portal vein involvement
2	Tumor involving biliary confluence ± unilateral extension to second-order biliary radicles *with ipsilateral portal vein involvement ± ipsilateral hepatic lobar atrophy*
	No main portal vein involvement
3	Tumor involving biliary confluence plus *bilateral extension to second-order biliary radicles*;
	OR unilateral extension to second-order biliary radicles with *contralateral portal vein involvement*;
	OR unilateral extension to second-order biliary radicles with *contralateral hepatic lobar atrophy*;
	OR *main or bilateral portal venous involvement*

PROGNOSIS

Prognosis after Resection for Hilar Cholangiocarcinoma

Unfortunately, the prognosis with hilar cholangiocarcinoma is limited by the fact that as many as 90% of patients have unresectable disease at the time of presentation.[213] In addition, of those patients in whom surgery with curative intent is undertaken, up to 50% are found to have unresectable disease at the time of surgery.[230,231] In patients who present with unresectable disease, the median survival time is 10 months.[230] The immediate cause of death in these patients is hepatic failure or cholangitis related to tumor growth and inadequate drainage of the biliary tree.[232] In patients amenable to curative resection, the median survival is 35 months with 5-year survival rates of 10% to 30%.[224,230,233–238] The results of major studies on resection of hilar cholangiocarcinoma are summarized in Table 84-10. Surgical resection provides not only improved survival but also improved quality of life.[239] The primary risk factors for recurrence include the presence of positive margins[230,239,240] and node-positive tumors.[241,242]

Table 84-10 Results after Resection for Hilar Cholangiocarcinoma

Study	No. of Patients	Resection Rate (%)	Postoperative Mortality (%)	5-Year Survival (%)	Median Survival (mo)

Prognosis after Resection for Intrahepatic Cholangiocarcinoma

In patients with intrahepatic cholangiocarcinoma, expected 3-year survival rates as high as 60% have been reported,[175,243] with 5-year survival rates of 30% to 45%.[231] Patients with unresectable disease have a median survival of 12 months.[222,244] Thus, the prognosis for completely resected intrahepatic cholangiocarcinoma appears to be improved prognosis over that for proximal (hilar) cholangiocarcinoma.

PRIMARY TREATMENT

Proximal (Hilar) Cholangiocarcinoma

Patients with unresectable bile duct cancers die within a year of diagnosis.[228] Surgical excision in those select patients with resectable disease is clearly the treatment of choice, because no other therapies have the potential for cure. The objectives of surgical management for patients with cholangiocarcinoma include both complete removal of tumor and adequate biliary drainage. It has become clear over the past 3 decades that curative treatment of tumors involving the upper half of the bile duct depends on aggressive excision, which often necessitates a major liver resection.[230,238] Until as recently as a decade ago, treatment of hilar cholangiocarcinoma was associated with mortality rates as high as 30%.[233,245–247] Fortunately, major improvements in the safety of these operations have been demonstrated by multiple investigators, and resection of hilar tumors now results in death in less than 10% of the patients, even when major liver resections are required.[233,240,245,247]

Assessment of Resectability and Surgical Procedure

Surgical exploration often is the only means of assessing resectability. Because of the potential morbidity of a laparotomy with no therapeutic benefit, staging laparoscopy has been advocated in order to save patients from unnecessary laparotomy. Of patients with hilar cholangiocarcinoma, up to 25% will benefit from staging laparoscopy because it may lead to detection of occult extrahepatic disease.[175] Laparoscopy is a very sensitive means to detect peritoneal metastases or additional intrahepatic disease through the use of laparoscopic ultrasound examination but is less sensitive in detecting nodal metastases.[175]

Hilar cholangiocarcinoma is considered unresectable owing to both local factors and metastatic spread. Clearly, disease outside the liver is not amenable to curative resection. Local factors that make these tumors unresectable include invasion of the main portal vein or both the right and left portal veins or hepatic arteries and tumor extension into second-order biliary radicals of both right and left hepatic lobes. By contrast, tumors extending into second- or third-order biliary radicles on one side of the liver or the ipsilateral portal vein can be resected with curative outcome.

The goals of surgical management for cholangiocarcinomas are both eradication of tumor and establishment of adequate biliary drainage. Tumors of the biliary confluence are particularly difficult to treat because symptoms often appear late in the disease course, when the lesion has already involved adjacent structures, such as the portal vein and adjacent hepatic parenchyma. Accordingly, complete resection requires biliary and hepatic resection and often major vascular reconstruction. Therefore, it is not surprising that historically, the surgical therapy for proximal biliary malignancies consisted mainly of biliary-enteric bypass as palliation for jaundice and cholangitis. The therapeutic approach to hilar cholangiocarcinoma was largely nihilistic, as a result of difficulty in delineating the extent of disease and the technical challenge of complete resection for such lesions.

Over the past decade, surgical approaches have become more aggressive, as demonstrated by the increasing number of hepatic resections which have been performed for bile duct cancers[230,233,234,245–247] (see Table 84-10). Recent improvements in ultrasonography, CT, and MRI have greatly facilitated preoperative evaluation and staging of cholangiocarcinoma. Such information has allowed improved patient selection and more realistic surgical planning.

The location and local extent of tumor dictate the extent of resection, with most lesions requiring an extended right or left hepatectomy for complete excision. Caudate resection often is required as a result of direct extension into caudate biliary radicles or parenchyma.[229,230,234,247] Common bile duct excision and portal lymphadenectomy also are essential for tumor clearance and accurate staging.

Surgical Treatment of Unresectable Hilar Cholangiocarcinoma

TRANSPLANTATION. Patients with unresectable disease due to bilateral extension into the liver may be candidates for neoadjuvant chemoradiation therapy followed by liver transplantation.[248,249] These patients are highly selected for better prognosis because they all undergo laparotomy and lymph node sampling to exclude patients with nodal involvement from transplantation.[250] In these good-risk patients with locally advanced disease but no evidence of metastatic or regional disease, disease-free survival rates may be as high as 60% after transplantation.[251]

PALLIATIVE PROCEDURES. For patients with unresectable hilar cholangiocarcinomas, significant improvement in quality of life can be obtained with percutaneous or open surgical bypass, because most patients are symptomatic with pruritus due to jaundice. Nonoperative palliative biliary decompression can be accomplished with percutaneous or endoscopic stenting, depending on the level of obstruction. Proximal lesions usually are approached percutaneously with placement of expandable stents or drainage catheters. Use of internal stents results in fewer electrolyte abnormalities and improvement in patient comfort, although morbidity or death has been reported in up to 30% of patients, and stent occlusion is common.[252–254]

Also reported is a significant risk of cholangitis with external and internal drainage, occurring in more than 90% of patients with metallic expandable internal stents in one series.[253] Bleeding and bile leaks also are frequent complications. More recent techniques such as photodynamic therapy have been used for relief of biliary obstruction and may hold some promise for the future.[255] Palliative surgical bypass can be performed by decompressing the biliary tree using the segment III bile duct, approached through the round ligament.

Because patients with unresectable disease have a short median survival, those with incontrovertible preoperative imaging evidence of unresectability should be managed with percutaneous internal or external drainage. In patients in whom surgical exploration reveals unresectable disease, surgical bypass offers the advantage of fewer episodes of cholangitis and stent obstruction, with an improved quality of life.[256] In some series, surgical bypass for unresectable disease is the only biliary drainage procedure ever required by the patient.

Intrahepatic Cholangiocarcinoma

Patients with intrahepatic cholangiocarcinoma typically present with single liver lesions. Standard treatment with anatomically based hepatic resection is the procedure of choice. Because these tumors frequently are asymptomatic, fewer issues with palliative management need to be addressed.

Adjuvant Therapy

Chemotherapy

No standard adjuvant chemotherapy option for cholangiocarcinoma has been established. In the most important study by Takada and colleagues, 508 patients with pancreaticobiliary malignancies (including 139 with bile duct cancers) were randomized to receive adjuvant chemotherapy or no adjuvant therapy after definitive resection of the tumor.[194] The chemotherapy regimen comprised mitomycin and 5U, and although a trend toward reduced recurrence and mortality was observed in the chemotherapy arm, the difference from treatment arm data was not statistically significant. Other reports of the use of adjuvant chemotherapy have been from small or retrospective series.[257,258]

Radiation Therapy or Chemoradiation Therapy

The tendency for cholangiocarcinoma to recur locally provides a rationale for additional local therapy after definitive surgery. This is in contrast with pancreas cancer, for instance, in which concern is focused predominantly on the potential for systemic relapse and has led to a relative diminution of the role of radiotherapy in recent years. This rationale, however, is not underpinned by hard prospective data, and the available evidence is mixed. Small retrospective studies have inferred a benefit.[259,260] Other reports have not shown a benefit.[261]

Chemoradiation therapy has a theoretical advantage stemming from the radiosensitization phenomenon associated with use of 5U. Again, the data do not address this issue satisfactorily. Although several phase II and retrospective series[262,263] suggest a benefit, phase III data on this aspect of treatment are extremely limited.

TREATMENT OF ADVANCED BILE DUCT CANCERS

Chemotherapy

To date, no chemotherapeutic regimen has consistently shown activity against cholangiocarcinoma. Many of the issues that pertain to chemotherapy trials in gallbladder cancer are directly relevant to the interpretation of data from trials for cholangiocarcinomas. Studies performed to date typically have been small, single-institution phase II trials, including patients with both gallbladder and bile duct cancers.[264]

Single-agent 5-FU-based chemotherapy has been shown to give a response rate of approximately 10%.[152] In recent years, gemcitabine has become the most widely used drug in biliary tract malignancies, primarily as a result of its established primacy for treatment of pancreas cancer. Use of gemcitabine as a single agent has resulted in response rates of 16% and 26% in two phase II studies.[265,266] The focus at present is on combining gemcitabine with other agents, and multiple phase II studies of gemcitabine doublets have been performed employing taxanes, platinum agents, fluoropyrimidines, and topoisomerase inhibitors.[202,267–270] The optimal chemotherapeutic regimen for advanced cholangiocarcinoma is unknown.

Intra-arterial Chemotherapy

Chemotherapy delivered by intra-arterial administration for unresectable hepatobiliary malignancies is an attractive concept because of the predilection of cholangiocarcinoma for locoregional relapse and the relative lack of systemic toxicity with this therapeutic approach. The major disadvantage is the need for a port, which requires a laparotomy for placement, as well as the availability of trained skilled surgeons, which limits widespread clinical application. Several small trials have demonstrated promising response rates, with acceptable toxicity, in selected patient populations.[271,272] Additional trials are under way to delineate the role of intra-arterial chemotherapy in cholangiocarcinoma and other biliary tree malignancies.

Radiotherapy in Bile Duct Cancers

In cases of unresectable but nonmetastatic cholangiocarcinoma, the use of external beam radiation therapy may improve pain control and biliary decompression.[273] Anecdotal reports of long-term survivors after external beam radiation therapy show that some patients may benefit from such treatment, but no controlled studies have proved such a benefit, and the potential for complications such as duodenal or bile duct stenosis and duodenitis must be a consideration. Newer techniques such as intraoperative radiotherapy, intraluminal brachytherapy, and intensity-modulated radiation therapy represent a technical advance in terms of dosage delivery and minimization of toxicity; however, their impact on survival is unclear at the present time.[274]

NOVEL THERAPEUTICS IN CHOLANGIOCARCINOMAS

As noted earlier, cholangiocarcinoma cell growth is strongly dependent on EGFR signaling,[275] so the EGFR is a rational therapeutic target. The success of this approach has been documented in mouse models.[276] The response to EGFR inhibition may be dependent on the presence of mutations in the *EGFR* gene,[277] as is the case in non-small-cell lung cancer. Case reports have inferred a benefit, and this approach needs further development.[278,279] COX-2 also is important in cholangiocarcinogenesis, and significant interplay between COX-2 and other growth-regulatory pathways is likely.[280] COX-2 inhibition may have a synergistic role with other strategies or as a chemopreventive agent.

TREATMENT COMPLICATIONS

Attesting to the difficult management of patients with hilar cholangiocarcinoma, the postoperative complication rate is as high as 50% to 60%.[230,281] A majority of these complications are infectious. In many series, treatment of hilar cholangiocarcinoma with aggressive resection results in a perioperative mortality rate of approximately 5% to 10%.[230]

Fewer postoperative complications are expected from surgical procedures for patients with intrahepatic cholangiocarcinoma, because these operations are usually more straightforward and do not usually require bile duct resection. The overall complication rate is approximately 20% to30%, with a mortality rate of less than 3%.[222,223,238,240,281]

FOLLOW-UP PROGRAM

After resection of a hilar cholangiocarcinoma, locoregional recurrence occurs most frequently,[282] followed by distant sites including the liver. For patients with intrahepatic cholangiocarcinoma, the most common site of recurrence is within the liver or regional nodes.[222,283] Therapy for recurrence is palliative, because curative surgical re-excision usually is impossible owing to the challenging anatomic location and the radical procedures that resection of the primary tumor would require. Therefore, the goal of follow-up evaluation is diagnosis of symptomatic recurrences in order to direct palliative therapy and diagnosis of benign complications of surgical treatment such as biliary strictures. The main symptoms of recurrence that demand palliation are pruritus and cholangitis associated with jaundice. For biliary drainage to relieve jaundice or cholangitis, either surgical drainage[253] or drainage by percutaneous transhepatic cholangiography (PTC) can be effective.[284] Endoscopic drainage has little role in the relief of jaundice in patients who have had Roux-en-Y biliary reconstruction. For limited recurrences, intraluminal brachytherapy or external beam radiotherapy[285] may improve palliation and, potentially, survival.

Routine follow-up evaluation consists of office visits every 3 months with physical examination and measurement of liver enzymes. Although a rising alkaline phosphatase level is a good indicator of evolving biliary obstruction, patients recovering from liver resection and biliary obstruction may have persistent elevations of alkaline phosphatase. In up to 10% of patients with biliary surgical reconstruction, however, a benign anastomotic stricture may develop. Most patients with recurrence or a benign stricture will present with jaundice or cholangitis.

ISSUES FOR THE FUTURE

The only known curative therapy for intrahepatic and extrahepatic bile duct cancers is surgical resection. No proven role has been established for adjuvant chemotherapy alone or adjuvant combined chemoradiation, although further studies are needed to fully define the role of these therapies. Continued assessment of new drugs, novel radiosensitizers, and biologic agents is warranted. A better understanding of the molecular pathogenesis and genetics of bile duct cancers may lead to new therapeutic and ultimately preventive strategies for high-risk populations.

85 Carcinoma of the Pancreas

Jeffrey A. Drebin, Weijing Sun, James M. Metz, and Emma E. Furth

SUMMARY OF KEY POINTS

Incidence
- Approximately 37,000 new pancreatic cancer cases accrued in the United States in 2007.
- Approximately 33,000 deaths from pancreatic cancer occurred in the United States in 2007.
- Pancreatic cancer remains the fourth leading cause of cancer-related death for both men and women.

Pathology
- Adenocarcinomas account for 90% of pancreatic cancers.
- Less than 5% are endocrine tumors.
- Less than 5% are cystic tumors.
- Less than 5% are lymphomas or sarcomas.

Clinical Presentation
- Two thirds of pancreatic tumors are located in the head of the pancreas; clinical features include vague pain, weight loss, fatigue, and jaundice.
- One third of pancreatic tumors are in the body or tail; clinical features include epigastric or back pain, weight loss, fatigue, and evidence of metastatic disease.

Staging Evaluation
- Triple-phase helical computed tomography (CT) scanning is performed in all patients.
- Cholangiography is used for severe jaundice if the patient is not scheduled for immediate surgical exploration or as the result of equivocal findings on the CT scan.
- Endoscopic ultrasound examination with biopsy is used for atypical lesions.
- Fine needle aspiration biopsy is performed before institution of palliative treatment if the lesion is unresectable.
- Magnetic resonance imaging (MRI), angiography, and positron emission tomography (PET) scans are used in selected cases.
- Preoperative tissue diagnosis is unnecessary with resectable lesions.
- Laparoscopic staging may avoid unnecessary laparotomy for unresectable lesions.

Therapy
- Surgical resection of the tumor (10% to 15% of all tumors are resectable; 70% to 80% of tumors staged preoperatively as resectable are resected) is performed.
- Adjuvant therapy (chemoradiation therapy or chemotherapy alone) is given.
- Neoadjuvant therapy may be of use in resectable disease and in rendering borderline-unresectable disease resectable.

Palliation
- Endoscopic or percutaneous transhepatic biliary stents are used.
- Operative gastric or biliary bypass is performed in selected patients.
- Alcohol celiac plexus block is used.
- Chemoradiation therapy is used for locally advanced unresectable lesions.
- Chemotherapy is used for metastatic disease.

Survival
- "Curative" surgical resection gives a median survival of 18 months and a 5-year survival rate of approximately 20%. New adjuvant approaches may substantially improve these results.
- Survival of patients with unresectable lesions is 4 to 8 months, with less than 20% surviving for 1 year.

INTRODUCTION

Pancreatic adenocarcinoma is one of the most lethal malignancies, with an overall 5-year disease-free survival rate on the order of 1% to 2%. Most pancreatic cancers are not diagnosed until they are locally advanced or until regionally disseminated disease has developed that is not amenable to curative surgical resection. Chemotherapy and radiation therapy are of only modest benefit in this disease, and typical survival is on the order of 6 months. Of those patients with apparently resectable disease who undergo surgical exploration, between 20% and 40% are found to have unresectable lesions. Even those patients in whom a margin-negative resection has been achieved have a 5-year disease-free survival rate of less than 30%, and in approximately half of the patients surviving 5 years, the cancer will recur between years 6 and 10. Thus, the treatment of pancreatic cancer remains a challenge to the surgical, radiation, and medical oncologist.

In recent years, a number of positive developments have occurred in the management of pancreatic cancer. Improvements in the preoperative staging of pancreatic cancer have reduced the number of patients undergoing laparotomy for what proves to be unresectable disease. Advances in surgical technique and perioperative management allow pancreatic cancer resections to be performed with very low mortality and tolerable morbidity. In patients who undergo resection, even when not cured, survival appears to be substantially longer than in patients managed with other modalities; thus, at a minimum, resection achieves substantial palliation and extension of survival. Furthermore, evolving approaches to adjuvant chemotherapy and chemoradiation therapy may substantially improve long-term survival after an attempted curative resection.

For patients who are first seen with unresectable disease, an appropriate focus has been placed on optimizing quality of life. Nonoperative methods of relieving obstructive jaundice avoid the need for laparotomy in most patients. Appreciation of the importance of palliating pain is of great benefit to those patients whose cancer is not potentially curable. Furthermore, new approaches to chemotherapy offer the hope of extending both quality and quantity of life in many patients. This chapter reviews current approaches to the management of patients with pancreatic cancer.

INCIDENCE

Pancreatic carcinoma is a relatively uncommon malignancy. Approximately 37,000 new cases were diagnosed in the United States in 2007, accounting for 2.6% of all cancer diagnoses. Because the annual death rate from pancreatic cancer approximates its incidence, pancreatic cancer is a fairly common cause of cancer mortality in the United States. Carcinoma of the pancreas ranks fourth behind carcinomas of the lung, colorectum, and breast as a cause of cancer deaths.[1–3] Because of the relative rarity of breast cancer in men and the nonexistence of prostate cancer in women, pancreatic cancer is the fourth most common cause of cancer-related death in both men and women, accounting for approximately 6% of cancer deaths overall.

The incidence of pancreatic carcinoma has increased three- to fourfold in the 20th century, but appears to have leveled off in recent decades. This probably reflects both improvements in the accuracy of diagnostic techniques such as CT scanning and a genuine increase in incidence. The risk of developing pancreatic cancer increases with age[1,4]; it has been estimated that this risk increases two- to threefold for each decade of life after age 40 years. Although patients typically are first seen in their 60s and 70s, diagnosis of pancreatic cancer in patients in their 40s and 50s is not uncommon; pancreatic cancer is rarely seen in patients younger than 30 years.

EPIDEMIOLOGY

Adenocarcinoma of the pancreas traditionally has been viewed as occurring more commonly in men than in women (relative risk, 1.5 : 1), although recent data suggest that relative risk in women is approaching that seen in men,[1,3] perhaps because of increased tobacco use by women in the latter half of the 20th century. In the United States, pancreatic cancer occurs more frequently in blacks than in whites (relative risk, 2 : 1) and may be somewhat less common in persons of Asian ancestry than in whites (relative risk, 0.7 : 1). Worldwide, incidence rates are highest in industrialized countries and lowest in African and Asian countries,[1,5] suggesting that environmental factors linked to a "Western lifestyle" substantially increase the risk of pancreatic cancer. The high incidence rates observed in African Americans, in contrast with the low rates observed in African countries, also argue strongly for the role of environmental as opposed to hereditary factors in the etiology of most pancreatic cancers.

Environmental Risk Factors

Studies of environmental factors linked to the development of pancreatic carcinoma have identified a number of agents that may play a role in pancreatic carcinogenesis, as summarized in Table 85-1.[1,6–25] Cigarette smoking significantly increases the risk of this form of cancer, as it does for a variety of other tumors. Certain industrial solvents, particularly those used in metal refining, have been linked to the development of pancreatic cancer. Dietary factors also play a role. High dietary fat intake and obesity clearly increase the risk of developing pancreatic cancer, whereas generous vitamin C intake and consumption of fruits and vegetables may decrease the risk of pancreatic cancer. Although alcohol consumption does not appear to be a risk factor for the development of pancreatic cancer, chronic pancreatitis almost certainly is.[8] Consumption of coffee and other caffeinated beverages, which had been suggested to be a risk factor on the basis of early studies, appears to be unrelated to the development of pancreatic cancer.

Table 85-1 Risk Factors for Pancreatic Cancer

Risk Factor	Relative Increase in Risk
Proven risk factors	
Cigarette smoking	2- to 3-fold
Industrial chemical exposure	3- to 5-fold
Chronic pancreatitis	2- to 10-fold
Diabetes mellitus	2- to 3-fold
Obesity	2- to 3-fold
Unproven or disproven risk factors	
Coffee consumption	
Alcohol consumption	

Perhaps the most controversial risk factor is diabetes. Approximately 15% of patients with pancreatic cancer become diabetic in the 6 months preceding the diagnosis of their cancer. This probably reflects local alterations in pancreatic function resulting from an occult tumor, rather than rapid development of cancer after the onset of diabetes. When patients in whom diabetes develops within 2 years of their diagnosis of pancreatic cancer are excluded, however, an approximately twofold increased risk for the development of pancreatic cancer is found among patients with long-standing diabetes.[9]

PATHOLOGY AND TUMOR BIOLOGY

If stromal tissue, nerves, and lymphatics are excluded, three principal cell types are seen in the pancreas: ductal cells, acinar cells, and endocrine cells (Fig. 85-1). Adenocarcinomas are malignancies derived from neoplastic transformation of the pancreatic ducts and comprise the vast majority (greater than 90%) of pancreatic neoplasms. These tumors display a glandular morphology, although occasionally squamous differentiation may be present. In such cases, the term *adenosquamous carcinoma* is used. The stage of pancreatic adenocarcinomas is related to survival, with adenosquamous carcino-

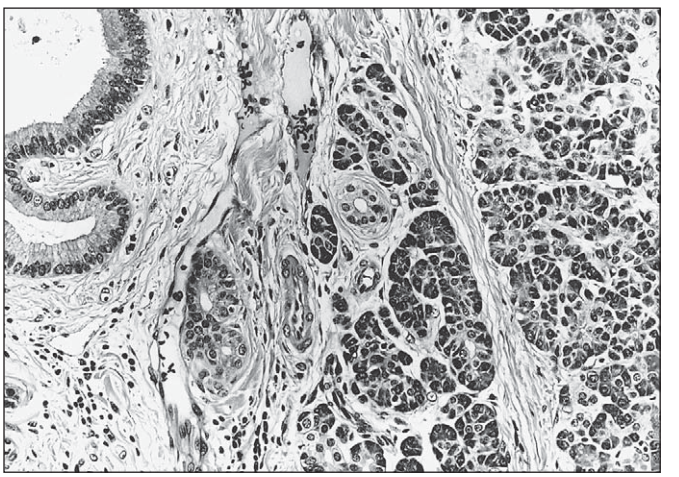

Figure 85-1 • Section of normal pancreas showing exocrine glands on the *right* and a portion of the wall of the large duct on the *left*. Note the regularity of the ductal lining epithelium. (Hematoxylin and eosin, ×200.)

mas representing a particularly lethal subset, with few 1-year survivors.[26] Although ductal adenocarcinoma is the most common pancreatic tumor, a variety of other benign and malignant pancreatic tumors have been described, as shown in Table 85-2. Most other malignant pancreatic lesions, such as pancreatic endocrine tumors, acinar cell carcinomas, and cystadenocarcinomas, appear to be less biologically aggressive than pancreatic adenocarcinomas and have a somewhat better prognosis.

Pancreatic adenocarcinomas arise most commonly in the head of the pancreas; the other lesions are distributed evenly in the body and tail of the gland. An important point is that nonpancreatic tumors of the distal bile duct, duodenum, and ampulla of Vater, although much less common than pancreatic adenocarcinoma, comprise almost one third of resectable tumors in the region of the pancreatic head. Furthermore, these tumors tend to be biologically less aggressive than pancreatic carcinomas, with 5-year disease-free survival rates after resection ranging from 30% to 50%.[27–29] It can be difficult, if not impossible, to distinguish these tumor types from routine adenocarcinoma of the pancreas on the basis of endoscopic, radiologic, or needle cytology criteria. Only histologic sectioning of a resected tumor mass can accurately classify the specific tumor type in some circumstances. Another possibility to be considered is a metastasis to the pancreas, which may mimic a primary tumor. For example, clear cell renal carcinomas that have metastasized to the ampullary region may be confused on imaging studies with a pancreatic carcinoma.

Pancreatic adenocarcinomas tend to be aggressive tumors that disseminate early and tend to follow similar patterns of metastatic spread in most patients. Local invasion into adjacent structures frequently is seen, with encasement of the superior mesenteric or portal vein and the superior mesenteric artery representing a common event that may preclude resection. Spread to regional lymphatics is common, as is metastasis to the liver by way of the portal vein. Spread to peritoneal surfaces (carcinomatosis) frequently is seen in advanced disease, as are lung metastases.

The pathologic staging of pancreatic cancer is based on the extent of tumor involvement of local and distant structures, as shown in Table 85-3. Stage I tumors are limited to the pancreas. Stage II tumors are regionally invasive, without involvement of the celiac or superior mesenteric artery, but may involve regional lymph nodes.

Table 85-2 Histologic Classification of Pancreatic Tumors

BENIGN TUMORS
Serous cystadenoma
Mature cystic teratoma
TUMORS OF INDETERMINATE MALIGNANCY
Mucinous tumors of the pancreas
Intraductal tumors
Solid and papillary tumors
Neuroendocrine tumors
MALIGNANT TUMORS OF PANCREATIC ORIGIN
Ductal adenocarcinoma
Acinar cell carcinoma
Adenosquamous carcinoma
Anaplastic carcinoma
Cystadenocarcinoma
Pancreaticoblastoma
Small cell carcinoma

Table 85-3 Staging for Pancreatic Cancer

PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor <2 cm
T2	Tumor >2 cm, confined to the pancreas
T3	Tumor extends locally beyond the pancreas
T4	Tumor involves celiac or superior mesenteric arteries
LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
DISTANT METASTASES (M)	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
STAGE GROUPING	
IA	T1, N0, M0
IB	T2, N0, M0
IIA	T3, N0, M0
IIB	T1–3, N1, M0
III	T4, N0–1, M0
IV	T1–4, N0–1, M1

Stage I and II tumors are considered potentially amenable to resection with curative intent. Stage III lesions are defined by direct involvement of the celiac or superior mesenteric arteries, and stage IV lesions are defined by the presence of distant metastases. Patients with stage III and IV disease generally are not considered candidates for potentially curative resection, although this view recently has been challenged for selected patients with isolated liver metastases.[30,31]

Cystic Neoplasms

Cystic neoplasms of the pancreas are distinguished from an inflammatory fluid collection (pseudocyst) by the presence of an epithelial lining. Cystic neoplasms of the pancreas can be divided into benign tumors and malignant tumors (cystadenocarcinomas).[26] The presence of invasion defines the cystic lesion as a carcinoma. Benign cystic tumors can be further divided, on the basis of radiologic factors and by analysis of cyst fluid, into lesions with little predilection to become malignant, termed *serous cystadenomas*, and those with a significant risk of malignant degeneration, termed *mucinous cystic neoplasms*. Although the mucinous tumors previously were subclassified as either benign mucinous cystadenomas or malignant cystadenocarcinomas, the preferred designation is *neoplasm*, because of the malignant potential of all mucinous cystic tumors, as evidenced by the frequent identification of cystadenocarcinoma in patients suspected of harboring a mucinous cystadenoma. The epithelial lining of a mucinous cystic neoplasm may range in cytoarchitecture from bland cells to cells with high-grade dysplasia. The biologic behavior of the lesion, however, is driven by the presence or absence of invasion. In order to evaluate for the presence of invasion, complete resection and histologic evaluation of the entire lesion may be needed. Mucinous cystic tumors occur primarily in women and may have ovarian-type stroma surrounding the neoplastic lining.

Although large lesions (greater than 3 cm in diameter) generally should be resected, the management of smaller asymptomatic lesions is controversial. Several centers are observing small asymptomatic cystic neoplasms.[32,33] The evolution of changes on surveillance imaging that led to resection was 8% within 2 years of study entry in one series of patients managed nonoperatively from Memorial Sloan-Kettering Cancer Center.[32] The lifetime risk of evolving malignant changes is the critical factor in determining whether resection should be carried out, and at present this is uncertain. With longer term follow-up in these sizable patient series, a better understanding of the risk of malignant progression should evolve.

Cystadenocarcinomas of the pancreas are less biologically aggressive than pancreatic adenocarcinomas, with a higher cure rate after complete resection. Because even serous cystadenomas can be locally invasive,[3] an aggressive approach to the removal of most serous cystadenomas as well as of all mucinous tumors of the pancreas is justified. In contrast with traditional pancreatic adenocarcinomas, mucinous tumors of the pancreas with an invasive component are less predictable in their biologic behavior, with some malignant tumors remaining indolent for months to years. They may be locally or regionally invasive without forming metastases. When mucinous tumors of the pancreas do disseminate, they tend to form peritoneal implants but rarely give rise to liver or lung metastases, much akin to mucinous malignancies of the appendix.

A related but distinct lesion is the intraductal papillary mucinous neoplasm (IPMN).[26,34] Unlike other cystic tumors, which do not communicate with the main pancreatic duct, IPMNs arise as a result of abnormalities of the pancreatic duct in which all or part of the pancreatic duct epithelium becomes dysplastic, and subsequently may degenerate to overt malignancy. IPMNs may arise from the main pancreatic duct or from side branch ducts; the risk of harboring invasive malignancy at diagnosis is greater for main duct lesions.[35] In some cases the entire pancreatic duct is ectatic and mucus-filled, giving a characteristic appearance on evaluation by endoscopic retrograde cholangiopancreatography (ERCP). Because of their predilection to harbor carcinoma in situ and even areas of invasive carcinoma, surgical resection of IPMNs may require total pancreatectomy in some patients, although margin-negative resections can be achieved with partial pancreatectomy in many patients. No consensus now exists on an appropriate follow-up strategy for patients who have undergone partial pancreatectomy for IPMNs, but the potential for recurrence or the development of new lesions mandates some form of surveillance. Our policy is to perform MRI with magnetic resonance cholangiopancreatography (MRCP) at 6-month intervals.

GENETICS

Molecular Genetics

Research performed over the last several decades has demonstrated that the development of malignancy is a multistep process in which distinct oncogenes are activated and tumor-suppressor genes inactivated in a clonal population of cells. This process ultimately gives rise to a cell population resistant to molecular mechanisms that normally regulate cell proliferation and programmed cell death.[36] Molecular events underlying the development of pancreatic cancer have been studied extensively, and a number of alterations in oncogenes and tumor suppressor genes that are thought to play a role in the development of this disease have been identified.[37–42] Common abnormalities include activating mutations in the K-ras oncogene (which occur in more than 90% of pancreatic cancers), overexpression of the HER2-neu oncogene (seen in 50% to 70% of pancreatic cancers), and loss of expression of the CDKN2, p53, and DPC4 tumor suppressor genes (seen in 100%, 70%, and 50% of pancreatic cancers, respectively).

The identification and characterization of histologically distinct premalignant precursor lesions that give rise to pancreatic adenocarcinomas, termed *pancreatic intraepithelial neoplasms* (PanINs), suggest that the activation of oncogenes and loss of tumor suppressor genes occur in a stepwise fashion. Activation of the K-ras oncogene is seen in very early preneoplastic lesions (PanIN1s) and even in secretions of patients with chronic pancreatitis and no known pancreatic cancer.[26,36] Similarly, HER2-neu overexpression frequently is seen in early intraepithelial neoplasms. By contrast, loss of the CDKN2, p53, and DPC4 tumor suppressor genes appears to be a relatively late event in tumorigenesis, seen in more advanced preneoplastic (PanIN2 and PanIN3) and frankly neoplastic lesions.

An intriguing animal model developed by Tuveson and colleagues in which activated K-ras is expressed in the pancreas of transgenic mice recapitulates the cellular and molecular events observed in human pancreatic cancer quite precisely.[43] In these animals, PanIn lesions develop that are indistinguishable from those seen in human patients, which progress to invasive carcinomas as a result of additional stochastic events. Additional studies have demonstrated that deleting the p53 gene in the pancreata of such mice results in the high-frequency development of invasive pancreatic carcinomas with metastases to regional lymphatics and the liver.[44] Such animal models may be of particular use in the development of novel approaches to treatment and chemoprevention.

Familial Pancreatic Cancer

Although a majority of pancreatic cancers appear to be sporadic in origin, approximately 5% of pancreatic malignancies are seen in patients with a familial history of pancreatic cancer.[45] Among patients with two first-degree relatives with pancreatic cancer, the relative risk of developing pancreatic cancer is increased 18-fold. In patients with three or more affected relatives, the increased risk is 57-fold. Such data strongly support the notion that familial pancreatic cancer is a real entity.

An additional unknown percentage of pancreatic cancers may reflect the presence of an overall cancer family syndrome that is less strikingly specific for the pancreas. For example, it has been shown that a subset of kindreds with the familial atypical mole–malignant melanoma syndrome (FAMM) have approximately a 20-fold increased risk for the development of pancreatic cancer,[42] although the relative risks for other forms of cancer are not substantially increased. Molecular analysis has demonstrated that this subset of FAMM patients has a germ-line alteration in the CDKN2 tumor suppressor gene.[42] Similarly, patients at risk for breast cancer as a result of inherited *BRCA2* gene abnormalities also have a risk of pancreatic cancer at least 10-fold that of the general population.[36,46] Other familial syndromes associated with an increased risk of pancreatic cancer include the hereditary nonpolyposis colon cancer syndrome, familial adenomatous polyposis, and ataxia-telangiectasia. Furthermore, the hereditary pancreatitis syndrome, caused by a mutation in the trypsinogen gene, is associated with a 40% to 70% risk of pancreatic cancer. Thus, genetic factors, although of variable penetrance, clearly play a role in the predisposition to pancreatic cancer development in many patients.

DIAGNOSIS

Signs and Symptoms

Patients with pancreatic cancer often describe feeling vaguely unwell for a number of months before the development of overt clinical manifestations that lead to the diagnosis of their illness. Common signs and symptoms of pancreatic cancer are summarized in Table 85-4. Although the development of "painless jaundice" often is thought of as a typical presenting feature of pancreatic cancer, most patients have mild to moderate abdominal pain. The presence of back pain is a particularly ominous symptom that may reflect retroperitoneal nerve invasion by tumor.

Table 85-4 Signs and Symptoms of Pancreatic Cancer

COMMON SIGNS AND SYMPTOMS
Jaundice
Anorexia
Weight loss
Abdominal pain
LESS COMMON SIGNS AND SYMPTOMS
Vomiting
Palpable mass
Palpable gallbladder (Courvoisier's sign)
Back pain
Splenomegaly
Constipation
Thrombophlebitis (Trousseau's sign)

The development of obstructive jaundice is related to the anatomic location of the primary tumor. It is almost universal in tumors of the pancreatic head and is quite rare in patients with primary tumors of the pancreatic tail. Liver function tests should be performed to distinguish obstructive jaundice from a primary hepatocellular process such as hepatitis. Patients with severe obstructive jaundice may have some degree of associated coagulopathy from hepatic dysfunction. Coagulation parameters should be tested in all jaundiced patients, and those with coagulation abnormalities should receive preoperative vitamin K or perioperative fresh-frozen plasma, or both.

Weight loss is relatively common in patients with pancreatic cancer. This finding may reflect duodenal obstruction by tumor, an as-yet poorly understood inhibitory effect of pancreatic cancer on gastric motility, or effects of tumor-related cytokines on host metabolism. Except in extremely malnourished patients, aggressive preoperative or perioperative nutritional support, or both, has not been shown to be of benefit.[3]

Findings on physical examination often are nonspecific.[3] Jaundice is common, as noted earlier, but not specific for the presence of a malignancy. The presence of a palpable pancreatic mass or gallbladder (Courvoisier's sign) is uncommon and usually is observed only in thin patients. Hepatomegaly due to liver congestion or the presence of metastatic disease is similarly seen in a minority of patients at the time of initial diagnosis.

Radiologic Evaluation

Patients suspected of having a pancreatic malignancy generally are evaluated by thin-cut, contrast-enhanced CT scanning. This modality is of use in identifying the tumor mass, as well as in assessing the liver for metastasis. Vascular involvement of superior mesenteric vein, portal vein, and celiac and superior mesenteric arteries also can be determined by CT scanning (Fig. 85-2). Ultrasonography is useful in identifying the primary tumor mass (Fig. 85-3), particularly in the pancreatic head, but is less sensitive than CT and provides less information regarding local and regional dissemination. MRI has not proved superior to CT scanning for assessment of the primary tumor, metastatic disease, or vascular encasement. Occasional patients with CT findings suggestive but not diagnostic of vascular encasement may benefit from preoperative visceral angiography, although improvements in CT methods, particularly the use of dynamic contrast infusion and helical (spiral) techniques, have largely supplanted angiography.

PET using [^{18}F]fluoro-2-deoxyglucose (FDG-PET) has not proved to be of general use in the diagnosis or staging of pancreatic cancer. Initial hopes that FDG-PET would distinguish chronic pancreatitis from pancreatic neoplasia have not been supported in clinical studies.[47] Furthermore, FDG-PET misses a substantial number of lymph node metastases and peritoneal metastases.[48] Although the addition of FDG-PET to CT-based diagnostic algorithms appears rarely to alter subsequent diagnostic or therapeutic maneuvers, it may be of use in determining tumor response to therapy.[49] Whether PET technology using agents that detect cell proliferation rather than cell metabolism will improve these results is currently under evaluation.

Patients with a pancreatic mass on CT and no evidence of metastatic disease or vascular encasement require no further testing and can be taken to the operating room for surgical resection. At the time of definitive surgery, a laparoscopic evaluation of resectability may be performed, as discussed later. It is not necessary to obtain a preoperative tissue diagnosis. Indeed, because of the frequent presence of a dense reactive stroma surrounding small islands of cancer cells, cytologic assessment of pancreatic malignancies is notoriously inaccurate, rendering absence of malignant cells on percutaneous or endoscopic biopsy of little value in the management of patients with a resectable pancreatic mass. An additional concern with percutaneous techniques is the possibility of tumor dissemination as a result of the biopsy process, as has been suggested in some studies.[50]

Endoscopic Retrograde Cholangiopancreatography

Patients with jaundice but no mass on CT scans generally are evaluated with ERCP. This study may reveal an irregular or tapering biliary stricture characteristic of an obstructing periampullary tumor (Fig. 85-4). Sometimes the biliary stricture is seen in conjunction with a pancreatic duct stricture—the "double duct" sign—which is highly suggestive of the presence of a malignancy. Irregular strictures of the pancreatic duct also may be seen in patients with pancreatic carcinoma. Such endoscopic findings, even in the absence of a pancreatic mass on CT scanning, justify proceeding to surgical resection. Examination of endoscopic brushings and biopsy specimens may confirm the presence of a pancreatic neoplasm but carries a relatively high false-negative rate, as discussed earlier. An aggressive surgical approach to the management of suggestive biliary strictures, particularly in patients without a history of gallstone disease, often will result in removal of tumors at a relatively early stage.

The risks and benefits of decompressing the biliary tree before resecting a pancreatic cancer remain controversial.[51–54] Although the rationale for relieving obstructive jaundice and normalizing liver function before surgery is clear, several randomized prospective trials have failed to show a benefit of preoperative biliary stenting by ERCP or percutaneous techniques. Furthermore, an increased incidence of complications is found in patients who undergo stenting before resection; the presence of an endoscopically placed stent appears to increase the risk of postoperative morbidity, particularly the development of infectious complications, in patients undergoing pancreaticoduodenectomy.[54]

Probably the critical factor in deciding whether to perform preoperative decompression in a jaundiced patient who will definitely be taken for surgical exploration is the interval to surgery. If the patient can be operated on in a few days and is not symptomatic from jaundice, it may be best to proceed directly to surgery. If a delay in scheduling surgery is expected or if the patient is extremely symptomatic from jaundice, it may be best to stent the patient, both for comfort and to minimize the risk of cholangitis.

Endoscopic Ultrasonography

Another important endoscopic technique that has begun to play a major role in the diagnosis and staging of patients with pancreatic malignancies is endoscopic ultrasonography (EUS).[55] EUS can assess tumor size, portal and mesenteric vein involvement, and regional

nodal involvement. EUS also can allow obtaining tissue samples for histologic analysis from virtually all pancreatic lesions and from suggestive lymph nodes located close to the stomach and duodenum. It has the advantage of not requiring a general anesthetic and can be performed outside an operating suite using only mild sedation. As in all sonographic procedures, the quality of clinical information achieved with EUS is highly operator dependent. Furthermore, EUS cannot evaluate lesions, such as peritoneal metastases, that are located at sites distant from the lumen of the gastrointestinal tract.

Tumor Markers

A number of tumor-associated antigens detectable in the serum of patients with pancreatic carcinoma have been described, the most useful being CA19-9.[56] CA19-9 is a mucin-associated carbohydrate antigen produced by normal pancreatic cells, as well as by pancreatic carcinoma cells. It is biochemically related to the Lewis blood group antigen, and Lewis antigen-negative patients cannot make CA19-9.[57] CA19-9 can be detected in serum and pancreatic juice. As with other tumor markers, the use of CA19-9 in the management of patients with pancreatic cancer is plagued by problems related to sensitivity and specificity. Small tumors often fail to produce enough CA19-9 to be detectable above the accepted serum threshold of 37 units/mL. Non-neoplastic disorders of the pancreas and biliary tract, particularly pancreatitis, are associated with elevations of CA19-9, which may reach several hundred units per milliliter. Patients with CA19-9 levels in the thousands almost definitely have pancreatic cancer but generally are quite asymptomatic from their tumors, which often are unresectable. Thus, little use is found for CA19-9 in screening asymptomatic populations. CA19-9 may be a predictor of pancreas cancer aggressiveness independent of tumor stage[58] and when elevated at diagnosis may be useful in following the response to therapy.

Analysis of tumor markers in pancreatic cyst aspirates may be of use in distinguishing pseudocysts from cystic neoplasms and in separating serous cystadenomas from mucinous neoplasms if radiologic criteria alone are inadequate. Of interest, CA19-9 levels in cyst aspirates are of little use in separating these different lesions. Nevertheless, analyzing the combination of amylase, carcinoembryonic antigen, and CA-125 allows fairly accurate but not perfect separation among the different cystic lesions of the pancreas.[59,60] These studies are particularly useful in the elderly or medically frail patient in whom resection of a cystic lesion of the pancreas poses an unusually high risk. When cyst fluid analysis suggests a low likelihood of malignancy, such high-risk patients can be managed without surgery.

Laparoscopic Staging

The development of laparoscopic staging procedures represents a significant advance in the preoperative staging of patients with pancreatic cancer and other periampullary tumors.[50,61–64] Among patients who appear to have a resectable pancreatic cancer as indicated by helical (spiral) CT scanning, a 20% to 30% incidence is seen of either locally advanced disease or small hepatic or peritoneal implants, undetected by radiologic imaging, which preclude curative resection. With advances in nonoperative palliation of advanced disease, particularly improvements in biliary stenting, as discussed later, no need may be found for formal laparotomy in patients with disease not amenable to curative resection. Avoiding unnecessary laparotomy is an important goal of palliation for patients with advanced disease, which may be facilitated by laparoscopic evaluation.

Simple laparoscopy with biopsy allows the evaluation of visceral and peritoneal surfaces and may reveal disease undetectable by other techniques. Patients may then avoid unnecessary open surgical procedures if adequate palliation of jaundice can be achieved with percutaneous or transhepatic biliary stent placement. Staging laparoscopy, with frozen-section evaluation of biopsy specimens if necessary, can be carried out in 15 to 20 minutes and can be followed by formal laparotomy and tumor resection with the patient under the same anesthetic. Available data suggest that this technique alone can reduce the incidence of unresectable disease at laparotomy by more than 50%.[62,64]

Several more complex techniques may further enhance the utility of laparoscopic staging. Laparoscopic ultrasonography can reveal abnormalities beneath the visceral surfaces and, with the use of flow Doppler techniques, may identify vascular encasement or occlusion.[61,62] Conlon and colleagues described more thorough laparoscopic staging of periampullary tumors, which includes pathologic evaluation of celiac, periportal, and peripancreatic lymph nodes.[63] Finally, the assessment of occult disease by cytologic assessment of peritoneal washings obtained at laparoscopy may further define patients with tumor dissemination who are unlikely to benefit from extensive surgical resection.[50] Of note, however, all of these techniques extend operative time, and several days may be required to obtain a definitive diagnosis in the case of lymph node biopsy or peritoneal fluid cytologic analysis. Surgeons favoring these approaches often perform laparoscopic staging procedures and definitive resections in separate anesthetic procedures, with a corresponding increase in cost and patient morbidity.

THERAPY

Surgical Resection

For patients with potentially resectable pancreatic malignancies, defined as those that have not yet metastasized to distant sites, encased the portal or superior mesenteric vein, or invaded the roots of the celiac or superior mesenteric artery, surgical resection remains the best hope for achieving prolonged disease-free survival. Most resectable tumors occur in the head of the pancreas and are resected by pancreaticoduodenectomy (Whipple procedure). This procedure initially was described as a two-stage operation,[65] although it fairly rapidly evolved into a one-stage procedure.[66] Although individual surgeons perform this procedure differently, in all cases, the head of the pancreas, distal bile duct, and most of the duodenum and proximal jejunum are resected en bloc. In many cases, the entire duodenum, as well as the gastric antrum, is included with the resection specimen. Reconstruction involves the performance of pancreatic, biliary, and gastric or duodenal anastomoses to the remaining jejunum. A schematic drawing of a pylorus preserving pancreaticoduodenectomy and reconstruction is shown in Figure 85-5.

Pancreaticoduodenectomy is a demanding technical operation, requiring meticulous dissection around portal and mesenteric blood vessels and three distinct anastomoses; the morbidity and mortality associated with the Whipple procedure can be significant. Indeed, in the mid-1970s, it was seriously considered whether patients with resectable pancreatic malignancies might be better managed with palliative bypass procedures.[67–69] Over the past several decades, however, a steady improvement has occurred in the results reported after pancreaticoduodenectomy with regard to morbidity and mortality, with a corresponding improvement in long-term survival of patients with resected tumors.

Perioperative Mortality

A steep decline in the perioperative mortality rate of patients undergoing pancreaticoduodenectomy has been noted in recent years.[70] During the past 30 years, postoperative mortality rates have declined from 20% to less than 5% in many institutions around the world. Near-zero mortality rates, which we define as 2% or less, are being reported with increasing frequency in case series numbering more than 100 patients. These mortality rates are so low that many hundreds of cases would be required to determine precise mortality rates. Nonetheless, it is safe to make the general statement that extremely low mortality rates are now the norm for pancreaticoduodenectomies performed in specialized centers.

The reason(s) for the precipitous decline in perioperative mortality rates is not completely understood. It appears, in part, to reflect concentration of pancreaticoduodenectomy procedures at high-volume centers[71–74]; low-volume centers still have perioperative mortality rates of 15% to 20% in national surveys.[73,74] The observed decrease in perioperative mortality in high-volume centers is no doubt multifactorial and parallels a general decline in operative mortality seen for other surgical procedures. Other contributing factors are improvements in intensive care, diagnostic and interventional radiology, and nutritional support. Prophylaxis and management of infection, venous thromboembolism, and gastrointestinal hemorrhage also have improved greatly during this period. As a result, postoperative cardiopulmonary complications and gastrointestinal hemorrhage, which used to be fairly common, have been sharply reduced. Other complications, such as disruption of the pancreaticojejunal anastomosis, which often were fatal 30-some years ago, now lead to death infrequently.[75]

Morbidity

Although mortality rates have decreased significantly, pancreaticoduodenectomy remains a procedure in which major morbidity is common. Complication rates are difficult to evaluate because no uniformly adopted method exists of reporting or even defining complications. Additionally, some series provide numbers of complications, whereas others report the number of patients with complications. Despite these limitations, it is apparent that some complications, such as pulmonary embolism, gastrointestinal bleeding, pneumonia, and myocardial infarction, are less common today than in the past.

Improvements in surgical technique have reduced the incidence of leakage at biliary-enteric anastomoses (biliary fistula) to less than 5% in many series.[70] By contrast, leakage at the pancreaticoenteric anastomosis (pancreatic fistula) is still a major complication of pancreaticoduodenectomy, occurring in 10% to 20% of patients in most series.[70] In reported case series, not much improvement in the incidence of this complication has been achieved over the years. For most surgeons, the pancreaticoenteric anastomosis continues to be the weak point of the operation, leakage being most common when the pancreatic duct is small and the gland very soft. Recent technical advances, however, may lower the incidence postoperative pancreatic fistulae, as described later on, and in the current era, leakage at the pancreaticojejunostomy generally leads to an increased length of hospital stay but rarely to reoperation or death.[75]

Probably the most common postoperative complication seen in patients undergoing pancreaticoduodenectomy is delayed gastric emptying. Although this effect is not well understood, disruption of enterogastric signaling after duodenectomy is thought to be responsible for the gastric motility problems so frequently seen. Although it once was thought to be more common in patients undergoing pyloric preservation,[76] randomized studies have demonstrated that delayed emptying is equally common in patients undergoing classic Whipple resection with hemigastrectomy.[77] Delayed gastric emptying is seen in more than 20% of patients and may range in severity from mild nausea and inability to eat to persistent vomiting requiring nasogastric suction for days to weeks after surgery. Problems with gastric emptying rarely are life-threatening but can significantly prolong postoperative hospitalization. A randomized prospective trial of erythromycin demonstrated modest but statistically significant benefits in improving gastric emptying after pancreaticoduodenec-

tomy, presumably through the effects of erythromycin on motilin receptors.[78]

Long-Term Survival after Surgical Resection

With decreased perioperative morbidity and mortality, some improvement in 5-year survival rates has been noted for patients undergoing pancreaticoduodenectomy for pancreatic cancer. Five-year survival rates after Whipple resection for ampullary, bile duct, and duodenal malignancies have always been reasonable, ranging from 30% to 50% in most series, and resection of a mucinous tumor of the pancreas results in 5-year survival rates of more than 75%. By contrast, the long-term survival of patients with pancreatic adenocarcinoma generally has been extremely poor. A review of the world literature dating back over 50 years suggests that the overall 5-year survival rate after attempted curative resection for adenocarcinoma of the pancreas is on the order of 4%.[79] Furthermore, some patients experienced recurrence beyond 5 years, suggesting that they had not been cured by resection of their tumors.

Several large case series from high-volume centers suggest that better long-term results are now being obtained, with greater than 20% of patients with documented pancreatic adenocarcinoma surviving 5 years after resection.[80–82] In patients with disease-free resection margins, small tumors, and no evidence of lymph node metastases, the results may be even better, with more than 40% of such patients expected to survive 5 years. An important point, however, is that not all recent series have noted such results. Researchers who believe that results have improved point to improvements in diagnosis, surgical technique, and the use of adjuvant chemotherapy and radiation therapy as possible contributing factors.

Technical Aspects of Pancreaticoduodenectomy

Variations in pancreaticoduodenectomy technique between experienced surgeons are the rule, and multiple approaches can be reviewed in surgical atlases and texts. Certain strategic aspects to the successful performance of this operation are worth emphasizing here. Probably first and foremost is that this is not an operation that should be carried out by surgeons who do pancreatic surgery on an infrequent basis. Studies from multiple centers have demonstrated a strong relation between surgical volume and outcome in patients undergoing pancreaticoduodenectomy.[71–74] The statewide mortality rates in Maryland and New York and the national Medicare database show remarkably similar findings, with mortality rates three- to fivefold higher in patients undergoing surgery at low-volume centers, defined as those handling fewer than five cases per year, compared with centers treating 20 or more cases per year. The experience of the operating surgeon also is a factor correlated with low postoperative mortality after pancreatic resection.[74] A significant fraction of pancreaticoduodenectomies are still performed by relatively inexperienced surgeons in low-volume centers,[73,74,82] which may account for the higher mortality rates reported in national surveys than in high-volume centers. Other specific technical issues are discussed later in the chapter.

Total Pancreatectomy

One of the oldest controversies regarding resection of pancreatic tumors in the periampullary region was between a classic Whipple-type pancreaticoduodenectomy with preservation of the pancreatic body and tail and a total pancreatectomy. Advocates of total pancreatectomy claimed that the more extensive resection offered the opportunity to resect extensive or multifocal disease and more thoroughly removed potentially involved peripancreatic nodes.[83,84] In addition, complete removal of the pancreas obviated performing a pancreaticoenteric anastomosis, thereby eliminating the risk of a postoperative pancreatic fistula.

Unfortunately, in patients undergoing total pancreatectomy, the development of diabetes, which frequently was quite brittle and difficult to control, was universal. Furthermore, it was shown that pancreatic carcinomas rarely are multifocal[85] and that a total pancreatectomy per se does not remove a significantly greater number of the lymph nodes to which periampullary tumors are likely to metastasize.[86] Improvement in the surgeon's ability to prevent or manage pancreatic anastomotic leaks has changed this once-dreaded complication into one that is rarely a cause of death.[75,87] Finally, analysis of a number of studies of partial and total pancreatectomy for periampullary tumors failed to show a benefit for total pancreatectomy and suggested an equivalent or inferior outcome compared with that for Whipple-type pancreaticoduodenectomy. Thus, total pancreatectomy has been largely discredited as an operation for pancreatic tumors, except for those relatively rare cases in which direct tumor extension into the body and tail of the pancreas, or the presence of an extensive intraductal papillary mucinous neoplasm involving the entire pancreatic duct, makes a total pancreatectomy the only way to excise the primary neoplasm completely.

Regional Pancreatectomy

After careful study of the patterns of local and lymphatic metastases in pancreatic carcinoma, Fortner's group at the Memorial Sloan-Kettering Cancer Center championed a more extensive operation for cancers arising in the pancreatic head, which they termed *regional pancreatectomy*.[88] This operation removed not only the pancreatic mass (with either a total or subtotal pancreatectomy) but also included resection and reconstruction of the superior mesenteric vein–portal vein confluence and an extensive en bloc regional lymph node dissection.[89] In some patients, resection and reconstruction of the superior mesenteric artery or hepatic artery were performed as well.

Fortner has summarized his experience with this procedure in 56 patients,[89] which demonstrated a near-universal occurrence of major morbidity and a 30-day surgical mortality rate greater than 5%. In addition, it appears that several other patients survived more than 30 days but succumbed to surgical complications after a continuous postoperative hospitalization in excess of 30 days. Long-term survival in patients undergoing this procedure was closely related to tumor size, with an estimated 33% 5-year survival rate in patients with tumors smaller than 2.5 cm in diameter and a 12% survival rate in patients with tumors ranging from 2.5 to 5.0 cm; no patients with larger tumors survived 5 years. The survival figures obtained with regional pancreatectomy are not significantly better than those reported with the standard Whipple-type pancreaticoduodenectomy,[60] whereas the morbidity and mortality are clearly greater.

Sindelar and colleagues at the National Cancer Institute also found the regional pancreatectomy to be associated with a significantly greater morbidity and mortality than is standard in pancreaticoduodenectomy.[90] Furthermore, they analyzed the sites of tumor recurrence in patients undergoing regional pancreatectomy and noted both locoregional recurrence and development of evidence of distant metastases in a majority of patients.[91] Thus, the more radical operation was not successful in providing better local control or survival when compared with pancreaticoduodenectomy.

Although few surgeons now perform the regional pancreatectomy as originally conceived by Fortner, two of its principles—portal vein resection and extensive regional lymph node resection—are being carried out elsewhere and may have a role in selected patients. These principles are discussed individually next.

Portal Vein Resection

Among the many factors complicating resection of cancers arising in the head of the pancreas is the close proximity of major vessels in the porta hepatis, particularly the portal vein. In a number of studies, tumor involvement of the portal vein has been associated with a poor outcome.[92,93] This may reflect a difference in the biology of such tumors, with tumors that are more aggressive and invariably associated with a poor outcome being more likely to invade the portal vein. By contrast, portal vein invasion also may be simply a consequence of where the tumor anatomically arises, so that if it can be adequately resected with negative margins, such patients may do as well as

patients undergoing resection who do not have portal vein involvement. Although somewhat controversial, the current data favor the latter conclusion.

The first reports of superior mesenteric vein–portal vein resection for periampullary tumors date to the 1950s. Only recently, however, have large series of patients undergoing portal vein resection been reported.[94,95] Results from both the M.D. Anderson Cancer Center and the Memorial Sloan-Kettering Cancer Center suggest that patients undergoing en bloc resection of the portal vein expereince morbidity and mortality comparable to those in patients undergoing a standard pancreaticoduodenectomy. Analysis of resected specimens from patients whose tumors had invaded the portal vein suggest that these tumors are no more likely to be associated with cancer-positive lymph nodes or to be aneuploid than are tumors that did not invade the portal vein.[94] Thus, vein invasion does not appear to reflect a difference in tumor biology and is most likely to be the unfortunate result of tumor anatomy.

Although the recent data are not completely mature with regard to survival in patients undergoing portal vein resection, preliminary analysis suggests that patients undergoing portal vein resection and reconstruction in whom tumor-negative surgical margins are achieved do no worse than patients in whom the portal vein is uninvolved.[93–95] It seems reasonable to conclude that in patients with tumors involving the portal vein that are otherwise resectable with tumor-negative margins, en bloc resection of the portal vein is warranted.

From a technical standpoint, resection of the portal (or superior mesenteric) vein can be relatively simple or quite complex. Involvement of a small segment of the side wall of the vein can be locally resected, followed by primary venorrhaphy. Longer or more circumferential involvement generally requires segmental vein resection. Reconstruction often can be carried out with primary anastomosis if the resected segment is shorter than 2 to 3 cm and the approximation can be achieved without undue tension. Resection of longer segments generally requires interposition grafting using autologous vein. Either the saphenous vein, the femoral vein, or the internal jugular vein can be used in reconstruction of the portal or superior mesenteric vein and generally can be harvested unilaterally without significant morbidity.

An important consideration is that portal or superior mesenteric vein involvement may be an indication of unresectability. Circumferential involvement (encasement) of the portal or superior mesenteric vein, and particularly occlusion of the portal vein with resulting mesenteric venous hypertension, render resection exceedingly difficult, if not impossible, in most circumstances. Tumors that encase the portal vein often invade or encase the superior mesenteric artery as well. We do not perform pancreaticoduodenectomy in patients in whom preoperative staging demonstrates encasement of the portal or superior mesenteric vein, a position taken at other high-volume centers as well.[94,95]

Extended Lymphadenectomy

Periampullary malignancies may metastasize to lymph nodes beyond the limits of a standard pancreaticoduodenectomy.[86] In an effort to eradicate regional nodal disease before the development of distant metastases, a number of groups of investigators have championed the performance of an extended lymphadenectomy in addition to the standard pancreaticoduodenectomy.[96,97] This procedure involves the wide resection of lymphatic tissue from the celiac axis to the iliac bifurcation, including resection of nodal tissues between the portal vein and the superior mesenteric artery; resection of the portal vein–superior mesenteric vein confluence often is included and renders this portion of the case simpler from a technical point of view.

The Japanese have aggressively adopted this technique, and a number of series demonstrate favorable results compared with historical controls or concurrent patient populations in which a standard pancreaticoduodenectomy was performed.[98,99] Other series, however, have not shown such a difference.[100] In an analysis of the results of multiple series of patients undergoing pancreaticoduodenectomy with extended lymph node dissection, it was concluded that the perioperative morbidity and mortality, as well as 5-year survival results, were not different from results with the standard Whipple-type pancreaticoduodenectomy.[97,101] A more formal meta-analysis reached the same conclusion,[102] and a prospective randomized trial of extended lymphadenectomy in patients undergoing pancreatic cancer resections at the Johns Hopkins Hospital also did not show a significant oncologic advantage.[97] These findings no doubt reflect the fact that, as in other malignancies, lymph node metastases reflect a more advanced stage of disease, in which systemic spread beyond the boundaries of possible resection has occurred. Thus, extensive lymphadenectomy generally is not performed.

Pylorus Preservation

Traverso and Longmire introduced the pylorus-preserving pancreaticoduodenectomy in an effort to minimize complications of the procedure related to the hemigastrectomy—specifically, dumping, marginal ulceration, and bile reflux gastritis.[103] This pylorus-preserving variant of the Whipple procedure preserves the entire stomach and pylorus, as well as the proximal 3 to 6 cm of duodenum, which is anastomosed to the jejunum to restore gastrointestinal continuity. Although this portion of duodenum occasionally is invaded by tumor, in many cases it can be preserved without apparent compromise of the tumor margin. Studies have confirmed preservation of pyloric function, with resulting decreases in dumping and enterogastric reflux.[104]

Surgeons critical of pylorus preservation raise a number of arguments, however. The incidence of marginal ulceration is quite low in the era of histamine H_2 receptor blockers and proton pump inhibitors. Furthermore, delayed gastric emptying, which can occur after either pylorus-preserving or classic Whipple resection, is thought by some investigators to be more common after pylorus preservation,[76] although this view is not supported by randomized studies.[77] Finally, the adequacy of pylorus preservation as a cancer operation has never been formally demonstrated in a randomized study. Of note, however, available data from case series do not suggest a markedly different 5-year survival among patients with pancreatic tumors undergoing either type of pancreaticoduodenectomy.[3]

Improvements in Pancreaticoenteric Anastomosis

As mentioned earlier, leakage at the pancreaticoenteric anastomosis remains a significant source of morbidity. Furthermore, this complication was reported in one large series to double the average postoperative hospital stay from 2 to 4 weeks.[87] Different types of pancreaticojejunostomies have been performed in an effort to minimize leakage from this anastomosis; most are variations on one of two very different techniques. The first approach, the so-called intussuscepting or "dunking" anastomosis, is performed by mobilizing the body of the pancreas 3 to 4 cm off the underlying splenic vein and then invaginating the cut end of the pancreas into the open end of the jejunal limb, which is sutured around the pancreas. This anastomosis is not dependent on the size of the pancreatic duct, although it may be technically difficult in certain circumstances, particularly when the pancreas is quite thick. A variation of this technique is to intussuscept the pancreas into the stomach.[87]

The alternative approach, the duct-to-mucosa anastomosis, is performed by anastomosing the cut edges of the pancreatic duct to the intestinal mucosa through a small opening made in the jejunum, using fine absorbable sutures. A reinforcing layer of sutures between the pancreatic capsule and the jejunal serosa commonly is placed to take tension off the anastomosis. This anastomosis is satisfying from a physiologic viewpoint but may be technically quite difficult in the presence of a nondilated pancreatic duct or a soft pancreas. Pancreatic fistula formation rates in series using either the duct-to-mucosa technique or the intussuscepting technique appear to be equivalent, and both are widely performed. A number of factors undoubtedly play a role in the success of pancreaticoenteric anastomoses.

Recently a number of reports suggesting that the incidence of pancreatic fistula development could be reduced to less than 5% have appeared in the surgical literature.[105–107] Although a number of distinct operative approaches have been used to achieve these remarkable results, several of the studies have championed the performance of a meticulous duct-to-mucosa anastomosis with fine absorbable suture material under loupe magnification. Although it may be impossible to prevent completely the development of pancreatic fistulae after pancreaticoduodenectomy, the incidence of this complication evidently can be substantially reduced. A number of studies have looked at the usefulness of somatostatin analogs such as octreotide in preventing the development of pancreatic fistulae. Although somatostatin analogs have proved effective in some European studies in patients undergoing a range of pancreatic surgical procedures,[108,109] these studies did not show a significant benefit in the subset of patients undergoing pancreaticoduodenectomy. Furthermore, several randomized trials of octreotide in patients undergoing Whipple resections in the United States have failed to demonstrate any benefit from the prophylactic use of this agent to prevent pancreatic fistula formation.[110,111] Octreotide also is expensive and, when administered subcutaneously, uncomfortable for patients. Its use to prevent pancreatic fistula development in the postoperative period cannot be recommended.

Distal Pancreatectomy

Patients with adenocarcinoma of the pancreas involving the body or tail of the pancreas generally do not become symptomatic until their tumors have reached an advanced stage and thus rarely are candidates for resection at the time of diagnosis. Furthermore, the long-term outcome after attempted surgical resection of more distal pancreatic adenocarcinomas is poor.[112,113] Probably the patients most likely to benefit from distal pancreatectomy are those with neuroendocrine or mucinous tumors of the pancreas. These tumors have a high cure rate after surgical resection and therefore warrant aggressive surgical measures regardless of their size or anatomic location.

Distal pancreatectomy is a less daunting technical undertaking than pancreaticoduodenectomy. This procedure involves en bloc resection of the spleen and pancreatic tail. As with the Whipple procedure, it is critical to achieve an adequate resection margin, in this case, the proximal pancreatic margin and the retroperitoneal margin; peripancreatic tissue should be widely mobilized from the retroperitoneum to ensure removal of adjacent lymphatic tissue. Distal pancreatectomy generally is performed by mobilizing the pancreatic tail (along with the spleen in most cases) and proceeding medially (retrograde) toward the pancreatic neck. Recently, the performance of this procedure from the pancreatic neck outward (antegrade) has been proposed as an approach to optimizing the retroperitoneal margin.[114] Whether this difference in technique will improve long-term outcomes is uncertain.

Adjuvant and Neoadjuvant Therapy

The modest success of surgical resection in producing long-term survival of patients with pancreatic tumors has led to a number of studies using chemotherapy and radiation therapy in an effort to diminish local and systemic recurrence after surgery. The classic study of adjuvant therapy for pancreatic carcinoma was performed by the Gastrointestinal Tumor Study Group (GITSG). This study prospectively randomized patients undergoing resection with curative intent to either no additional therapy or combined-bolus 5-fluorouracil (5-FU) and external-beam radiation therapy. Despite small numbers of patients in each arm of the study, a significant difference in outcome was observed between the two groups, with treated patients who received the adjuvant treatment surviving 20 months, versus 11 months for patients in the resection-only control group.[115] The GITSG subsequently completed a small confirmatory trial.[116]

Subsequent studies have yielded conflicting results. Although the initial report of European Organization for Research and Treatment of Cancer (EORTC) trial did not show a statistically significant benefit of adjuvant postoperative chemoradiation therapy, a recent re-analysis demonstrated a positive result, with a 14% improvement in overall survival at 2 years (37% versus 23%) favoring adjuvant chemoradiotherapy in patients with pancreatic head cancers that reached statistical significance ($P = 0.049$).[117] A distinct multi-institutional study also conducted in Europe, ESPAC-1 (European Study Group for Pancreatic Cancer-One), suggested a significant survival benefit of adjuvant chemotherapy with 5-FU but not of adjuvant chemoradiotherapy.[118] Although this study has been criticized for methodologic shortcomings, it has led to significant controversy about the role of adjuvant radiation therapy in pancreas cancer patients.

As another approach to determining whether adjuvant radiation improves overall survival in patients with resected pancreatic cancer, a population-based study of the Surveillance, Epidemiology, and End Results (SEER) registry with 2636 patients records from 1973 to 2003 (1123 received adjuvant radiation therapy and 1513 did not) was conducted.[119] With a mean follow-up period of 19 months, median overall survival for the patients receiving radiation therapy was 18 months, compared with 11 months for the group of patients who did not ($P < 0.01$)—results virtually identical to those seen in the small GITSG trials that initially addressed the role of adjuvant chemoradiation. Cox regression analysis demonstrated that patients who received adjuvant radiation therapy had a statistically significant increase in overall survival when compared with patients who received no such therapy (hazard ratio, 0.57; 95% confidence interval, 0.52 to 0.63; $P < 0.01$), suggesting that adjuvant radiation therapy is of benefit.[119]

A recent European phase III trial has demonstrated a benefit of single-agent gemcitabine chemotherapy in the adjuvant setting.[120] The median disease-free survival time was 13.4 months in the gemcitabine group and 6.9 months in the control group ($P < 0.001$). The estimated disease-free survival rates at 3 and 5 years were 23.5% and 16.5% in the gemcitabine group and 7.5% and 5.5% in the control group, respectively. Although overall survival was not significantly different, a nonsignificant trend favoring the gemcitabine group was observed that may reach significance as the data mature.

A single-institution phase II chemoradiation adjuvant therapy study by Picozzi and colleagues in Seattle, using a combination of 5-FU, cis-platinum, and interferon-α as radiation sensitizers, demonstrated a remarkable improvement in median survival time and 5-year survival rate (longer than 36 months and approximately 50%, respectively) in a cohort of patients after surgical resection.[121] Although only 53 patients received this treatment, these results have led to confirmatory trials at single institutions, as well as a multi-institutional phase II trial conducted by the American College of Surgeons Oncology Group. Results of these trials should be available in the near future. If the improvement in postoperative survival described by the Seattle investigators is verified by these studies, this adjuvant regimen will prove to be one of the most striking advances in the treatment of pancreatic cancer.

Neoadjuvant Chemotherapy and Radiation Therapy

Recently several groups of investigators reported results from studies of preoperative neoadjuvant therapy in patients with periampullary tumors.[122,123] Such therapy is theoretically attractive from several perspectives. Shrinkage of the primary tumor mass may make technical aspects of surgical resection easier. Data from animal experiments suggest that such therapy may reduce the incidence of tumor dissemination at the time of surgery. Furthermore, some otherwise eligible patients may fail to receive postoperative adjuvant therapy in a timely fashion because of the development of postoperative complications.

Although the feasibility and safety of neoadjuvant chemoradiation therapy have been demonstrated clinically, and efficacy is considered encouraging as indicated by the data from recent phase II studies,[124,125]

such treatment should be considered experimental at present and is not recommended outside of a clinical trials setting. In view of the ongoing controversies regarding the roles of radiation therapy, preoperative versus postoperative adjuvant treatment, and newer agents in the adjuvant setting, enrollment in clinical trials should be encouraged. In practice, postoperative adjuvant chemotherapy or chemoradiation therapy should be considered in patients who have undergone curative-intent surgery if no clinical studies are available.

MANAGEMENT OF PATIENTS WITH LOCALLY ADVANCED OR METASTATIC DISEASE

Downstaging

A substantial proportion of pancreatic cancer patients are first seen with locally advanced disease—either encasement of the superior mesenteric or portal veins or involvement of the celiac or superior mesenteric arteries—which precludes curative resection. This recognition has led to a number of studies attempting to use chemoradiation therapy to "downstage" the patient's tumor and permit a margin-negative surgical resection.[126,127] Unfortunately, the results of these studies generally have been poor, with zero to 15% of patients achieving sufficient tumor shrinkage to permit surgical resection; survival after resection for down-staging may be more limited than that usually seen after pancreaticoduodenectomy for resectable disease.[128]

Radiation Therapy

Pancreatic cancer is a challenging target for radiation therapy for a number of reasons. It is difficult to deliver adequate doses of radiation therapy owing to the location of the tumor and regional lymph nodes. Surrounding normal tissues such as the kidneys, liver, bowel, and spinal cord all have limited tolerance to radiation therapy that is below the dose required for sterilization of the pancreatic cancer. Strategies to overcome this issue have included intraoperative radiation therapy, brachytherapy, intensity-modulated radiation therapy (IMRT), and radiosensitizing chemotherapy.[129–134] To date, none of these strategies have had an overwhelming impact on the disease. Many pancreatic cancer patients also are nutritionally depleted, have experienced significant weight loss, and have poor performance status, further limiting the ability to provide aggressive therapy. Use of radiosensitizing drugs has been limited by the concurrent sensitization of surrounding normal tissues.

Currently, the standard of care remains concurrent chemotherapy and radiation therapy for the treatment of locally advanced, unresectable pancreatic cancer. This standard was first established by randomized trials by the Mayo Clinic in the late 1960s and later confirmed by the GITSG. These trials showed a significant benefit with 5-FU plus irradiation over that with radiation therapy alone, with a doubling of the median survival time of about 6 months for radiation therapy alone, to almost 12 months for 5-FU plus irradiation.[135] The GITSG also compared chemotherapy alone with chemoradiation therapy and demonstrated a significant survival advantage for the chemoradiation therapy treatment group, with a 1-year rates of 41% versus 19%.[129] Attempts to substitute other radiosensitizing chemotherapy such as gemcitabine are ongoing. The trend in most of these studies, however, has been to reduce the systemic dose of gemcitabine or to decrease the radiation field size because of toxicity of this combination. Resultant effects may therefore be similar to those seen with 5-FU and full-dose radiation.[134]

Proton therapy, which is now expanding in clinical centers, may offer a better approach for the combination of chemotherapy and radiation therapy in the setting of locally advanced disease. Because of the physical characteristics of the proton beam, the dose of radiation can be conformed to the tumor, with a significant reduction in dose or amount of radiation delivered to normal tissues.[136]

The use of radiation in this disease requires diligence in field design and aggressive nutritional and hydration support of the patient. Radiation technique and field design are critical in the treatment of pancreatic cancer. Treatment typically involves use of 15-MV or higher-energy beams. Conventional fields include the tumor volume with appropriate margins for setup and microscopic extension. Regional lymph nodes for cancer of the pancreatic head include the peripancreatic, celiac, superior mesenteric artery, and porta hepatis lymph node regions. For tumors of the pancreatic tail, the splenic hilum should be included in the radiation fields. Care should be taken to allow for adequate margins for organ motion, particularly with treatment of the portal nodes, because motion with diaphragm movement can be significant.

Radiation therapy can play a role in the adjuvant treatment of patients after resection, as described earlier, and can modestly extend survival in patients with advanced disease.[137] Irradiation thus remains an important palliative treatment in pancreatic cancer; it also can substantially ameliorate pain in some patients with disseminated disease.[138]

Chemotherapy for Advanced Disease

Chemotherapy for pancreatic cancer has had a modest positive impact on the survival of patients with advanced disease.[139] For many years, 5-FU-based therapy, with 5-FU used either as a single agent or in combination with other drugs, was the principal treatment strategy in patients with advanced pancreatic cancer. Although a number of studies suggested that such therapy resulted in a measurable survival advantage over that in patients receiving supportive care alone, the gains were quite modest.

The development and approval of gemcitabine for the treatment of advanced pancreatic cancer represent an advance in both the therapeutic armamentarium and the approach to identifying agents of benefit to patients with this disease. In a prospective randomized study, it was demonstrated that gemcitabine resulted in substantial clinical benefit (including better pain control and improved nutritional status) in approximately 25% of patients, compared with fewer than 5% of patients who received 5-FU.[139] This study also demonstrated a modest but statistically significant extension of median survival in patients receiving gemcitabine (5.4 versus 4.3 months; $P < 0.05$). Furthermore, the fraction of patients surviving more than 1 year was higher in the gemcitabine group (18% versus 2%). Of note, the fraction of patients achieving a partial radiologic response in this study was less than 5% and was not significantly different in the two treatment groups. Thus, this study not only identified an agent that improves the quality and the quantity of life for patients with advanced pancreatic cancer but also demonstrated the limitations of traditional radiologic measures of tumor response and the importance of alternative criteria in testing novel agents for the treatment of pancreatic cancer.

The identification of gemcitabine as an active agent in pancreatic cancer has led to the study of additional regimens using single-agent gemcitabine on different dosing schedules[140] or gemcitabine-based combinations.[138] Unfortunately, gemcitabine-based combinations generally have failed to show activity significantly better than that for gemcitabine alone and, in some cases, have been more toxic.[138,141,142] A notable exception was a randomized phase III study conducted by the National Cancer Institute of Canada, which compared the combination of gemcitabine and erlotinib, a tyrosine kinase inhibitor, with gemcitabine alone in advanced pancreatic cancer patients.[143] A modest difference in overall survival was observed (5.9 versus 6.4 months; $P = 0.025$) that favored the combination arm (hazard ratio, 0.81; 95% confidence interval, 0.67 to 0.97). The corresponding 1-year survival rates were 24% and 17%, respectively, for the two regimens. Additional studies of other targeted therapeutics, both alone and in combination with gemcitabine, are ongoing in patients with advanced pancreas cancer. It is hoped that one or more of these combinations will have substantially greater activity in patients with

pancreatic cancer and will thus represent a real advance in the management of patients with this disease.

Palliative Management of Patients with Advanced Disease

Modern approaches to surgical management of pancreatic carcinoma and the use of adjuvant therapy have made pancreatic resection safer and more effective. Such therapy has resulted in significant extension of survival for many patients. Long-term eradication of disease, however, is still the exception among patients with pancreatic carcinoma who undergo attempted curative resection. Furthermore, only 10% to 20% of patients with pancreatic carcinoma are first seen at an early-enough stage to be eligible for resection. Thus, in the vast majority of patients with pancreatic cancer, either advanced disease already is present or it develops in the setting of tumor recurrence. For physicians involved in the palliative management of patients with advanced pancreatic cancer, a number of important issues must be addressed: palliation of pain, palliation of jaundice, and palliation of gastric outlet obstruction.

Palliation of Pain

Advanced pancreatic cancer can be extremely painful, and most patients experience moderate or severe pain in the course of their illness. Pancreatic malignancies commonly invade neural and perineural tissues. Invasion of neural structures in the retroperitoneum by the growing pancreatic tumor mass is associated with a steady, unrelenting pain, which can be psychologically devastating. In the management of such patients, important aspects include the use of long-acting analgesics in appropriate doses and consideration for celiac plexus ablation. Whereas the use of long-acting oral or topical narcotic preparations should be well understood by all physicians that care for patients with advanced cancer, the use of celiac plexus blockade is less often appreciated.

Probably the best study of celiac plexus ablation was performed by Lillemoe and colleagues.[144] They randomized patients with unresectable disease, who were undergoing laparotomy for palliative biliary and gastric bypass, to receive injections of either 50% alcohol or saline into the celiac ganglia bilaterally. The study was carried out in a double-blind, prospective fashion, and outcomes of interest included pain, narcotic use, and survival among treated patients. This study convincingly demonstrated that patients undergoing chemical splanchnicectomy had significant relief of pain and required less narcotic use than did patients receiving saline. The benefit of such therapy appeared to last for 4 to 6 months. In the subset of patients with moderate to severe pain at the time of treatment, a statistically significant survival advantage was seen among those treated with alcohol injection. Celiac plexus block can be easily and safely performed at the time of a palliative surgical bypass procedure, and it also can be performed percutaneously, with or without CT guidance, in patients who have no other indication for laparotomy.

Palliation of Jaundice

Most patients with tumors of the periampullary region have jaundice when first seen. Although pancreaticoduodenectomy is an effective method of relieving jaundice, most patients have disease too extensive for attempted curative surgical resection. Multiple approaches are available for the management of jaundice in such patients, including endoscopic and percutaneous biliary stent placement and surgical biliary bypass. Several trials compared surgical with nonsurgical approaches for the management of biliary tract obstruction.[145] In general, these trials demonstrated a lower initial morbidity among patients undergoing nonoperative stenting. The stent occlusion rates, however, were significantly higher than the failure rates of surgical biliary bypass, resulting in more frequent bouts of cholangitis and the need for multiple procedures over time in patients managed nonoperatively.

The greater long-term morbidity among stented patients was thought to be approximately equivalent to the greater short-term morbidity among patients undergoing surgical bypass, leading to the conclusion that the treatments were approximately equivalent. It has been suggested that patients with a relatively short life expectancy due to extensive disease, and those with increased operative risk due to other medical problems, may best be managed with biliary stenting. By contrast, patients thought to have less extensive disease and to be reasonable operative candidates may benefit more from surgical biliary bypass.[146]

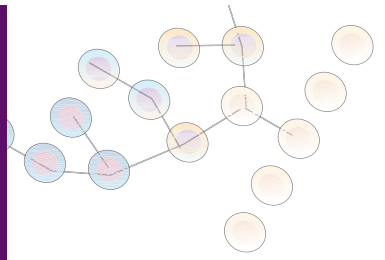
The development of expandable wall stents has changed this treatment algorithm. Wall stents can be placed endoscopically or percutaneously, and time to stent failure is significantly longer with wall stents than with older stent technology. In one study, it was demonstrated that the stent occlusion rate among patients receiving wall stents was less than 30% at 10 months.[146] Because the median survival of patients with advanced pancreatic cancer ranges from 4 to 8 months, with survival rarely exceeding 1 year, a wall stent will be provide adequate palliation for life in most patients. The rare patient who outlives the functional life of a wall stent generally can be restented using endoscopic or percutaneous techniques. Our practice, therefore, is to spare patients with unresectable pancreatic tumors the morbidity and mortality of surgical biliary bypass in favor of wall stent placement.

Of note, surgical biliary bypass will be preferable in some instances. The most common scenario in which this procedure is indicated is that in which a patient undergoing laparotomy for attempted curative resection is found to have unresectable disease. In such cases, it is our practice to perform surgical gastric and biliary bypass as well as an intraoperative chemical splanchnicectomy. Another group of patients who benefit from surgical biliary bypass are those with duodenal obstruction at the time of diagnosis. Such patients generally require laparotomy for creation of a gastrojejunostomy and should undergo surgical biliary bypass under the same anesthetic procedure. The precise type of biliary bypass created is largely a choice of the operating surgeon. Choledochojejunostomy to a defunctionalized jejunal loop is the preferred approach to surgical biliary bypass, but cholecystojejunostomy may be an acceptable alternative, except in cases in which the tumor is encroaching on the cystic duct.

Palliation of Gastric Outlet Obstruction

Approximately 15% of patients with periampullary tumors experience symptoms of gastric outlet obstruction at the time of diagnosis, and in another 20% to 30% of patients, symptomatic duodenal obstruction will develop in the course of their disease. Surgical gastrojejunostomy is the preferred approach to palliation in such patients. When carcinomatosis involving the small bowel also is present, it is our practice to place a gastrostomy tube along with performing surgical bypass of the gastric or intestinal obstruction. In patients with carcinomatosis, almost invariably, a reobstruction forms in a matter of weeks, and the presence of a gastrostomy tube can greatly facilitate terminal care by avoiding the need for nasogastric suction in most patients.

SUMMARY



Pancreatic cancer is a particularly virulent neoplasm. Most patients are first seen with disease that is too advanced to permit an attempt at curative resection, and in most patients who undergo resection, tumor will eventually recur. Radiation therapy and chemotherapy are of only modest benefit in extending survival in patients with unresectable tumors. However, a number of advances have been made, including enhanced understanding of the molecular mechanisms leading to pancreatic carcinogenesis, improvements in staging, optimization of surgical techniques, improvements in adjuvant therapy for patients with resectable disease, and a focus on effective palliation for patients with more advanced disease.

86 Cancer of the Kidney

Roberto Pili and Ronald Rodriguez

SUMMARY OF KEY POINTS

- Renal cell carcinoma (RCC) accounts for 3% of malignancies in adults.
- Cigarette smoking (in more than 20% of cases) and obesity (in more than 30%) are established causal factors for RCC.
- Clear cell RCC is the most common histologic subtype, representing 70% of all RCCs among adults.
- Different subtypes of RCC are characterized by distinct genetic abnormalities and molecular signatures.
- The von Hippel-Lindau tumor suppressor gene is mutated in more than 50% of sporadic cases of clear cell RCC.
- 4% of cases of RCC arise from hereditary syndromes.
- Prognosis for RCC is dependent primarily on tumor stage.
- Radical nephrectomy is the gold standard of care for treatment of RCC; however due to increasing sensitivity of imaging studies, nephron-sparing surgery also has become an effective option.
- Follow-up guidelines for resected RCC include history, physical examination, periodic metabolic panels, and abdominal and chest computed tomography (CT) studies 4 to 6 months after surgery.
- High-dose bolus interleukin-2 (IL-2) is approved by the U.S. Food and Drug Administration (FDA) for the treatment of selected stage IV RCC patients; however, this agent is toxic and limited in efficacy. Better identification of the potentially responsive patient population is needed.
- Antiangiogenesis drugs recently have been approved in the treatment of RCC, although success of single agents is limited. Investigation into rational combination strategies may promise greater success of this strategy.
- Conventional cytotoxic therapy offers little benefit to patients with RCC.

INTRODUCTION

RCC accounts for approximately 3% of adult malignancies. Tumors that arise in the kidney exhibit a variety of histologic patterns that may be benign or malignant. Tumors of benign histology include oncocytomas, angiomyolipomas, fibromas, lipomas, lymphangiomas, and hemangiomas. Historically, RCC was widely known as *hypernephroma*. This term, coined originally by Grawitz in 1883 in the belief that these tumors arise from the adrenal gland, has been replaced by *renal cell adenocarcinoma*. RCC exists in sporadic and hereditary forms. The sporadic form of the disease usually is first seen in the fifth decade or later in life. The clinical presentation of RCC has been described with the classic triad of symptoms of hematuria, flank pain, and fever. With the increased general use of imaging techniques, however, a majority of kidney tumors are being detected incidentally. Improved surgical techniques for treatment of localized disease and recently developed novel systemic therapies for metastatic RCC have changed the management of this condition.

INCIDENCE AND RISK FACTORS FOR SPORADIC RENAL CELL ADENOCARCINOMA

The estimated new cases of kidney and renal pelvis tumors for 2007 are 51,190.[1] A predominance of cases in male patients has been reported, with an estimated 31,590 men developing disease in 2007, compared with 19,600 women. The estimated number of deaths each year is 12,890 for both sexes (8080 in men and 4810 in women). The increasing incidence of RCC observed in the past had been attributed to increased detection due to the widespread use of imaging modalities such as computed tomography (CT), ultrasonography, and magnetic resonance imaging (MRI).[2,3] Although a decrease in the size of diagnosed renal cell tumors over time has been noted, an increasing incidence of large and late-stage RCC also has been observed and accounts in part for the overall increase in incidence.[3] In the United States, increases in incidence have been more rapid among women than men and among African Americans than Caucasians, leading to a shift in excess from among Caucasians to among African Americans.[4] A slight decline in the death rate, however, occurred in 2003 from that for 1991 (−1.5% in men and −7.5% in women), as reflected also by a decline in the general cancer death rate.[1]

Cigarette smoking and obesity are the most consistently established causal risk factors, accounting for more than 20% and 30% of renal cell cancers, respectively.[4,5] Hypertension, rather than antihypertensive drugs, appears to influence renal cell cancer development, although the mechanism is unknown.[4,5] This was the conclusion of a large study of 363,992 Swedish men who received at least one physical examination between 1971 and 1992 and who were followed up until death or until the end of 1995.[5] During the follow-up period, 759 cases of RCC and 136 cases of renal pelvis cancer were diagnosed. The relative risk for RCC was 1.3 for former smokers and 1.6 for current smokers. The relative risk for renal pelvis cancer was even higher at 1.6 for former smokers and 3.5 for current smokers. With regard to obesity, patients with a body mass index in the highest one-eighth of the cohort had a relative risk of 1.9 when compared with patients in the leanest subgroup. Hypertension was confirmed as a third risk factor for RCC. A recent study has tested whether smoking is associated with mutations in the von Hippel-Lindau tumor supressor gene (*VHL*) in 337 cases of sporadic RCC among

120,852 people over a mean follow-up period of 11.3 years; the findings suggest that smoking causes RCC independently of *VHL* mutations.[6]

Patients with end-stage renal disease (ESRD) have an increased incidence of RCC when compared with the general population. Patients receiving prolonged dialysis tend to develop acquired renal cystic disease (ARCD), possibly as a result of disordered proliferation within the native kidney. In these patients, the tumors often are bilateral and multifocal, with a papillary histology.[7] Accordingly, these patients should be monitored regularly with renal ultrasound examinations. Analgesics have not been convincingly linked with renal cell cancer risk. In general, a protective effect has been observed for fruit and vegetable consumption, although no particular component of diet has been clearly implicated. Sporadic and inconsistent reports have noted an association of specific occupations or occupational exposures with this cancer. Additional epidemiologic studies are needed.

PATHOLOGY

Kidney tumors usually are unilateral but may be bilateral in 2% to 4% of cases.[8] These tumors tend to grow into the renal vein and may form a tumor thrombus that extends into the vena cava and even the right atrium. Vascular involvement is present in 4% to 10% of patients at the time of presentation.[9]

RCC is a clinically and pathologically heterogeneous disease.[10] The 2004 World Health Organization (WHO) classification for renal neoplasms recognizes several distinct histologic subtypes of RCC (Table 86-1). These subtypes include clear cell RCC, papillary RCC, chromophobe RCC, hereditary cancer syndromes, multilocular cystic RCC, collecting duct carcinoma, medullary carcinoma, mucinous tubular and spindle cell carcinoma, neuroblastoma-associated RCC, Xp11.2 translocation–*TFE3* carcinoma, and unclassified lesions.[11,12] Clear cell RCC is the most common adult RCC, representing 70% of all RCCs. Papillary type I and type II RCC accounts for 10% to 15%, chromophobe RCC for 4% to 6%, collecting duct carcinoma for less than 1%, and unclassified lesions for 4% to 5% of RCCs. Tumors may be composed of mixed histologic subtypes, and each subtype may feature high-grade sarcomatoid characteristics. Histologic differentiation of most subtypes of RCC can be accomplished with hematoxylin-eosin staining techniques. The conventional histologic pattern is the most common, characterized by large clear cells with abundant cytoplasm. The chromophobe pattern is granular with abundant mitochondria. The papillary or tubulopapillary variant may represent a different type of tumor, because they tend to be smaller with fewer anaplastic features. The most widely used grading system for RCC is the nuclear grading system developed by Fuhrman and colleagues.[13] This system assigns a grade from I to IV, based on nuclear size, roundness, and other morphologic features such as the prominence of nucleoli and the presence or absence of clumped chromatin. Patients with tumors of high Fuhrman grade tend to have poorer clinical outcomes.

GENETICS

Until recently, RCC was thought to represent a monomorphic disease arising from a probable common precursor cell but with different histologic and clinical manifestations. Genetic characterization based

Table 86-1 Histologic Classification of Renal Cell Carcinoma

SPORADIC RCC 2004 WHO CLASSIFICATION

Histologic Tumor Type	Prevalence (%)	Cytogenetic Findings
Clear cell RCC	70	3p deletions, von Hippel-Lindau gene mutations
Papillary RCC	10	3p25-26
Chromophobe RCC	5	Trisomy of chromosomes 7 and 17, loss of Y chromosome, 7q34 chromosomal abnormality
Hereditary cancer syndromes	5	Loss of multiple chromosomes: 1, 2, 6, 10, 13, 17, 21
Multilocular cystic RCC	<1	Loss of multiple chromosomes: 1, 6, 14, 15, 22; gain of chromosome 3
Collecting duct carcinoma	<1	Extracellular matrix gene loss
Medullary carcinoma	<1	Loss of multiple chromosomes: 1, 4, 6, 8, 13, 14
Mucinous tubular and spindle cell carcinoma	<1	
Neuroblastoma-associated RCC	<1	
Xp11.2 translocation–*TFE3* carcinoma	<1	Multiple gene loss (most often 20q13)
Unclassified lesions	4	Translocations involving Xp11.2

HEREDITARY RCC: SYNDROMES AND HISTOLOGIC TUMOR TYPES

Hereditary Syndrome	Chromosome Abnormality	Histologic Type of Renal Tumor	Systemic Manifestations
von Hippel–Lindau	3p26	Clear cell RCC	Retinal angiomas, central nervous system hemangioblastomas, pheochromocytoma
Hereditary papillary RCC	7q34	Type 1 papillary RCC	None
Hereditary leiomyoma–RCC	1q42-43	Type 2 papillary RCC	Cutaneous and uterine leiomyomas
Birt-Hogg-Dube syndrome	17p11.2	Chromophobe RCC, oncocytoma, hybrid tumors	Skin lesions, lung cysts
Medullary carcinoma	11p	Medullary carcinoma	Sickle cell trait

RCC, renal cell carcinoma; WHO, World Health Organization.

Adapted from Prasad SR, Humphrey PA, Catena JR, et al: Common and uncommon histologic subtypes of renal cell carcinoma: imaging spectrum with pathologic correlation. Radiographics 2006;26:1795–1806.

on cytogenetics and molecular biology has established that different subtypes of RCCs are characterized by distinct genetic abnormalities and molecular signatures reflecting the differences in the cell type, biology, and underlying molecular mechanisms.[14] Additional tumor metabolic pathways may explain the biologic diversity of RCC.

Sporadic Renal Cell Carcinoma

A molecular signature of a majority of sporadic cases of RCC is the inactivation of a critical gene on the short arm of chromosome 3. The von Hippel-Lindau tumor suppressor gene (*VHL*), which resides on chromosome 3p25, is mutated or silenced in greater than 50% of sporadic clear cell renal cell carcinomas.[15,16] Germline *VHL* mutations give rise to von Hippel-Lindau disease, which is characterized by an increased risk of blood vessel tumors (hemangioblastomas) and renal cell carcinomas. In this setting, *VHL* inactivation gives rise to premalignant renal cysts. Additional genetic alterations are presumably required for conversion of these cysts to renal cell carcinomas. The *VHL* gene product, pVHL, is the substrate recognition module of an E3 ubiquitin ligase that targets the hypoxia-inducible factor (HIF) for destruction in the presence of oxygen. Hypoxic cells, or cells lacking pVHL, accumulate high levels of HIF, which activates the transcription of a variety of genes, including vascular endothelial growth factor, platelet-derived growth factor B, and transforming growth factor alpha. Restoration of pVHL function in *VHL*–/– mutant renal carcinoma cells suppresses their ability to form tumors experimentally by reducing HIF-1α levels. Inhibition of HIF is necessary and sufficient for tumor suppression by pVHL in renal cell carcinoma nude mouse xenograft assays. This provides a rationale for treating *VHL*–/– renal cell carcinoma with inhibitors of HIF or its downstream targets. The pVHL protein also has other targets in addition to HIF. Elucidating these targets will lead to further knowledge of how pVHL suppresses tumor growth.

Analysis of mutations in exon 3 of the *VHL* gene may be useful in refining the diagnostic criteria for conventional RCC versus chromophobe RCC with clear cells.[17] Single-strand conformational polymorphism (SSCP) has been used to identify mutations in the *VHL* gene in RCCs of various histologic subtypes. The cohort ($N = 67$) included cases of conventional or clear cell ($N = 24$), chromophobe ($N = 14$), and papillary ($N = 14$) RCC and renal oncocytomas ($N = 15$). Thirteen of the 14 *VHL* gene mutations identified were novel. Of interest, no mutations were found in the papillary and oncocytoma subtypes. Mutations in exon 3 appeared to confer a more aggressive phenotype on conventional RCC. Expression profiling of renal epithelial neoplasms with complementary DNA (cDNA) microarrays also may be used to identify novel molecular markers with potential diagnostic utility. A comparison of the expression profiles of 7075 genes has been reported for four conventional RCCs and one chromophobe RCC, as well as two oncocytomas.[14] Conventional RCCs were found to underexpress mitochondrial and distal nephron genes and were distinguished from chromophobe RCC and oncocytomas by overexpression of vimentin and class II major histocompatibility complex-associated molecules. Vimentin was found to be a sensitive and specific marker for conventional RCC. Gene-profiling experiments such as these should lead to improvements in the basic understanding of renal tumor pathogenesis.

The genetic studies in familial RCC have led to the identification of specific molecular signatures in non-clear cell histotypes as well, such as c-Met overexpression in papillary type I, fumarate hydratase in papillary type II, and c-Kit in chromophobe RCC (see later). Preliminary results from ongoing genetic studies have shown the possibility of clustering different histotypes based, for example, on kinase expression[18] (Fig. 86-1).

Familial Renal Cell Carcinoma

In a small percentage (4%) of cases, RCC is a feature of one of several hereditary syndromes.[14,19] Such syndromes are associated with different subtypes of RCC, and tumor presentation can range from a solitary lesion to multifocal.[14,19] Management is dependent on preservation of renal function. Close surveillance and minimization of surgical procedures constitute the mainstay of treatment.

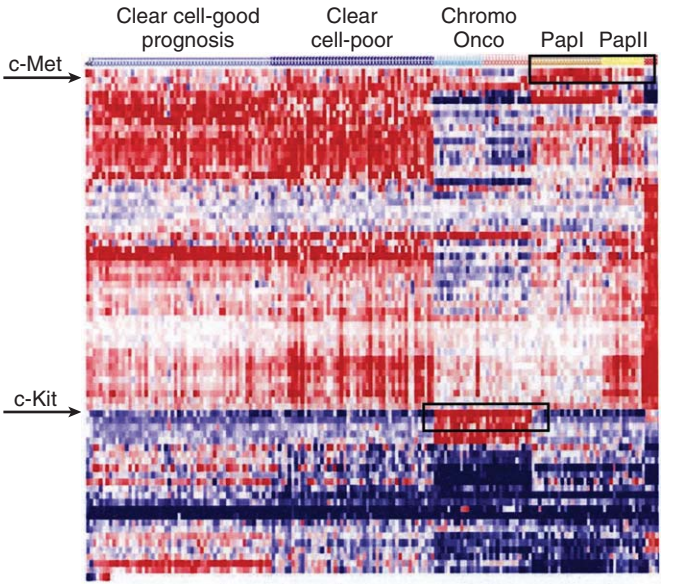

Figure 86-1 • Kinase expression in RCC: Genetic signatures. Determining the genetic signature in renal tumors not only has advanced the tumor classification but also will contribute to patient selection. These data show the gene expression of approximately 80 kinases (of 518) that have differential expression across the subtypes, with *red* meaning strong expression. Recognition of c-Met and c-Kit expression allows clustering the samples in specific subtypes. These types of data will guide the selection of patients undergoing treatment with kinase inhibitors. Chromo, chromophobe; onco, oncocytoma; PapI, papillary type I, PapII, papillary type II. (Adapted from Teh B: Kinome in renal cell carcinoma: mutation analysis of 518 kinases and expression in 400 tumors. J Clin Oncol 2007 ASCO Annual Meeting Proceedings 2007;25[18S]:5013.)

von Hippel-Lindau disease is a disorder of autosomal dominant inheritance that occurs in 1 in 40,000 births. The mean age at onset is in the fourth decade of life. The *VHL* gene is a tumor suppressor gene located on chromosomal band 3p25-26.[14,19,20] The product of this gene is expressed in multiple tissue types including the central nervous system (CNS). Manifestations include retinal or CNS angiomas and hemangioblastomas. The endocrine system is affected by adrenal pheochromocytomas and by pancreatic lesions, leading to pancreatic insufficiency, diabetes mellitus, biliary obstruction, and islet cell tumors. Benign papillary cystadenomas of the epididymis or broad ligament also may develop. Bilateral cystadenomas are pathognomonic for von Hippel-Lindau disease. Endolymphatic sac tumors of the inner ear also may be seen. Renal manifestations include renal cysts and RCC. Clear cell RCC, which tends to be bilateral and multifocal, develops in 70% of patients with von Hippel-Lindau disease.[14,19,20]

Birt-Hogg-Dubé syndrome is a disorder of autosomal dominant inheritance. The *BHD* gene, which codes for the protein folliculin, is located on chromosomal band 17p11.2.[14,19–22] Folliculin has an unknown function. Signs and symptoms usually manifest in the fifth decade of life. This syndrome is characterized by benign skin tumors, which include fibrofolliculomas, trichodiscomas of hair follicles, and skin tags. Other manifestations include medullary carcinoma of the thyroid; multifocal pulmonary cysts, which can lead to spontaneous pneumothorax; and renal epithelial neoplasms. The renal neoplasms are multifocal and bilateral tumors that consist of oncocytomas and clear cell, chromophobe, and papillary types. Tumor size increases with malignant potential. The *BHD* gene appears to have the characteristics of a loss-of-function tumor suppressor gene.[23] Although

studies are under way to determine how damage to this gene leads to chromophobe renal carcinoma, sporadic chromophobe renal carcinoma has been shown to overexpress c-Kit.[24]

Tuberous sclerosis is a syndrome of autosomal dominant inheritance, with two genes identified, *TSC1*, located on 9q34, and *TSC2*, located on 16p13.3. It affects 1 in 6000 people and is usually diagnosed at birth.[14,19,20] This syndrome encompasses multiple organ systems, including dermatologic, cardiac, pulmonary, and renal. Skins lesions include facial angiofibromas, periungual fibroma, shagreen patches, and hypopigmented macules. Patients also develop cardiac rhabdomyomas, pulmonary lymphangioleomyomatosis, retinal hamartomas, subependymal nodules, and giant cell astrocytomas. The renal manifestations include bilateral and multifocal angiomyolipomas (AMLs), clear cell renal carcinoma, and oncocytomas. In contrast with spontaneous AML, AML in this setting can be associated with a low risk of occult RCC.

Hereditary papillary renal cell carcinoma (HPRCC), inherited as an autosomal dominant trait, is caused by mutations in c-*met* protooncogene on chromosomal band 7q31-34.[14,20,25] It is characterized by bilateral, multifocal papillary RCCs. These tumors are not aggressive and rarely metastasize. Age of onset is around the fifth decade. It is associated with tumors of the pancreas, lung, skin, and stomach. Malchoff and colleagues have described a three-generation family with five cases of papillary thyroid carcinoma and two cases with papillary renal neoplasia.[25] With the use of linkage analysis, these investigators demonstrated that the fPTC/PRN phenotype was linked to 1q21.[25] They characterized a distinct inherited tumor syndrome that may establish a link between papillary RCC and familial papillary thyroid carcinoma.[25]

Familial clear cell renal cell carcinoma (FCCRCC) is defined as RCC in persons with a family history of clear cell renal carcinoma in two or more first-degree relatives.[19,20] The genetic defect has not yet been identified. Age at onset is variable, and the tumor tends to be solitary and confined to the kidney.

Hereditary leiomyomatosis and renal cell carcinoma (HLRCC) is a disease of autosomal dominant inheritance. The gene for this disorder has been localized to chromosomal band 1q42.3-43.[14,19,20] Age at onset is between the third and fourth decades of life. The syndrome consists of cutaneous leiomyomas, uterine fibroids, and papillary RCC. Affected patients also have a predisposition to uterine leiomyosarcoma. Thirty percent of patients have solitary and unilateral renal tumors, which are aggressive.[19,20] HLRCC is a hereditary cancer syndrome in which affected persons are at risk for the development of cutaneous and uterine leiomyoma and an aggressive form of type 2 papillary renal carcinoma. The gene for HLRCC has been found to be that encoding the Krebs cycle enzyme fumarate hydratase (*FH*).[26] Mutations of *FH* are found in the germline of affected persons in HLRCC kindreds.[27] *FH* appears to function as a tumor suppressor gene; loss of the second allele has been detected in kidney tumors from patients with HLRCC. The type 2 papillary kidney cancer found in these patients is a particularly aggressive form of renal carcinoma; it can metastasize early and often is fatal.

Familial oncocytoma is characterized by multiple and bilateral oncocytomas and cystic lesions.[28] Renal oncocytomas account for 5% of all renal tumors. Teh and colleagues described a patient with bilateral multifocal renal oncocytomas and cysts with a constitutional reciprocal translocation (8;9)(q24.1;q34.3).[28]

DIAGNOSIS OF RENAL CELL CARCINOMA

As the use of imaging methods has become more widespread, the frequency of incidental detection of RCC has increased. Patients with RCC typically present with a mass involving the kidney that is suggestive of the diagnosis. Nephrectomy is the most effective therapy for RCC that is confined to the kidney and should be used both diagnostically and therapeutically in most patients who are suitable surgical candidates. In certain clinical settings, percutaneous biopsy of a renal mass should be considered. In a retrospective study of 115 consecutive percutaneous biopsies performed on renal masses in 113 patients, investigators found percutaneous biopsy to be of high sensitivity in three clinical groups: patients with a known malignancy ($N = 55$), patients with no known malignancy and suspected unresectable tumor ($N = 36$), and nonsurgical patients with a mass suspected to be a resectable RCC ($N = 8$).[29] Percutaneous biopsy of renal masses appears to be safe, carrying only a minimal risk of tumor spread. Urologists should consider increasing the indications for renal biopsy of small renal masses that appear to be RCC, especially in elderly and surgically unfit patients. With more experience and follow-up preoperative biopsy, this strategy has the potential to decrease unnecessary treatment, because up to a third of small renal masses are now reported to be benign at surgery. Percutaneous biopsy also may allow better selection of renal tumors for active surveillance and minimally invasive ablative therapies. Finally, initial therapy for metastatic RCC may potentially be stratified by histologic subtype and, in the future, molecular characteristics.

STAGING SYSTEMS FOR RENAL CELL CARCINOMA

The tumor-node-metastasis (TNM) system is a dynamic staging method that continually changes on the basis of new evidence from clinical studies (Table 86-2).[30] This staging system is a method of stratifying patients with cancer and is based on data from large multicenter studies with large numbers of patients and a good level of evidence. Despite continual revisions to the methodology to incorporate new clinical evidence, however, the optimal RCC patient stratification using the TNM staging system remains controversial, and further revisions probably will be needed. Revision of the TNM staging system for RCC is likely to result in the simultaneous update of the integrated prognostic systems currently used with this traditional method of staging.

The first TNM staging system for RCC was developed in 1978.[31] In the TNM system, tumors are characterized on the basis of the degree of local extension of the tumor at the primary site (T), the involvement of regional lymph nodes (N), and the presence or absence of distant metastases (M). The addition of numbers to each of the TNM components allows one more precisely to categorize the extent of malignant disease at the primary, lymph node, and metastatic sites, respectively. The classification may be clinical (cTNM) or histopathologic (pTNM). In the case of RCC, the regional lymph nodes are defined as the hilar, abdominal para-aortic, and paracaval nodes. Laterality does not affect N categories. A retrospective study ($N = 252$) conducted to validate this system found that survival was most dependent on the local extent of the primary tumor, with 5-year overall survival rates of 100% for pT1, 91% for pT2, 58% for pT3, and 25% for pT4.[32] The system also resulted in poor stratification of patients, with few patients in the pT1 ($N = 7$) and pT4 ($N = 9$) categories.

In the 1987 revision of the TNM system, a value of 2.5 cm was chosen to distinguish pT1 from pT2 tumors, and an entirely new set of criteria was introduced to evaluate lymph node status. Perhaps most important, comprehensive stage groupings were introduced to define more precisely the impact of TNM characteristics on survival. Again, however, very few patients were stratified to stage I, with only 11 of 872 patients classified in this category in one study.[32,33] Furthermore, a study of 337 RCC tumors confined to the kidney found no survival difference between stage I and stage II tumors at the 2.5-cm breakpoint, although a significant difference was identified at the 7.5-cm breakpoint.[34] In 1997, the American Joint Committee on Cancer (AJCC)[35] and the International Union Against Cancer (UICC)[36] published an updated version of the TNM system. The result of this international collaboration was a more uniform categorization of RCC based on improved clinical evaluation and management. In this version, the breakpoint between pT1 and pT2 was

Table 86-2 Tumor-Node-Metastasis (TNM) Staging System for Renal Cell Carcinoma

Staging	Classification	1987	1997	2002
Tumor	T1	Tumor ≤2.5 cm, limited to kidney	Tumor ≤7 cm, limited to kidney	NA
	T1a	NA	NA	Tumor ≤4 cm, limited to kidney
	T1b	NA	NA	Tumor >4 cm and ≤7 cm, limited to kidney
	T2	Tumor >2.5 cm, limited to kidney	Tumor >7 cm, limited to kidney	Tumor >7 cm, limited to kidney
	T3	Tumor extends into major veins or invades adrenal or perinephric tissues, but not beyond Gerota's fascia	Tumor extends into major veins or invades adrenal or perinephric tissues, but not beyond Gerota's fascia	Tumor extends into major veins or invades adrenal or perinephric tissues, but not beyond Gerota's fascia
	T3a	Perinephric or adrenal extension	Perinephric or adrenal extension	Perinephric or sinus fat or adrenal extension
	T3b	Renal vein involvement	Renal vein or vena cava involvement below diaphragm	Renal vein or vena cava involvement below diaphragm
	T3c	Vena cava involvement below diaphragm	Vena cava involvement above diaphragm	Vena cava involvement above diaphragm
	T4	Outside Gerota's fascia	Outside Gerota's fascia	Outside Gerota's fascia
	T4a	Vena cava involvement above diaphragm	NA	NA
	T4b	NA	NA	NA
Node	Nx	Regional lymph nodes cannot be assessed	Regional lymph nodes cannot be assessed	Regional lymph nodes cannot be assessed
	N0	No regional lymph node metastasis	No regional lymph node metastasis	No regional lymph node metastasis
	N1	Metastases in one lymph node ≤2 cm in greatest dimension	Metastases in one regional lymph node	Metastases in one regional lymph node
	N2	Metastases in one lymph node >2 cm, but not >5 cm in greatest dimension	Metastases in more than one regional lymph node	Metastases in more than one regional lymph node
	N3	Metastases in one lymph node >5 cm in greatest dimension	NA	NA
Metastasis	Mx	Distant metastasis cannot be assessed	Distant metastasis cannot be assessed	Distant metastasis cannot be assessed
	M0	No distant metastases	No distant metastases	No distant metastases
	M1	Distant metastases	Distant metastases	Distant metastases

From Ficarra V, Galfano A, Mancini M, et al: TNM staging system for renal-cell carcinoma: current status and future perspectives. Lancet Oncol 2007;8:554–558.

increased from 2.5 cm to 7.0 cm. In addition, the requirement for the T3a classification was more precisely defined as invasion of the adrenal gland by direct extension of the tumor or invasion of perinephric fat. The subcategories of venous tumor extension (pT3) were revised so that venous tumor extension above the diaphragm was classified as T3c, whereas venous tumor extension limited to the vena cava below the diaphragm was classified as T3b.This reflected the decreased adverse prognostic significance of venous tumor extension alone. The classification of lymph node metastasis also was simplified to include involvement of a single lymph node (N1) or multiple lymph nodes (N2), with the stipulation that four to eight nodes should be analyzed before assigning the pN0 classification.[37]

In 2002, the AJCC published the sixth edition of the *AJCC Cancer Staging Handbook*.[38] The manual was developed in close collaboration with the UICC to refine further the uniform staging system to bring worldwide consistency to cancer staging. In the case of RCC, the key change was to subdivide T1 lesions into T1a and T1b. The rationale was based on evidence from studies of patients undergoing partial nephrectomy, a procedure commonly used for tumors that are 4 cm or smaller. It has been reported that patients who undergo partial nephrectomy for RCC tumors smaller than 4 cm have equivalent survival to those undergoing radical nephrectomy.[39] In a separate study of 485 patients undergoing nephron-sparing surgery for RCC with a mean follow-up period of 47 months, patients were divided into four groups based on the size of the primary.[40] Patients in group 1 (tumors less than 2.5 cm in diameter) and those in group 2 (tumors 2.5 to 4.0 cm) had equivalent survival, although survival was significantly greater for groups 1 and 2 than for group 3 (tumors 4 to 7 cm) and group 4 (tumors greater than 7 cm). These findings were similar to those previously published in a separate series of 394 patients.[41]

Since the last revision of the system in 2002, data from several studies have provided issues for discussion in the next revision of the system.[30] New data are available from large multicenter studies that recruited adequate numbers of patients with level 2 or 3 evidence.[42–44] Prognostic systems include not only anatomical features but also other clinical and pathological variables, but will also eventually provide more accurate information for patient counseling, follow-up planning, patient selection for clinical trials, and adequate assessment of the results.[30] Integrated systems are less widely used than the TNM

system, because they are difficult to apply and contain several inadequately defined clinical and histopathologic variables. The TNM system will become a more refined and advanced instrument used by all clinicians and researchers involved in the management of RCC.

PROGNOSTIC FACTORS FOR RENAL CELL CARCINOMA

Although TNM stage, Fuhrman grade, and Eastern Cooperative Oncology Group (ECOG) performance status are the most widely recognized prognostic factors in RCC, research continues to determine strong and easily available prognostic parameters that may help to classify patients in groups with different risks for death from renal cancer. The prognosis for patients with RCC is dependent primarily on disease stage. Patients with histopathologic stage pT1 or pT2 (organ confined) disease have the best prognosis, with 5-year cancer-specific survival rates after nephrectomy ranging from 71% to 97%.[45] For patients with locally advanced tumors, 5-year cancer-specific survival rates after nephrectomy decrease by 20% to 53%, and once RCC has metastasized, the 5-year survival rate is less than 10%.

Numerous models exist to predict disease recurrence after nephrectomy for all histologic types and specifically for clear cell RCC.[46] The natural history and risk group stratification have also been evaluated in those with newly diagnosed metastatic RCC and in patients with previously treated metastatic disease. Currently, RCC histologic subtypes are classified according to the UICC and AJCC recommendations.[47] These recommendations are based on the Heidelberg classification system,[48] which categorizes RCCs as clear cell, papillary, chromophobe, collecting duct, and unclassified RCC subtypes. Recent studies have suggested that stratification by histologic subtype could lend prognostic value.[49,50]

To assess the role of different histologic types in outcome, four thousand sixty-three patients from eight international centers were included in a retrospective study.[46] Histologic subtype (1997 UICC criteria of tumor response), age, sex, TNM stage, Fuhrman grade, tumor size, ECOG performance status, and overall survival were determined in all cases. The prognostic value of clear cell, papillary, and chromophobe histologic patterns was assessed by univariate and multivariate analysis using the Kaplan-Meier method and Cox model, respectively. Clear cell, papillary, and chromophobe carcinomas accounted for 3564 (87.7%), 396 (9.7%), and 103 (2.5%) cases, respectively. In univariate analysis, a trend toward a better survival was observed when clear cell, papillary, and chromophobe histologic patterns were considered prognostic categories. In multivariate analysis, however, TNM stage, Fuhrman grade, and ECOG performance status, but not histology, were retained as independent prognostic variables. The stratification in three main RCC histologic subtypes as defined by the 1997 UICC–AJCC consensus probably should not be considered a major prognostic variable comparable with TNM stage, Fuhrman grade, and ECOG performance status. The prognostic issue is not the only reason that it is important to recognize different histologic subtypes in RCC. Different subtypes have different predilections for stage, as well as different metastatic profiles. Further understanding of the molecular basis of histologic subtyping will provide greater insight into the various tumorigenic pathways of kidney carcinogenesis.

The University of California at Los Angeles (UCLA) Integrated Staging System (UISS) was developed for the purpose of improving the prognostic accuracy of the 1997 TNM staging system by incorporating clinical variables.[51] The study was based on the analysis of data for patients with RCC treated at a single institution between 1989 and 1999 ($N = 661$). All patients underwent radical or partial nephrectomy, and most patients with metastatic disease received recombinant IL-2-based immunotherapy within the context of 11 clinical trials. The median follow-up period was 37 months. Patients with papillary tumors ($N = 42$) showed a trend toward improved prognosis that did not achieve statistical significance, whereas patients with sarcomatoid ($N = 45$) and collecting duct tumors ($N = 3$) had worse prognosis. Survival rates for patients with clear cell and chromophobe histologic patterns were similar. The UISS uses five stratification groups (I through V) that incorporate variables commonly used in clinical practice, including 1997 TNM stage, ECOG performance status, and Fuhrman grade. The projected 5-year survival rates published by the UISS group weres as follows: 94% for group I, 67% for group II, 39% for group III, 23% for group IV, and 0% for group V. The original UCLA integrated staging system has since been modified so that patients are grouped into two general categories: those with nonmetastatic disease at the time of diagnosis and those with metastatic disease.[52] Each category is then divided into high-, intermediate-, and low-risk subcategories, based on the 1997 TNM staging system, the Fuhrman grade, and the ECOG performance status.

To confirm the ability of the UISS to stratify patients with localized and metastatic RCC into risk groups, an international multicenter study was conducted.[46] A total of 4202 patients from eight academic centers were classified according to the UISS. The UISS stratified both localized and metastatic RCC cases into three different risk groups. For localized RCC, the 5-year survival rates were 92%, 67%, and 44% for low-, intermediate-, and high-risk groups, respectively. A trend toward a higher risk of death was observed in all centers for increasing UISS risk category. For metastatic RCC, the 3-year survival rates were 37%, 23%, and 12% for low-, intermediate-, and high-risk groups, respectively. In six of eight centers, a trend toward a higher risk of death was observed for increasing UISS risk category. A greater variability in survival rates among centers was observed for high-risk patients. These results suggest that the UISS is an accurate predictor of survival for patients with localized RCC, applicable to external databases. Although the UISS may be useful for patients with metastatic RCC, it may be less accurate in this subset of patients because of the heterogeneity of patients and treatments.

A retrospective, single-institution review of 24 consecutive clinical trials conducted at Memorial Sloan-Kettering Cancer Center using cytokines or chemotherapy for the treatment of advanced RCC ($N = 670$) identified a small subgroup of patients ($N = 30$) who were long-term survivors after nephrectomy and treatment with interferon-α, IL-2, or surgical resection of metastasis.[53] The five most prominent negative prognostic factors that were identified by multivariate analysis included low Karnofsky performance status (less than 80%), elevated lactate dehydrogenase (greater than 1.5 times the upper limit of normal), low serum hemoglobin (below the lower limit of normal), high corrected serum calcium (greater than 10 mg/dL), and absence of nephrectomy. Patients with zero risk factors were assigned a favorable-risk status; those with one or two risk factors, an intermediate-risk status; and those with three or more risk factors, a poor-risk status. All long-term survivors in this study were in either good- or intermediate-risk groups.

In an additional study from the Memorial Sloan-Kettering Cancer Center, the relationship between pretreatment clinical features and survival was assessed in 251 patients with advanced RCC treated during 29 consecutive clinical trials between 1975 and 2002.[54] Clinical features were first examined in univariate analyses, and then a stepwise modeling approach based on Cox regression was used to form a multivariate model. The median survival time for the 251 patients was 10.2 months and differed according to year of treatment, with patients whose tumor was treated after 1990 showing longer survival. In this group, the median overall survival time was 12.7 months. Because the purpose of this analysis was to establish prognostic factors for present-day clinical trial design, prognostic factor analysis was performed on data for these patients. Pretreatment features associated with a shorter survival in the multivariate analysis were low Karnofsky performance status, low hemoglobin level, and high corrected serum calcium. These features were used as risk factors to categorize patients into three different groups. The median time to death in patients with zero risk factors was 22 months. The median

survival time in patients with one of these prognostic factors was 11.9 months. Patients with two or three risk factors had a median survival time of 5.4 months. These results suggest that the Memorial Sloan-Kettering Cancer Center risk categories (proposed by Motzer and coworkers[54]) can be used in clinical trial design and interpretation.

The natural history and risk group stratification also have been evaluated in patients with newly diagnosed metastatic RCC. For patients diagnosed with disease recurrence, no specific risk stratification tools have been available at the time of recurrence. A recent retrospective study sought to evaluate the utility of the prognostic score suggested by Motzer and coworkers.[54] From January 1989 to July 2005, patients with localized RCC treated by nephrectomy in whom recurrent disease subsequently developed were identified. Each patient was given a total risk score of 0 to 5, with 1 point for each of five prognostic variables (recurrence at less than 12 months after nephrectomy, serum calcium concentration greater than 10 mg/dL, hemoglobin concentration less than the lower limit of normal, lactate dehydrogenase level greater than 1.5 times the upper limit of normal, and Karnofsky performance status less than 80%). Patients were categorized into low- (score = 0), intermediate- (score = 1 to 2), and high-risk subgroups (score = 3 to 5). The final cohort included 118 patients, with a median survival time of 21 months from the time of recurrence. Median duration of follow-up for survivors was 27 months. Overall survival was associated with risk group category. Low-risk, intermediate-risk, and high-risk criteria were fulfilled in 34%, 50%, and 16% of patients, respectively. Median survival times for low-risk, intermediate-risk, and high-risk patients were 76, 25, and 6 months, respectively. Two-year overall survival rates for low-risk, intermediate-risk, and high-risk patients were 88%, 51%, and 11%, respectively. These additional data support the use of a scoring system based on objective clinical and laboratory data to achieve meaningful risk stratification for both patient counseling and clinical trial entry.

The Memorial Sloan-Kettering Cancer Center and UCLA prognostic systems are similar in several ways. First, both systems are based on a series of consecutive clinical trials for RCC conducted at single institutions. Second, good performance status was found to correlate with lower risk in both systems. Third, cytoreductive nephrectomy for metastatic disease before immunotherapy was found to confer a more favorable prognosis (Memorial Sloan-Kettering Cancer Center) or was used as standard therapy (UCLA) in both systems. More recently, Karakiewicz and associates have proposed a nomogram for prediction of RCC-specific survival in nonmetastatic and metastatic disease, using a development cohort of 2530 patients and an external validation cohort of 1422 patients.[56] The nomogram differs from the UISS with respect to one predictor. The symptom classification replaces the ECOG performance system within the nomogram. Moreover, the nomogram provides individual estimation of RCC-specific survival, instead of grouping patients within discrete strata. Direct comparison of the nomogram with the UISS strata, within an external validation cohort, demonstrated higher accuracy for the nomogram, with 89% and 87%, respectively, at 2 and 5 years, compared with 86% and 82% for UISS.

SURGICAL APPROACH FOR LOCALIZED DISEASE

The surgical approach for localized disease depends in large part on the extent of disease, tumor location, and the training and experience of the surgeon. For lesions that appear to be locally extensive with potential involvement of neighboring organs, open surgery is still preferred. This is particularly true if a colectomy, splenectomy, or distal pancreatectomy is anticipated. In addition, local adenopathy or invasion by tumor thrombus into the renal vein and vena cava also may be a relative indication for consideration of open surgery as opposed to laparoscopy. Even with extension of tumor thrombus into the vena cava, however, laparoscopic resection may be possible, provided that the thrombus just enters the cava and can be manipulated back into the renal vein with certain maneuvers. Large tumors often are best approached in open fashion. In some instances, however, even large tumors can be approached laparoscopically if the local anatomy is favorable.

When open surgery is required, the choice of surgical approach also is dictated by the surgeon's training and experience and by the location and extent of disease. Resection of tumors with thrombus extending into the inferior vena cava above the level of the hepatic veins usually is performed through a midline incision to allow extension to a sternotomy, if required. Tumors with thrombus extending into the inferior vena cava but below the hepatic veins often can be accessed by a thoracoabdominal approach if the primary lesion is on the right side. For other, less extensive tumors, laparoscopy is the preferred approach when nephrectomy is deemed necessary.

Laparoscopy has gained widespread popularity because it carries less morbidity than open surgery and results in a faster convalescence. Although most laparoscopic surgeons prefer a transperitoneal (transabdominal) approach for this operation, many surgeons prefer the retroperitoneal approach. The difference in approach seems to matter relatively little to the patient but rather is a technical issue for the surgeon. The transabdominal approach allows complete visualization of the viscera with multiple landmarks and visual cues for orientation, but does require more anterior and anteromedial dissection. Surgery through the retroperitoneal approach can be faster in the hands of an experienced laparoscopic surgeon, but many visual cues and landmarks to ensure dissection in the proper planes are lacking with this procedure. Regardless of approach, however, current surgical practice in the United States is to perform nephrectomy laparoscopically (with or without hand assistance), except when an excessively large tumor, locally advanced disease, local adenopathy, or tumor thrombus is present. Even in these situations, it often is beneficial to start a case laparoscopically and then complete it in a controlled open fashion. Such a strategy can result in a smaller incision often in the midline, with less pain and morbidity, than is typical if the entire case is performed in open fashion.

Morcellation

There has been controversy with radical laparoscopic nephrectomy, whether to morcellate the specimen or remove the kidney as a whole. An intact extraction has the benefit of maintaining kidney and tumor integrity for more precise histopathologic evaluation, decreases chance of tumor seeding of the port sites or renal fossa, and requires shorter surgery time.[57] Pautler and colleagues compared the histopathologic diagnosis of their operative needle biopsy before morcellation with the morcellated specimen.[58] They found adequate histopathologic material for diagnosis.[58] They were able to stage only 3 of 15 morcellated specimens. Owing to the increased sensitivity of CT scanning today and other imaging modalities, it has been argued that lack of staging information from surgical specimen does not affect management of the patient. Barrett and associates found precise pathologic staging did not change subsequent tumor management in their patients.[59] Enclosing the kidney in an impermeable sac before morcellation prevents seeding. No difference has been found in length of hospital stay, recovery time or postoperative treatment.[59] While there was initially great enthusiasm among the laparoscopic surgeons to remove the kidneys and tumors through morcellation, this practice has been waning—in part because now most urologic oncologists are performing laparoscopic nephrectomies and prefer intact extraction of the kidney and mass for accurate histopathologic staging purposes.

A retrospective Japanese study of 100 patients with tumors smaller than 5 cm in diameter revealed a longer mean operative time (5.2 versus 3.3 hours), less mean blood loss, and a shorter time to completion of convalescence for patients managed with laparoscopic radical nephrectomy ($N = 60$) rather than open radical nephrectomy ($N = 40$). No significant difference was found in 5-year disease-free

survival rate for patients who had laparoscopy (95.5%) and those who underwent open nephrectomy (97.5%).[60] Cytoreductive radical nephrectomy commonly is performed in patients with metastatic RCC before administration of systemic IL-2. In this setting, laparoscopic techniques that use tumor morcellation reduce surgical trauma and allow resection of larger tumors. In patients with metastatic disease, the precise delineation of local invasiveness and the possibility of surgically mediated tumor dissemination are not primary concerns. Laparoscopic techniques offer the possibility of lower morbidity and faster recovery, to minimize the delay in starting treatment with high-dose IL-2.

Nephron-Sparing Surgery

With increasing sensitivity of imaging studies, nephron-sparing surgery has become an effective surgical option for RCC. Although the classic radical nephrectomy still remains the standard of care for treatment of RCC, nephron-sparing surgery has proved to be a very effective curative therapy for patients with localized disease. Leibovich and associates compared outcomes in 91 patients managed with nephron-sparing surgery and 841 patients who underwent radical nephrectomy for 4- to 7-cm tumors.[61] These investigators found no statistical difference in cancer-specific survival and distant metastases between the two groups. Nephron-sparing surgery can be done with low morbidity, mortality and good surgical outcomes.

Traditionally, indications for nephron-sparing surgery for the treatment of RCC have included conditions such as unilateral renal agenesis, horseshoe kidney, or bilateral RCC in which radical nephrectomy would leave the patient anephric, resulting in the need for immediate dialysis. Additional indications have included unilateral RCC with a diseased contralateral kidney that is at risk for severe compromised function. Examples of such conditions are diabetes, hypertensive nephrosclerosis, renal artery stenosis, renal calculi, and chronic pyelonephritis. Other indications include tumor diameter of 4 cm or less, anatomic position of the tumor, and localized disease.[61,62] With respect to tumor size, an experienced urologist may use this approach to remove larger tumors with curative intent. The indications for nephron-sparing surgery are partly dependent on the skill of the surgeon and the availability of the equipment.

Laparoscopy has become the mainstay of management of RCC. Today the choice between open partial nephrectomy and laparoscopic partial nephrectomy depends on anatomic location of the tumor, body habitus, and ability to tolerate pneumoperitoneum. With increasing usage of minimally invasive therapies the indications for laparoscopy are expanding. Steinberg and coworkers retrospectively reviewed outcomes for 13 patients who had minimally invasive surgery on two or more ipsilateral tumors.[63] Using either LPN (in 7 of the patients) or cryotherapy (in 6 patients), these investigators reported no intraoperative complications, negative surgical margins, and good renal function in the remnant kidney. An experienced surgeon can perform technically challenging laparoscopy with good surgical and oncologic outcomes.

With the standardization of staging and earlier diagnosis of the disease, a more tumor-specific surgical management has proved to be advantageous to maximizing the preservation of functional renal tissue. With increased evidence of the need for long-term dialysis in patients undergoing total nephrectomy, maintenance of renal function in both kidneys represents the strongest argument for nephron-sparing surgery in patients with RCC who have the best chance for cure.

Cryosurgery for Renal Cell Carcinoma

Urologists pioneered minimally invasive surgery and have been constantly searching for less invasive techniques. With the advent of energy-based ablative alternatives to open and laparoscopic surgeries in selected patients, it is now possible to achieve cancer-specific survival with decreased surgical morbidity. Renal cryosurgery is a technique that is being developed for resection of small renal tumors as an alternative to nephron-sparing surgery, with the goal of reducing the morbidity associated with open partial nephrectomy. Use of standard cryoprobes of 3 to 8 mm can cause rupture of the renal capsule and parenchyma, resulting in significant bleeding. The use of multiple 1.5-mm cryoprobes under intraoperative real-time ultrasound guidance may decrease the risk of bleeding and make this technique a more feasible approach.[64]

Increasing evidence suggests that cryoablation is an acceptable surgical alternative to traditional open and laparoscopic nephrectomy.[65–69] In addition to shorter hospital stay and less morbidity, cryoablation has been shown to be a very effective nephron-sparing cancer therapy.[69] Patients selected for this option tend to have peripheral lesions 5 cm or less in diameter.[65,69] Owing to the increased use of CT scan, the number of incidentally found renal lesions has increased; 20% to 40% of these lesions usually are benign or slow-growing tumors.[65,69] Many such lesions tend to enhance on CT and require some treatment modalities. Minimally invasive therapy without the sequelae of open or laparoscopic surgery may be reasonable in these situations, particularly in patients not eligible for surgery. Cryoablation surgery has been described in the literature with open, laparoscopic, and, more recently, imaging-guided percutaneous approaches.[70,71]

Multiple theories have been proposed for the mechanism of action of cryoablative surgery. The most accepted theory postulates direct cellular injury leading to coagulative necrosis.[67,68] Injury to the cancer cells occurs as a result of intracellular ice crystal formation during the freezing phase of the treatment.[67,68] The decreased temperature causes damage to cellular structures, leading to cell death.[67] The freezing process causes protein damage, which injures the cell membrane and essential enzymatic processes.[67] Ice crystals that form within the cell disrupt intracellular organelles and membranes. Additionally, indirect ischemic injury due to occlusion of the microvasculature during the thaw phase creates stasis within blood vessels, leading to end-tissue infarction. These ensuing insults to renal tissue lead to liquefactive necrosis.[67]

In most cases, the cryoprobes used are 2.4 mm in diameter. The usual procedure is percutaneous CT guidance cryotherapy, in which each lesion is treated with a double freeze-thaw cycle, with active freeze at 100% efficiency for a minimum of 10 minutes and a passive thaw of 8 minutes.[65] These cycle times consistently deliver the lethal freeze of −4° C within 1 cm of the iceball edge.[65] The critical threshold for necrosis has been reported as between −19.4° and −40° C.[65] The number of probes used is specific to the size and shape of the lesion, with freeze margins of 0.5 to 1 cm of the lesion.

Some advantages to CT-guided cryotherapy include general availability and its excellent capability to differentiate among the visceral organs. It also provides visualization of the entire ice ball while differentiating between frozen and unfrozen tissue. In addition, it provides real-time guidance in the CT fluoroscopy mode. One major disadvantage with CT guidance is the constant radiation exposure to the patient and the surgeon. This can be corrected by using adequate and appropriate protection from radiation.

No current long-term follow-up study of cryotherapy has been performed. Gill and colleagues described a 98% cancer survival rate at 3 years after surgery.[65] These investigators also found a significant decrease in tumor size 3 to 6 months after surgery. These are promising results, but longer-term data are needed. Because the renal tumor is not excised, with documentation of histopathologic margins, whether the entire tumor has been extirpated remains uncertain.[65] This challenge forces frequent CT and MRI follow-up studies on patients who receive this therapy.

Surveillance after Complete Resection: Sporadic Renal Cell Carcinoma

A need has been recognized for standardization of surveillance protocols after nephrectomy for sporadic RCC. Multiple surveillance

protocols have been proposed.[44,72–74] An important consideration in determining the appropriate frequency of surveillance imaging after surgery is the ability to provide curative or palliative salvage therapy. Because improved survival can be achieved for certain subsets of patients with recurrent disease, an active approach to surveillance is warranted. For instance, patients with solitary metachronous metastases treated aggressively with surgical resection have a 5-year survival rate of 20% to 44%.[75–78] Extended survival (21 to 136 months) also can be achieved in as many as 33% of patients who undergo resection of an isolated local recurrence in the retroperitoneum.[79,80] Follow-up imaging after curative therapy has been challenged on the basis of survival benefit and cost-effectiveness.[81]

No current randomized trials exist, so little evidence on the appropriate follow-up after surgery available. Too much surveillance places a financial and psychological burden on the patient, whereas too little surveillance may increase morbidity and mortality. Patients are risk stratified, and a follow-up schedule is determined on the basis of stage and grade of the disease. Most recurrence occurs within 3 to 5 years after nephrectomy.[82] Ljungberg and colleagues prospectively reviewed data for 187 patients with pT1 to pT3 disease who underwent radical nephrectomy at their center.[74] These investigators found that 80% of metastatic cancers were diagnosed within 3 years after surgery.[74] It has been documented that Furman nuclear grade, TNM stage, ECOG status, and DNA ploidy are good predictors of tumor progression and tumor recurrence.[82] T1 tumors recur between 38 and 45 months; T3 tumors recur between 17 and 28 months.[82] Furman grade 1 through 4 tumors are associated with risk of metastasis of 9%, 61%, 79%, and 87%, respectively. Diploid tumors carry a decreased risk of recurrence compared with aneuploid tumors.[74]

Imaging for surveillance is based largely on risk of of metastasis by anatomic site. The major metastatic sites in order frequency include lung (3% to 16%), bone (2% to 8%), regional lymph nodes, liver (1% to 7%), ipsilateral adrenal, contralateral kidney, and brain (2% to 4%). Currently, a history and physical examination (H&P), serum studies (calcium level, alkaline phosphatase level, and liver transaminases), and imaging studies (chest plain radiographs or chest CT scan and abdominal CT scan) done at time points when disease recurrence is likely are used for surveillance.[83] The lung has the greatest incidence of metastasis, so early diagnosis is pertinent.[83] Chest radiography has been shown to detect up to 90% of lung metastases.[82] Although chest CT is more sensitive than chest radiography, it yields more false positives, and its role in surveillance is still unknown.[82] In the case of bone metastasis however, only palliative therapies are available, therefore screening bone scintigraphy and radiographs are not warranted.[83] Abdominal CT and liver transaminase determination are an integral part of surveillance because of treatment options available for local recurrence or liver recurrence.[83]

Levy and coworkers have suggested a surveillance protocol based on TNM staging.[73] For T1 disease, a 6-month H&P and serum studies are performed annually for 3 years. For T2 disease, 3-month H&P and semiannual chest radiographs and serum studies are performed; at 24 and 60 months an abdominal CT is recommended. For T3 disease, 3-month follow-up visits that include serum studies and chest x-ray are suggested. Then at 24 and 60 months, a CT scan of the abdomen is recommended. Close follow-up is suggested for T4 disease, including H&P, CT of the abdomen, chest radiographs, and serum studies every 3 months for 2 years and every 4 months for the third and fourth years. Complete follow-up is indicated semiannually in year 5 and then annually.

Zisman and coworkers, in an attempt to standardize RCC staging and management protocol, developed the UISS, described earlier.[84] This system incorporates histologic grade, ECOG status, and TMN stage to improve prognostication for RCC.[84] With this system, they created a surveillance protocol for patients grouped according to recurrence risk. For the low-risk group, these investigators recommend H&P, serum laboratory studies, and chest CT scan annually. At 2 and 4 years after surgery, the patient should have an abdominal CT scan. The intermediate-risk group is recommended to have H&P, serum laboratory studies, and chest CT scan semiannually for 3 years and then annually for 10 years. They should also have an abdominal CT annually for 2 years and then every 2 years up to 10 years post surgery. The high-risk group should have H&P, serum studies, and chest CT semiannually for 3 years and then annually for 10 years. These patients also should have an abdominal CT scan semiannually for 2 years and then annually for 5 years and then every 2 years up until 10 years. Throughout the protocol after 3 years of surveillance the chest CT can alternate with chest radiography.

According to the National Comprehensive Cancer Network (NCCN) guidelines, follow-up evaluation for patients with completely resected disease includes abdominal and chest CT scans obtained approximately 4 to 6 months after the surgery to serve as baseline and then as clinically indicated. Patients are seen periodically, and each visit should include a history, physical examination, and comprehensive metabolic panel (i.e., determination of blood urea nitrogen, serum creatinine, calcium levels, lactate dehydrogenase, and liver enzymes).

Lifelong surveillance is necessary for patients with RCC. Late recurrence is arbitrarily defined as a recurrence more than 10 to 20 years after nephrectomy. In sporadic RCC, recurrences has been documented as long as 45 years after initial surgical resection.[85] The appropriate intensity of follow-up after 5 years remains to be established. Approximately 85% of recurrences, however, will be detected in the first 3 years after resection of the primary.[86]

von Hippel-Lindau Disease and Other Familial Renal Cell Carcinomas

Patients with von Hippel-Lindau RCC or other familial forms of RCC are at high risk for local recurrence after nephron-sparing surgery and require close lifelong surveillance. Greater than 80% of patients with von Hippel-Lindau disease treated with nephron-sparing surgical resection will have a recurrence in the ipsilateral kidney within 10 years, and lesions will develop in the contralateral kidney if they have not done so already.[87] This is because multiple microscopic lesions are present throughout the kidneys despite the grossly normal appearance of the parenchyma.[88] A diagnosis of von Hippel-Lindau disease should be considered in any patient with early-onset or multifocal RCC or RCC in conjunction with the following: a history of visual or neurologic symptoms; a family history of blindness, central nervous system (CNS) tumors, or RCC; or coexisting pancreatic cysts, epididymal lesions, or inner ear tumors.[89,90] Standard recommendations for surveillance in patients with von Hippel-Lindau disease include (1) CT of the abdomen and pelvis every 6 months, (2) annual physical and ophthalmologic evaluations, (3) estimation of urinary catecholamines every 1 to 2 years, (4) MRI of the CNS every 2 years, and (5) periodic auditory examinations. Molecular genetic and clinical screening should be offered to appropriate family members based on an autosomal dominant pattern of inheritance.[87,90,91]

ADJUVANT THERAPY AFTER NEPHRECTOMY

A role for adjuvant therapy after nephrectomy remains to be established, and to date observation remains the standard of care outside a clinical trial. Clinical studies with immunotherapies have failed to demonstrate a clinical benefit. One randomized, multicenter prospective study has reported on the efficacy of adjuvant interferon alfa-2b given after nephrectomy to patients with Robson stages II and III RCC.[92] Patients randomized to receive interferon alfa-2b were given a dose of 6 million IU intramuscularly three times per week for 6 months, starting within 1 month of surgery. Patients in the observation-only group who relapsed were given interferon alfa-2b,

10 million IU intramuscularly, three times per week, or the best available treatment at the time of relapse. Treatment groups were well matched at baseline for patient and tumor characteristics. No significant differences were observed in overall or event-free survival for patients randomized to management by observation ($N = 124$) and patients receiving interferon alfa-2b ($N = 123$). This study did not support the use of adjuvant interferon alfa-2b after nephrectomy. A recently analyzed and reported phase III study of interferon-α as adjuvant treatment for resectable RCC by the ECOG/Intergroup showed that adjuvant treatment with interferon did not contribute to better overall survival or relapse-free survival.[93]

As new drugs have become available for the treatment of metastatic disease, a rationale has arisen for testing these agents in micrometastatic disease. A large, randomized, double-blind phase III study conducted by the ECOG (E2805) is currently accruing patients who have undergone nephrectomy for kidney cancer. Patients with lesions staged as above T1c or Fuhrman grade of 3 or higher (or both) are randomly assigned to a placebo group or to either a sorafenib or sunitinib treatment group. Treatment is to continue for 1 year with close monitoring. The primary clinical endpoint will be time to tumor progression among the three groups. The goal of this important study is to identify a possible role for vascular endothelial growth factor receptor (VEGFR) tyrosine kinase inhibitors (TKIs) in the adjuvant setting; confirmation of a positive effect will establish a new standard of care after nephrectomy for patients with risk for recurrence.

CYTOREDUCTIVE NEPHRECTOMY FOR PATIENTS WITH METASTATIC RENAL CELL CARCINOMA

Approximately one third of patients diagnosed with RCC present with metastatic disease and around 50% of patients will develop metastasis after initial diagnosis.[94] The role of nephrectomy in patients with metastatic disease at the time of diagnosis has long been the subject of debate. A general consensus exists that noncurative nephrectomy is appropriate when symptoms produced by the primary tumor require palliation, when the metastatic tumor burden is less than that of the primary tumor, and when the patient wishes to receive treatment with high-dose IL-2. With the approval of newer drugs (i.e., sunitinib, sorafenib, and temsirolimus), palliative nephrectomy also is now considered the standard of care in patients who will receive small molecule inhibitors for RCC.

Cytoreductive surgery with systemic therapy has been shown to induce clinical benefit.[94] The Southwest Oncology Group (SWOG) conducted a randomized study in which patients who were acceptable candidates for nephrectomy either underwent radical nephrectomy followed by therapy with interferon alfa-2b ($N = 120$) or received interferon alfa-2b alone ($N = 121$). The primary endpoint was survival, with objective response (OR) as the secondary endpoint. The patients were stratified by SWOG performance status (0 or 1), the presence or absence of lung metastases only, and the presence or absence of at least one measurable metastatic lesion in the region not to be resected. After randomization, patients either underwent immediate radical nephrectomy followed by interferon alfa-2b or were immediately given interferon alfa-2b without surgery. Interferon alfa-2b was then continued until disease progression. The median survival time was 11.1 months for patients who received nephrectomy plus interferon alfa-2b and 8.1 months for patients who received interferon alfa-2b alone ($P = 0.05$), Nonetheless, interpretation of these data is difficult in light of the poor median survival seen in both arms of this study.[95]

The patients benefiting the most from cytoreductive surgery appear to be those who have a good ECOG performance status (0 or 1) and preferably with metastasis limited to the lungs.[96] Risk and benefits, however, need to be weighed in the decision to perform cytoreductive surgery. Patients with poor performance status and a large metastatic disease burden (greater than the tumor in the kidney) are less likely to derive benefit from surgery. Frequently, patients with metastatic disease can undergo resection laparoscopically. This is always preferred when technically feasible, because it allows a shorter recovery interval until starting systemic therapy.

Mickisch and colleagues, in the European Organization for Research and Treatment of Cancer (EORTC) randomized trial, compared radical nephrectomy plus immunotherapy with immunotherapy alone.[97] These investigators found that nephrectomy plus immunotherapy delayed time to progression of the disease and improved survival. Bromwich and associates found a mean survival benefit of 4 to 10 months.[98] Of the 268 patients selected for the study, only 20 (7%) were selected for cytoreductive nephrectomy. Owing to the associated risks of the surgery, recovery time, and adverse reactions of the immunotherapy, they concluded after careful patient selection that cytoreductive surgery may only be beneficial to a small segment of renal cell patients.

Rabets and coworkers compared outcomes data for laparoscopic and for open cytoreductive nephrectomy.[99] The selection criteria for laparoscopic surgery were presence of lesions 15 cm or less in diameter and confined to the kidney. These investigators found no statistically significant survival benefits between the surgical modalities. Laparoscopic nephrectomy was found to have fewer morbidities, including less operative blood loss and shorter hospital stay. They concluded that even with advanced disease, laparoscopic nephrectomy is a safe alternative to open nephrectomy in metastatic disease. With proper patient selection patients with metastatic RCC may still benefit from laparoscopic surgery.[94,96,99,100]

RESECTION OF METASTASES IN RENAL CELL CARCINOMA

Resection of solitary metastases from RCC is associated with improved survival, although the selection criteria have been poorly defined. This issue was addressed in a retrospective, single-institution analysis of patients with recurrent RCC ($N = 278$) at the Memorial Sloan-Kettering Cancer Center.[101] Recurrent disease was defined as solitary if it recurred within the resected renal bed or if one organ system or site was involved. Multiple unilateral lesions in the lung were considered to represent a solitary site of metastasis. Bilateral lung involvement or recurrence in two or more sites was considered to constitute multiple sites. Surgery for metastatic disease was considered curative if metastases were curatively resected and noncurative if gross tumor was left behind. Of the 278 patients who underwent initial curative nephrectomy, recurrence was solitary in 155 patients and multiple in 123 patients, with a median time to first recurrence of 25 months. The overall 5-year survival rate of patients who underwent curative resection for the first recurrence was 44% ($N = 141$), 14% for those who received noncurative resection ($N = 70$), and 11% for those who were treated nonsurgically ($N = 67$). Favorable predictors of survival by multivariate analysis included a single site of first recurrence, curative resection of the first metastasis, a disease-free interval of more than 12 months, and a metachronous presentation with recurrence. Curative resection of isolated metastases to glandular tissue (thyroid, salivary gland, pancreas, adrenal, ovary) was associated with the best 5-year overall survival rate (63%), followed by resection of isolated lung metastases (54%). In this study, resection of solitary brain metastases, however, was associated with poor outcome, with an 18% 5-year overall rate. The 5-year overall survival rates of 46% and 44%, respectively, for patients who underwent second ($N = 62$) or third curative resection ($N = 22$) of subsequent metastases after initial curative metastectomy were not significantly different from those for patients who received only initial curative metastasectomy (44%; $N = 141$). Thus patients who undergo complete resection of metastatic disease in a solitary site after a disease-free interval of longer than 12 months may experience long-term survival. As with previous reports, complete resection is the important factor, rather than the number

of sites resected, even in patients who have undergone prior metastectomy.[102,103]

Brain metastases from RCC raise specific therapeutic problems because they are relatively unresponsive to whole-brain radiation therapy and tend to bleed. Recently, stereotactically guided high-precision irradiation (radiosurgery) has shown promising results in selected patients with brain metastases from RCC.[104] Radiosurgery appears attractive owing to its low risk of toxicity and minimal invasiveness. Multiple lesions can be treated at the same time, and retreatment can be performed for local or distant recurrences.

Lymphadenectomy in Locally Advanced Disease

The role of lymphadenectomy in RCC remains controversial. Nodal disease has been found to be a predictor of poor prognosis even with M0 disease, although, there is very little evidence to support the value of lymph node dissection.[105–107] The decision for LND should be based on multiple factors. The need for accurate staging, decreased local recurrence rates, and improved survival should be weighed against risk of morbidity and mortality.[105,108] One argument against lymph node dissection is that the kidney is drained hematologically and lymphatically through multiple pathways.[105] Owing to the unpredictable pathways of spread accurate staging may not be possible. From 58% to 95% of patients with lymph node disease also have synchronous metastasis[109]; consequently, the likelihood of finding patients with localized disease is low at 2% to 9%. Canfield and associates did a retrospective study supporting the need for aggressive nodal resection in the presence of positive lymph nodes without evidence of metastasis.[109] Blom and coworkers of the EORTC Genitourinary Group conducted a large randomized trial comparing radical nephrectomy with lymph node dissection and radical nephrectomy alone.[107] At 5-year follow-up evaluation, these workers found no significant difference in morbidity and mortality between the two groups after surgery. They also found no significant difference in survival. A small subset of patients may benefit from lymph node dissection. Pantuck and asociates have shown improved survival in patients found to have disease-positive lymph nodes who undergo cytoreductive nephrectomy and postoperative immunotherapy.[108] The literature is variable on the benefits of lymph node dissection in patients with renal neoplasms. Overall, lymphadenectomy provides little staging information and confers no clear benefit in decreasing risk of recurrence or in survival.

CYTOKINE THERAPIES FOR ADVANCED DISEASE

Inpatient high-dose bolus IL-2 received FDA approval for treatment for patients with stage IV RCC in 1992 based on data presented on 255 patients who were entered into seven phase II clinical trials.[110,111] In these studies, patients received 600,000 to 720,000 IU/kg of recombinant human IL-2 by 15-minute infusion every 8 hours during two 5-day courses (maximum, 14 doses per course) separated by 5 to 9 days of rest. Stable or responding patients received two to five courses of therapy at 8- to 12-week intervals and then were observed while not receiving any additional therapy. Objective responses were seen in 37 (15%) of the 255 patients, including 17 complete responses (CRs; 7%) and 20 partial responses (PRs; 8%). The median duration of response was 54 months for all of the responders and 20 months for partial responders; the median has not yet been reached for complete responders. The median survival was 16 months for all 255 patients. Most patients who achieved a CR that lasted longer than 30 months and those with PRs after resection resulting in "no evidence of disease" after a response to high-dose IL-2 were unlikely to experience disease progression and may actually be cured.

Although the inpatient high-dose bolus IL-2 regimen produces favorable outcomes in a handful of patients, it also is associated with significant toxic effects and cost and is not universally available. Low-dose IL-2 regimens (with or without interferon-α) have produced similar response rates and survival in nonrandomized phase II trials, but responses appeared to be less durable than those seen with high-dose IL-2.[112–115]

In an effort to determine the value of outpatient subcutaneous IL-2 and interferon-α relative to high-dose intravenous IL-2, the Cytokine Working Group did a phase III trial in which patients were randomized to receive either outpatient IL-2 and interferon-α every 6 weeks or standard high-dose inpatient IL-2 every 12 weeks.[116] One hundred ninety-three patients were enrolled, and 192 were evaluable for toxicity and tumor response. The response rate for high-dose IL-2 was 23%, versus 10% for IL-2 and interferon-α. Eight patients achieved a CR while taking high-dose IL-2, versus only three patients taking low-dose IL-2 and interferon-α. The median response durations were 24 months for high-dose IL-2 and 15 months for IL-2 and interferon-α. Median overall survival times were 17.5 and 13 months, favoring high-dose IL-2. Ten patients (nine major responders) who received high-dose IL-2 were progression free at 3 years, versus three patients (two major responders) who received IL-2 and interferon-α. Of note, responses to high-dose IL-2 were seen with equal frequency across the stratification criteria, whereas low-dose IL-2 and interferon-α seemed to produce fewer responses in patients with liver or bone metastases and in those who had not undergone prior nephrectomy to remove the primary tumor. For patients with bone or liver metastases, or with unresected primary tumor, survival was superior with high-dose IL-2 compared with IL-2 and interferon-α, whereas no significant survival differences between the two treatments were noted for patients who had undergone prior nephrectomy or who were without bone or liver metastases.

Taken together, these studies suggest that high-dose intravenous bolus IL-2 is superior in terms of response rate and possibly response quality to regimens that involve either low-dose IL-2 and interferon-α, intermediate- or low-dose IL-2 alone, or interferon-α alone.[117] The superiority of high-dose IL-2 is particularly apparent in patients with tumor metastases in immune-sequestered sites, such as liver or bone, or whose primary tumor has not been resected, or who fall into the intermediate-risk or poor-risk group defined by the French Immunotherapy Group. Consequently, although low-dose cytokine therapy has a limited role in metastatic RCC, it must be concluded that high-dose intravenous IL-2 should remain the preferred therapy for appropriately selected patients with access to such therapy. In view of the toxicity and limited efficacy of high-dose intravenous IL-2 therapy, however, additional efforts should be directed at better defining the patient population for whom this therapy is appropriate.[118]

Use of interferon-α as a single agent has resulted in only a modest survival benefit in the randomized setting, although combination of this agent with low-dose IL-2 (and perhaps with fluorouracil) may lead to an improved response rate, but evidence of survival benefit in a prospective randomized trial is lacking.[119–121] Although interferon-α has been the outpatient treatment of choice in most of Europe and the United States until recently, benefit again appears to be restricted to patients with good prognostic risk.[122]

Predictors of Response to Cytokine Therapy

Responses to immunotherapy most frequently are seen in patients with RCC of clear cell histology.[123–126] This observation was detailed in a retrospective analysis of pathology specimens obtained from 231 patients (163 primary and 68 metastatic tumor specimens) who had received IL-2 therapy on Cytokine Working Group clinical trials.[126] For patients with primary tumor specimens available for review, the response rate to IL-2 was 21% (30 of 146) for patients with clear cell histology primary tumors, compared with 6% for patients with non-clear cell histology (1 responder in 17 patients). Among the patients with clear cell carcinoma, response to IL-2 was also associated with

the presence of alveolar features and the absence of papillary or granular features. The response rate in patients whose primary tumors had "good" predictive features (e.g., greater than 50% alveolar and no granular or papillary features) was 39% (14 of 36). Patients with tumors that contained "poor" predictive features (e.g., greater than 50% granular or any papillary features) had a response rate of 3% (1 of 33). When this model was then applied to the 68 patients with specimens from metastatic sites, those patients who were treated without resection of their primary tumors, five tumor responses were seen in the 20 patients with "good" predictive features, whereas no tumor responses were seen in the 16 patients in the "poor" predictive group, thus supporting the validity of the model developed from the primary kidney tumor specimens. As a result of these data, it may be appropriate for patients whose primary tumor is of non-clear cell histologic type, or of clear cell histologic type but with "poor" predictive features, to forgo IL-2-based treatment altogether. Even in the most favorable predictive group, however, more than 50% of patients failed to respond to IL-2 therapy, so additional investigations to identify tumor-associated predictors of responsiveness to IL-2 are still necessary.[123]

Some investigators have begun to examine tumor tissue to identify immunohistochemical markers that may predict the outcomes for patients with RCC. Carbonic anhydrase IX (CAIX) has been identified as one potential marker. Bui and colleagues used a monoclonal antibody designed to detect CAIX expression to perform an immunohistochemical analysis of paraffin-embedded RCC specimens. These investigators showed that greater than 90% of RCCs express CAIX, and that its expression decreases with advancing stage.[127] In their analysis, high CAIX expression in primary tumors was seen in 79% of patients and was associated with improved survival and possibly improved response to IL-2-based therapy. Building on this work, Atkins and coworkers performed a nested case-control study within the larger cohort of patients for whom the histopathologic findings were analyzed.[128] CAIX expression levels were correlated with response to IL-2, pathologic risk categorization, and survival. Median survival times were 3 years and 1 year for high and low CAIX expressors, respectively. Although tumor response was seen in six patients with low CAIX staining, survival beyond 5 years was seen only in the patients with high-CAIX-expressing tumors. High CAIX staining was associated with better histopathologic features but remained an independent predictor of response. Although this model with its associated assumptions require prospective validation, it highlights the potential for using pathologic and molecular features of the tumor to identify optimal patients to receive IL-2 therapy. Additional studies to explain these preliminary observations and correlate results with previously described clinical features are necessary.[123]

Recently, the Cytokine Working Group launched the high-dose IL-2 "Select" Trial. The primary objective of this study is to determine, in a prospective fashion, if the predictive model proposed by Atkins and associates can identify a group of patients with advanced RCC who are significantly more likely to respond to high-dose IL-2-based therapy ("good" risk) than a historical, unselected patient population.[128] New factors (including baseline immune function, immunohistochemical markers, and gene expression patterns) that might be associated with response to high-dose IL-2 therapy will also be explored in an attempt to more narrowly limit the application of IL-2 to those patients most likely to benefit.[123]

ANGIOGENESIS INHIBITORS FOR ADVANCED RENAL CELL CARCINOMA

Inhibiting the development of new blood vessels (antiangiogenesis) has been demonstrated as a valid approach to cancer therapy—particularly for RCC. The discovery of the *VHL* gene–HIF-1α connection in kidney cancers has further intensified interest in drug development for approaches aimed at the disruption of angiogenesis in the treatment of RCC.

Vascular endothelial growth factor (VEGF) thus far is the best-characterized proangiogenic factor. It is virtually ubiquitous in human tumors, and higher levels have been correlated with more aggressive disease in kidney cancer. VEGF-A is a potent stimulator of angiogenesis because its binding to VEGFRs has been shown to promote endothelial cell migration and proliferation, two vital features required for the development of new tumor-induced blood vessels. In addition, VEGF-A increases vascular permeability, which also may contribute to angiogenesis and tumor growth. HIF-1α regulates the activation of *VEGF* gene expression. Several approaches are being taken to block the HIF-1/VEGF axis (Fig. 86-2). Clinical efficacy of antiangiogenic therapy in RCC has led to the recent approval of three antiangiogenesis drugs by the FDA for the treatment of advanced kidney cancer (Fig. 86-3).

Sorafenib

Sorafenib (BAY 43-9006) is an oral kinase inhibitor targeting both tumor cells and the tumor vasculature. It originally was developed as an inhibitor of Raf-1, a member of the Raf/MEK/ERK signaling pathway.[129,130] Sorafenib was subsequently found to have activity against B-Raf, VEGF receptor-2 (VEGFR-2), platelet-derived growth factor receptor (PDGFR), Fms-like tyrosine kinase-3 (Flt-3), and stem cell growth factor (c-Kit).[131] In phase I studies investigating various oral dosing schedules, sorafenib generally was well tolerated; the recommended dose for future trials was 400 mg twice daily continuously. Dose-limiting toxic effects seen at continuous doses higher than 400 mg twice daily were diarrhea, fatigue, and skin toxicity.[132,133] A multicenter placebo-controlled randomized discontinuation trial was performed to determine whether sorafenib inhibits tumor growth in patients with metastatic solid tumors who maintain stable disease after a 12-week run-in period.[134] Patients initially received oral sorafenib 400 mg twice daily during the initial period. After 12 weeks, patients with changes in bidimensional tumor measurements that were less than 25% from baseline were randomly assigned to receive sorafenib or placebo for an additional 12 weeks; patients with 25% or greater tumor shrinkage continued open-label sorafenib treatment; patients with 25% or greater tumor growth discontinued treatment. The primary endpoint was the percentage of randomly assigned patients remaining progression free at 24 weeks after the initiation of sorafenib. Of 202 patients who received treatment during the run-in period, 73 patients had tumor shrinkage of 25% or greater. Sixty-five patients with stable disease at 12 weeks were randomly assigned to receive sorafenib ($N = 32$) or placebo ($N = 33$). At 24 weeks, 50% of the patients in the sorafenib treatment group were progression free, versus 18% of those in the placebo group. Median progression-free survival from randomization was significantly longer with sorafenib (24 weeks) than with placebo (6 weeks). Median overall progression-free survival was 29 weeks for the entire population of patients with RCC ($N = 202$). Sorafenib was readministered in 28 patients whose disease progressed during placebo treatment; these patients continued on sorafenib until further progression, for a median period of 24 weeks. Common adverse events were skin rash or desquamation, hand-foot skin reaction, and fatigue; 9% of patients discontinued therapy, and no patients died from toxicity. These data supported the conclusion that sorafenib has significant disease-stabilizing activity in metastatic RCC carcinoma and is tolerable with chronic daily therapy.

The positive results from the phase II study led to a phase III randomized, double-blind, placebo-controlled trial of sorafenib in patients with advanced clear cell RCC.[135] From November 2003 to March 2005, 903 patients with RCC that was resistant to cytokine therapy were randomly assigned to receive either continuous treatment with oral sorafenib (at a dose of 400 mg twice daily) or placebo. A total of 451 patients received sorafenib; 452 received placebo. The primary endpoint was overall survival. A single planned analysis of progression-free survival in January 2005 showed a statistically sig-

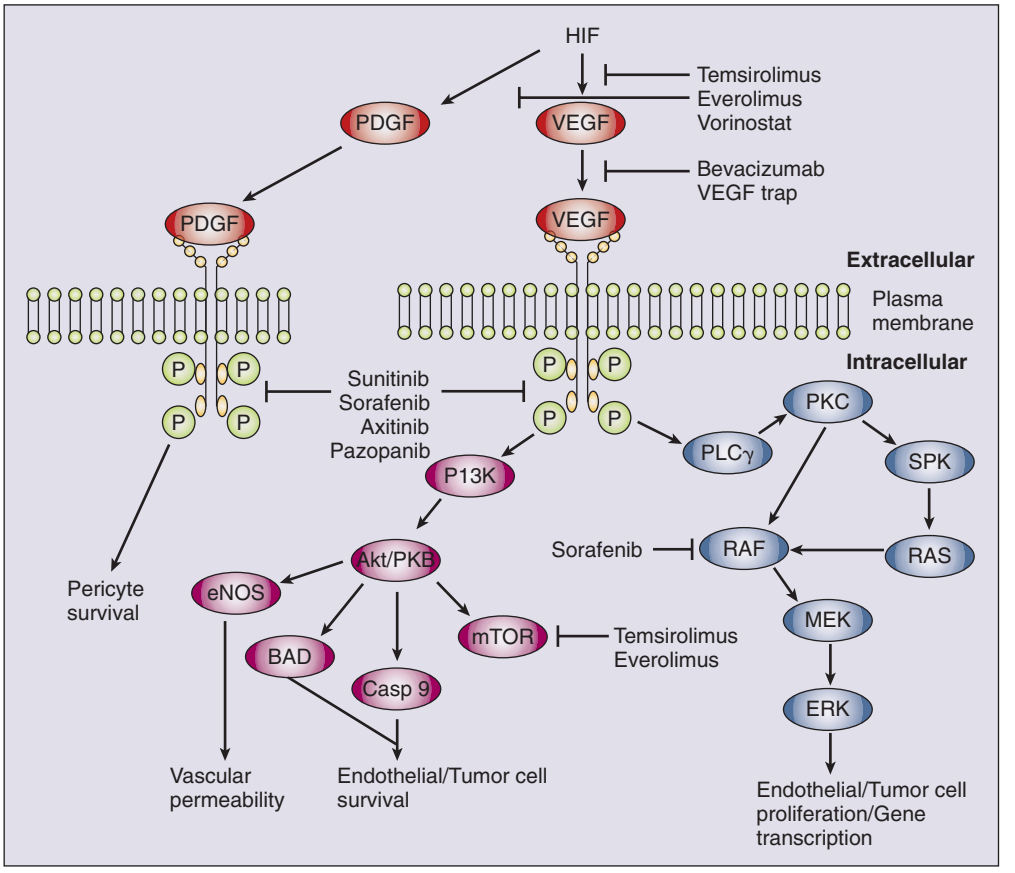

Figure 86-2 • Molecular targets for clear RCC. Several steps in the process of tumor angiogenesis are being targeted for therapeutic purposes.

nificant benefit of sorafenib over placebo. Consequently, crossover was permitted from placebo to sorafenib, beginning in May 2005. At the January 2005 cutoff, the median progression-free survival time was 5.5 months in the sorafenib group and 2.8 months in the placebo group (hazard ratio for disease progression in the sorafenib group, 0.44). The first interim analysis of overall survival in May 2005 showed that sorafenib reduced the risk of death, as compared with placebo (hazard ratio, 0.72), although this benefit was not statistically significant according to the O'Brien-Fleming threshold. Partial responses were reported as the best response in 10% of patients receiving sorafenib and in 2% of those receiving placebo. Diarrhea, rash, fatigue, and hand-foot skin reactions were the most common adverse events associated with sorafenib. Hypertension and cardiac ischemia were rare serious adverse events that were more common in patients receiving sorafenib than in those receiving placebo. As compared with placebo, treatment with sorafenib prolonged progression-free survival in patients with advanced clear cell RCC in whom previous therapy has failed. On the basis of these data, the FDA approved sorafenib in December 2005 for the treatment of advanced kidney cancer.

Sunitinib

Sunitinib (SU11248) is a multitargeted receptor TKI of VEGFRs and PDGFRs. Patients with metastatic RCC who demonstrated progression on first-line cytokine therapy were enrolled into a multicenter phase II trial.[136] SU11248 monotherapy was administered in repeated 6-week cycles of daily oral therapy for 4 weeks, followed by 2 weeks off. Overall response rate was the primary endpoint, and time to progression and safety were secondary endpoints. Twenty-five (40%) of 63 patients who received SU11248 achieved PRs; 17 additional patients (27%) demonstrated stable disease with duration of 3 months or longer. Median time to progression in the 63 patients was 8.7 months. Dosing generally was tolerated well, with manageable toxicities. SU11248 demonstrated antitumor activity in metastatic RCC as second-line therapeutic agent. Based on the phase II study results, the FDA approved sunitinib for the treatment of advanced kidney cancer in early 2006.

Because sunitinib has shown activity in two uncontrolled studies in patients with metastatic RCC, a comparison of the drug with interferon-α in a phase III trial was warranted. A total of 750 patients with previously untreated, metastatic RCC were enrolled in a multicenter, randomized phase III trial to receive either repeated 6-week cycles of sunitinib (at a dose of 50 mg given orally once daily for 4 weeks, followed by 2 weeks without treatment) or interferon-α at a dose of 9 MU given subcutaneously three times weekly.[137] The primary endpoint was progression-free survival. Secondary endpoints included the OR rate, overall survival, patient-reported outcomes, and safety. The median progression-free survival was significantly longer in the sunitinib group (11 months) than in the interferon-α group (5 months), corresponding to a hazard ratio of 0.42. Sunitinib was also associated with a higher OR rate than was interferon-α. The proportion of patients with grade 3 or 4 treatment-related fatigue was significantly higher in the interferon-α treatment group, whereas diarrhea was more frequent in the sunitinib group. Patients in the sunitinib group reported a significantly better quality of life than did patients in the interferon-α treatment group. Progression-free survival was longer and response rates were higher in patients with metastatic renal cell cancer who received sunitinib than in those receiving interferon-α.

Temsirolimus

Temsirolimus (CCI-779) is a novel mammalian target of rapamycin (mTOR) kinase inhibitor. It has been shown to bind with high

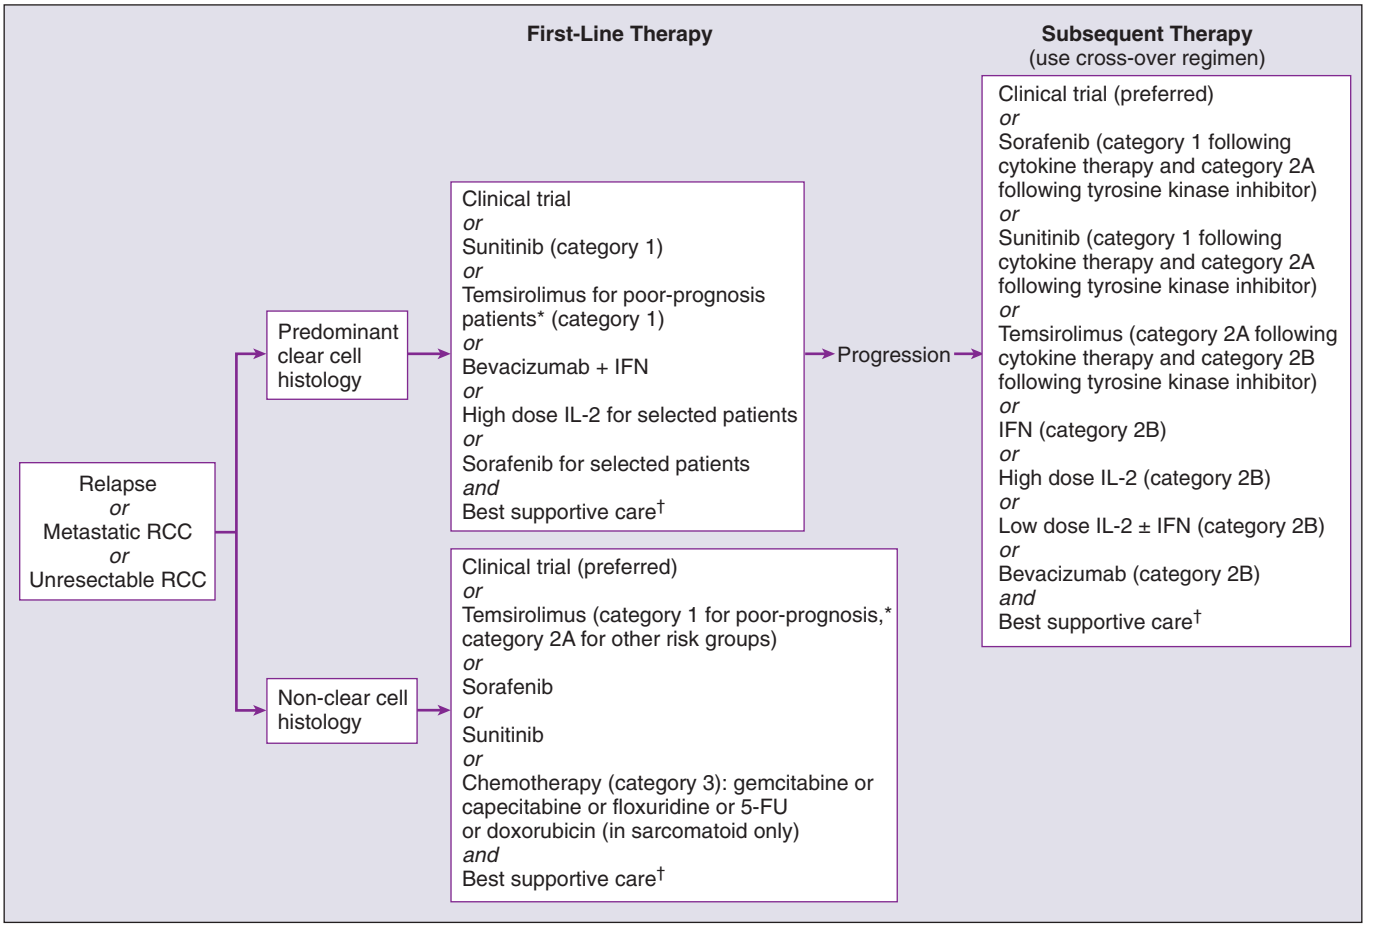

Figure 86-3 • National Comprehensive Cancer Network (NCCN) 2008 guidelines for the treatment of metastatic renal cell carcinoma (RCC). Recent NCCN treatment guidelines show the incorporation of newly approved antiangiogenic agents into standard treatment regimens. 5-FU, 5-fluorouracil; IFN, interferon; IL-2, interleukin-2. *Temsirolimus indicated for poor-prognosis patients, defined as those with 3 or more predictors of short survival. †Best supportive care can include palliative radiation therapy, metastasectomy, or bisphosphonates for bone metastases. (Adapted from The NCCN Kidney Cancer Guideline. Clinical Practice Guidelines in Oncology [Version 1.2008]. © 2007 National Comprehensive Cancer Network, Inc. Available at: http://www.nccn.org. Accessed November 30, 2007. To view the most recent and complete version of the guideline, go online to www.nccn.org.)

affinity to the immunophilin FKBP, and this complex inhibits mTOR kinase activity as evidenced by inhibition of phosphorylation of the eukaryotic translation initiation factor 4E-binding protein-1 and the 40S ribosomal protein p70 S6 kinase, the primary downstream effectors of mTOR.[138–140] The upstream activator of mTOR is the serine-threonine kinase Akt. Akt activity is in turn regulated by phosphoinositol-3 (PI3)-kinase and the *PTEN* tumor suppressor gene. Although mutations in *PTEN* have not been detected in RCC, *PTEN* gene expression often is downmodulated.[141,142] In addition, the mTOR pathway appears to be involved in the development of a hereditary form of RCC seen in patients with tuberous sclerosis.

Activation of mTOR increases HIF-1α gene expression at the levels of both messenger RNA (mRNA) translation and protein stabilization.[143] Thus, inhibition of mTOR by CCI-779 also could prevent the enhanced angiogenesis associated with sporadic RCC and loss of *VHL* function.

In a phase II study, 111 patients were randomly assigned to receive 25, 75, or 250 mg of CCI-779 weekly as a 30-minute intravenous infusion.[144] Patients were evaluated for tumor response, time to tumor progression, survival, and adverse events or effects. Blood samples were collected to determine CCI-779 pharmacokinetics. CCI-779 produced an OR rate of 7% (one CR and seven PRs) and minor responses in 26% of these patients with advanced RCC. Median time to tumor progression was 5.8 months, and the median survival time was 15.0 months. The most frequently occurring CCI-779-related adverse effects of all grades were maculopapular rash (76%), mucositis (70%), asthenia (50%), and nausea (43%). The most frequently occurring grade 3 or 4 adverse effects were hyperglycemia (17%), hypophosphatemia (13%), anemia (9%), and hypertriglyceridemia (6%). Neither toxicity nor efficacy was significantly influenced by CCI-779 dose level. Patients were retrospectively classified into good-, intermediate-, or poor-risk groups on the basis of criteria used by Motzer and colleagues for a first-line study population with metastatic RCC treated with interferon-α. Within each risk group, the median survival rates of patients at each dose level were similar. In patients with advanced RCC, CCI-779 showed antitumor activity, encouraging survival, and generally was well tolerated over the three dose levels tested.

The promising data from the phase II study led to a multicenter phase III trial in which 626 patients with previously untreated, poor-prognosis metastatic renal cell carcinoma were randomly assigned to receive 25 mg of intravenous temsirolimus weekly, 3 million U of interferon-α (with an increase to 18 million U) subcutaneously three times weekly, or combination therapy with 15 mg of temsirolimus weekly plus 6 million U of interferon-α three times weekly.[145] The primary endpoint was overall survival in comparisons of the temsirolimus group and the combination-therapy group with the interferon group. Patients who received temsirolimus alone had longer

overall survival (hazard ratio for death, 0.73) and progression-free survival than did patients who received interferon-α alone. Overall survival in the combination-therapy group did not differ significantly from that in the interferon group (hazard ratio, 0.96). Median overall survival times in the interferon group, the temsirolimus group, and the combination-therapy group were 7.3, 10.9, and 8.4 months, respectively. Rash, peripheral edema, hyperglycemia, and hyperlipidemia were more common in the temsirolimus group, whereas asthenia was more common in the interferon-α group. There were fewer patients with serious adverse events in the temsirolimus group than in the interferon-α treatment group. Compared with interferon-α, temsirolimus improved overall survival among patients with metastatic RCC and a poor prognosis. The addition of temsirolimus to interferon-α did not improve survival. These recent data led the FDA to approve temsirolimus for the treatment of advanced kidney cancer in July 2007.

Bevacizumab

Because of the mechanistic link between VEGF overexpression and *VHL* inactivation in clear cell RCC, a randomized, placebo-controlled, double-blind study of bevacizumab in patients with measurable metastatic clear cell RCC was conducted.[146,147] The two bevacizumab doses selected were 3 mg/kg (predicted by pharmacokinetics to produce a serum level equal to the optimally effective level in nude mice bearing human tumor xenografts) and 10 mg/kg (the maximum dose in the phase 1 trial, although limiting toxicity was not reached). Beginning 1 week after a loading dose of 150% of the assigned dose, treatment was given by intravenous infusion every 2 weeks. The primary endpoints were time to tumor progression (by WHO criteria) and response rate. Survival was a secondary endpoint, because crossover from placebo to 3 mg/kg of bevacizumab was allowed for patients with disease progression on placebo. Minimal toxic effects were seen, with hypertension and asymptomatic proteinuria predominating. The trial was stopped after the interim analysis met the criteria for early stopping. With 116 patients randomly assigned to treatment groups (40 to placebo, 37 to low-dose antibody, and 39 to high-dose antibody), a significant prolongation of the time to progression of disease was found for the high-dose antibody group, compared with the placebo group (hazard ratio, 2.55). A small difference, of borderline significance, was observed between the time to progression of disease in the low-dose antibody group and that in the placebo group (hazard ratio, 1.26). The probability of being progression-free for patients given high-dose antibody, low-dose antibody, and placebo was 64%, 39%, and 20%, respectively, at 4 months and 30%, 14%, and 5% at 8 months. In this trial, four partial responses occurred for a 10% response rate, and time to tumor progression was substantially prolonged in patients receiving the higher dose of bevacizumab. No major responses to the 3 mg/kg dose were noted, and the effect on time to progression was minimal and of borderline statistical significance. No difference in survival was shown. A substantial number of patients taking bevacizumab showed evidence of mixed tumor responses. Because sensitive criteria for tumor progression were used (a 25% increase in the product of perpendicular diameters of any lesion; even a single lesion increasing in diameter by 12% could meet this criterion), protocol therapy was truncated in some patients who may have been experiencing a net benefit from bevacizumab. No significant differences in overall survival between groups were found.

In view of the positive results from the phase II study, a phase III trial was conducted to evaluate the efficacy and safety of bevacizumab in combination with interferon-α as first-line treatment in metastatic RCC.[148] Nephrectomized patients with clear cell RCC, KPS of 70%, no CNS metastases and adequate organ function received interferon-α (given three times weekly at a recommended dose of 9 MIU for up to 1 year) plus bevacizumab (10 mg/kg every 2 weeks) or placebo until disease progression. Tumor assessments were performed every 8 weeks until week 32 and then every 12 weeks thereafter. Patients were stratified according to Motzer score. Between June 2004 and October 2006, 649 patients were randomized (641 for treatment) at 101 centers in 18 countries. At data cutoff, 505 progression events had occurred, 111 patients remained on treatment, 287 had discontinued (rates of discontinuation due to adverse events were 12% with interferon and 28% with interferon-α plus bevacizumab), and 251 died. Bevacizumab-related side effects generally were mild and consistent with previous observations. The addition of bevacizumab to interferon-α significantly increased progression-free survival (10.2 versus 5.4 months) (hazard ratio, 0.63) and objective tumor response rate (30.6% versus 12.4%). A trend toward improved overall survival was observed with the addition of bevacizumab to interferon-α. These data suggest that bevacizumab improves progression-free survival when combined with interferon-α in RCC. No unexpected safety events were observed. These results were presented at the American Society of Clinical Oncology (ASCO) plenary session in 2007, and FDA approval of bevacizumab is expected soon.

Other Angiogenesis Inhibitors

A critical survival step for proliferating endothelial cells is the ligation of fibronectin in the extracellular matrix to integrin $\alpha_5\beta_1$. Voloxicimab, a chimeric monoclonal antibody, blocks fibronectin binding to $\alpha_5\beta_1$ and induces apoptosis of proliferating endothelial cells. Voloxicimab activity is independent of growth factor stimulus, suggesting that $\alpha_5\beta_1$ signaling occurs downstream of growth factor signaling, and is possibly a final common pathway for the development of neovasculature. A multicenter, open-label phase II study of volociximab for RCC was recently conducted.[149] Patients received intravenous volociximab 10 mg/kg every 2 weeks until disease progression was noted. Patients were evaluated for efficacy of this agent every 8 weeks using response evaluation criteria in solid tumors (RECIST). A total of 40 patients were enrolled. Median time since first diagnosis was 2.5 years. Nineteen patients (47.5%) had received up to 2 prior therapies. The most frequent side effects were fatigue in 27 patients (67.5%), nausea in 14 (35%), dyspnea in 8 (20%) and arthralgia in 7 (17.5%), of which none were grade 3 or 4. Seven (17.5%) patients experienced serious adverse effects. Stable disease was observed in 32 (80%) patients, including 1 confirmed PR. Duration of disease stability ranged from 2 to 22 months. Median time to progression was 4 months. Median overall survival has not been reached after 22 months. Overall survival rates at 6 months were 79% and 68%, respectively, at 22 months. Six (15%) patients died in the study, 5 (12.5%) from progressive disease and 1 with arrhythmia (unrelated to volociximab). Volociximab was demonstrated to be well tolerated at a dose of 10 mg/kg every 2 weeks. Stable disease was noted in 80% of patients. Based on clinical activity, a randomized controlled trial is planned.

AG13637 (axitinib) is a potent inhibitor of VEGFRs 1, 2, and 3 and showed substantial efficacy in a phase II study in patients with cytokine-refractory RCC.[150] The activity of AG13637 in metastatic RCC patients refractory to prior TKI therapy was recently evaluated.[151] Patients with sorafenib-refractory RCC were enrolled in this multicenter, open-label phase II study. All patients received a starting dose of AG13637 5 mg orally twice daily, titrated according to tolerance. The primary endpoint was RECIST-defined OR, with a null hypothesis of OR = 8%, versus OR = 20% under the alternative hypothesis. Partial response was observed in 6 of 42 evaluable patients (14%), stable disease was noted in 15 patients (36%), 12 patients (29%) experienced progressive disease, and 9 patients (21%) withdrew because of adverse effects. Overall, 57% of patients experienced some degree of tumor regression. With a median follow-up period of 5.3 months, the median progression-free survival was not reached. Preliminary analysis indicates an overall median progression-free survival longer than 7.1 months. No ORs have yet been observed in patients who received prior sunitinib treatment, although

tumor regression was demonstrated in 55% of patients with median progression-free survival longer than 6.1 months. Treatment-related grade 3 or 4 adverse events included hypertension (16%), fatigue (14%), and hand-foot syndrome (14%).

Pazopanib is a potent and selective multitargeted receptor TKI (of VEGFR-1, VEGFR-2, VEGFR-3, PDGFR-α/β, and c-Kit) that blocks tumor growth and inhibits angiogenesis. In a phase II randomized discontinuation trial, the effects of pazopanib on tumor growth in patients with RCC was assessed after 12 weeks of treatment.[152] Patients with cytokine-naive and -refractory (as indicated by failure to respond to 1 previous cycle of a cytokine- or bevacizumab-containing regimen) RCC ECOG stages 1 and 2 were enrolled. Pazopanib 800 mg was given orally once daily. In the first 60 patients, response at week 12 by independent review showed PR in 24 (40%); stable disease in 25 (42%); disease progression in 5 (8%); unknown response in 2 (3%); and withdrawal before week 12 in 4 (7%). On the basis of findings on investigator review at week 12, 27 (45%) patients were randomized for treatment. Total disease control rate was 82% (PR plus stable disease). Approximately 67% of patients were treatment naive, and the remaining 33% had failed to respond to one previous treatment regimen. Most common adverse effects or laboratory abnormalities in all patients were alanine and aspartate aminotransferase elevations, diarrhea, fatigue, nausea, hair depigmentation, and hypertension. Grade 3 or 4 adverse effects occurred in 26% of patients; most common were hypertension (8%) and increase in alanine transaminase (8%). Interim analysis of findings in this phase II study demonstrated that pazopanib treatment resulted in a PR rate at week 12 of 40% among patients with RCC and an acceptable toxicity profile.

RAD001 (everolimus) is an oral mammalian target of rapamycin (mTOR) inhibitor. A phase II study was recently conducted.[153] Forty-one patients have been enrolled, and 37 patients were evaluable for response and toxicity. Twelve patients had PRs; 19 patients were stable for longer than 3 months. Median duration of therapy is greater than 8 months (range, 1 to 20 months). Treatment-related adverse effects included mucositis, skin rash, pneumonitis, hypophosphatemia, hyperglycemia, hypertriglyceridemia, hypercholesterolemia, thrombocytopenia, anemia, and elevated liver enzymes. PET scans have demonstrated decreased metabolic activity in responding or stable patients. Median overall survival was 11.5 months (range, 1 to 20 or longer). RAD001 has promising antitumor activity in patients with MRCC demonstrated by partial response rate. Antitumor activity is further suggested by a prolonged time to progression of 3 months. A phase III randomized trial of RAD001 versus supportive care in patients with metastatic RCC recently has been completed, and the results are pending.

Future Directions for Antiangiogenesis Therapies

Although sorafenib, sunitinib, temsirolimus, and bevacizumab have added greatly to the therapeutic armamentarium for patients with advanced renal cancer, as single agents, these drugs produce PRs rather than CRs in a minority of patients, require long-term administration for continued disease control, and have side effects. Treatment resistance typically develops within 6 to 12 months, and tumors often progress quickly once treatment is stopped. Reasons for these results can be multifold: (1) optimal dosing has not been achieved; (2) the signaling pathway is not sufficiently understood; or (3) tumor heterogeneity may be responsible for different dependence from the targeted pathway among patients. Combination therapy has been proposed as a way of potentially producing more durable benefit. Although critically important, testing of combination regimens must proceed cautiously because of the potential for synergistic toxicity or countervailing activity inherent with use of these multitargeted agents.[154] Approaches to combination therapy currently being investigated include "vertical" combinations, in which the HIF/VEGF pathway is blocked at several steps, and "horizontal" combinations, in which multiple separate signaling pathways are blocked simultaneously[155] (Fig. 86-4).

The term *targeted* with respect to therapies in kidney cancer raises several questions: (1) Can the selected target be effectively inhibited? (2) Is the target the same in each patient? (3) Is the therapy endothelial cell or tumor cell specific? New clinical tools to determine whether a patient is going to respond to a certain targeting agent or whether the inhibition of an alternative target will lead to a greater clinical benefit are urgently needed. The vast majority of patients eventually progress through anti-VEGF therapies. Different hypotheses for the resistance mechanisms have been proposed. A recent report suggests that in a transgenic mouse model of pancreatic cancer, an early phase of response to anti-VEGF therapy leads to decrease in blood vessel formation and consequent hypoxia with induction of HIF-1α with downstream overexpression of proangiogenesis growth factors.[156] It is conceivable that overexpression of HIF-1α is responsible for increased levels of VEGF that cannot be counteracted by VEGF TKI, or that such overexpression induces alternative growth factors such as placental growth factor and basic fibroblast growth factor. Clinical evidence also indicates that circulating VEGF levels are increased in patients receiving TKIs. Taken together, these observations suggest that the anti-VEGF therapy "escape" may be neutralized with a therapeutic strategy aimed to achieve a "vertical" inhibition of the VEGF pathway. For example, inhibition of tumor cell adaptation to hypoxia induced by TKIs may be achieved with HDAC or mTOR inhibitors that block the HIF pathway. These hypotheses can be tested in rationally designed clinical trials. An upcoming ECOG study (E4805) will test the strategy of sequential inhibition of angiogenesis by means of treatment with VEGF-trap, a neutralizing decoy consisting of VEGFRs 1 and 2, after TKI failure (Fig. 86-5A). A second upcoming ECOG trial (E2804) will randomize patients to receive duplets of agents including sorafenib, CCI-779, or bevacizumab to test concomitant inhibition (see Fig. 86-5B). Our institution has recently opened a trial combining bevacizumab with suberoylanilide hydroxamic acid (SAHA), a small-molecule inhibitor

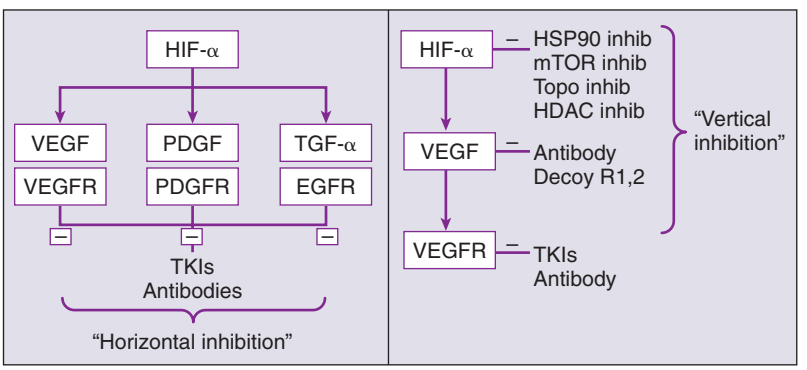

Figure 86-4 • Strategies targeting the HIF-1α pathway. Dysregulation of the HIF pathway is likely to contribute to the development of renal cell carcinoma. Therefore, drugs that inhibit HIF or its downstream targets warrant testing for treatment of this disease. EGFR, epithelial growth factor receptor; HIF, hypoxia-inducible factor; PDGF, placenta-derived growth factor; PDGFR, platelet-derived growth factor receptor; TGF-α, transforming growth factor-α; TKIs, receptor tyrosine kinase inhibitors; VEGF, vascular endothelial growth factor; VEGFR, VEFG receptor. (Adapted from Kaelin WG Jr: The von Hippel-Lindau tumor suppressor protein and kidney cancer. Clin Cancer Res 2004;10:6290S–6295S.)

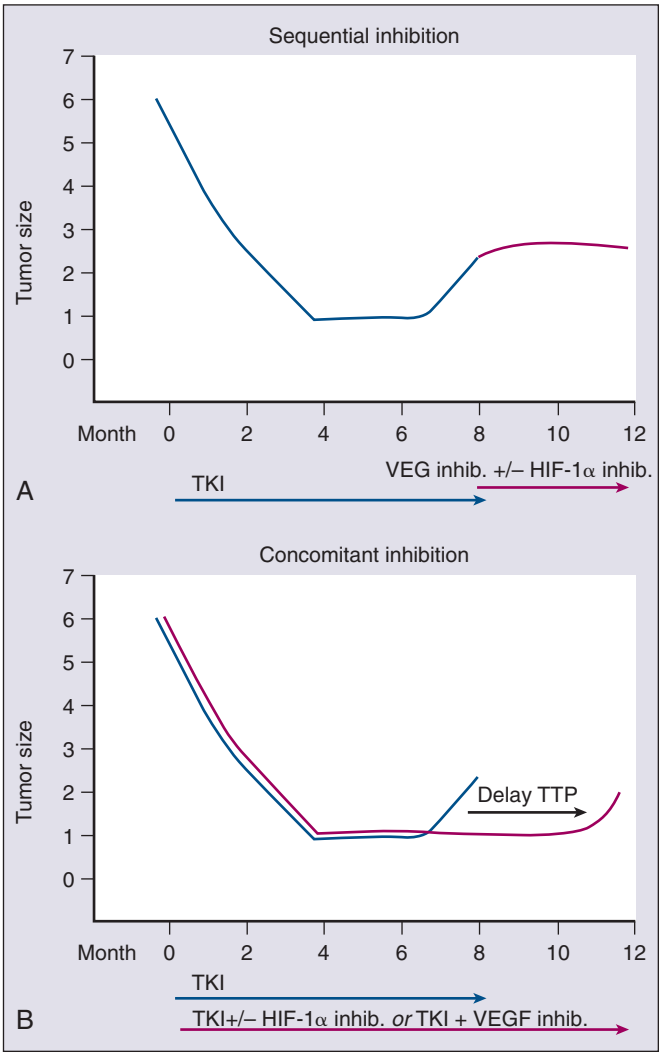

Figure 86-5 • Combination strategies to inhibit angiogenesis: sequential (**A**) versus concomitant (**B**) schedule. The diagram shows a potential lesion that responds initially to a tyrosine kinase inhibitor (TKI) but eventually progresses. A rational intervention at the time of progression would be to treat the patient with an antibody that neutralizes elevated levels of vascular endothelial growth factor (VEGF) (**A**). Another therapeutic strategy to delay the occurrence of anti-VEGF therapy escape is to add a hypoxia-inducible factor-1α (HIF-1α) inhibitor or an anti-VEGF ligand antibody at the time of starting the TKI and delaying the time of tumor progression (TTP) (**B**).

of histone deacetylase (HDAC), in patients with metastatic RCC. SAHA is a potent inhibitor of HDAC, and can be administered orally with good bioavailability.[157] HDAC inhibitors have been shown to reduce HIF-1α protein expression both in tumor and endothelial cells.[158,159] The combination of HDAC inhibitors with VEGF inhibitors has an additive antiangiogenic and antitumor activity in animal models, and may achieve a "vertical" inhibition of the VEGF pathway.[158]

Combination of anti-VEGF therapies with immunotherapies also has shown promising results in phase I/II setting. In particular, the combination of the TKI sorafenib and interferon-α has been reported to have clinical activity that seems greater than historical single-agent activity.[160] Preclinical studies have suggested an immunomodulatory effect of anti-VEGF treatment by effecting dendritic cell maturation.[161]

NONMYELOABLATIVE ALLOGENEIC PERIPHERAL BLOOD STEM CELL TRANSPLANTATION

Allogeneic hematopoietic stem cell transplantation (HSCT)has been used successfully for decades to treat lethal hematologic malignancies. Nonmyeloblative allogeneic peripheral blood stem cell transplantation also has been tested as a therapeutic approach in metastatic RCC. Evidence supporting the existence of graft-versus-tumor effects against metastatic RCC has been reported recently by a number of transplant centers using a variety of different nonmyeloablative transplantation approaches.[162–167] At the National Heart, Lung, and Blood Institute, 10 of the first 19 patients (54%) to undergo this treatment demonstrated tumor regression, including 7 PRs and 3 CRs.[162] The first patient in this series remains without evidence of disease more than 6 years after transplantation. Responses occurred most commonly in patients with a clear cell histologic subtype that was limited to the lungs, although regression of tumor lesions in multiple sites, including the bones, liver, and lymph nodes, occasionally was observed. Although significant and occasionally complete regression of metastatic disease has been observed, a number of factors currently limit the application of allogeneic immunotherapy for RCC. Unfortunately, most responses have been partial, with CRs occurring in a small subset of patients. Although toxicity appears less compared with conventional myeloablative approaches, regimen-related mortality rates of 10% to 15% persist, largely as a consequence of severe grade III to IV acute graft-versus-host disease (GVHD).

The experience with allogeneic HSCT for RCC in 124 patients from 21 European centers has been recently reported.[168] The cumulative incidence of moderate to severe, grades II to IV acute GVHD was 40%; for chronic GVHD, it was 33%. The transplantation-related mortality rate was 16% at 1 year. Complete ($N = 4$) or partial ($N = 24$) responses, median 150 (range, 42 to 600) days after transplantation, were associated with time from diagnosis to HSCT, mismatched donor, and acute GVHD II to IV. Factors associated with survival included chronic GVHD, donor lymphocyte infusion, fewer than 3 metastatic sites, and a KPS score greater than 7. Patients ($N = 17$) with chronic GVHD and given donor lymphocte infusion had a 2-year survival rate of 70%.

Second-generation allogeneic HSCT trials that incorporate methods to enhance the donor immune system against the tumor through the use of adoptively infused tumor-reactive donor T cells and NK cells, as well as post-transplantation tumor vaccination strategies are being considered for further investigation.[169]

VACCINE STRATEGIES FOR RENAL CELL CARCINOMA

Many cancer vaccines are in various stages of preclinical and clinical development. These vaccines are based on the hypotheses that tumor-associated antigens (TAAs) are inherently weakly immunogenic or functionally nonimmunogenic and that effective vaccines will enhance the efficacy of presentation of TAAs to the immune system, resulting in dramatically increased activation of host T cells. To "break tolerance" against TAAs is the common purpose of antigen presentation by vaccination. Strategies for the development of cancer vaccines include (1) identifying novel TAAs for RCC reactive cytotoxic T lymphocytes, (2) improving modes of antigen delivery and antigen presentation by using dendritic cells, (3) enhancing antigen immunogenicity (e.g., alternating vaccine prime and boost, enhancing T-cell costimulation, and engineering amino acid sequences in peptide TAAs); (4) improving systemic T-cell dissemination, (5) enhancing destruction of tumor cells (effector phase), (6) improving T-cell memory, and (7) enhancing the adaptive response to tumor variants (e.g., use of cytokines as vaccine adjuvants). Thus, multiple hurdles must be overcome before the promise of cancer vaccines as adjuvant therapy becomes a reality for patients with RCC.

To date therapeutic cancer vaccines have little proven effect in the area of RCC. Vaccine approaches have included isolated tumor cell suspensions either alone or mixed with heat-shock protein, gene-modified tumor cells, and dendritic cells that express RCC-associated antigens. These cancer vaccines have reported response rates ranging from 1.9% to 9.5%.[170]

Recent insights into the tumor-derived factors that inhibit the immune system have provided new opportunities to enhance vaccine-mediated antitumor immunity and thereby potentially increase vaccine efficacy. Future vaccine investigations probably will incorporate concomitant modulation of proinflammatory and immune inhibitory pathways that have hindered generation of tumor-specific immunity. Promising approaches include the combination of vaccines with antibodies to B7 molecules or agents that deplete $CD25^+$ T-regulatory cells or block the generation of arginase-expressing tumor-associated myeloid cells. In addition, combinations of dendritic cell vaccines with cytokines, such as IL-2, interferon, or granulocyte macrophage colony stimulating factor, may produce more clinical benefit in patients with RCC.[171]

CHEMOTHERAPY FOR ADVANCED RENAL CELL CARCINOMA

Conventional cytotoxic agents generally offer little benefit to patients with RCC. The response rates for a wide variety of chemotherapeutic agents in phase II trials generally have been in the range of 6% to 20%. Although these responses are durable on occasion, no improvement in median survival has been reported.[172] In a review of 83 trials of a variety of chemotherapeutic regimens published from 1983 to 1993, Yagoda and colleagues reported a 6% overall response rate for 4093 patients with advanced RCC.[173] Data from a multi-institutional phase II trial of gemcitabine and 5-FU suggested that this regimen could be active for patients with advanced RCC.[174] Another multi-institutional study with gemcitabine and capecitabine, however, showed only modest activity in patients with metastatic renal cancer, and the degree of clinical benefit and its associated toxicity did not support further evaluation in a phase III trial in unselected patients.[175] More focused investigations to identify patients most likely to benefit from chemotherapy or to enhance activity with additional agents such as anti-VEGF drugs would be worthwhile.

TREATMENT OF KIDNEY CANCERS WITH NONCONVENTIONAL HISTOLOGIC FEATURES

The incidence of non-clear cell carcinoma of the kidney has been reported as approximately 20% to 30%. These percentages, however, reflect data from surgical series of patients undergoing primary nephrectomy. Because primary non-clear cell carcinomas tend to have a better prognosis than clear cell carcinomas, the percentage of metastatic non-clear cell carcinomas is much lower.[176,177] Recent reviews suggest that only 5% to 8% of patients who receive treatment in clinical trials have non-clear cell histologic characteristics.[178–180] The data on response rates for non-clear cell RCC also are relatively limited. This is not only because of the rarity of these variants in the metastatic setting, but also because in the past, studies have not typically reported on response by subtype. More recently, the Cytokine Working Group has reported that only 1 of 17 patients with non-clear cell tumors responded to high-dose IL-2,[179] and in the Memorial Sloan-Kettering Cancer Center series, only 1 of 37 responded to interferon-based therapy,[178] suggesting that immunotherapy should not be offered to patients with non-clear cell RCC.

Sarcomatoid differentiation in RCC indicates an aggressive subtype of renal parenchymal tumors, and is associated with a poor prognosis.[181,182] Some evidence suggests that metastatic RCC with sarcomatoid differentiation do not respond to immunotherapy and should be treated with combination chemotherapy.[183] Based on the antitumor activity of doxorubicin and gemcitabine in collecting duct carcinoma of the kidney, Nanus and coworkers have tested this combination for treatment in selected patients with sarcomatoid or rapidly progressing RCC.[184] Eighteen patients with RCC (56% sarcomatoid; 44% other) were treated at two institutions. Seven patients had received previous treatment with interferon or IL-2. Sites of metastases included the lung, soft tissue, bone, liver, and brain, with 88% of patients prersenting with three or more sites of disease. Treatment consisted of doxorubicin (50 mg/m^2) and gemcitabine (1500 or 2000 mg/m^2) every 2 to 3 weeks with granulocyte colony stimulating factor support. A median of 5 courses was administered (range, 2 to 12 cycles). Therapy was well tolerated with no grade 4 toxicity. Two patients had a CR, five had a PR, three had a mixed response, and one had stable disease. The median duration of response was 5 months (range, 2 to 21 months or longer). These data suggested that the combination of doxorubicin and gemcitabine has antitumor activity in patients with sarcomatoid RCC or with rapidly progressing RCC. An ongoing ECOG study is testing this combination in patients with sarcomatoid RCC.

Collecting duct RCC is a rare and aggressive neoplasm of the distal collecting duct system for which no effective therapy has been established. In a case report, a 37-year-old woman with metastatic collecting duct RCC demonstrated 80% reduction in her tumor burden, including complete regression of lymph node metastases and significant shrinkage of the primary, after treatment with paclitaxel and carboplatin. The patient was subsequently rendered free of disease by nephrectomy without evidence of recurrence on follow-up evaluation at 20 months.[185] A number of case reports have described responses of collecting duct carcinoma to gemcitabine- or taxane-based therapies similar to those used in transitional cell carcinoma.[186,187] This finding is consistent with expression data suggesting that these tumors are closely related to transitional cell cancers.[188]

The activity of sunitinib and sorafenib in non-clear cell histologic tumor types has been recently evaluated.[189] Clinical features at study entry and treatment outcomes were evaluated in all patients with metastatic papillary and chromophobe RCC who received either sunitinib or sorafenib as their initial TKI treatment at one of five different cancer centers in France and USA between 2002 and 2006. Overall response rate, progression-free survival, and overall survival for the entire cohort were 10%, 8.9, and 12.2 months, respectively. Twenty (38%) and 33 (62%) patients received sunitinib and sorafenib, respectively. Three of 12 patients (25%) with chromophobe histology had an OR, versus two of forty-one (4.8%) with papillary histology. Progression-free survival for patients with chromophobe histology was 9.3 months, compared with 6.6 months for those with papillary histology. Overall survival was not different across histologic types and types of TKI received. Patients who received sunitinib had an overall response rate of 15% and progression-free survival of 11.9 months, compared with 6% and 5.5 months, respectively, for patients who received sorafenib. Other factors found to be associated with shorter progression-free survival include ECOG performance status greater than 0 and subnormal hemoglobin concentration. These preliminary results suggest that TKI may have activity in metastatic chromophobe RCC, similar to what is seen with tumors of clear cell histology. Minimal activity, however, was noted in papillary RCC, justifying continued investigations of novel agents for treatment of this histologic tumor type.

SUMMARY

Recent advances in molecular classification of RCC with techniques such as DNA microarray analysis with laser capture of single malignant cells and comparative genomic hybridization will lead in the near future to novel targeted therapies to be developed for specific histologic subtypes. Surgical resection remains the principal therapeutic modality when RCC is confined to the kidney. Surgical tech-

niques continue to be refined through the growing use of laparoscopic procedures and nephron-sparing resections that resulted in less morbidity, preservation of renal function, and comparable therapeutic outcomes. Patients at high risk for recurrence after nephrectomy include those with positive lymph nodes, high Fuhrman grade, extension beyond Gerota's fascia, or extension into the renal vein or vena cava. Overall survival is influenced by stage, performance status, Fuhrman grade, and histologic subtype (sarcomatoid or collecting duct). No adjuvant therapy for resected disease has been established, but a large adjuvant trial with TKIs is ongoing. Cytoreductive nephrectomy for patients with metastatic disease may enhance responsiveness to high-dose IL-2 and also remains the standard treatment modality for patients receiving the new antiangiogenesis drugs. Metastasectomy is considered acceptable if all disease can be resected, and in some instances, this may be curative.

Recent years have witnessed an explosion of new potential systemic therapeutic options for metastatic RCC. Accordingly, many standards of initial care are in place for management of this disease. High-dose IL-2 remains the only approach to produce durable CRs and can thus be considered in appropriately selected patients with excellent performance status, normal pulmonary and cardiac functions, and limited disease burden. As indicated by currently available data on antiangiogenic and molecularly targeted therapies, sunitinib is recommended for first-line treatment for patients in low- and intermediate-prognosis groups, and temsirolimus is recommended for patients with multiple adverse prognostic features.

Great progress in treatment for patients with advanced renal cancer has been made. Three potentially distinct therapeutic approaches (targets) have been identified: VEGF+/− platelet-derived growth factor (PDGF), mTOR, and immunotherapy. Considerable room for additional improvement remains, however. Any of these approaches alone is not sufficiently active to achieve durable clinical benefit in a majority of patients. Continued exploration of molecular pathways and investigations to identify prognostic and predictive markers in this disease will be critical. Physician encouragement of patient participation in clinical trials will dictate the pace of progress in the development of rationally designed and effective combination strategies.

87 Carcinoma of the Bladder

David C. Smith, James Montie, and Howard Sandler

SUMMARY OF KEY POINTS

Incidence
- Bladder cancer accounts for 5% of all cancers in the United States, with an estimated 67,160 cases and 13,750 deaths in 2007. The male-to-female ratio is 3:1.

Epidemiology and Risk Factors
- Risk increases with advancing age, with 70% of male bladder cancers and 75% of female bladder cancers occurring in individuals over the age of 65 years.
- Cigarette smoking is an established cause of bladder cancer, accounting for half of male and one third of female bladder cancers in Western populations. Smokers have twice the risk of bladder cancer as nonsmokers.
- Occupational chemical exposure associated with bladder cancer includes arylamines and derivatives (also found in cigarette smoke), O-toluidine, and benzidine-based dyes; those at risk include workers in the dye, rubber and leather industries, painters, truck drivers, and drill press operators.
- Long-term cyclophosphamide therapy increases bladder cancer risk, probably by as much as 30-fold.
- Schistosomiasis and spinal cord injury are associated with increased risk for squamous cell carcinoma of the bladder.

Clinical Presentation
- The primary symptom of bladder cancer is hematuria; 20% to 30% of patients will have symptoms of frequency, urgency, and dysuria.

Diagnosis
- Cystoscopy with transurethral resection (TUR) is the mainstay of diagnosis.
- Upper tract imaging is necessary to detect additional urothelial tumors and obstruction.

Pathology and Staging
- Almost all bladder cancers are urothelial (transitional cell) in origin. Most present with a papillary growth pattern: flat carcinoma in situ (CIS) and solid nodular tumor are other forms.
- At diagnosis, approximately one third of cases are noninvasive (Ta/TIS), one third are minimally invasive (T1), and another third are more deeply invasive (T2 and higher).
- Grade and stage are strong prognostic factors and primary determinants of therapy.

Therapy
- Most bladder cancers recur in the bladder, but can be managed with a combination of TUR and intravesical chemotherapy or immunotherapy.
- Few low-grade cancers progress (invade the bladder wall), but high-grade cancers have significant risk.
- Bacillus Calmette-Guérin (BCG) vaccine is the most effective agent for treating high-grade superficial lesions, resulting in decreased progression and potentially increased survival.
- Most muscle-invasive cancers are not cured by TUR alone.
- Radical cystectomy with urinary diversion is the most effective means to eliminate the cancer.
- Orthotopic diversion with a neobladder provides improved rehabilitation by allowing volitional voiding.
- Pelvic recurrence rates, as well as distant metastases, in patients with locally advanced cancer remain disappointingly high.
- Radiation therapy combined with an aggressive TUR and a chemotherapeutic radiation sensitizer, such as cisplatin, may allow bladder preservation.
- Preoperative radiation has not been demonstrated to be consistently effective.
- Traditional systemic chemotherapy for urothelial cancers such as MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin), have not produced durable results, and toxicity is high.
- New agents, such as paclitaxel and gemcitabine, are active, and combinations of these agents with platinum-based compounds have comparable response rates with substantially less toxicity.
- Neoadjuvant chemotherapy prior to cystectomy is supported by increasing evidence, particularly in patients with locally advanced (T3b) tumors.
- Fewer data are available on the degree of benefit for adjuvant chemotherapy. Treatments must be individualized based on risk, benefits, and patient preference.

BACKGROUND AND INCIDENCE

Bladder cancer poses a wide spectrum of risk to the patient. Well-differentiated, papillary tumors rarely present a threat of death or loss of the bladder. High-grade cancers commonly are lethal, and treatment may greatly alter urinary and sexual function. The physician and patient often face difficult decisions about under- and overtreatment. The initiation of therapy at every stage depends heavily on clinical judgment, because this cancer typically occurs in an older population with significant comorbidities. Even experienced clinicians often find it difficult to separate patients who are appropriate candidates for cystectomy from those in whom it may be unnecessary at one extreme or futile at the other. The integration of effective and less toxic systemic chemotherapy as well as radiation therapy remains

a challenge. Substantial progress in the delivery of bladder cancer care is clearly evident in the last two decades, but fundamental uncertainties in management decisions persist.

EPIDEMIOLOGY AND RISK FACTORS

Bladder cancer represents approximately 7% in men (fourth most common neoplasm) and 2.5% in women (eleventh most common neoplasm) of new cases of cancer in the United States.[1] In 2007, there were an estimated 67,160 cases. The age-adjusted incidence in the United States is 32 per 100,000 men and 8 per 100,000 women. The historic male-female ratio of 3 : 1 remains essentially stable despite the changing pattern of smoking in women. Overall there were an estimated 13,750 deaths from bladder cancer in 2007. Bladder cancer incidence and mortality rates increase strongly with age and will be an increasing problem as the population ages. Based on 2007 data, the probability of being diagnosed with invasive bladder cancer is increases 3.5-fold in both men and women over the age of 70 when compared with those 60 to 69 years of age. Bladder cancer mortality rates continue to decrease, although the rate of decrease has slowed. Death rates decreased 0.2% per year in the period from 1987 to 2003 after decreasing 2.1% per year from 1977 to 1987.

Most bladder cancers are noninvasive or minimally invasive at the time of diagnosis. Based on Surveillance, Epidemiology, and End Results (SEER) data, 74% were localized in the pelvis at diagnosis.[1] Women are slightly more likely to be diagnosed with advanced stages than men. African-Americans are more likely to be diagnosed with regional or distant disease than whites. Women, particularly African-American women, appear to have a shorter survival when diagnosed with bladder cancer.[2] Marriage has a positive influence on survival in patients with bladder cancer independent of other known factors.[3] The incidence of familial transitional cell carcinoma is uncertain, although some data support a familial form.[4]

Defined risk factors account for an estimated 80% of all bladder cancer cases.[5,6] In Western populations, cigarette smoking may account for 50% of cases of bladder cancer. Zeegers and associates[7] performed a meta-analysis of 43 epidemiologic studies on smoking characteristics for bladder cancer risk and concluded that current cigarette smokers have an approximately threefold higher risk of urinary tract cancers than nonsmokers. The carcinogenic effect of cigarette smoking is related to dose as well as the type of tobacco used. Black (air-cured) tobacco carries a higher risk than blond (flue-cured) tobacco, most likely because of higher concentrations of the known carcinogens arylamines. Quitting smoking is associated with a drop in the risk of bladder cancer, regardless of type of tobacco.[8] The age at which one begins smoking also carries an associated risk; those starting at a younger age have an increased risk for bladder cancer, even 10 to 15 years after quitting. Cigarette filters do not provide protection. The increased risk is likely due to exposure to the carcinogens 4-aminobiphenyl and 2-naphthylamine in cigarette smoke, possibly with modulation based on metabolic phenotype which governs noninducible enzymes in the liver under autosomal dominant control. The carcinogens are metabolized in the liver by N-acetylation; "slow" acetylators are homozygous for the slow acetylator gene and at higher risk for bladder cancer.[9]

Data from the U.S. National Bladder Cancer Study on Occupation and Bladder Cancer suggest that population-attributable risks for occupation in Caucasian men range from 21% to 25%.[6] Occupational bladder cancer remains a public health issue around the world. Leather and rubber workers are at increased risk, but this risk is decreasing as workplace exposure diminishes. New higher-risk occupations—for example, painters, truck drivers, primary aluminum workers, and metal machinery workers—are being recognized. There is a positive trend for increased risk associated with increasing duration of employment in such jobs, particularly longer than 10 years. Recent studies have shown an increased risk in several occupations not traditionally associated with chemical exposure. These include physicians, clerical workers, male and female sales workers, and female health service personnel.[10–12]

Several medications increase bladder cancer risk as use and exposure increase. Chronic phenacetin use increases risk of transitional cell carcinoma (TCC) of the bladder and the renal pelvis. Long-term oral cyclophosphamide use increases the risk for bladder cancer by as much as 30-fold.[13] In a cohort of 1065 patients treated with cyclophosphamide for Wegener's granulomatosis, the risk of bladder cancer was both dose and duration dependent, with an absolute risk of 10% at 16 years. The presence of an upper tract TCC is highly associated with bladder cancer. Forty percent of patients with this lesion will have a bladder cancer at some point in the course of their disease; thus, surveillance cystoscopy is appropriate and necessary. Chronic irritation of the bladder also is associated with bladder cancer, typically squamous cell carcinoma (SCC) rather than TCC. Schistosomiasis also is highly associated with development of SCC of the bladder and remains a major public health problem in endemic areas, even though a true causal link has not been established.[14] Patients with spinal cord injury who have chronic or recurrent urinary tract infections, particularly with indwelling catheters, are at increased risk for bladder cancer by as much as 25 times that of the general population.[15] Periodic cystoscopy is advocated in patients with spinal cord injury after more than 10 years following the injury.

CLINICAL PRESENTATION

The classic symptom of bladder cancer is hematuria, usually gross and painless, but occasionally only microscopic. Some patients (20% to 30%) may have primarily "irritable" bladder symptoms of frequency, urgency, and dysuria, particularly those patients with carcinoma in situ of the bladder. It is remarkably common for patients to present to a urologist with a substantial delay in diagnosis, which may be either patient- or physician-driven, because of attributing the hematuria to an infection or a stone without proper investigation. Gross hematuria requires a urologic evaluation. One study suggests that microscopic hematuria may be present years before the detection of the bladder cancer, and thus may be a predictor of bladder cancer.[16]

More advanced local disease causes pelvic pain, bladder outlet obstruction, or flank pain secondary to an obstructed upper tract. Extensive pelvic disease can cause rectal obstruction, lymphedema of the extremities, and deep venous thrombosis from compression of iliac veins.

DIAGNOSIS AND NATURAL HISTORY

No current accepted screening methods for bladder cancer are available. The prevalence of bladder cancer, particularly if male current or previous smokers were targeted, could justify a screening program. Bladder cancer rarely is diagnosed at autopsy, and so overdiagnosis is not a concern. Messing and colleagues[17] performed two pilot studies between 1987 and 1992 on 1575 men, and the long-term outcome was recently updated. Using home hematuria dipsticks, men tested their urine for 14 consecutive days; 16.4% were determined to have at least one unexplained abnormal test and thus underwent further testing. Of these, 9.7% were found to have urinary tract cancer, including 21 bladder cancers. These cases were compared with a matched cohort of men for the State of Wisconsin Tumor Registry. The noteworthy finding of this pilot study was confirmation that repetitive home hematuria screening could detect high-grade bladder cancers at a noninvasive stage and thus a prospective, randomized screening could be supported.

The mainstay of detection of bladder cancer is cystoscopy.[18] Most diagnostic cystoscopies are now done in an outpatient setting using a 16F flexible cystoscope (approximately the caliber of a small Foley catheter) and local intraurethral lidocaine for topical anesthesia. A flexible instrument with excellent optics substantially decreases

discomfort associated with the procedure, particularly in men. Most bladder cancers appear grossly as a papillary, exophytic tumor, and low-grade tumors have a reliable, characteristic appearance. A higher-grade, invasive cancer may appear as erythema and edema of the mucosa with distortion of the bladder wall. If an abnormality is visualized in the bladder, an outpatient transurethral resection (TUR) or biopsy is done with anesthesia. This TUR is diagnostic, important for staging, and often therapeutic, in cases when it is the only treatment needed. In many cases, an examination under anesthesia to identify a pelvic mass or induration of the bladder is necessary. Occasionally, patients require a brief hospital admission after the procedure for hematuria, urinary retention, or bladder perforation.

During the evaluation of hematuria or after the diagnosis of bladder cancer is established, imaging of the upper urinary tract collecting system is essential. An intravenous pyelogram (IVP), retrograde pyelogram, or computed tomographic (CT) or magnetic resonance (MR) urogram identifies additional urothelial tumors and obstruction of the upper tract due to bladder cancer.[19] With typical papillary tumors, 2% to 4% of patients have or will develop an upper tract tumor. Patients with carcinoma in situ may have a substantially greater risk for upper tract cancers. Imaging of the bladder with an IVP, CT scan, or ultrasonography can demonstrate a bladder cancer as a "filling defect" displacing contrast material or urine.

The natural history of bladder cancer is such that recurrences in the bladder are the rule, with documented recurrence in 50% to 75% of patients.[20] This propensity for recurrences requires surveillance of the bladder at defined intervals. The mainstay of surveillance is cystoscopy, which is easily performed as an outpatient procedure with local anesthesia. If the cystoscopy is likely to be positive and require biopsy or resection, general or regional anesthesia is necessary. The classical follow-up protocol for patients without recurrence entails cystoscopy at 3-month intervals for 1 year, 4-month intervals during the second year, 6-month intervals for years 3 and 4, and then annually. This regimen is excessive in many patients at low risk for recurrence and very low risk for progression and can be altered by lengthening the intervals between cystoscopies more quickly. The results of the first cystoscopy 3 months after the initial diagnostic resection often set a precedent for the future recurrence pattern.[21]

Bladder cancer requires lifelong follow-up consisting of cystoscopy and periodic imaging of the upper tracts, because recurrences may occur late, even after prolonged disease-free intervals.[22] Supplemental diagnostic aids in addition to or in place of an "invasive" cystoscopy are attractive. A test performed on a voided urine sample would be ideal. Unfortunately, no currently available test in the urine can replace cystoscopy for either detection or follow-up.[23] Research is expanding on urinary markers for detection, but performance remains disappointing.[24]

Urinary cytologic examination plays an important role in detection and monitoring of bladder cancer and has stood the test of time. Cytologic testing is particularly effective in patients with carcinoma in situ manifested by irritable symptoms and nonspecific inflammatory changes on visual cystoscopic examination. In these cases, cytologic examination may be the most important test to alert the physician to the presence of the cancer. Unfortunately, cytologic examination has substantial limitations in detection of bladder cancer; the sensitivity is approximately 60% and specificity is 70% to 80%.[24,25] Urine cytologic assessment is subjective, has considerable interobserver variability, and depends on an adequate number of cells in the specimen; interpretation can also be influenced by collection method and cellular preservation techniques. Cytologic testing is extremely valuable for detection and follow-up of high-grade lesions populated by cells with substantial abnormal morphologic characteristics, but less definitive in low-grade cancers in which the cells often closely resemble normal bladder epithelial cells. Methods to improve cytologic assessment using immunostaining, either with Lewis-X antigen or cytokeratin 20, also are under exploration.[26]

Several urinary tests are now approved by the U.S. Food and Drug Administration (FDA) as aids for the detection or monitoring of bladder cancer. However, their clinical utility remains uncertain.[25] The ideal test fulfills at least one of two requirements: (1) it is highly sensitive so that a cystoscopy could be avoided, or (2) it identifies patients with occult mucosal disease not visualized at cystoscopy, allowing a better assessment of treatment response or identification of a recurrence earlier. No test currently available consistently performs these functions well enough.

More than 300 proteins shed into the urine of bladder cancer patients have been detected.[27] The first urine assay available for bladder cancer detection, the BTA test, detected basement membrane complexes and was attractive as a point-of-service urine test that gave immediate results.[28] Initial trials demonstrated superiority over urinary cytologic testing, but cytologic accuracy in these trials was less than the degree commonly accepted. Several nuclear matrix proteins are present in bladder cancer but not in normal urothelium.[29] Urinary nuclear matrix protein (NMP-22) is approved by the FDA for detection of occult or rapidly recurring disease after a TUR and may perform better than cytologic examination as a diagnostic tool.[30] Higher NMP-22 levels correlated with cancer with a favorable receiver operating characteristic curve, but experience is limited. Antigens associated with bladder cancer, such as M344 and DD23, are potential detection targets.[31] Measurements of the urinary level of hyaluronic acid and hyaluronidase have shown promising results.[24] Telomerase is an enzyme responsible for maintenance of the chromosome-end telomere, which commonly is active in cancer. A polymerase chain reaction-based telomeric repeat amplification protocol assay on urine yielded a high sensitivity, but special collection techniques may be required.[32] Other molecular studies, such as fluorescent in situ hybridization (FISH) of centromere probes for abnormalities of chromosomes 3, 7, 17, and band 9p21 (Urovysion) recently have been shown to predict recurrent disease.[26,33]

A study of three bladder tumor markers in urine (NMP22, BTA stat test, and urinary bladder cancer antigen test for fragments of cytokeratin 8 and 18) and bladder wash cytologic test by Boman and colleagues demonstrated that no combination of the studies could reliably replace surveillance cystoscopy, primarily because most recurrences are small.[34] Similarly, "virtual cystoscopy" with multiplanar CT did not provide comparable sensitivity to cystoscopy, even when a catheter was inserted into the bladder to improve visualization.[35] Bladder "washing" to obtain a larger cellular yield improve sensitivity of cytology and is used commonly in the follow-up of bladder cancer patients.

In summary, cystoscopy remains a requirement for the diagnosis of bladder cancer. Cytology is widely available and particularly valuable in high-grade cancers. Newer urinary diagnostic tests are fascinating, but not, as yet, practically helpful.

PATHOLOGY AND NATURAL HISTORY

An appreciation of the growth pattern and histology of bladder cancer is essential for appropriate treatment decisions. Most bladder cancers are epithelial in origin, and 95% of epithelial tumors demonstrate transitional cell histology.[36] Grade and depth of invasion (stage) are both independent prognostic variables. A complete review of bladder cancer pathology is beyond the scope of this discussion, but certain aspects are crucial. A superb review by Grignon is available.[37]

An important consensus on the terminology of urothelial tumors by members of the International Society of Urological Pathology is available (Table 87-1).[38] These recommendations have been incorporated into the description of bladder cancers, and clinicians must be cognizant of the changes. A consensus statement was necessary because of considerable confusion regarding the definition of a papilloma and poor reproducibility of grading, with a preponderance of cases falling into the intermediate grade category. Nevertheless, the acceptance and use of the new classification is an ongoing process.[39]

Table 87-1 International Society of Urological Pathology Consensus Classification

NORMAL
Normal urothelium*
HYPERPLASIA
Flat urothelial hyperplasia
Papillary urothelial hyperplasia
FLAT UROTHELIAL LESIONS WITH ATYPIA
Reactive (inflammatory) atypia
Atypia of unknown clinical significance
Dysplasia (low-grade intraurothelial neoplasia)
Carcinoma in situ (high-grade intraurothelial neoplasia)†
PAPILLARY UROTHELIAL NEOPLASMS
Urothelial papilloma
Inverted urothelial papilloma
Papillary urothelial neoplasm of low malignant potential
Papillary urothelial carcinoma, low grade
Papillary urothelial carcinoma, high grade
INVASIVE UROTHELIAL NEOPLASMS
Urothelial carcinoma with lamina propria invasion
Urothelial carcinoma with muscularis propria (detrusor muscle) invasion

*May include cases formerly diagnosed as "mild dysplasia."
†Includes cases with "severe dysplasia."
Rasmussen HH, Orntoft TF, Wolf H, Celis JE: Towards a comprehensive database of proteins from the urine of patients with bladder cancer. J Urol 1996;155:2113–2119.

A basic aspect of terminology is preference for the more precise term *urothelial* to describe the epithelium as opposed to *transitional*. The term *superficial* also is imprecise and is discouraged.[39] A *papilloma*, defined as an exophytic papillary growth lined by urothelium of normal thickness and cytologic appearance, is a rare, benign condition. A *papillary urothelial neoplasm of low malignant potential* has minimal cytologic and architectural abnormalities but is an important entity because of a propensity for recurrent lesions, occasionally of higher grade. *Papillary urothelial carcinoma, low grade* is composed of overtly neoplastic cells and may invade in a small percentage of cases. *Papillary urothelial carcinoma, high grade* is disorganized by both cytologic and architectural abnormalities. High-grade papillary lesions that originally are noninvasive may progress in 15% to 40% of cases.

Carcinoma in situ (CIS), a high-grade intraurothelial neoplasia, is worthy of special attention. CIS is defined as high-grade (anaplastic) carcinoma confined to the epithelium growing in a flat, disordered, nonpapillary configuration, and is likely underdiagnosed.[39] CIS can be focal, multifocal, or diffuse. Diffuse CIS often is characterized by irritable voiding symptoms of frequency, urgency, and dysuria, but smaller-volume disease may be asymptomatic. The gross appearance of CIS is a slightly raised, reddened, velvety mucosa, occasionally with associated edema. Smaller areas of CIS not associated with underlying bladder inflammation may not be so apparent cystoscopically, and it is common for a urologist to underestimate the extent of mucosal disease. The mechanism of mucosal spread of CIS is poorly understood, but a substantial portion of cases have involvement of the prostatic urethra, prostatic ducts, seminal vesicles, or distal ureters resulting in frequent failure of intravesical treatments.[40] Extension into von Brunn's nests is not uncommon and must be distinguished from invasion.

Most bladder cancers are composed of urothelial cells. Mixed histology tumors with areas of squamous or adenocarcinoma differentiation are not uncommon and are well recognized. Less common variants such as nested, micropapillary, or small cell carcinoma are seen with increasing frequency either de novo or after intravesical treatments and are critically important to recognize because of a required change in therapy from what would be based on stage only. The nested variant, which has a deceptively bland-appearing pattern, and the micropapillary variant, which may be a form of glandular differentiation, usually metastasize early, and prompt cystectomy usually is warranted.[41,42] A small cell component usually requires initial treatment with chemotherapy followed by consolidation with either surgery or radiation therapy.[43]

STAGING

An experienced urologist recognizes the gross differences between well and poorly differentiated cancers. Also, whether or not the lesion is grossly invasive often is easily apparent. Nevertheless, confirmation of depth of invasion relies on the pathologic examination of the resected tissue. Adequate tissue must be provided to the pathologist for proper interpretation of depth of invasion. Cold-cup biopsies of the tumor have the advantage of avoiding cautery artifact and are useful for sampling mucosa, but a TUR is the common method to remove the cancer as completely as possible and provide tissue to the pathologist. In general, sampling of the muscle beneath the papillary tumor is necessary to exclude muscle invasion (with the possible exception of an extremely well-differentiated, grossly noninvasive lesion). Carcinoma in situ has a propensity for the mucosa to become denuded, leaving only the appearance of "chronic cystitis" in the underlying stroma. When CIS is suspected, special care is needed to minimize mucosal trauma during the biopsy process. Cytologic examination of the urine is particularly helpful in this setting.

The staging of bladder cancer greatly influences treatment decisions. The American Joint Committee on Cancer (AJCC) 2002 TNM staging classification is recommended (Table 87-2).[44] The 2002 system retains the modifications initially described in 1997 by (1) placing all tumors invading muscularis propria into the T2 category (T2a superficial muscle, T2b deep muscle) and (2) segregating tumors outside the bladder into microscopic (T3a) and macroscopic (T3b). In practice, the clinical differentiation between T2a and T2b based on a TUR only is difficult and arbitrary and is barely reliable on a cystectomy specimen.[37] In addition, the segregation of prognosis becomes most evident when comparing organ-confined (≤T2) versus extravesical (≥T3a) disease. CIS in the prostatic urethra or ducts does not decrease survival, but prostatic stromal invasion does, thus justifying classification as T4a. Based on large data sets from

Table 87-2 Primary Tumor Staging of Bladder Cancer

Ta:	Noninvasive papillary carcinoma
T1:	Tumor invades lamina propria
T2:	Tumor invades muscle
T2a:	Invades superficial muscularis propria
T2b:	Invades deep muscularis propria
T3:	Tumor invades perivesical tissue
T3a:	Microscopic perivesical fat invasion
T3b:	Macroscopic perivesical fat invasion (extravesical mass)
T4a:	Invades adjacent organs (uterus, ovaries, prostate stoma)
T4b:	Invades pelvic wall, abdominal wall

hospitals in the United States and Germany, the stage at diagnosis typically is Ta or TIS in 30% to 35% of cases, T1 in 25% to 30%, and T2 and higher in 30% to 35% of cases.[36,45] However, the microscopic assessment of depth of invasion is subject to interobserver variability, exemplified by an alteration in stage observed in 18% of cases when reviewed at a single referral center.[46]

The staging of bladder cancer, along with the grade, provides the basis for most treatment decisions. Noninvasive cancers (Ta and TIS) represent a biologically different tumor from those demonstrating invasion (T1 and greater). T1 cancers often are lumped together with Ta as "superficial" cancers, but these tumors often behave differently in terms of recurrence rates, risk for later invasion into the muscle, and response to intravesical therapy.[21,47] Use of the imprecise term *superficial tumor* should be discouraged.[37,38] Ta and grade 1 and 2 (low-grade) tumors have a propensity for recurrence but a low risk for progression to muscle invasion. The later recurrence risk depends on several factors. The presence of three or more tumors and larger cancers (>2 cm) are predictive of more recurrences.[21,48] A recurrence at the time of first cystoscopy heralds a pattern of more recurrences.[22] Progression to muscle invasion is seen in only 5% to 10% of patients.[48] Thus, the primary goal of therapy is to decrease or eliminate recurrences. Intravesical therapy should be reserved for patients demonstrating a need for treatment based either on the initial characteristics or, more commonly, on the recurrence pattern evident.

Disease invading the lamina propria represents a more dangerous disease (low or high grade, T1). Such disease has a higher recurrence rate and a substantial progression rate of 30% to 50% in spite of therapy.[46,48] Incomplete resection may lead to understaging, and a repeat TUR 6 to 8 weeks after the initial resection may identify such patients earlier.[48–50] The risk of understaging is as high as 60% in patients in whom no muscle demonstrating invasion of lamina propria is present in the specimen.[50] The risk for death due to progression is as high as 30% of patients with long follow-up.[47,48] Thus, the goal of therapy for such patients with high-grade cancers must be complete elimination of the cancer; simply reducing the recurrence rate will be insufficient in the long term. Increasing evidence (although not all of the evidence is consistent) indicates that the depth of penetration into the lamina propria is important. The muscularis mucosa (MM) is a discontinuous band of muscle fibers in the lamina propria. Invasion deep to the MM causes a higher risk for later muscularis propria invasion.[49] Orientation of the specimen often makes precise interpretation of the depth of invasion difficult.

Imaging studies of the bladder contribute minimally to the staging of bladder cancer. However, imaging of the upper tracts with an IVP, retrograde pyelogram, or CT scan at the time of diagnosis is essential. The practical information obtained from pelvic imaging is limited.[51] CT is the study applied most commonly, but understandably cannot differentiate noninvasive disease from small volume muscle-invading cancers. Also, the depth of muscle invasion cannot be reliably differentiated (Fig. 87-1). Bulkier tumors with gross invasion of perivesical fat are reliably visualized on CT, but the incremental increase in information gained over that provided by a cystoscopy and examination under anesthesia is poorly quantified. In addition, CT imaging commonly occurs after the diagnostic/therapeutic TUR, which distorts the bladder wall and surrounding tissue. Stage divergence between clinical and pathologic staging is common, with downstaging and upstaging occurring in 27% and 49% of patients, respectively, in one institutional study.[51] The limitation may be that scans may be obtained 4 to 8 weeks prior to the actual cystectomy, allowing for disease progression in the interval. Nevertheless, the appearance of a mass in the bladder wall and the presence of perivesical fat generally predict a large-volume tumor with a worse prognosis. The presence of a palpable mass on examination under anesthesia portends a poor response to external radiation therapy, and the presence of T3 disease at cystectomy corresponds to a diminished survival. CT scan identifies large, probably malignant, lymph nodes, but not all abnormal nodes harbor cancer, especially if the scan is done soon after a TUR. Percutaneous biopsy of an abnormal lymph node to confirm cancer is necessary prior to major treatment decisions.

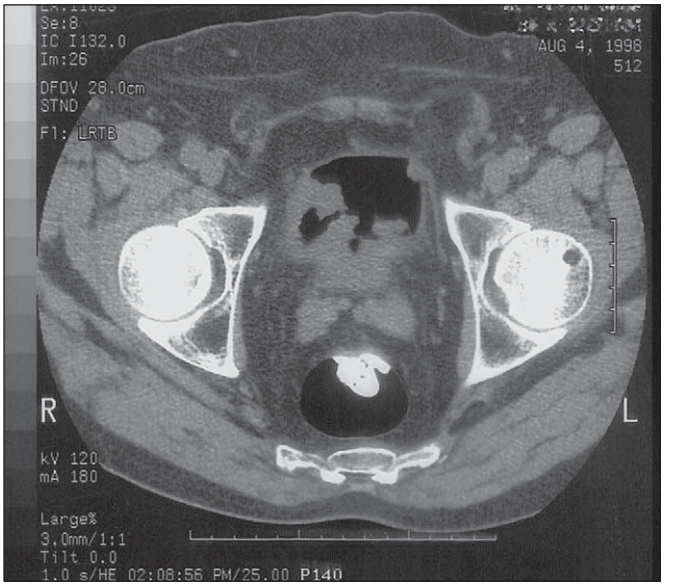

Figure 87-1 • Pelvic computed tomographic (CT) scan demonstrating multiple exophytic bladder cancers with thickening of the bladder wall on the right. Muscle invasion is suspected, but the depth of invasion is uncertain.

MRI provides some advantages over CT scanning with multiplanar projections.[52] However, this somewhat better demonstration of the tumor is offset by greater expense and inconvenience to the patient. Evolving refinements in CT data manipulation allow image display in different planes as well, further diminishing any incremental benefit of MRI over CT scan. Positron emission tomography (PET) theoretically is attractive in evaluating bladder cancer, but use of the radiotracer 2-FDG is significantly limited by urinary excretion of the radiotracer, and 11C-choline may provide better imaging.[53,54] Studies to search for metastases in patients with invasive bladder cancer are not standardized. Common sites of metastases from bladder cancer are regional lymph nodes, lungs, liver, and bone. A chest x-ray and abdominal/pelvic CT scan are in essence part of standard practice, although the clinical utility of such studies is poorly quantified. Bone scans are not obtained routinely unless a clinical suspicion has arisen because of bone pain or an elevated alkaline phosphatase level.

MOLECULAR BIOLOGY

Stage and grade provide the most important prognostic information for bladder cancer. However, mounting evidence points to molecular biologic characteristics of malignant lesions as an important aid in treatment decisions. Currently, no molecular characteristics are sufficiently reliable to dictate a conservative or aggressive deviation from traditional therapy. A large number of genetic alterations occur in bladder cancers, and some may correlate with clinical behavior.[55] Noninvasive Ta tumors have fewer genetic alterations than invasive cancers, but changes commonly occur at 9q, 9p, 1p, and the Y chromosome.[56] Over the last decade, alterations in two distinct molecular pathways have been identified.[57] The receptor tyrosine kinase-Ras pathway often is activated in low-grade papillary lesions. Mutations in the fibroblast growth factor receptor 3 (FGFR3) and HRAS genes result in activation of this pathway in up to 70% of these lesions, suggesting a significant role in tumorigenesis.[58]

Invasive cancers, T1 and higher, have many more genetic abnormalities, and the challenge is to both categorize the gene abnormalities and correlate with functional alterations in the cell. The pathway altered in these cancers involves the fundamental regulation of the cell cycle.[57] Regulatory proteins p53 and RB appear to be particularly important in urothelial cancer. The p53 tumor suppressor protein is a critical molecule in control of the cell cycle, and an increased accumulation of p53 protein as a result of mutation is a signal event in the development of many cancers.[59] In urothelial cancer, accumulation of p53 protein correlates with progression and is prognostic for poor outcomes in patients with muscle invasive disease. Downstream of p53, the p21 protein plays a modulating effect. Encoded by the p21(WAF1/CIP1) gene, this protein is a cyclin-dependent kinase inhibitor (CDKI). Loss of this protein predicts for progression independent of alterations in p53, while retained expression modulates the effect of p53 mutation.[60] Loss of expression of the retinoblastoma (RB) protein has been documented in both low-grade noninvasive cancers and high-grade invasive lesions.[61] The interaction among p53, p21, and Rb is complex, and abnormalities in these proteins may have an additive prognostic effect.[62] The relationships between these cell cycle regulators, growth factors (including the epidermal growth factor family), and tumor angiogenesis further complicates the picture. Molecular alterations in all of these pathways have been implicated in tumorigenesis and progression of urothelial cancers.

THERAPY

The common papillary, noninvasive growth pattern of most bladder cancers makes them amenable to TUR. TUR as primary therapy has low rates of immediate complications and long-term morbidity. However, the multifocal and recurrent nature of bladder cancer emphasizes the limitations of TUR as an isolated modality. Because TUR is the mainstay of bladder cancer therapy, all urologists are assumed to be proficient with TUR, but the procedure is more difficult than commonly appreciated (Fig. 87-2). Data from the European Organization for the Research and Treatment of Cancer (EORTC) suggest that the quality of a TUR may influence recurrence rates.[63] Tumors may range from a few millimeters to many centimeters. Cancer location at the dome or anterior wall makes the resection considerably more difficult and increases the risk for incomplete resection or perforation of the bladder. Tumors in obese patients also are more difficult to resect. Tumors on the floor or trigone of the bladder may involve a ureteral orifice, causing obstruction and hydronephrosis. Tumors at the bladder neck may extend into the prostatic urethra or prostatic stroma. The fundamental value of an adequate TUR to diagnose, stage, and potentially cure the cancer cannot be overemphasized. Inappropriate treatment decisions often are grounded in an inadequate initial TUR. For most cancers, the TUR should include sampling of the muscularis propria of the bladder at the base of the bladder.

For noninvasive (Ta) or minimally invasive (T1) cancers, a TUR often is sufficient to eradicate individual lesions. If there are multiple tumors, a large tumor (>5 cm), recurrent tumors, or adjacent carcinoma in situ, TUR alone is less likely to provide durable cancer elimination. Another important prognostic factor for recurrence is the findings of the first cystoscopy 2 to 3 months after the initial resection.[22] If additional tumors are present, then the probability of continuing recurrences is as high as 80%. At the time of the TUR, the urologist commonly can estimate if the cancer is high or low grade and if gross muscle invasion is present (see Fig. 87-1).[19] The presence of an invasive, palpable mass at the time of the TUR is an important indicator of gross extravesical (T3b) disease and is an adverse prognostic factor. A long-term consequence of repeated TUR may be fibrosis of the bladder wall, causing a small-capacity bladder. This process can take 5, 10, or more years to become evident and can be accelerated by intravesical treatments or radiation therapy. Symptoms of a small-capacity bladder are frequency, urgency, and nocturia; bilateral hydronephrosis may occur due to increased intravesical pressure.

Intravesical Treatments

A TUR of a noninvasive or minimally invasive tumor (Ta, TIS, T1) often is supplemented with intravesical therapy to either decrease recurrences or lower the risk of progression to a more invasive cancer. Introduced in the 1950s, intravesical treatments are based on either the cytotoxic effects of the agent or an immunologic response.[64]

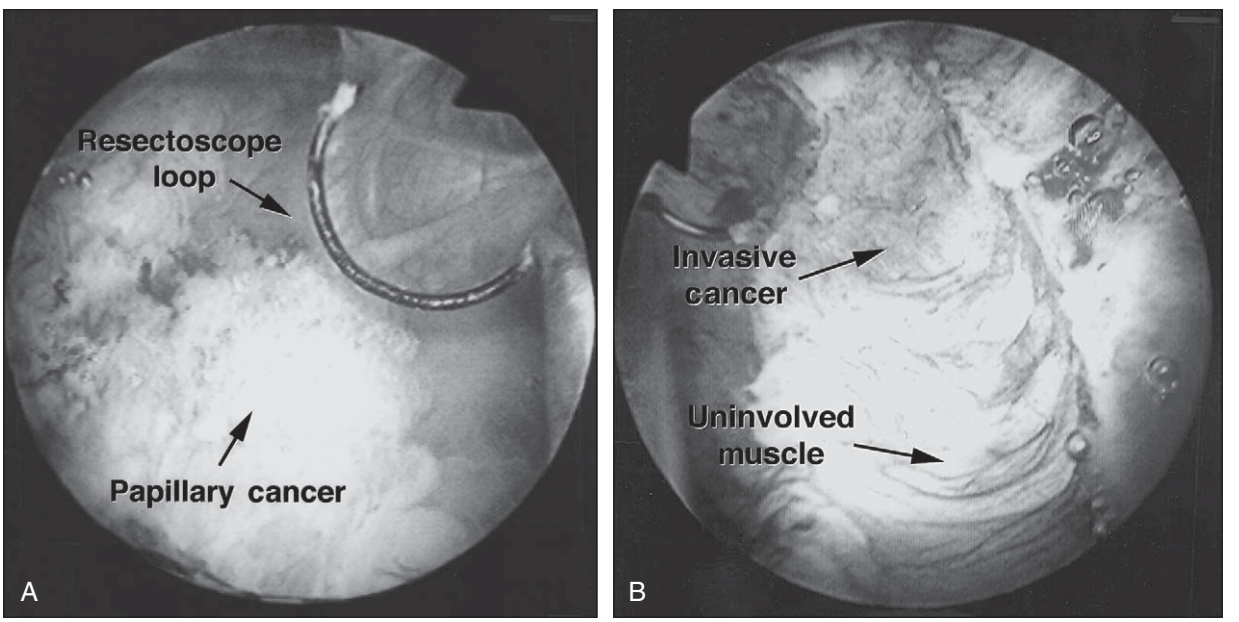

Figure 87-2 • **A,** Papillary bladder cancer with resection loop poised to begin transurethral resection. **B,** Demonstration of grossly uninvolved muscularis propria *(bottom)* and cancer grossly invading the bladder wall *(top)*.

Treatments commonly are administered on a weekly or monthly schedule by inserting a catheter into the bladder, emptying the bladder of urine, instilling the medication, and then emptying the bladder after 2 hours by either voluntary voiding or catheterization. Much of the literature on the results of extravesical treatments is flawed owing to poorly designed studies with small numbers of patients, heterogenous patient populations with varying risk for relapse, and poorly defined outcomes.[65] Data suggest intravesical chemotherapy with mitomycin C, doxorubicin, ethoglucid, epirubicin, or thiotepa may reduce recurrence rate (the number of positive cystoscopies), but has no impact on progression (i.e., development of muscle-invading disease) rate.[64–68] The most commonly used chemotherapeutic intravesical agent in the United States is mitomycin, which has few systemic or local side effects because of its high molecular weight and minimal systemic absorption. Recent animal and human studies have aimed at enhancing mitomycin efficacy by increasing the concentration, decreasing urine volume during treatment, and causing urine alkalinization to stabilize the drug.[69] Thiotepa is used less commonly now than previously because of marginal efficacy, although it causes relatively few local symptoms; life-threatening hematologic toxicity from bone marrow suppression is possible with chronic use. Noteworthy but as yet unexplained is the observation that most agents selected for topical therapy are ineffective systemically, and, likewise, effective systemic agents, such as cisplatin, methotrexate, or vinblastine, are ineffective intravesical treatments. However, in recent small trials of intravesical gemcitabine in bacillus Calmette-Guérin (BCG)-refractory patients, up to 50% of patients had an apparent complete response.[70]

Urologists historically have overused intravesical treatments, treating some patients at very low risk for recurrence or prolonging treatment when it was minimally beneficial.[65] In general, patients chosen for such treatment should have either a high-grade Ta, TIS, or T1 cancer or frequently recurring low-grade cancers. Several mechanisms may produce recurrence of bladder cancers, including incomplete resection, implantation of tumor cells to spatially separate sites, or mucosal migration of carcinoma in situ. Immediate intravesical therapy consisting of a single dose of a chemotherapeutic agent instilled in the bladder within 24 hours of the resection is designed to interfere with the implantation process. Randomized studies using either mitomycin C or thiotepa support such a strategy, and use is increasing.[68]

The most efficacious, although somewhat more toxic, intravesical therapy available is BCG, an attenuated strain of live tuberculosis organisms.[47,64,71] Surprisingly, of all the strategies employing BCG treatment for a wide variety of cancers, intravesical BCG has stood the test of time and has been proved to increase patient survival by diminishing the rate of progression to invasive cancers. The mechanism of BCG's effect is unknown, but contact between live BCG organisms and the tumor plus an intact host immune response is necessary. The dose and schedule are empirically derived; the most common protocol uses 120 mg intravesically weekly for 6 weeks. A reinduction with another 6 weeks of therapy may benefit partial responders. Approximately 70% to 80% of patients with carcinoma in situ alone or carcinoma in situ associated with a resected papillary tumor will have a complete response to BCG.[72,73] In a landmark randomized trial, Herr and colleagues[72] demonstrated a significant decrease in the need for a cystectomy and decreased death rate from bladder cancer when BCG plus TUR was compared with TUR alone. BCG also is more effective than mitomycin C (20 mg/dose) and doxorubicin.[71,73,74] Finally, maintenance BCG for complete responders, using a schedule of one weekly dose for 3 weeks administered every 6 months for approximately 2 to 3 years, is superior to a 6-week induction cycle only.[73] Monthly maintenance BCG is not effective, particularly due to a high dropout rate from bladder toxicity.[74] Nevertheless, the ideal amount of BCG required to obtain the highest and most durable response is variable; some patients respond to half the originally recommended dose, some patients obtain a complete response with only the 6-week induction course, and others cannot tolerate intravesical BCG because of local bladder or systemic symptoms.

The drawbacks of BCG are common local bladder symptoms and rare, but potentially serious, systemic complications.[75] Dysuria, frequency, a flulike syndrome with fever, and some degree of hematuria are seen for approximately 24 hours in most patients treated with BCG. Such symptoms are self-limiting, and persistence beyond 48 hours causes concern for active *Mycobacterium* infection. Prophylactic isoniazid does not appear to decrease the frequency of side effects, but may be of value for persistent but non-life-threatening symptoms.[76,77] Deaths have occurred secondary to overwhelming BCG sepsis, and aggressive antibacterial therapy, possibly with corticosteroids, is necessary.[76] Severe systemic symptoms are more likely if treatment is initiated too soon after a large TUR or if there is a traumatic catheterization at the time of instillation of the BCG.

Although BCG is highly effective initially, its durability raises some concerns. Witjes has decribed a useful catagorization of BCG "failures": *intolerant* means the patient cannot continue the treatments due to side effects; *recurring* implies later tumors after a period of complete response; and tumors are *refractory* when a complete response cannot be attained.[78] Early failure at 6 months is ominous, and more aggressive treatment usually is needed.[79] Later relapse after many years of a disease-free state can occur in the bladder, upper tracts, or prostate in 20% to 40% of patients.[47,78,80,81] Continued surveillance of patients with previous CIS requires cystoscopy, upper tract imaging, and cytologic testing.

Many other agents are available or under testing as intravesical treatments for bladder cancer, but none are comparable to BCG. Interferon-α has been studied extensively, but its role is still uncertain.[82] More promising but yet unconfirmed results have been suggested with a combination of interferon and low-dose BCG.[82,83] The mainstays of follow-up after intravesical therapies remain cystoscopy and urine cytology. However, there is increasing confidence that the urine FISH test (Urovysion) may identify recurrences of high-grade tumor in patients with only an atypical abnormal cytology and negative cystoscopy.[26,33]

Treatment of Invasive Cancers

Historically, bladder cancers were segregated into "superficial" and "invasive" cancers. The inclusion of T1 cancers into the "superficial" category is not necessarily inaccurate, but is biologically unsound because T1 cancers have already demonstrated invasion by penetration of the basement membrane and thus may access angiolymphatic spaces and the deeper muscle, and potentially metastasize.[38,84] T1 cancers represent the early part of the spectrum of invasive cancers and thus have a somewhat better prognosis than more deeply invading cancers. The classical paradigm of treatment of T1 cancers was endoscopic management, with or without intravesical therapy, until muscle invasion was found, and then a cystectomy was recommended. Such a strategy has not proven wise, however, because when muscle invasion was discovered and the patient subjected to a cystectomy, the chance of survival was no better than that for an individual presenting with a muscle-invasive cancer, implying some decrement in survival for those progressing to muscle invasion while under observation.[85,86] Thus the last decade has witnessed an increased respect for the danger posed by such tumors, prompting some to favor early cystectomy as opposed to more conservative approaches, such as TUR and intravesical therapy.[87] T1 cancers have a molecular phenotype more typical of lethal cancers, and the urologist's biggest worry is underestimation of the extent of the disease, thereby leaving cancer remaining in the lamina propria (or muscle) that will be undertreated.[84,85] Early re-resection by TUR of the site of a T1 lesion shows a rate of up to 25% to 50% of persisting cancer and thus is worthwhile to assure accurate staging and complete excision.[88,89] Once the tumor is completely resected, intravesical agents, such as

BCG, may treat the rest of the mucosa, which likely harbors incipient cancers.

Transurethral Resection Alone

Historically, TUR was used as long as possible to treat muscle-invading cancers because of the severe morbidity of cystectomy. As cystectomy became safer, TUR alone was employed more selectively but with admirably good results. An oft-quoted figure of approximately 50% 5-year survival rate is not substantially different from cystectomy results in large series. However, the patients treated with TUR alone often were selected by a second TUR at a referral institution that did not demonstrate any residual disease, indicating the initial TUR removed the cancer entirely.[90] The comparison of survival of such selected patients with smaller cancers to the entire group of patients undergoing a cystectomy is inappropriate; indeed, the good survival rate of these TUR-only patients might have been even better had they had an immediate cystectomy.[87,91] Circumstantial evidence to support such an expectation exists in the survival data of patients with small-volume muscle-invading disease at cystectomy in which the 5-year survival rate is in the range of 60% to 80%.[91] Nevertheless, some patients are cured by a TUR alone, based on the survival data, absence of recurrence in bladder, and a p0 (no residual cancer) in a cystectomy specimen. Selection of patients cured with TUR alone or who may have only a small volume of residual disease, making cure possible with the addition of radiation with or without chemotherapy, is the perplexing dilemma. One can hope that molecular markers predicting responsiveness to either radiation therapy or chemotherapy would be particularly helpful in such a setting. Because of the inherent uncertainty of the completeness of the TUR, it rarely is used alone for muscle-invading cancers if the patient is medically fit for aggressive treatments.

Partial Cystectomy

Removal of a portion of the bladder wall may cure a patient in whom the cancer is confined to the segment removed. A 50% 5-year survival rate is reported for partial cystectomy, similar to that for cystectomy and TUR alone.[92] However, selection criteria are critical, and may be best summarized as the patient has a "single tumor in space and time." Additional criteria include no or minimal carcinoma in situ, a site amenable to a partial cystectomy, and no history of previous multifocal bladder cancers. In general, only about 5% of patients with muscle-invading cancers meet such criteria. A recent review of a 21-year experience at M.D. Anderson Cancer Center found that only 2.8% of patients with muscle invasive bladder cancer were deemed suitable for a partial cystectomy.[92,93] Partial cystectomy is best accomplished by removal of the overlying peritoneum along with the involved bladder wall; high posterior and anterior wall locations of the cancer are better suited for partial cystectomy than other sites.[92] If too much of the bladder is excised, the patient can be left with a small-capacity bladder with poor function. A bilateral pelvic lymphadenectomy should be performed at the time of a partial cystectomy. The impetus for partial cystectomy is diminishing in view of better functional results of total cystectomy followed by orthotopic neobladder formation, as discussed later.

Total Cystectomy

The current most effective local therapy for potentially lethal bladder cancer is total cystectomy. The term *radical cystectomy* implies removal of the bladder plus the prostate in men, and the uterus and anterior vaginal wall in women, as well as a pelvic lymphadenectomy. The rationale for removal of the prostate in men is the historical observation of a 40% to 50% pelvic recurrence rate in cystectomy series from 40 to 50 years ago when the prostate was left in situ, but also the more relevant and recent identification of carcinoma in situ in the prostatic urethra or ducts in 30% to 40% of men undergoing cystectomy.[94] Such disease would be left behind if the prostate was not removed entirely. However, the concept of preservation of the prostate in selected patients has been proposed.[95] Removal of the uterus and anterior vaginal wall in women provides a greater soft tissue margin of normal tissue, but may be necessary only for larger, posterior wall or trigonal cancers. Currently, cystectomy in men almost always includes resection of the prostate, whereas in women the extent of removal of adjacent organs is based more on the local extent of the tumor.[96]

If cystectomy is the most efficacious treatment to control bladder cancer, why is it not used exclusively as the sole treatment? The reason is the undeniable morbidity from cystectomy imposed by the risk of the operation and the long-term impact on urinary and sexual function. Cystectomy historically has been the most dangerous operation performed by a urologist. Mortality rates after cystectomy in the 1940s were in the 40% to 50% range. In the last 50 years, steady progress is evident, such that the mortality rate has now been reduced to 1% to 3%.[97] Previously in the United States and still in some segments of the world, cystectomy was reserved only for the young and healthy, with older patients (>70 years of age) being relegated to less effective therapies. It is now clear that cystectomy can be done safely in patients of all ages when attention to perioperative care of comorbid disease is emphasized.[91,97] A higher operative mortality rate in older patients (>80 years of age) of 3% to 5% is evident, but defensible when the potential ineffectiveness of alternative therapies in this population is considered and when the risk imposed by the cancer is greatest in the short term. For a relatively healthy 80-year-old, the greater risk in the ensuing 3 to 4 years is the invasive bladder cancer rather than general cardiovascular concerns. Thus there is a growing appreciation that an expedient cystectomy in the relatively healthy elderly person offers the greatest potential for tumor control and successful rehabilitation when compared with external radiation therapy or chemotherapy, in which optimal intensity of the treatment may not be deliverable.

The therapeutic results of cystectomy can be evaluated by two parameters: pelvic recurrence rate and survival, a reflection of local recurrences and systemic disease. Pelvic recurrence rates after cystectomy are approximately 10% to 20% and clearly depend on clinical stage.[91] Large cancers, clinical T3b, may have a pelvic recurrence rate as high as 25%, and thus additional strategies may be necessary to specifically address this failure site in such patients. Preoperative radiation therapy is not beneficial to the entire group of patients undergoing cystectomy, but some data suggest a possible role for preoperative radiation in the subset of patients with stage T3b disease, who are at higher risk for local recurrence.[98] Neoadjuvant or adjuvant chemotherapy needs additional investigation in this patient subset and is discussed later.

Survival after cystectomy depends largely on pathologic stage.[91,99] Grade is an important overall prognostic factor; most patients coming to cystectomy have grade III or poorly differentiated cancers, so the discriminatory value is lost. However, pathologic stage is clearly relevant. The overall 5-year survival rate after cystectomy is 50%. However, it is more evident now that an apparent cut point of organ-confined (≤T2b, muscle-invading) disease has a substantially better prognosis than extravesical disease (≥T3a) as reflected in the newer staging system.[44]

Lymphatic metastases are a strong predictor of relapse, but again a spectrum of risk is evident, and some patients are cured by surgery alone in the face of positive lymph nodes.[91,100–102] Both the extent of the nodal metastases and the pathologic stages of bladder cancer are important variables; a single positive microscopic lymph node involvement associated with organ-confined disease (≤T2b) has a 5-year survival rate of up to 50%. Greater volume of nodal metastases and more extensive local disease progressively increase the risk of later metastases, such that involvement of multiple pelvic lymph nodes associated with a T3b cancer may have only a 10% 5-year survival rate with surgery alone. Increasing evidence supports the therapeutic value of a pelvic lymphadenectomy, particularly in patients with lower stage local disease in whom micrometastases may

be present, but cure is still possible and particularly when a sufficiently complete pelvic node dissection was accomplished. The traditional pelvic lymphadenectomy has a superior limit bounded by the bifurcation of the common iliac artery; however, some advocate a more extensive dissection up to the aortic bifurcation.[102] Standardization of the limits of a pelvic node dissection is needed, and data suggest a sufficient number of nodes must be removed for the therapeutic benefit to be realized.[101]

Improvements in perioperative care have fueled the decrease in operative mortality rate evident in the last few decades.[91,97,103,104] Of note, recent data suggest that comorbidity also may negatively affect cancer control and survival after cystectomy. In a study of 2538 cystectomies captured in the National Surgical Quality Improvement Program, the 30- and 90-day mortality rates were 2.9% and 6.8%, respectively.[105] Preoperative factors associated with death and prolonged length of stay were older patient age (OR 1.2–1.4), American Society of Anesthesiologists class 3 or greater (OR 1.5–3–3), dependent functional status (OR 1.7–2.0), and low serum albumin (OR 2.1–12.0). A major etiologic factor for bladder cancer, cigarette smoking, also contributes to greater risk for cardiovascular and pulmonary disease, with attendant increased risk for postoperative complications. Optimization of pulmonary and cardiac function preoperatively, as well as aggressive perioperative monitoring, are valuable adjuncts. The overall complication rate in 6577 patients undergoing cystectomy in the Nationwide Inpatient Sample of the Healthcare Cost and Utilization Project from 1998 to 2002 was 28.4%, and the mortality rate was 2.6%.[106] Surgical complications greatly increase the cost of cystectomy and prevention of a complication, and recognition of a complication early in its evolution (e.g., congestive heart failure before an arrhythmia or myocardial infarction or deep venous thrombosis before a pulmonary embolism) reduces morbidity and potentially can decrease length of stay and costs.[104,105] A perioperative "care pathway" in which anticipated milestones for care are articulated and incorporated into the care delivery is beneficial for the resident staff, nursing caregivers, outpatient support personnel, and the patient. Not only are costs diminished, but deviations from the anticipated quality of care become quickly evident and are opportunities for improvement. The potential role of laparoscopic or robot-assisted cystectomy remains uncertain, although experience is gradually increasing.[107,108]

Urinary Diversion

After cystectomy, the urinary system must be reconstructed to preserve renal function and to keep the patient dry. The mainstay of urinary diversion since 1951 has been the ileal conduit, in which a 15- to 20-cm isolated segment of small bowel drains urine from the ureters to the skin; urine flows directly from the stoma of the bowel into a collecting pouch that adheres to the skin around the stoma Although considerable adjustment is necessary, ultimate return to usual activities is anticipated, including walking, exercising (including swimming), and social events. Improved quality of appliances and stomal care by enterostomal therapists lessens the risk for urinary leakage or "accidents" and improves confident rehabilitation. Nevertheless, the presence of a stoma and the need for an external collecting device have a negative impact on body image, possibly disabling some patients.[109] In the early 1980s, continent cutaneous reservoirs became available, with the advantage of not needing an external collecting pouch, but the disadvantage remained of requiring an abdominal stoma that was catheterized every 4 to 6 hours by the patient to empty an internal reservoir configured from the bowel. Such reservoirs initially were plagued with a reoperation rate of 20% to 50% to obtain continence, easy catheterization, and adequate reservoir function. Ultimately, the ileal colic reservoir termed the *Indiana pouch* became the most popular surgical procedure, with a reoperation rate of less than 10%. Nevertheless, the higher complication rate and continued need for intermittent catheterization offset the marginal benefit of avoiding a collecting device for many patients and surgeons.

Later in the 1980s, experience increased with an internal, orthotopic urinary reservoir termed a *neobladder*. Most urologists and patients believe the neobladder to be a substantial improvement in rehabilitation of urinary function by allowing volitional urination with continence and excellent preservation of renal function in both men and women. Refinements in the operation providing an adequate size and detubularized bowel segment reconfigured into a spherical shape now allow reliable reservoir formation with minimal increase in operative time and no increase in postoperative complications, even in patients with more comorbid medical conditions[110] (Fig. 87-3). Patient satisfaction appears to be better, although the quality-of-life studies are difficult to interpret because of unavoidable selection biases inherent in the choice of urinary diversion.[109]

Selection of patients for neobladder urinary diversion depends on characteristics of both the cancer and the patient. Because the bowel reservoir is anastomosed to the urethra, patient selection should identify those patients with a low risk for a urethral recurrence. No or minimal involvement of the prostatic urethra in men and absence of involvement of the bladder neck in women is needed, both with a negative margin at the time of surgery.[111,112] Such practices select patients with a risk of urethral recurrence of only 2% to 3%. Even with ideal selection, the remnant urothelium remains at some risk for further urothelial cancer and consequently must be monitored.[113] Advanced local disease is not necessarily a contraindication to orthotopic diversion because adjuvant treatments, such as radiation or chemotherapy, also can be administered as necessary. From a patient's perspective, both motivation to endure some initial frustration with the function of the reservoir until it enlarges and tolerance for potential nocturnal incontinence are necessary. For many elderly patients who are frail and sedentary, the ileal conduit remains the best choice because of the quickest and easiest rehabilitation.[114] Adequate renal function of a serum creatinine level less than 2.5 to 3 mg/mL to prevent postoperative electrolyte abnormalities, as well as normal preoperative bowel function, are necessary for orthotopic diversion. Lifelong follow-up is necessary to monitor upper tracts and the metabolic and functional consequences of the diversion.[113,114]

The functional benefits of neobladder formation in both men and women have potentially lessened the pressure to delay cystectomy until absolutely necessary, and some authors have suggested that such a strategy will improve overall survival results.[115] Also, bladder preservation strategies using combinations of TUR, chemotherapy, and external radiation therapy provide a smaller incremental gain in the functional preservation that must be measured against the risk of incomplete elimination of the cancer.[116] However, it must be stressed that the neobladder does not reproduce entirely normal bladder function, with some persisting annoyance for many patients, including nocturnal enuresis and stress incontinence in a few.[116] Maturation of the neobladder takes several months following surgery, and patient expectations must accommodate such an adjustment period. Despite increased experience with this procedure, there are still disparities in the use of continent diversion, particularly in women, African-Americans, and less educated patients.[117]

Interference with sexual function in men after cystectomy and urinary diversion remains problematic. A "nerve-sparing" dissection, which preserves the neurovascular bundles containing microscopic nerves that innervate the corpora cavernosa, is feasible.[91,110] Even in highly selected patients, return of even adequate erectile function is seen in only 20% to 40% of men. Continued refinement in techniques is necessary. Measures to assist erections, such as alprostadil or Viagra (Pfizer), will help in some, but experience is currently limited. The emotional adjustment after a very large operation, changes in body image, and concern about cancer recurrence all contribute to alterations in health-related quality-of-life (HR QOL) concerns.[109] No widely accepted, validated measurement tool for HR QOL is yet available for postcystectomy patients.

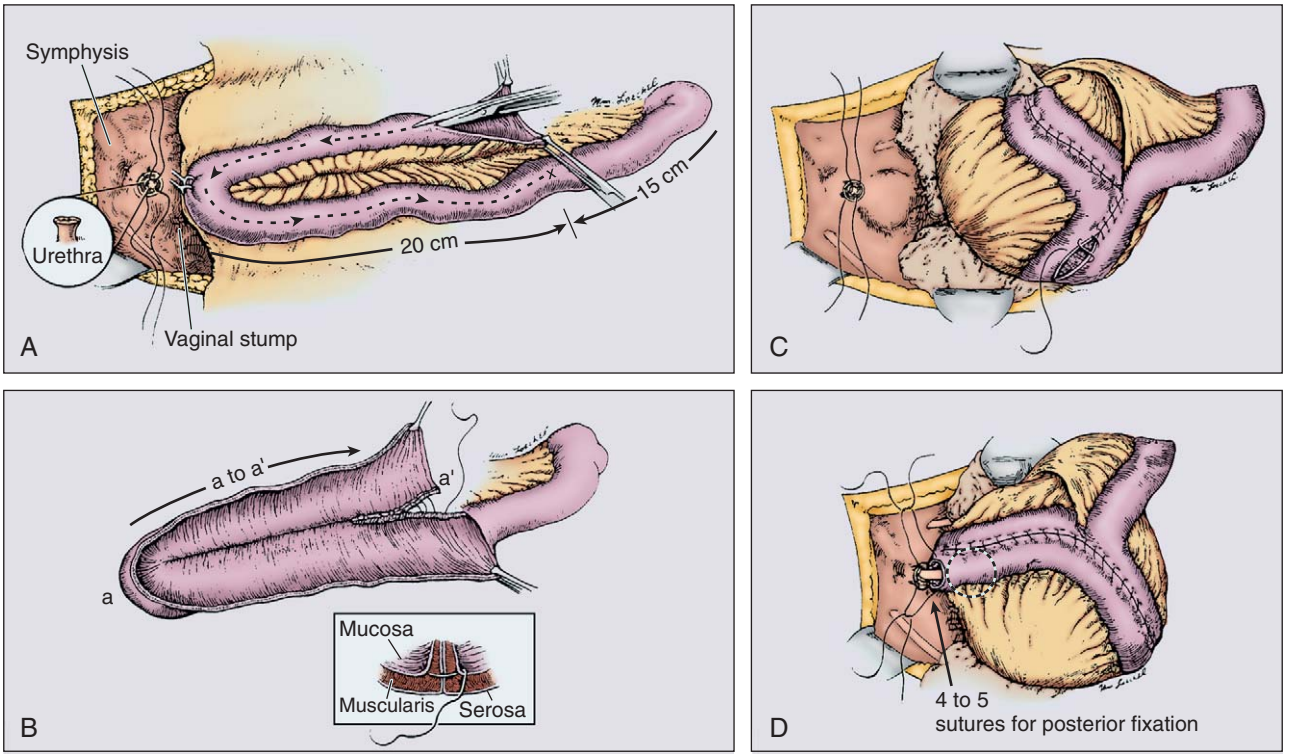

Figure 87-3 • Studer reservoir neobladder construction in a woman. **A,** The urethral stump is shown at the left of the drawing. A segment of ileum is isolated from continuity and opened on the antimesenteric border for approximately 45 cm. **B,** Posterior walls of adjacent limbs are anastomosed to form the "back" wall of the reservoir. **C,** Anterior wall of the reservoir is closed to detubularize the segment and give a spherical shape. **D,** After construction of the neobladder is complete, the dependent portion on the left is anastomosed to the urethra. The ureters are anastomosed to the afferent limb, which protrudes superiorly. (From Montie JE: Orthotopic bladder replacement in women. In Webster GD [ed]: Urinary Diversion: Scientific Foundation and Clinical Practice. Oxford, Blackwell Scientific Publications, 1995.)

Radiation Therapy

Preoperative Radiotherapy

Preoperative radiotherapy (RT) has a long history of use in bladder cancer treatment, although it currently is not employed frequently. The purported benefit has been a decreased risk of local failure following the combination of RT and radical cystectomy compared with radical cystectomy alone.[118,119] The available data are difficult to interpret but generally confirm that preoperative RT results in significant downstaging. This downstaging occurs when doses of 40 to 50 Gy are used preoperatively rather than short courses of RT followed within a few days by radical cystectomy. Older data, primarily using RT without concurrent chemotherapy, have been summarized and seem to suggest that a survival benefit exits,[118] but a more recent systemic review[120] concludes that a survival benefit cannot be confirmed with the available literature. Nevertheless, a modern experience[121] shows that for a series of patients most of whom had stage cT3 disease, a well-tolerated schedule consisting of two courses of cisplatin concurrently with 40 Gy of RT followed one month later by cystectomy led to a pT0 rate of 36%, which compares with the rate of 38% with preoperative methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) in a series more heavily weighted toward patients with cT2 disease.[122]

Given the problems with comparing retrospective reviews and the methodologic problems with the available prospective clinical trials, it seems clear that published data are insufficient to either confirm or refute the hypothesis that preoperative RT results in a survival advantage compared with radical cystectomy alone. However, assuming that a decrease in local recurrences, and the potential morbidity which local failures bring, is beneficial, there may be a role for preoperative RT in some patients with bladder cancer, especially those with locally advanced disease who are at higher risk for pelvic recurrences. Although local failure estimates for pathologically staged cases are low,[123] other reports suggest that the failure rate for cT3b disease is relatively high. A study compared patients receiving preoperative RT treated between 1960 and 1983 to the more modern patients treated with radical cystectomy only, many of whom received adjuvant chemotherapy.[124] In this review, the 5-year actuarial pelvic failure rate for clinical T3b disease was substantially reduced, from 28% without preoperative RT to 9% with preoperative RT. No significant difference in pelvic failure was observed for patients with T2 and T3a disease. The 28% failure rate with surgery alone for T3b patients is similar to that reported earlier by Greven for clinically staged T3 patients (39%).[125] Thus, for locally advanced disease, surgery alone has a substantial pelvic failure rate and, despite the high rate of distant failure, an argument can be made in favor of preoperative RT. This issue may be worthy of further study in future clinical trials.

Palliative Therapy

Radiation therapy often is used to palliate locally advanced bladder cancer, particularly when gross hematuria, not amenable to local surgical procedures, is causing clinical problems. Usually, this situation is treated with a shorter course (hypofractionation) of RT than is used for the definitive treatment of potentially curative disease. In bladder cancer, like many other malignancies that have bleeding as a symptomatic manifestation, hematuria usually is well controlled. Control of other local urinary symptoms is not as good, with control of dysuria and urinary frequency of approximately 25%. It is expected that some acute RT effects will occur during a course of therapy, but

they usually are mild, if multiple treatment fields and customized blocks are created to spare normal tissues.

Jose and coworkers[126] from the Royal Marsden Hospital performed a phase II study evaluation of a palliative, hypofractionation regimen consisting of either 5 or 6 weekly fractions of 6 Gy each for a total dose of 30 to 36 Gy; 65 poor-performance status patients with median age of 81 years were enrolled. Median survival time was just 35 weeks, but 23 of 37 patients who were evaluated cystoscopically at 3 months had a complete response. In addition, although nocturia rarely was improved, most patients had symptomatic control of hematuria, frequency, and dysuria. Duchesne and associates[127] reported the results of an international, multicenter, randomized trial of two palliative radiotherapy regimens for bladder cancer; 500 patients were entered and were randomized to receive either 35 Gy in 10 fractions over 2 weeks or 21 Gy in 7 Gy fractions over 1 week on alternating weekdays. To be eligible, patients were either medically unable to tolerate cystectomy (64%) or had advanced disease (T4b, N1, or M1) (36%). Median age was 80 years. The median survival time was 7.5 months. Of 272 patients available for assessment at 3 months, 68% had improvement in at least one bladder cancer symptom by at least one grade without worsening of any other symptoms. There were no differences between the two regimens for either survival or symptom control. Recent trials thus confirm older data indicating that radiation therapy can play an important role in ameliorating local symptoms from inoperable or unresectable bladder cancer.

Bladder Preservation Using Radiotherapy with or without Chemotherapy

Organ preservation approaches, using RT as one of the treatment modalities, have been applied to several malignant diseases. Given the potential disruption in lifestyle associated with radical bladder surgery, there has been strong motivation for exploring bladder-conserving techniques and decades of experience to draw on. Early attempts using RT for preservation focused on RT as the sole modality of treatment with surgery reserved for salvage treatment; more recent studies have used concurrent chemotherapy agents to increase the efficacy of RT.

Bladder preservation using RT as the only treatment modality, with surgery reserved for salvage of local, nonmetastatic recurrences has been compared to radical cystectomy in randomized trials. Although differences in 5-year survival rates have been detected in these studies, which favor early cystectomy, the differences are small and usually do not reach statistical significance. For example, Bloom and colleagues reported for the Institute of Urology, London, the 5-year results of a randomized trial of preoperative pelvic RT (40 Gy) and radical cystectomy versus RT only (60 Gy) for patients with T3 bladder cancer.[128] Nearly 200 patients were randomized. The 5-year survival rate was 38% for the immediate cystectomy arm and 29% for the RT alone arm ($P = 0.2$). Although salvage cystectomy was not part of the planned protocol therapy, 18 patients underwent this salvage treatment with 60% 5-year survival rate for this subset. This study completed patient accrual in 1975, and it is unclear how relevant it is to today's patients, given changes in staging evaluation and improvements in surgical and radiotherapeutic techniques over the past 25 years. Nevertheless, it remains interesting that the survival rate differences are small enough to be due to chance alone, despite the higher risk of local recurrence in the RT-alone group. Tumors that recur locally after RT may serve as markers for lesions that tend to recur distantly. Thus local recurrence may not adversely affect the overall survival rate. In a more recent study, Sell and colleagues performed a randomized trial with treatment arms similar to the Bloom study (preoperative RT and radical cystectomy versus RT with surgical salvage), and which randomized patients between 1983 and 1986. The results are remarkably similar to the Bloom report: 5-year survival rate is 29% for immediate surgery versus 23% for RT alone (P = NS). In this study, 28% of the patients receiving RT underwent salvage surgery.[129]

Thus RT, as a sole modality, has an appreciable 5-year survival rate in the treatment of invasive bladder cancer, although the local control rate is only approximately 25% to 50% at 5 years. Favorable prognostic factors for patients who are treated with RT alone include papillary morphology, extensive TUR, lack of ureteral obstruction, and higher pretreatment hemoglobin level.[130,131]

As discussed fully elsewhere in this chapter, chemotherapy has become a highly useful treatment for bladder cancer, and approaches combining active agents with RT to improve bladder conservation have proliferated. Strategies have included the use of concurrent RT and 5-FU; concurrent RT and intra-arterial cisplatin; concurrent 5-FU, cisplatin, and large dose per fraction RT; and, more recently, concurrent paclitaxel.[132–136] However, most interest has been in the use of RT with concurrent intravenous cisplatin, with or without the use of neoadjuvant chemotherapy to address the issue of systemic disease.[137–141] Most of these strategies employ an aggressive TUR prior to conservative therapy, and this procedure is considered to be an important component of therapy.

A recent update of results from Massachusetts General Hospital (MGH) and the Radiation Therapy Oncology Group (RTOG) summarizing the results of sequential clinical trials employing transurethral resection of the bladder tumor (TURBT), chemotherapy, and radiotherapy for bladder preservation illustrates the outcome with this approach.[142] Most commonly, the studies led by Shipley and colleagues have used neoadjuvant chemotherapy with methotrexate, cisplatin, and vinblastine (MCV) up front for two cycles followed by RT. However, as discussed later in this chapter, the use of neoadjuvant therapy in this setting is debatable. Regardless of the use of neoadjuvant chemotherapy, concurrent chemotherapy and RT is used, and a dose of 39.6 Gy with two courses of concurrent cisplatin (70 mg/m^2 or 100 mg/m^2) was the most common regimen. Frequently at this point in the treatment regimen—two thirds through the radiotherapy—treatment is paused, and patients are restaged. Those with tumors sensitive to treatment, as demonstrated by a complete response (i.e., negative biopsies and negative urinary cytology) continue with additional concurrent cisplatin and RT to a total dose of 64.8 Gy. Patients with less than a CR go on to radical cystectomy. Other clinicians who perform bladder-sparing treatment forgo the intra-RT tumor assessment and perform a restaging shortly after the completion of the full dose of radiation therapy, with salvage surgery performed on incomplete responders.[137]

Results of treatment for 190 patients with the MGH approach reveal a 5-year survival rate of 54% and a 10-year survival rate of 36%.[143] Of the surviving patients, 73% (46% of the total) have an intact bladder at 5 years. Bladder function after TURBT, chemotherapy, and RT is reported to be good as quality of life data emerges. For example, in a large German series of 282 consecutive patients treated with RT alone ($N = 98$) or RT and concurrent cisplatin or carboplatin ($N = 184$), only three patients underwent a cystectomy for poor bladder function or radiation cystitis.[144] Of note, approximately 25% of patients who achieve a complete response when treated with bladder-sparing approaches subsequently develop noninvasive recurrences, and the long-term outcome of these patients remains of some concern. Zietman and coworkers[145] have examined the results of 32 patients who developed noninvasive recurrences. These cancers usually were carcinoma in situ and usually occurred at the site of the original tumor. Of the 32 patients, 27 were treated conservatively, and the irradiated bladder tolerated this therapy well; ten patients ultimately required salvage cystectomy. In general, the noninvasive recurrences that occur after RT-containing, bladder-sparing approaches can be managed with conventional intravesical therapies.

A recent review article discussed the status of quality of life after bladder-sparing and noted that a main objective of bladder preservation is improvement in quality of life by preserving a functional

bladder and avoiding the need for a urinary diversion.[146] Shipley and associates[147] have reported a less than 1% rate of salvage cystectomy for radiation cystitis or bladder contracture. A series by Henningsohn and coworkers[148] reported the results from 71 patients in Stockholm treated between 1977 and 1995 with doses ranging from 58 to 63 Gy. Anonymous questionnaires were used to compare irradiated patients with 460 age-matched controls and 250 patients who underwent cystectomy. Of note, 74% of irradiated patients reported little or no distress from urinary symptoms, and 68% denied moderate or severe gastrointestinal symptoms. More irradiated patients retained sexual function compared with patients who had had cystectomy. Of surveyed patients, 38% of irradiated patients had intercourse in the previous month compared with 13% of cystectomy patients. For surviving patients, 75% retained an intact urinary bladder after radiation therapy; this was similar to other multimodality series. Zietman and colleagues[149] reported the experience from Massachusetts General Hospital using both QOL questionnaires and formal urodynamic studies. QOL questionnaires revealed no significant urinary symptoms in more than 80% of patients. On urodynamic evaluation, 80% of patients (19/26) had normal bladder function. Bowel dysfunction was low, and 55% of men reported sufficient erection for intercourse within the month prior to the survey. A French study assessed 53 patients treated with concurrent chemotherapy and radiation therapy between 1999 and 2001.[150] With a median follow-up of 2 years, 82% of patients had preserved bladders. Of the patients with a preserved bladder, 67% reported satisfactory urinary function at 2 years.

As mentioned earlier, the role of neoadjuvant chemotherapy as a part of bladder preservation has come into question. This component of treatment was added to provide additional downstaging and also to address the potential for subclinical metastatic disease. However, this chemotherapy also added to the acute morbidity of treatment. The RTOG recently reported on a randomized study that compared the approach described previously, with two cycles of MCV prior to concurrent cisplatin/RT, to a treatment arm that had no pre-RT MCV.[147] With a median follow-up of 5 years, no significant difference in survival was detected. Thus, although systemic relapse is an important component of treatment failure, it is not clear yet how to decrease the probability of this event in patients undergoing a modern bladder preservation approach.

A phase I trial of twice-weekly gemcitabine with concurrent radiation for patients with muscle-invasive bladder cancer was undertaken at the University of Michigan.[151] Gemcitabine has known radiosensitizing properties at doses that are below cytotoxic levels. Dose levels of 10 mg/m^2 and 20 mg/m^2 were well tolerated when given twice weekly with radiation, with a maximum tolerated dose (MTD) of 27 mg/m^2. Radiation therapy was delivered with a three-dimensional conformal technique to the bladder and extravesical tumor to a dose of 60 Gy in 2-Gy fractions. Prophylactic nodal irradiation was not given due to concerns about gemcitabine toxicity with a large field, as well as to limit the dose should salvage surgery with neobladder formation be needed. Complete response was noted in 21 of 23 patients (91%). Formal quality-of-life data were collected as well.[152] No statistical difference was seen in the quality-of-life (QOL) scores for the concurrent radiation therapy and gemcitabine patients before, during, or after treatment. However, those patients who received higher gemcitabine doses with dose-limiting toxicities reported lower bladder-specific QOL.

The RTOG continues to evaluate and refine bladder preservation strategies. An active RTOG study (RTOG 0233) is assessing the tolerability and efficacy of two regimens in a randomized phase II trial. Patients receive radiosensitization with cisplatin and either 5-FU or paclitaxel. Adjuvant systemic therapy is then delivered with gemcitabine, cisplatin, and paclitaxel. One additional subset of patients is under evaluation in RTOG. These are patients who are not surgical candidates, usually because there are medical comorbidities that do not allow either reasonably safe cystectomy or delivery of cisplatin. A recently activated RTOG trial (RTOG 05–24) evaluates therapy for these patients and also examines the role of targeted therapy. Based on examination of specimens from RTOG's bladder cancer tissue repository, it was noted that overexpression of Her-2 was significantly associated with a decreased complete response rate.[153] Thus, an approach to target the Her-2 pathway was initiated. This trial (05–24) enrolls patients with T2-T4a urothelial bladder cancer. Patients will have tissue examined at a central laboratory for Her-2 expression. Patients with 2+ or greater immunohistochemical staining will be treated with radiation therapy for 7 weeks along with 7 weekly treatments of paclitaxel and trastuzumab. Patients with less than 2+ staining will receive RT and weekly paclitaxel but not trastuzumab. The sample size is 88 patients and the primary endpoint is tolerability, but secondary efficacy endpoints will be obtained.

Future studies will examine the role of newer chemotherapy agents, such as docetaxel and gemcitabine as radiosensitizers in bladder preservation approaches, and at present, bladder preservation using TURBT, chemotherapy, and RT should be considered a method that is still being enhanced. However, it is clear that for selected patients, this conservative approach is a feasible technique to achieve both tumor eradication and organ preservation.

Chemotherapy

Adjuvant and Neoadjuvant Chemotherapy

Advances in surgery and radiation therapy have markedly improved the treatment of invasive transitional cell carcinoma, providing improved local control while decreasing the morbidity and mortality associated with therapy. Despite these advances, a large proportion of patients with muscle-invasive disease will develop metastases, accounting for much of the morbidity and almost all the deaths associated with this disease. These metastatic lesions presumably are due to the presence of disseminated disease at the time of local therapy. The development of chemotherapeutic agents and regimens with activity in the setting of metastatic transitional cell carcinoma, along with the demonstrated efficacy of both neoadjuvant and adjuvant chemotherapy in other diseases, has prompted considerable interest in these strategies for the treatment of transitional cell carcinoma.

Both approaches aim to improve the overall mortality rate associated with bladder cancer by treating in the setting of minimal metastatic disease. The hope is that the disease will be more susceptible to therapy and that the patients will be more tolerant of associated side effects. Adjuvant therapy is given following definitive local therapy, and neoadjuvant chemotherapy is given prior to local treatment. The decision to proceed with adjuvant therapy can be based on the pathologic stage as dictated by the findings at cystectomy. Criteria can be defined for patient eligibility, and the population enrolled on trials can be fairly uniform. The disadvantage, however, is that definitive local therapy may render some patients either unable or unwilling to undergo adjuvant therapy due to complications associated with the procedure. Patients may develop overt metastatic disease while recovering from their definitive local therapy, which may render the advantage of adjuvant therapy moot.

Neoadjuvant chemotherapy, by contrast, delivers treatment at the earliest possible time. It allows assessment of the chemotherapeutic responsiveness of the primary tumor, which has been shown to be a prognostic indicator for response.[25] In addition, tumors that initially may be judged unresectable may be rendered resectable by neoadjuvant therapy. Neoadjuvant therapy also allows maximal delivery of chemotherapy, because vascular beds have not been disrupted by either surgery or radiation. The disadvantages of neoadjuvant therapy are that it must be based on clinical staging criteria, which often overstate the extent of disease when compared to pathologic review, and that a significant proportion of patients will receive treatment when they do not need chemotherapy.

Although both neoadjuvant and adjuvant therapy are attractive in concept, major problems have arisen in the study of these approaches.

To date there is suggestive, but no definitive, evidence that either approach improves overall survival of patients with bladder cancer.

Adjuvant Chemotherapy

Adjuvant chemotherapy of transitional cell carcinoma has been the subject of several single-institution randomized trials. Unfortunately, no multicenter randomized study has ever been conducted. The single center studies which have been reported have been flawed by being either retrospective or limited in their enrollment.[154–158] Although these studies demonstrate a clear improvement in time to progression for adjuvant therapy, they have never shown a definitive benefit in terms of overall survival, primarily because they are too small to show a difference.

The results of these studies are summarized in Table 87-3. Despite the widespread use of adjuvant chemotherapy for invasive transitional cell carcinoma, we still do not have definitive evidence of benefit in terms of overall survival. This is primarily due to the limited number of patients entered on the randomized studies reported to date, resulting in too few patients being treated and followed to detect a difference in overall survival. Only 75 patients have actually received chemotherapy on the three randomized trials reported to date; the conclusions that can be drawn from such small studies are extremely limited. The improved disease-free survival in patients treated with adjuvant chemotherapy on the trials provides a tantalizing hint that this approach may result in a higher cure rate for this disease. Proof of the benefit of adjuvant chemotherapy will require a multicenter randomized trial with appropriate sample size, and clinical trials designed to address this question should be the first priority for these patients. In the absence of such a trial, adjuvant chemotherapy remains of uncertain benefit.

These hints of activity led investigators at M.D. Anderson Cancer Center to address the question in a different way.[159] They randomized 140 patients with high-risk resectable bladder cancer to receive either two cycles of neoadjuvant MVAC followed by surgery and three additional cycles of adjuvant therapy, or surgery followed by five cycles of MVAC. Only 65% of the patients received at least four cycles of chemotherapy because of a variety of reasons, but chiefly because of toxicity. There was no difference in overall survival in the two groups, suggesting that the timing of chemotherapy is not a major factor in determining its impact. The design of this study does not allow evaluation of the overall efficacy of chemotherapy in either setting, but two observations emerged confirming prior findings that have potential impact on future trials. First, a high rate of clinical understaging in terms of nodal involvement was documented and lymphatic or vascular invasion on the initial resection specimen is correlated with this finding. Second, tumor downstaging by neoadjuvant therapy is associated with a high rate of long-term survival. Both factors are critically important in the design of future neoadjuvant trials.

Neoadjuvant Chemotherapy

Despite the theoretic advantages cited for neoadjuvant chemotherapy, its use remains limited. The primary reason is that large multicenter trials with the potential to provide definitive evidence of benefit have only recently been completed, and the results have not been fully incorporated into the standard armamentarium. Neoadjuvant chemotherapy has been used in multiple single-agent trials. Chemotherapy has been used alone, concurrently with radiation therapy, sequentially, or alternating with radiotherapy. Most of these trials used cisplatin either singly or in combination, with pathologic complete response rates reported from 0% to 96%. The wide range of response rates points to the major problems in interpreting this data. Case selection is based entirely on clinical criteria, and biologic markers of invasive metastatic potential were unknown at the time these studies were designed and conducted. Most of the studies enrolled patients who had undergone TUR in their bladder tumor and may, therefore, have been in complete response at the time they were treated. At least a fraction of these patients may actually have been cured by their local therapy. Finally, the initial workup of patients enrolled on these studies varied widely, with some of the studies being conducted prior to the incorporation of modern diagnostic techniques into the eligibility criteria. Some of the early studies may well have included patients with early metastatic disease, resulting in a significant impact on the survival data. Drawing any conclusion from these nonrandomized studies is extremely difficult.

Seven randomized studies have been completed. Most of these studies have been relatively small and failed to show a definitive benefit for neoadjuvant chemotherapy. A total of 845 patients were enrolled on five phase III trials completed in the late 1980s using primarily cisplatin alone as the chemotherapy regimen. These trials were the subject of a meta-analysis, published in 1995, that used individual patient data from 479 of the patients.[160] Two of these trials tended to favor chemotherapy, while two showed no benefit. The fifth and largest trial, which provided no individual patient data for the meta-analysis, enrolled 325 patients and used a combination of cisplatin and doxorubicin. This trial favored chemotherapy.[161] The overall survival curves for the meta-analysis showed no statistically significant benefit to chemotherapy ($P = 0.33$).

Two large modern studies have reported their results. The largest randomized trial of neoadjuvant therapy was conducted in Europe

Table 87-3 Adjuvant Combination Chemotherapy Trials

First Author Reference	Arms	Total No. of Patients (No. Receiving Chemotherapy)	Results
Logothetis[155]	Nonrandomized trial	339 (71)	Improved survival in chemotherapy group
Skinner[156]	PAC	44 (33)	Improved disease-free survival in chemotherapy group; survival advantage for single-node-positive group
	Observation	46	
Stockle[157]	MVAC or MVEC	26 (18)	Halted early with improved disease-free survival in chemotherapy group
	Observation	23	
Freiha[154]	CMV	25 (24)	Improved disease-free survival in chemotherapy group
	Observation	25	

CMV, cisplatin, methothexate, vinblastine; MVAC, methothexate, vinblastine, doxorubicin, cisplatin; MVEC, methothexate, vinblastine, epirubicin, cisplatin; PAC, cyclophosphamide, doxorubicin, cisplatin.

by the Medical Research Council (MRC) and the EORTC.[162] The study was designed to detect a difference in 3-year survival of 10% or greater with the use of chemotherapy. A total of 975 patients were enrolled, with patients randomized to receive CMV every 3 weeks for three cycles, or no chemotherapy prior to a previously selected definitive local therapy. The definitive local therapy was either radical cystectomy, full-dose external beam radiotherapy, or preoperative radiotherapy followed by cystectomy. Four hundred eighty-nine patients were randomized to receive chemotherapy, and 486 received local therapy alone. A total of 484 underwent cystectomy, 414 received radiotherapy, and 77 were treated with combined radiotherapy and surgery. There was a 21% improvement in the pathologic complete response rate at cystectomy in the patients receiving chemotherapy. At 3 years the overall survival rate was 55.5% for the chemotherapy arm and 50% in the no chemotherapy arm ($P = 0.075$). The chemotherapy therefore failed to demonstrate the anticipated 10% improvement in overall survival at this time. However, subsequent follow-up has shown that the survival curves clearly diverge with an advantage for the arm receiving chemotherapy.[163]

In the United States, results of an Intergroup randomized trial compared MVAC plus cystectomy versus cystectomy alone.[122] This trial randomized 317 patients enrolled over 11 years. By intention to treat analysis, the median survival of the combination arm of therapy was 77 months compared to 46 months in the cystectomy alone arm. At 5 years 43% of the subjects in the cystectomy alone arm were still alive while 57% of those who received combined modality therapy survived ($P = 0.06$). Improved survival was associated with pathologic complete response in the cystectomy specimen. There were significantly more patients with no residual disease at operation in the combination therapy arm (38% versus 15%, $P < 0.001$). These data have been the subject of considerable debate.[164,165] The results of both the Intergroup and EORTC/MRC trials strongly suggest that there may be a benefit to neoadjuvant chemotherapy.

One limitation to the use of neoadjuvant chemotherapy is the toxicity associated with cisplatin-based regimens. A multicenter phase II trial recently explored the use of paclitaxel, carboplatin, and gemcitabine in the neoadjuvant setting. This combination demonstrated an unexpectedly high rate of toxicity in this setting, but the pathologic complete response rate was comparable to that reported for MVAC on the Intergroup trial.[166] A similar phase II trial of this regimen with a variation on the drug schedule has recently been completed by the Southwest Oncology Group.

Chemotherapy for Metastatic Disease

Urothelial carcinoma has long been known to be a chemotherapy-sensitive malignancy. Single-agent phase II trials conducted in the 1970s identified cisplatin and methotrexate as the most active agents, with response rates of approximately 30%.[167] Doxorubicin, 5-fluorouracil, vinblastine, vincristine, and mitomycin C were all shown to have single-agent response rates of approximately 15%. These phase II trials provided the basis for the development of combination regimens such as CMV (cisplatin, methotrexate, and vinblastine), CISCA (cisplatin, cyclophosphamide, and doxorubicin), and MVAC (methotrexate, vinblastine, doxorubicin, and cisplatin). The initial trial of MVAC, with 121 evaluable patients, showed an overall response rate of 72%, with a complete clinical response rate to chemotherapy alone of 18%.[168] An additional 11 patients were rendered disease-free by surgery following chemotherapy. The median survival time for the entire group was 13.3 months, and only 20% of the patients were long-term disease-free survivors. MVAC subsequently was compared to CISCA in a phase III randomized trial.[169] The combined complete and partial response rate was significantly better for patients treated with MVAC (65% versus 46%), as was the overall survival time (median 11 months versus 10 months). Based on these studies MVAC has emerged as the standard therapy for metastatic transitional cell carcinoma, although it has never been compared head-to-head with CMV.

Despite the encouraging early results, MVAC has not proved to be curative therapy for transitional cell carcinoma, nor has the high response rate been replicated in the cooperative group or community setting. A randomized trial comparing MVAC to single-agent cisplatin showed an overall response rate to MVAC of 39%, with only 13% complete responses.[170] Median survival time for patients receiving MVAC was 12.5 months, similar to prior studies, but an update showed that only 4% of patients were alive at 5 years.[171]

Several attempts have been made to improve both the toxicity profile and response rate of MVAC. Even at standard doses, MVAC is a highly toxic regimen, and most patients are unable to receive the full prescribed dose over sequential cycles. Use of colony-stimulating factors has yielded mixed results in terms of allowing patients to receive standard therapy.[172–174] Subsequent efforts to improve the efficacy of the regimen have focused primarily on the use of dose-escalated MVAC, which demonstrated responses in up to 40% in initial trials with patients with disease refractory to prior systemic chemotherapy including standard dose MVAC. A randomized trial conducted by the EORTC demonstrated that high-dose MVAC given on an every-2-weeks schedule with granulocyte colony-stimulating factor (GCSF) had markedly increased complete and overall response rates when compared to standard MVAC.[175] Median time to progression and 2-year progression-free survival times favored the high-dose arm, but the trial did not demonstrate the 50% improvement in median overall survival it was designed to detect. Toxicities were roughly equivalent in the two arms of the study, slightly favoring the high-dose arm, presumably due to the use of the GCSF. To date dose escalation of MVAC has not demonstrated a significant benefit to patients.

The toxicity and relatively limited efficacy of MVAC have prompted a search for new agents and combinations. The two most promising agents to emerge are paclitaxel and gemcitabine. Both show significant activity as single agents. Single-agent trials of gemcitabine showed response in approximately 25% of patients treated.[176–178] These trials reported relatively minimal toxicity and serve as a basis for the incorporation of gemcitabine into combination chemotherapy regimens. Three phase II trials combined gemcitabine with cisplatin (GC) and demonstrated response rates comparable to MVAC.[179–181] Based on these results, this regimen was compared to MVAC in a randomized multicenter trial conducted in Europe and North America,[182] in which 405 patients were randomized between the two therapies. Overall survival times (median: GC 13.8 months, MVAC 14.8 months) and response rates (GC 49.4%, MVAC 45.7%) were similar in the two arms of the study, but patients receiving GC had much less severe toxicity despite receiving much more therapy. Although this study was not designed to demonstrate that GC was equivalent to MVAC, it does appear that efficacy is roughly similar with markedly less toxicity.

The next major questions under investigation are whether taxanes can add to the efficacy of therapy for advanced disease, and what the role of targeted therapy is in metastatic urothelial cancer. A phase II trial of paclitaxel was conducted by the Eastern Cooperative Oncology Group in patients who had received no prior chemotherapy or radiotherapy.[183] Using a 24-hour continuous infusion of 250 mg/m^2 every 3 weeks along with GCSF, 11 patients out of 26 (42%) showed evidence of response, with 7 patients (27%) achieving a complete response. Paclitaxel was then combined with carboplatin in a phase I–II trial.[184] With a target area under the curve (AUC) for carboplatin of 6 mg/mL/min and paclitaxel at 225 mg/m^2, the overall objective response rate was 50%. A nearly identical response rate of 52% was documented in a phase II trial of paclitaxel at 200 mg/m^2 over 3 hours, followed by carboplatin at a target AUC of 5 mg/mL/min every 3 weeks.[185] These results prompted further investigation in the cooperative group setting. The Southwest Oncology Group used this regimen in previously untreated patients, demonstrating an overall response rate of only 21%.[186] The Eastern Cooperative Oncology Group evaluated the combination in patients with renal insufficiency

and demonstrated an overall response rate of 24%.[187] Although the combination was well tolerated in both trials, this low response rate has discouraged further development.

Subsequent studies added gemcitabine to the paclitaxel–carboplatin doublet. In a multicenter phase II trial, this triplet showed an overall response rate of 68%, with 32% of patients showing complete response.[188] Investigators in Spain added paclitaxel to the gemcitabine–cisplatin doublet, demonstrating a 77% response rate in a phase I/II trial.[189] These trials served as the basis for several new studies including an ongoing phase III trial comparing GC to GC plus paclitaxel and a recent trial adding trastuzumab to the paclitaxel/carboplatin/gemcitabine triplet in patients with tumors overexpressing Her2.[188]

These new regimens hold significant promise in terms of both efficacy and increased tolerability. In assessing a patient with metastatic transitional cell carcinoma for chemotherapy, toxicity is a major consideration. In general, patients with bladder cancer are older and may have significant comorbidity. Currently therapy is not curative, and toxicity has a significant impact on quality of life. This situation is particularly true with MVAC, although the newer regimens also can be associated with significant toxicity in patients with poorer performance status.

88 Prostate Cancer

William G. Nelson, H. Ballentine Carter, Theodore L. DeWeese, and Mario A. Eisenberger

SUMMARY OF KEY POINTS

Incidence

- Prostate cancer is the most commonly diagnosed life-threatening cancer in men (218,890 cases and 27,050 deaths in 2007).
- Small prostate cancers are present in 29% of men between age 30 and 40 and 64% of men between age 60 and 70.
- The lifetime risk of a prostate cancer diagnosis is 1 in 6, and the risk of dying from prostate cancer is 1 in 35.
- Age, family history, diet and lifestyle, and ethnicity are risk factors for prostate cancer development.

Molecular Pathogenesis

- Germline mutations in *RNASEL* and *MSR1*, encoding proteins that function in host responses to infection, appear responsible for some cases of hereditary prostate cancer.
- An inflammatory lesion, proliferative inflammatory atrophy (PIA), may be an early precursor to prostate cancer.
- Somatic inactivation of *GSTP1*, encoding a carcinogen-detoxification enzyme, may initiate prostatic carcinogenesis by increasing the vulnerability of prostate cells to damage mediated by oxidant and electrophilic carcinogens.
- Gene fusions, involving TMPRSS2 and ETS family transcription factor genes, may contribute to the androgen dependence of prostate cancers.
- Defects in the functions of NKX3.1, PTEN, and CDKN1B are common in prostate cancer cells.

Prevention

- The type 2 5α-reductase inhibitor finasteride reduced the overall number of prostate cancers, but may have increased the number or the detection of high-grade cancers, in a randomized clinical trial.
- The antioxidants selenium and vitamin E are under scrutiny in a large randomized clinical trial for prevention of prostate cancer.

Screening and Diagnosis

- Prostate cancer screening using serum prostate-specific antigen (PSA) and digital rectal examination detects prostate cancers early, when the disease is clinically localized to the prostate gland.
- Transrectal ultrasound (TRUS)-guided core needle biopsies are used to diagnose prostate cancer.
- Stage, histological grade (Gleason score), and serum PSA levels are prognostic factors.

Treatment of Localized Disease

- Treatment options include watchful waiting, anatomic radical retropubic prostatectomy, external beam radiation therapy, and brachytherapy.
- Adjuvant androgen suppression can improve survival for some men with prostate cancer treated with external beam radiation therapy.
- A progressive rise in the serum PSA after treatment indicates prostate cancer recurrence.
- Depending on the approach used, side effects associated with treatment of localized prostate cancer can include erectile dysfunction, irritative voiding symptoms or difficulties with urinary control, and rectal irritation.
- Radiation therapy can be used to treat local prostate cancer recurrences following radical prostatectomy.

Treatment of Advanced Disease

- Androgen suppression, most often accomplished via the use of luteinizing hormone-releasing hormone (LHRH) agonists, with or without anti-androgens, is the most commonly used treatment.
- Side effects can include loss of libido, hot flashes, gynecomastia, loss of lean muscle mass and bone density, and the development of metabolic syndrome.
- Docetaxel chemotherapy improves the survival of men with progressive androgen-independent prostate cancer.
- Bisphosphonates antagonize loss of bone density accompanying androgen deprivation, and reduce skeletal complications associated with metastatic prostate cancer progression.
- Other agents, including various immunotherapies, are under development in clinical trials.

INTRODUCTION

In 2007, an estimated 218,890 prostate cancer diagnoses will be made in the United States, accompanied by an estimated 27,050 prostate cancer deaths.[1] Since about 1994 to 1996, with widespread use of serum prostate-specific antigen (PSA) testing and digital rectal examination for prostate cancer screening, and with increased treatment of clinically localized prostate cancer with surgery or radiation therapy, age-adjusted prostate cancer death rates have fallen steadily. Although this trend might indicate a beneficial impact of prostate cancer screening and/or early prostate cancer treatment on prostate cancer mortality, mass screening of the general population for prostate cancer remains controversial.[2,3] One challenge for prostate cancer screening is the prevalence of the disease in the U.S.: autopsy series have revealed small prostate cancers in as many as 29% of men between age 30 and 40 and 64% of men between age 60 and 70.[4] Obviously, not all of these men are at risk for symptomatic or life-threatening prostate cancer progression. In fact, many such men, if diagnosed with prostate cancer, may be at greater risk for treatment-associated morbidity.

Currently, for U.S. men, the lifetime risk of a diagnosis of prostate cancer is about 1 in 6, while the lifetime risk of death from prostate cancer is on the order of 1 in 35.[1] Over the past two decades, treatment approaches for men with prostate cancer have changed dramatically, with improvement in established prostate cancer treatments and the introduction of new prostate cancer treatment approaches. Now, men diagnosed with prostate cancer often face a bewildering array of treatment choices. Physicians must weigh the risks of prostate cancer progression against the potential for side effects from treatment, in the context of other health risks and life choices, to use the current collection of treatments for the greatest benefit.

This chapter provides an overview of prostate cancer etiology, biology, screening, detection, diagnosis, prevention, and treatment.

PROSTATE ANATOMY AND FUNCTION

The prostate is a male sex accessory gland that surrounds the urethra and contributes secretions to the ejaculate (Fig. 88-1). Located in the pelvis, the prostate sits adjacent to the bladder and rectum, is surrounded incompletely by a thin capsule composed of collagen, elastin, and smooth muscle, and at the apex of the gland, forms part of the urethral sphincter apparatus.[5] Nerves to the corpora cavernosa of the penis, needed for penile erection, travel through fascia along the posterolateral surface of the prostate. These nerves can be recognized as a neurovascular bundle by urologists and preserved during radical prostatectomy to minimize sexual dysfunction postoperatively.[6,7] The prostate parenchyma has been divided into three zones that can be seen by transrectal ultrasonography, and recognized readily by surgical pathologists examining radical prostatectomy specimens: a central zone, surrounding the ejaculatory ducts and accounting for some 25% of the prostate; a transition zone, near the prostatic urethra with 10% of prostate tissue normally; and a peripheral zone, with the bulk of prostate tissue encompassing posterolateral region of the prostate (Fig. 88-2).[8,9]

In addition to prostate cancer, the prostate also frequently manifests benign enlargement (benign prostatic hyperplasia [BPH]) and chronic or recurrent inflammation (prostatitis). Like prostate cancer, each of these conditions can elevate the serum prostate-specific antigen (PSA), confounding the use of serum PSA testing for prostate cancer screening. When present, BPH usually is located near the prostatic urethra (in the transition zone), while prostate cancer, as well as the prostate cancer precursor lesion prostatic intraepithelial neoplasia (PIN), usually arises in the periphery (the peripheral zone). Prostatic inflammation, although often prominent in the peripheral zone, can be seen throughout the prostate. Although prostate cancer, BPH, and prostatitis all commonly afflict U.S. men, and can be simultaneously present in a single prostate gland, mechanistic associations of the three diseases have been difficult to demonstrate.

The prostate requires androgenic hormones and an intact androgen receptor for normal growth and development. In the prostate, the major circulating androgenic hormone, testosterone, produced by Leydig cells in the testes upon stimulation by luteinizing hormone (LH), is converted by 5α-reductase (nicotinamide-adenine dinucleotide phosphate-dependent Δ(4)-3-ketosteroid 5α-oxidoreductase) to 5α-dihydrotestosterone (DHT).[10] DHT, a more potent androgen than testosterone, binds to intracellular androgen receptors, alters androgen receptor conformation to promote dissociation from chaperone proteins, triggers androgen receptor dimerization and transport into the cell nucleus, and activates the expression of selected target genes.[11,12] Stereotypically, androgen receptor target genes are characterized by the presence of androgen response element (ARE) DNA sequences within the transcriptional regulatory region, permitting direct binding and *trans*-activation by the androgen receptor.[13] For genes like *PSA*, which are activated by the androgen receptor selectively in prostate cells, and not in cells of other tissues, the transcriptional regulatory region also contains additional DNA sequences (prostate-specific enhancer [PSE]) conferring prostate-specific expression.[14]

The normal prostate epithelium is composed of (1) basal epithelial cells, characterized by the expression of cytokeratins K5 and K14, and p63; (2) columnar secretory epithelial cells, which express the androgen receptor, PSA, cytokeratins K8 and K18, prostate-specific membrane antigen (PSMA), and prostate-specific acid phosphatase (PAP); and (3) rare neuroendocrine cells, which secrete chromogranin A, neuron-specific enolase, and synaptophysin (Fig. 88-3).[15,16] The basal epithelial cell compartment likely contains pleuripotent prostatic stem cells, capable of self-renewal proliferation and of differentiation. In contrast, columnary secretory cells, specialized to produce secretions for the ejaculate, are terminally differentiated, particularly under the influence of androgenic hormones. The

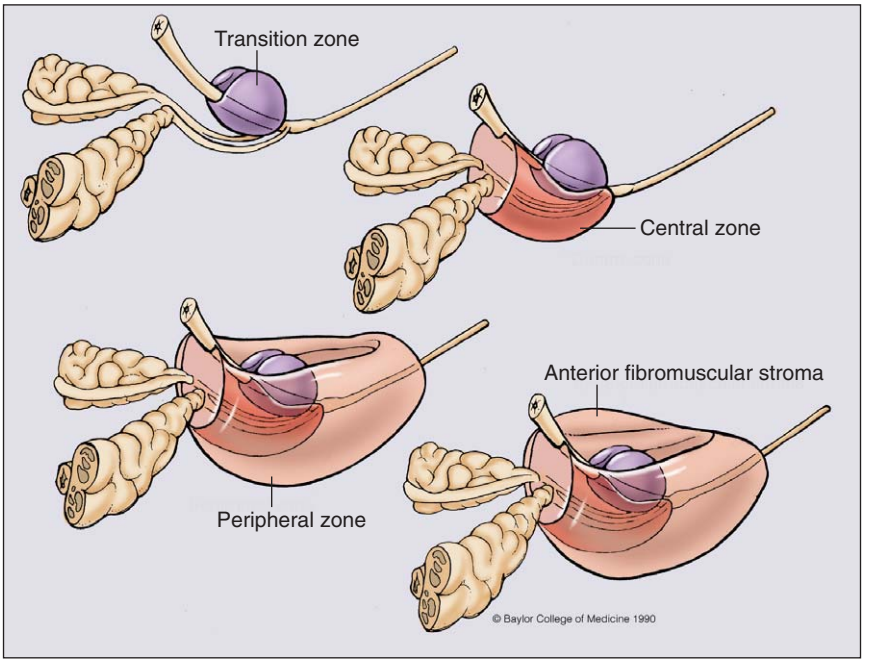

Figure 88-2 • Zones of the prostate. The peripheral zone, accounting for 70% of the prostate gland, is the site of origin of ≥70% of prostate cancers; the central zone, approximately 25% of the prostate gland, gives rise to only 1% to 5% of prostate cancers; and the transition zone, ~5% to 10% of the prostate gland, gives rise to 20% of prostate cancers and is the site of origin of benign prostatic hyperplasia (BPH). (From Green DR, Shabsign R, Scardino PT: Urological ultrasonography. In: Walsh PC, Rettic AB, Stamey CA, Vaughan ED Jr [eds]: Campbells's Textbook of Urology, 6th ed. Philadelphia, WB Saunders, 1992.)

prostate epithelium is supported, in turn, by a stroma containing fibroblasts, smooth muscle cells, nerves, and blood vessels. Stromal cells, which also express the androgen receptor, secrete polypeptide growth factors, such as keratinocyte growth factor (KGF), that contribute to the regulation of epithelial homeostasis via a paracrine signaling mechanism.[17,18] Abnormal stromal–epithelial interactions, with disordered regulation of epithelial cell proliferation and differentiation, may contribute to the pathogenesis of both prostate cancer and BPH.[19]

Prostate cancer cells and PIN cells arise from the prostatic epithelium. Even though transformed, such cells typically retain many of the phenotypic attributes characteristic of differentiated columnar secretory cells, including the expression of androgen receptor, PSA, PSMA, and PAP. Prostate cancers reminiscent of basal epithelial cells are exceptionally rare; prostate cancers with features of neuroendocrine cells are somewhat more common.[20] However, unlike normal columnar epithelial cells, neoplastic prostate epithelial cells are capable of proliferation. This feature has led to the concept that the target cell for neoplastic transformation in the prostate may be an "intermediate" cell, in transit from a basal epithelial stem cell to a differentiated columnar secretory epithelial cell, with properties of both stem cells and differentiated cells.[15,16] Another feature of neoplastic prostate epithelial cells, as compared to normal basal or columnar secretory cells, is that the neoplastic cells appear to use androgen receptor signaling not only for differentiation, but also for proliferation, as most prostate cancer cells tend, at least initially, to display

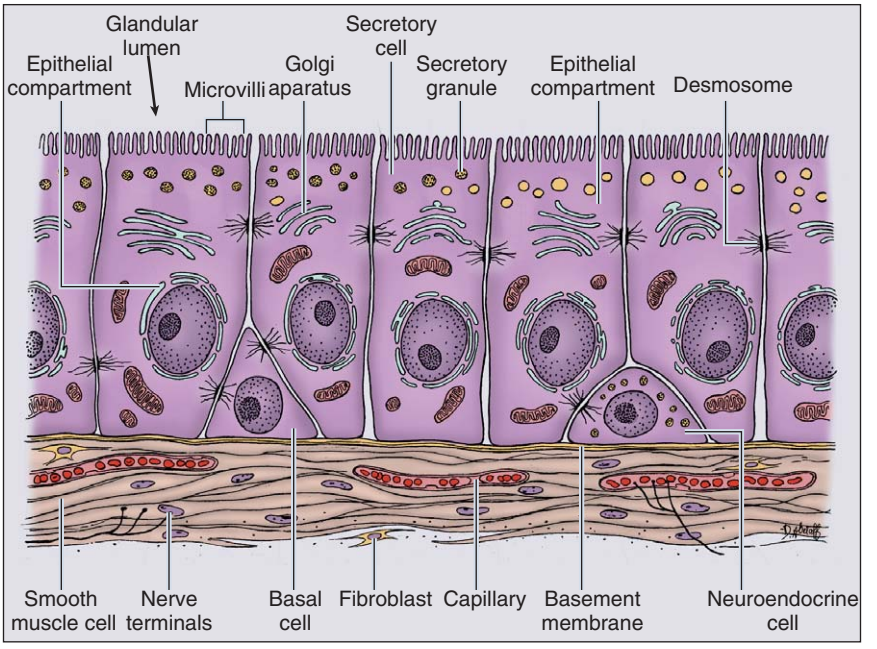

Figure 88-3 • The prostate epithelium.

some dependence on androgens for maintenance of growth and survival.[21] Somatic fusions between an androgen-regulated gene, *TMPRSS2*, at chromosome 21q22, and genes encoding members of the ETS family of transcription factors, commonly found in prostate cancers, may provide a mechanistic explanation by which androgen signaling can promote prostate cancer cell growth.[22] Ultimately, in life-threatening prostate cancer, prostate cancer cells escape from the prostate gland, proliferate to lymph nodes, in bones, and in other organs, and become less and less dependent on androgenic hormones.

ETIOLOGY OF PROSTATE CANCER

Genetic Predisposition to Prostate Cancer

Familial clusters of prostate cancer have been recognized since at least 1956, when Morganti and colleagues[23] reported that men with prostate cancer were more likely to have relatives with prostate cancer than men without a prostate cancer diagnosis. In a study conducted more than 3 decades later, when detailed family histories were collected from men with prostate cancer and their spouses, the men with prostate cancer were more likely to have a brother or father with prostate cancer.[24] Furthermore, the presence of one, two, or three affected family members appeared to increase the risk of prostate cancer to first-degree relatives by two-, five-, and eleven-fold, respectively, while the risk to more distant relatives was only marginally increased.[24] Similar findings have been reported in a number of additional studies. Twin studies, comparing the tendency for concordant prostate cancer development between monozygotic twins, sharing all of their genes, and dizygotic twins, sharing half of their genes, also have hinted at a significant contribution of hereditary to prostate cancer. In one study of 44,788 pairs of twins in Sweden, Denmark, and Finland,[25] 42% of the prostate cancer cases (with a 95% confidence interval of 29% to 50%) were attributed to heredity.

In principle, familial clustering of prostate cancer cases could be a result of inherited susceptibility genes, shared exposure to carcinogenic stresses, or to some sort of detection or diagnosis bias (e.g., the brother of a man diagnosed with prostate cancer may be more likely to pursue screening for prostate cancer). To discriminate these possibilities, several complex segregation analyses have been undertaken testing the mode of prostate cancer inheritance in familial prostate cancer clusters. In one study, rare autosomal dominant prostate cancer genes were predicted to account for as many as 43% of prostate cancer cases before age 55 and some 9% of all prostate cancer cases.[26] In another study, an additional X-linked gene also appeared to be responsible for inherited prostate cancer in certain families.[27] Mendelian inheritance of prostate cancer risk has been further supported by a number of genome-wide screens of polymorphic DNA markers; when data from more than 1233 hereditary prostate cancer families have been combined, several regions of linkage have been identified.[28]

Genetic mapping studies have identified *RNASEL* and *MSR1* as potential prostate cancer susceptibility genes.[29,30] *RNASEL*, a candidate *HPC1*, encodes a latent endoribonuclease component of an interferon-inducible 2′,5′-oligoadenylate-dependent RNA decay pathway that functions to degrade viral and cellular RNA upon viral infection.[31] The evidence that *RNASEL* mutations might predispose to hereditary prostate cancer development included the finding that four brothers with prostate cancer were found to carry *RNASEL* alleles with a base substitution $795^{G\rightarrow T}$, predicted to result in the conversion of a glutamic acid codon to a termination codon at amino acid position 265 ($aa256^{glu\rightarrow X}$), and that four of six brothers with prostate cancer in another family were found to carry *RNASEL* alleles with a base substitution $3^{G\rightarrow A}$, affecting the initiator methionine codon ($aa1^{met\rightarrow ile}$).[29] In addition, in a case-control study, a common polymorphic variant *RNASEL* allele with a base substitution $1385^{G\rightarrow A}$, encoding a less active enzyme (with an amino acid change $aa462^{arg\rightarrow glu}$), was correlated with increased prostate cancer risk ($P = 0.011$).[32] In this study, the polymorphic *RNASEL* allele accounted for as many as 13% of all prostate cancer cases. Provocatively, a new retrovirus, XMRV, has been detected in prostate tissues from men with *RNASEL* defects.[33,34] Whether this virus may lead, directly or indirectly, to prostate cancer in these men has not been determined. *MSR1* encodes subunits of a trimeric class A macrophage scavenger receptor capable of binding bacterial lipopoylsaccharide and lipoteichoic acid, and oxidized high- and low-density serum lipoproteins (oxidized HDL and LDL).[35] For *MSR1*, mutations not only have been linked to prostate cancer susceptibility in some prostate cancer families, but one mutant allele, encoding a receptor subunit polypeptide with an $aa293^{arg\rightarrow X}$ expected to have "dominant negative" function, has been detected in ~3% of non-hereditary prostate cancer (HPC) cases but only 0.4% of unaffected men ($P < 0.05$).[30,36]

The identification of *RNASEL* and *MSR1* as candidate prostate cancer susceptibility genes has intensified interest in the possibility that infection and/or inflammation might contribute to the pathogenesis of human prostate cancer. In mice, targeted disruption of *RnaseL* leads to increased diminished interferon-α activity and increased susceptibility to viral infection,[37] while targeted disruption of *Msr-A* leads to increased vulnerability to infection with *Listeria monocytogenes*, *Staphylococcus aureus*, *Escherichia coli*, and herpes simplex virus type 1.[35,38–40] Further genetic support for this etiologic mechanism has come from analyses of common variants of other genes encoding participants in host inflammatory responses, including *TLR4,* and other members of toll-like receptor signaling pathways, *MIC-1*, *IL1-RN*, and *COX-2*, also have been associated with prostate cancer risk.[41–45]

Androgenic hormones are necessary for prostate growth and development. Thus, it is not surprising that polymorphic variants of genes involved in androgen action, such as *AR*, *CYP17*, and *SRD5A2*, may affect prostate cancer risk. Polymorphic polyglutamine (CAG) repeats, varying in length from 11 to 31 amino acids,[46] and polymorphic polyglycine (GGC) repeats, varying in length from 10 to 22 amino acids, have been described for *AR*. For the polyglutamine repeats, androgen receptors with shorter repeats may possess increased transcriptional *trans*-activation activity.[47] African-Americans, who have higher prostate cancer risks than Asians, also have shorter androgen receptor polyglutamine repeats. Furthermore, genetic epidemiology analyses have correlated high prostate cancer risk with short androgen receptor polyglutamine repeats.[48–51] Variations in androgen receptor polyglycine repeats also may affect prostate cancer risk.[48,50–52]

SRD5A2, encoding the type 2 5α-reductase, the enzyme that generates DHT from testosterone in the prostate, has several polymorphic variants.[53,54] Some variant alleles encoding enzymes with increased activity have been associated with increased prostate cancer risk, and with poor prostate cancer prognosis.[53,55] 5α-reductase variants also may respond differently to inhibition by finasteride, used to treat BPH and under scrutiny as a prostate cancer prevention drug.[56,57] *CYP17*, encoding cytochrome P450c17α, an enzyme that functions to synthesize sex steroids, also has polymorphic variants. One variant allele, with a T→C transition in the transcriptional regulatory region of the gene that creates an Sp1 transcription factor recognition site, has been subjected to both population and genetic linkage analyses for association with prostate cancer, with inconsistent results.[58]

Prostate Cancer Epidemiology

Accumulated epidemiologic evidence implicates the environment as the major contributor to the development of most prostate cancers. Prostate cancer incidence and mortality display wide geographic variation, with high rates of prostate cancer incidence and mortality in the United States and Western Europe, and low prostate cancer risks more characteristic of Asia.[59] African-Americans in the United

States have very high prostate cancer risks.[60] The geographic variation in prostate cancer incidence and mortality can best be explained by lifestyle influences, as Asian immigrants to North America typically adopt higher prostate cancer risks.[61–63]

The key aspect of lifestyle in the United States most likely responsible for high prostate cancer incidence and mortality is the diet, generally rich in animal fats and meats and poor in fruits and vegetables. In the Health Professions Follow-up Study, a prospective cohort study involving 51,529 men, total fat intake, animal fat intake, and consumption of red meats were associated with increased risks of prostate cancer development.[64] Red meat consumption was similarly correlated with prostate cancer risks in the Physicians' Health Study[65] and in a large cohort study in Hawaii.[66] The cooking of red meats at high temperatures, or on charcoal grills, is known to lead to the formation of both heterocyclic aromatic amine and polycyclic aromatic hydrocarbon carcinogens.[67,68] Ingestion of 2-amino-1-methyl-6-phenylimidazopyridine (PhIP), one of the heterocyclic amine carcinogens that appear in "well-done" red meats, leads to prostate cancer in rats.[69] Consumption of dairy products also appears to increase prostate cancer risks, an effect that may be more attributable to calcium intake than to dietary fat or protein.[70]

Consumption of vegetables and antioxidant micronutrients reduces prostate cancer risks. High intake of tomatoes, which contain lycopene, and of cruciferous vegetables, which contain sulforaphane, may protect against prostate cancer development.[71,72] Lycopene likely prevents prostate cancer development by acting as an antioxidant. As part of a recent clinical trial, men were provided tomato sauce-based pasta dishes for three weeks before radical prostatectomy for prostate cancer.[73] For these men, tomato consumption was associated with increased lycopene levels in the blood and in the prostate, with decreased oxidative genome damage in leukocytes and in prostate cells, and with a reduction in serum PSA.[73] Sulforaphane, a compound that can prevent cancer in animals by triggering induction of carcinogen-detoxification enzymes, also can act as an antioxidant.[74–76] In addition to lycopene and sulforaphane, other antioxidants, such as the micronutrients vitamin E and selenium, also may reduce prostate cancer risks.[77–79] A clinical trial of supplementation with vitamin E and selenium to prevent prostate cancer (the SELECT Trial), involving a planned 32,400 men, has just been initiated.[80] The consistent finding of a protective effect of various antioxidants against prostate cancer development suggests that oxidative stresses might contribute to prostatic carcinogenesis. Oxidants can be generated by metabolic processes, by a number of different exposures, and by inflammation.[81,82] Androgens, necessary for normal prostate development and function, have been reported to increase oxidant production in prostate cancer cells.[83,84]

Prostate Inflammation, Proliferative Inflammatory Atrophy, and Prostate Cancer

Chronic or recurrent inflammation is known to play a causative role in the development of many human cancers, including cancers of the liver, esophagus, stomach, large intestine, and bladder. Inflammatory changes have been recognized in prostate tissues for many years, leading to speculation that inflammation might contribute in some way to prostate cancer development.[85] However, over the past few years, evidence has accumulated in support of a more critical role for prostatic inflammation in the pathogenesis of prostate cancer. Inflammatory changes are present in almost all radical prostatectomy specimens from men with prostate cancer. Because inflammation in the prostate usually is not associated with symptoms, the prevalence of prostate inflammation is not known, and the association with prostate cancer has been difficult to test.[86,87] A syndrome of irritative voiding symptoms and pelvic pain, perhaps attributable to inflammation near the prostatic urethra, is reported by about 9% or more of men between 40 and 79 years of age, with as many as 50% of such men suffering more than one episode by age 80 years.[88] Most episodes of symptomatic prostatitis are not clearly attributable to specific infectious agents. Even so, sexually transmitted infections do appear to increase prostate cancer risks.[89,90] Nonetheless, if prostate infection and inflammation lead to prostate cancer, the mechanism does not appear likely to involve direct transformation of prostate epithelial cells by microbial DNA. Instead, the production of microbicidal oxidants by inflammatory cells, such as superoxide, nitric oxide, and peroxynitrite, may promote prostate cancer development by triggering cell and genome damage.[91,92] Increased production of oxidants by inflammatory cells in the prostate may be why decreased prostate cancer risk has been associated with intake of a variety of antioxidants or of nonsteroidal anti-inflammatory drugs, and why *RNASEL* and *MSR1*, the two prostate cancer susceptibility genes identified thus far, encode proteins that function in host responses to infections.

Despite these provocative hints, the contribution of prostate inflammation to prostatic carcinogenesis has been difficult to assess. However, in 1999, De Marzo and associates[93] provided the most compelling linkage of prostate inflammation to prostate cancer by proposing that a prostate lesion might be a precursor to PIN and to prostate cancer (Fig. 88-4). Areas of the prostate containing epithelial cells that do not fully differentiate into columnar secretory cells have long been recognized as focal atrophy lesions by prostate pathologists.[85,94] The term *proliferative inflammatory atrophy (PIA)* has been used to describe those focal atrophy lesions that contain proliferating epithelial cells, are associated with chronic inflammation, and often

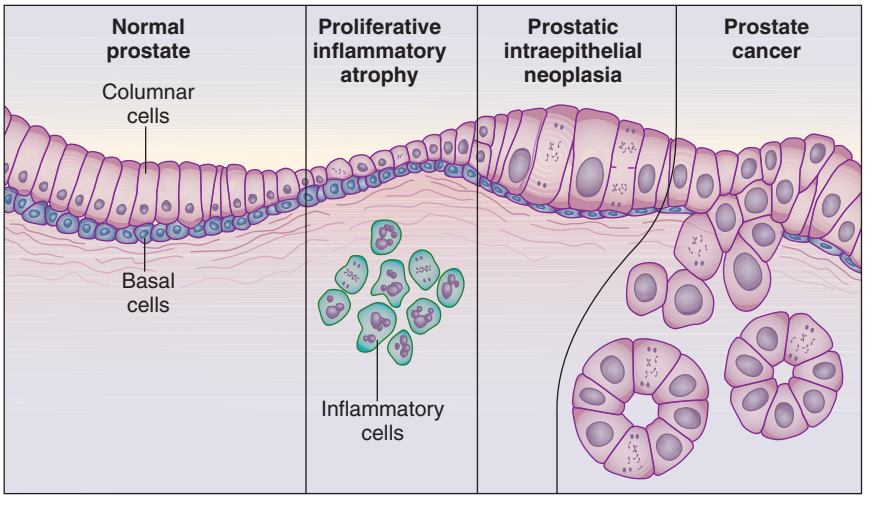

Figure 88-4 • Proliferative inflammatory atrophy (PIA) as a precursor to prostatic intraepithelial neoplasia (PIN) and prostate cancer. (Adapted from Nelson WG, DeMarzo AM, Isaacs WB: Prostate cancer. N Engl J Med 2003;349:366–381.)

Box 88-1. PROSTATE INFLAMMATION AND PROSTATE CANCER

Several lines of evidence have stimulated a renewed interest in the notion that prostate infection and/or inflammation may contribute to the development of prostate cancer. First, two of the inherited susceptibility genes so far identified for prostate cancer, *RNASEL* and *MSR1*, encode proteins that function in host responses to infection. Second, a new candidate prostate cancer precursor lesion, proliferative inflammatory atrophy (PIA), appears to arise as a consequence of prostate inflammation. Third, prostate cancer cells typically acquire defects in genes, like *GSTP1*, that encode enzymes that defend against cell and genome damage inflicted by oxidants, such as those elaborated by inflammatory cells. Finally, epidemiology and early clinical trial data suggest that consumption of a variety of different antioxidants, including selenium, vitamin E, and lycopene, may protect against prostate cancer development.

are located adjacent to PIN lesions and/or prostate cancers.[95] The epithelial cells in PIA lesions typically express high levels of stress-response polypeptides such as GSTP1, GSTA1, and cyclo-oxygenase 2 (COX-2). Loss of GSTP1 expression in rare PIA lesions, attributable to de novo *GSTP1* CpG island hypermethylation, may be what leads to the development of PIN and prostate cancer.[96]

The hypothesis that inflammation might promote prostate cancer development offers new challenges to prostate cancer epidemiology, to the search for prostate cancer susceptibility genes, and to the molecular pathogenesis of prostate cancer (Box 88-1). Although prostatic inflammation is common in regions of the world with high prostate cancer risks, whether regions of the world with low prostate cancer risks have less prostatic inflammation has not been determined. New strategies for assessing the presence and extent of PIA and of prostate inflammation may be needed. Perhaps new biomarkers of prostate inflammation, assayable in blood, urine, or prostate fluid, can be developed for use in epidemiology studies. In addition, it probably will be necessary to evaluate polymorphic genes encoding regulators of immune responses systematically for prostate cancer risk associations. As for prostate cancer pathogenesis, PIA lesions, appearing to arise in response to prostatic inflammation or some other noxious stimulus, may be precursors to PIN and/or prostate cancer.[97] However, whether prostatic inflammation is initiated in response to a prostatic infection or to some other provocation has not been ascertained. Finally, whether prostate cancer risks can be reduced by therapeutically attenuating prostate inflammation must be tested in clinical trials.

MOLECULAR PATHOGENESIS OF PROSTATE CANCER

Somatic Genome Alterations in Prostate Cancer Cells

Prostate cancer cells typically contain a plethora of somatic genome alterations, including gene mutations, gene deletions, gene amplifications, chromosomal rearrangements, and changes in DNA methylation (Fig. 88-5). In the United States, prostate cancer diagnoses typically are made in men 60 to 70 years of age, while small prostate cancers have been detected at autopsy in nearly 30% of men between 30 and 40 years of age.[4] Thus, the somatic genome changes present in prostate cancers often have accumulated over many decades. The acquisition of somatic genome changes in the prostate may be influenced by lifestyle as well: although small prostate cancers have been detected at autopsy in men from geographic regions with low prostate cancer mortality, these small prostate cancers usually are present only in much older men.[98–100] In the United States, prostates removed at radical prostatectomy for prostate cancer usually contain more than one prostate cancer lesion. Several techniques, including karyotyping, fluorescence in situ hybridization (FISH), comparative genome hybridization, and loss of heterozygosity analyses, have been used to catalog somatic genome changes in prostate cancers. Often, these analyses reveal different chromosomal abnormalities in different cancer cases, in different cancer lesions in the same cancer case, and in different areas within the same cancer lesion (Fig. 88-6). Chromosomal abnormalities, including gains and losses, tend to be distributed throughout the genome.[101] The propensity to develop such a heterogeneous collection of somatic genome lesions over so many years, and in a manner so sensitive to environment and lifestyle, suggests strongly that prostate cancers likely arise as a consequence of either chronic or recurrent exposure to genome-damaging stresses, defective protection against genome damage, or some combination of both processes. The resultant genomic instability may be the

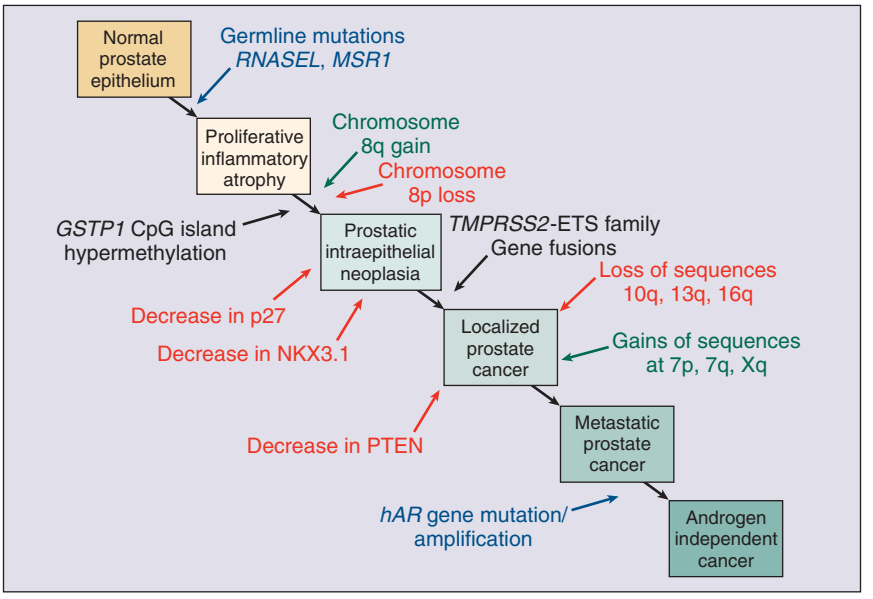

Figure 88-5 • The molecular pathogenesis of prostate cancer.

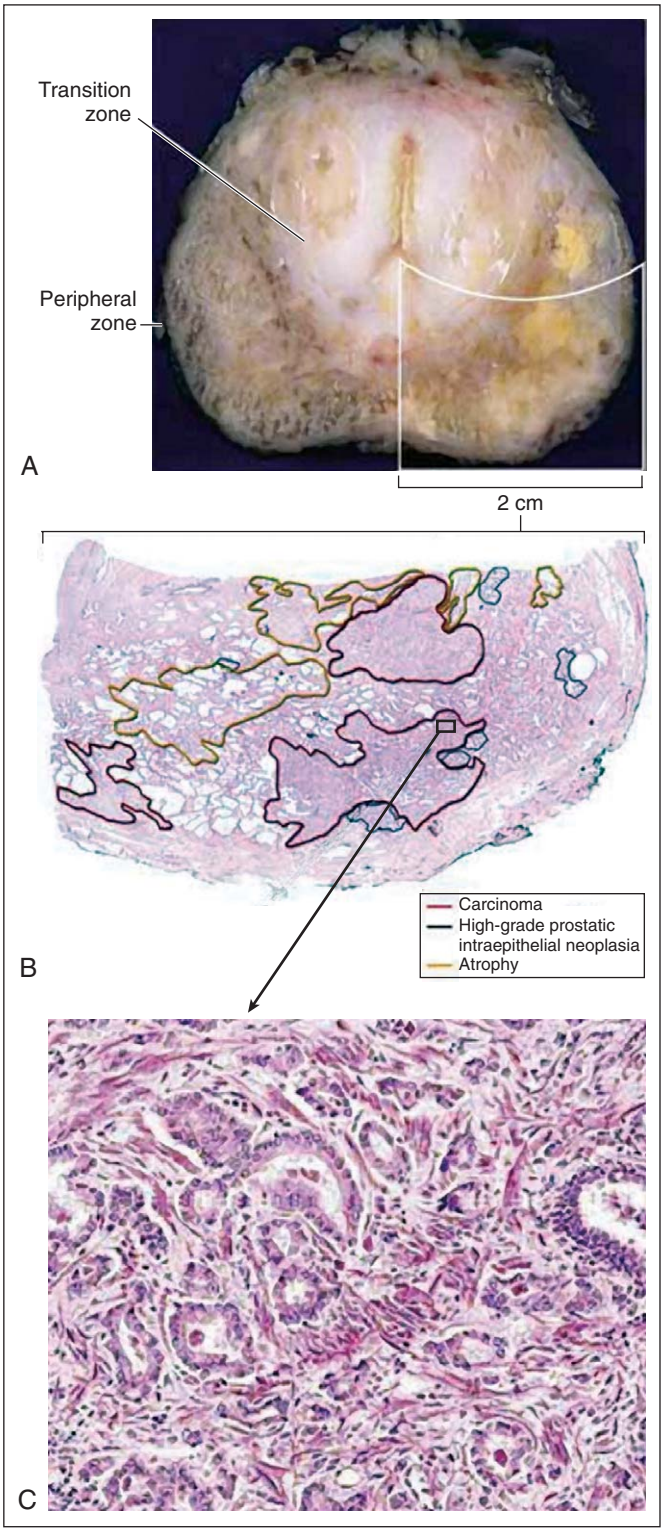

Figure 88-6 • Multiple foci of prostate cancer, and of prostate cancer precursor lesions, in the peripheral zone of the prostate. (From Nelson WG, DeMarzo AM, Isaacs WB, et al: Prostate cancer. N Engl J Med 2003;349:366–381, with permission.)

reason some prostate cancers progress to become life-threatening. Although most prostate cancers initially respond well to therapeutic reductions in circulating androgens, the cancers ultimately become androgen-independent, a process likely resulting from selection of pre-existing variant androgen-independent cancer cell clones, spontaneously generated via the acquisition of critical somatic genome changes.[102,103]

One newly described somatic genome alteration drives the production of fusion transcripts between an androgen-regulated gene, *TMPRSS2*, at chromosome 21q22, and members of the ETS family of transcription factors (Fig. 88-7).[22] Fusion partners for *TMPRSS2* include *ERG* (also at chromosome 21q22), *ETV1* (at chromosome 7p21), and *ETV4* (at chromosome 17q21).[22,104,105] The occurrence of these fusion transcripts provides a plausible mechanism for the dependence of prostate cancer cells on androgenic hormones for growth and survival, as the expression of ETS family transcription factors can be stimulated by androgen action. *TMPRSS2-ERG* fusions have been detected in about 60% of prostate cancers and in more than 20% of PIN lesions.[106] *ERG* is highly expressed by many prostate cancers, although whether *ERG* expression or the presence of *ERG* fusion transcripts has an impact on the prognosis of prostate cancer has not been determined.[106–109]

Hypermethylation of CpG island sequences encompassing the regulatory region of *GSTP1*, encoding the π-class glutathione *S*-transferase (GST) is the most common somatic genome change yet reported for prostate cancer.[110,111] GSTs catalyze the detoxification of carcinogens, and of other reactive chemical species, via conjugation with the intracellular scavenger glutathione. In mice, targeted disruption of π-class GST genes leads to increased skin tumors after treatment with the carcinogen 7,12 dimethylbenz anthracene (DMBA).[113] Similarly, human prostate cancer cells devoid of GSTP1 appear especially vulnerable to genome damage mediated by exposure to *N*-OH-PhIP, the charred meat carcinogen that causes prostate cancer when fed to rats, and by exposure to oxidant stresses.[114] In the normal prostate epithelium, GSTP1 is present in basal cells, but in lower amounts than in columnar secretory cells, although the enzyme can be induced in columnar epithelial cells subjected to genome-damaging stresses. In contrast, the enzyme is almost never

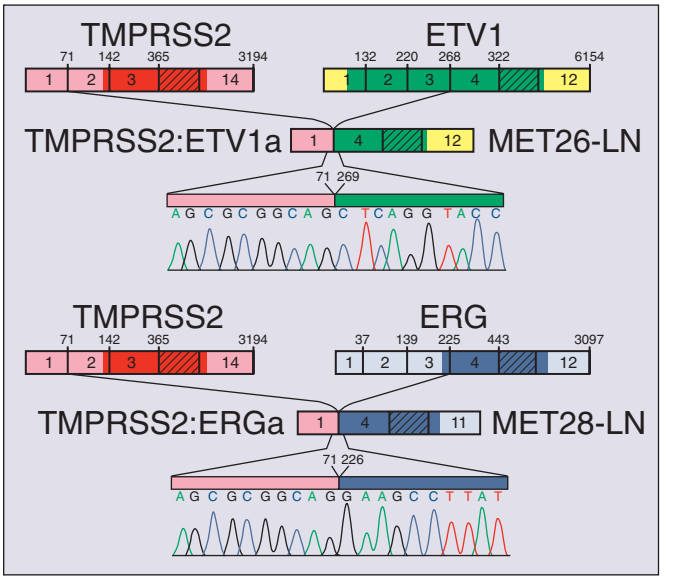

Figure 88-7 • Fusion of transcripts from the androgen-regulated *TMPRSS2* gene and ETS family genes *ETV1* and *ERG* in prostate cancers. (Adapted from Tomlins SA, Rhodes DR, Perner S, et al: Recurrent fusion of TMPRSS2 and ETS transcription factor genes in prostate cancer. Science 2005;310:644–648).

present in prostate cancer cells. For more than 90% of prostate cancer cases, this absence of GSTP1 expression in prostate cancer cells can be attributed to hypermethylation of *GSTP1* CpG island sequences, a somatic genome change that prevents *GSTP1* transcription. Absence of GSTP1 expression and *GSTP1* CpG island hypermethylation also may be characteristic of cells comprising PIN lesions, thought to be precursors to prostate cancer.[115] The mechanism by which hypermethylated *GSTP1* CpG island alleles arise during prostatic carcinogenesis remains to be elucidated. Nonetheless, prostate cells carrying inactivated *GSTP1* genes appear to enjoy some sort of selective growth advantage early during the development of prostate cancer.

NKX3.1 encodes a prostate-specific homeobox gene essential for normal prostate development that may be a target for somatic loss on chromosome 8p21.[116] NKX3.1 has been shown to bind DNA and to repress *PSA* expression via interactions with ETS transcription factors.[117,118] Mice carrying one or two disrupted *Nkx3.1* alleles manifest prostatic epithelial hyperplasia and dysplasia.[119,120] In men, loss of 8p21 DNA sequences occurs early during prostatic carcinogenesis, with 63% of PIN lesions and more than 90% of prostate cancers showing loss of heterozygosity at polymorphic 8p21 marker sequences in one report.[121] However, although mapping studies have indicated that *NKX3.1* lies within a common region of deletion, encompassing two megabases at 8p21, molecular pathology analyses have not yet established *NKX3.1* as a somatic target for inactivation during prostatic carcinogenesis because somatic *NKX3.1* mutations have not been identified. Nonetheless, loss of NKX3.1 expression does appear to accompany prostate cancer progression.

PTEN, a tumor suppressor gene encoding a phosphatase active against both proteins and lipid substrates, appears to be a common target for somatic alteration during prostate cancer progression.[122–129] PTEN is an inhibitor of the phosphatidylinositol 3′-kinase/protein kinase B (PI3K/Akt) signaling pathway needed for cell cycle progression and cell survival. Although PTEN is expressed by normal prostate epithelial cells, and by cells present in PIN lesions, the expression of PTEN is often diminished in prostate cancers, with many prostate cancers containing collections of neoplastic cells with no PTEN.[130] *PTEN* defects have been found in a wide variety of cancers and cancer cell lines.[124] For prostate cancer, a number of somatic *PTEN* alterations have been reported, including homozygous deletions, loss of heterozygosity, mutations, and probable CpG island hypermethylation. However, despite common losses of 10q sequences near *PTEN* in prostate cancers, somatic mutations at the remaining *PTEN* alleles are not as frequent. In a study of prostate cancer metastases recovered at autopsy, somatic *PTEN* alterations were even more common than in primary prostate cancers, and a significant heterogeneity in *PTEN* defects in different metastatic deposits from the same patient was also evident.[129] Haploinsufficiency for *PTEN* may contribute to the phenotype of transformed cells in the prostate. *Pten*$^{+/-}$ mice display prostatic hyperplasia and dysplasia, and crosses of *Pten*$^{+/-}$ mice with *Nkx3.1*$^{+/-}$ mice have revealed that *Pten*$^{+/-}$*kx3.1*$^{+/-}$ mice and *Pten*$^{+/-}$ *kx3.1*$^{-/-}$ mice develop lesions reminiscent of human PIN.[131–133]

Defective regulation of p27, a cyclin-dependent kinase inhibitor encoded by *CDKN1B*, also may accompany prostatic carcinogenesis.[134,135] In PIN cells and prostate cancer cells, p27 levels almost always are diminished, although the mechanism(s) for the reduction in p27 levels appear complex: somatic loss of DNA *CDKN1B* sequences at 12p12–13 has been reported for only 23% of localized prostate cancers, 30% of prostate cancer lymph node metastases, and 47% of distant prostate cancer metastases.[136] In place of *CDKN1B* gene alterations, p27 polypeptide levels may be lowered indirectly by inadequate PTEN repression of the PI3K/Akt signaling pathway.[137–139] In this way, low p27 levels may be as much a result of loss of PTEN function as of *CDKN1B* alterations. The critical contribution of PTEN to epithelial growth regulation in the prostate is evident in mice, where disruption of *Cdkn1b* alleles leads to prostatic hyperplasia, and *Pten*$^{+/-}$*dkn1b*$^{-/-}$ mice develop prostate cancer by 3 months of age.[134,140]

Metastatic prostate cancer almost always is treated with androgen deprivation, anti-androgens, or a combination of androgen deprivation and anti-androgens.[141,142] However, despite such treatment, androgen-independent prostate cancer cells eventually emerge and progress to threaten life. Curiously, in these cells, androgen receptor expression and androgen receptor signaling remain intact despite the absence of androgens.[21,143] Somatic alterations of *AR* have been reported for many prostate cancers, especially for androgen-independent prostate cancers. *AR* amplification, accompanied by high-level expression of androgen receptors, may promote the growth of androgen-independent prostate cancer cells by increasing the sensitivity of the cells to low androgen levels.[144] *AR* mutations encoding androgen receptors with altered ligand specificity also have been detected; for some of the mutant androgen receptors, even anti-androgens can act as agonist ligands.[145–147] When 44 mutant androgen receptors from prostate cancers were evaluated for transcriptional regulatory capabilities, 16% of the receptors had lost transcriptional activation activity, 45% of the receptors had gained some transcriptional regulatory ability, 32% of the receptors maintained some partial transcriptional modulatory activity, and the remaining 7% behaved like wild-type receptors.[148] In addition to somatic *AR* gene changes, androgen-independent prostate cancer cells with wild-type androgen receptors may activate androgen receptor signaling even in the absence of androgens, via post-translational modifications of the androgen receptor and/or androgen receptor co-activators in response to other growth factor signaling pathways.[21,149–152]

Changes in Gene Expression in Prostate Cancers

Alterations in gene expression in prostate cancers have been catalogued using cDNA microarray technologies.[153–164] Among the many genes exhibiting over- or underexpression in prostate cancers, the products of at least two genes appear consistently increased, and the product of a third gene appears to become elevated during androgen-independent progression. Hepsin, located at 19q11–13.2, encodes a transmembrane serine protease, expressed at high levels in many normal tissues.[165] Hepsin may contribute to prostate cancer progression: forced overexpression of hepsin in mouse prostates leads to disorganization of the epithelial basement membrane and increased metastasis.[166] α-Methylacyl-CoA racemase (AMACR), a mitochondrial and peroxisomal enzyme that acts on pristanoyl-CoA and C27-bile acyl-CoA substrates to catalyze the conversion of *R*- to *S*-stereoisomers in order to permit metabolism by β-oxidation, has been reported to be overexpressed in almost all prostate cancers.[167,168] Germline *AMACR* mutations lead to adult-onset neuropathy.[169] Immunohistochemistry studies, which have revealed that AMACR occasionally is present in normal prostate cells, increased in PIN cells, and further elevated in prostate cancer cells, have prompted the use of antibodies against AMACR as tools for prostate cancer diagnosis by surgical pathologists.[168,170] The polycomb protein enhancer of zeste homolog 2 (EZH2), a transcriptional regulatory protein, is elevated in metastatic androgen-independent prostate cancer.[171] The mechanism by which EZH2 contributes to prostate cancer progression has not been established. However, elevated EZH2 expression in primary prostate cancers portends a poor prognosis.[171]

Telomere Shortening During Prostatic Carcinogenesis

Telomeres, containing repeat DNA sequences at the termini of chromosomes, protect against loss of chromosome sequences during genome replication. DNA ends tend to shorten each generation as a consequence of bidirectional DNA synthesis (the "end-replication" problem); the telomere repeat sequences serve as templates for the enzyme telomerase, which can extend the chromosome termini and maintain chromosome integrity through cell division.[172] Growth dysregulation accompanying the development of most human cancers

tends to lead to cell proliferation in the absence of telomerase, and to shortened chromosome telomeres.[173] Critically shortened telomere sequences may promote genome instability by increasing illegitimate DNA recombination.[174,175] Mice carrying disrupted genes needed for a functioning telomerase show increased numbers of cancers, especially when crossed to mice with defective *p53* genes.[176] In the prostate, short telomere repeat sequences appear characteristic of cells in both PIN lesions and prostate cancer.[177–179] At some point, most cancer cells activate the expression of telomerase, providing some maintenance of chromosome termini. Telomerase expression has been detected in prostate cancers, but not at high levels in normal prostate tissues or in BPH.[177]

PREVENTION OF PROSTATE CANCER

The high lifetime risks of prostate cancer development, the morbidities associated with treatment of established prostate cancer, and the inability to eradicate life-threatening metastatic prostate cancer offer compelling reasons for prostate cancer prevention. In addition, epidemiology data, indicating a dominant role for lifestyle factors in prostate cancer development, suggest that prostate cancer risk modification may be feasible, if only through lifestyle modification. Also, because prostatic carcinogenesis takes many decades, there may be a broad window of opportunity to make lifestyle changes in an effort to retard prostate cancer development. Clearly, although the specific lifestyle factors fostering prostate cancer development have not been conclusively identified, it is likely that consumption of a diet rich in fruits, vegetables, and antioxidant micronutrients, and poor in saturated fats and "well-done" red meats, may significantly reduce risks of prostate cancer development, and of the development of other diseases characteristic of life in the developed world. Nonetheless, as the etiology of prostate cancer is better understood, new opportunities for prostate cancer prevention will arise. For example, if prostate inflammation contributes to prostate cancer development, anti-inflammatory drugs might be considered candidate prostate cancer prevention drugs. For drugs to be developed and tested for prostate cancer prevention, randomized clinical trials, capable of assessing both drug safety and drug efficacy, will be required.[180] Ideally, such trials can be targeted at men with a high risk for prostate cancer development, analogous to women thought to be at high risk for breast cancer development identified by the Gail model.[181] Thus far, two classes of agents, 5α-reductase inhibitors and antioxidant micronutrients, have been subjected to large randomized clinical trials.

Prostate Cancer Prevention Trial

In the Prostate Cancer Prevention Trial (PCPT), the propensity for the type 2 5α-reductase inhibitor finasteride to reduce the prevalence of prostate cancer in healthy men age 55 years and older when given for 7 years was tested.[57] Finasteride, which has been marketed both for BPH and for alopecia, was known to have few worrisome side effects and to lower the serum PSA in some men with prostate cancer.[182,183] Also, 5α-reductase inhibitors had shown promising activity in preventing prostate cancer development and/or prostate cancer progression in animal models.[184–186] However, the effects of finasteride on prostate cancer development in various clinical trials have not been as encouraging. In one randomized placebo-controlled trial, in which finasteride was used to treat BPH ($N = 3040$), 4.7% of men treated with finasteride and 5.1% of men treated with placebo ultimately were diagnosed with prostate cancer ($P = 0.7$).[187] In another randomized trial ($N = 52$), 30% of men with an elevated serum PSA but no cancer on an initial prostate biopsy who were given finasteride for 12 months had cancer on a subsequent prostate biopsy versus 4% of men who did not receive finasteride.[188] In this small trial, finasteride also had little beneficial activity in men with PIN.[188] For PCPT, 18,882 men with a PSA of 3.0 ng/mL or less and a normal digital rectal examination were randomized to treatment with finasteride (5 mg/day) or to placebo.[57] While on-study, men with a PSA elevation or an abnormal rectal examination were subjected to prostate biopsy; in addition, at the end of the treatment period, a prostate biopsy was planned for all of the men in the trial. The Data and Safety Monitoring Committee for PCPT closed the study 15 months before the anticipated completion, with some 9060 men evaluable for the presence of prostate cancer.[57] Prostate cancer was detected in 18.4% of the men treated with finasteride versus 24.4% of men receiving placebo ($P < 0.001$).[57] Of concern, however, high-grade prostate cancers appeared more commonly associated with finasteride treatment than with placebo (6.4% versus 5.1%).[57] This may mean that finasteride prevents or treats low-grade cancers better than high-grade cancers. Also, some 37% of men treated with finasteride, versus 29% of men receiving placebo ($P < 0.001$), discontinued treatment, usually citing side effects of reduced ejaculate volume, erectile dysfunction, loss of libido, and gynecomastia.[57] These mixed results—a reduction in overall prostate cancer prevalence, but an increase in high-grade prostate cancers—associated with finasteride treatment make recommendations for healthy men who want to reduce their prostate cancer risks very difficult. A large clinical trial testing the effects of dutasteride, an inhibitor of both type 1 and type 2 5α-reductases used to treat BPH, on prostate cancer development is ongoing.[189]

Selenium and Vitamin E Cancer Prevention Trial

Epidemiologic studies have provided compelling evidence that intake of selenium and of vitamin E might diminish prostate cancer risks.[190–196] In addition, two clinical trials have provided further evidence for protection against prostate cancer through consumption of these antioxidant micronutrients.[77–79,112,197] In one of the studies, men and women ($N = 1312$) with a history of nonmelanoma skin cancer received 200 μg selenized brewer's yeast or a placebo daily to ascertain whether selenium consumption might decrease the risk of a second skin cancer.[78] Although selenium supplementation failed to prevent new skin cancers, a reduced risk of prostate cancer was noted for men receiving selenium supplements, particularly men with low baseline selenium levels.[77,78,197] In the other study, α-tocopherol, β-carotene, the combination of α-tocopherol and β-carotene, or placebo was administered to male smokers ($N = 29,133$) in Finland for lung cancer prevention.[112] Again, although neither of the supplements appeared to prevent lung cancer, a reduced risk of prostate cancer was evident for men receiving α-tocopherol.[79,112]

A prospective, randomized, placebo-controlled clinical trial of selenium and vitamin E, the Selenium and Vitamin E Cancer Prevention Trial (SELECT; $N > 32,400$) was initiated in 2001 to test the ability of the antioxidant micronutrients to prevent prostate cancer.[198] Selenium (200 μg selenomethionine), α-tocopherol (400 mg), the combination of selenium and α-tocopherol, or neither, will be given to men randomized to four different treatment groups, using a 2×2 factorial design, for 7 to 12 years.[198] The trial subjects will be men, age 55 years or older (50 years or older for African Americans), with an unremarkable digital rectal examination and a serum PSA of 4 ng/mL or less.[198] Until the SELECT results are available, it will be difficult to make definitive recommendations about micronutrient supplementation to prevent prostate cancer. Nonetheless, the limited data available from epidemiology studies and early clinical trials suggest that men with low blood levels of the micronutrients tend to be at the highest risk for prostate cancer development, and that micronutrient supplementation might be most effective at preventing prostate cancer if given to such men.[191,192,196,197] For this reason, perhaps a supplementation strategy designed to correct antioxidant micronutrient deficiencies might ultimately prove generally safe and effective. The risks and benefits of high doses of antioxidant micronutrients, or other supplements, are not known.

PROSTATE CANCER SCREENING, DIAGNOSIS, AND STAGING

Clinical Evaluation

The staging system for prostate cancer includes the results of histopathology analysis and of imaging studies in the stage assignment (Table 88-1).

Prostate cancer rarely causes symptoms early in the course of the disease, because most of the adenocarcinomas arise in the periphery of the gland (the peripheral zone) distant from the urethra. The presence of symptoms attributable to prostate cancer suggests locally advanced or metastatic disease. With progressive growth of prostate cancer into the urethra, or into the bladder neck, lower urinary symptoms of obstruction (e.g., urinary hesitancy, decreased force of urine stream, intermittency) and irritation (e.g., urinary frequency, nocturia, urgency, urge incontinence) can occur. Local progression of prostate cancer and obstruction of the ejaculatory ducts can result in hematospermia and a decrease in the ejaculate volume. Extension of prostate cancer outside the prostate capsule can damage the branches of the pelvic plexus (neurovascular bundle) responsible for innervation of the corpora cavernosa and cause erectile dysfunction.

Metastatic cancer involving the axial or appendicular skeleton can lead to bone pain, or, via replacement of the bone marrow, can cause pancytopenia. Lower extremity edema can result from cancerous involvement of the pelvic lymph nodes and compression of the iliac veins. Less common consequences of metastatic disease include malignant retroperitoneal fibrosis from dissemination of cancer cells along the periureteral lymphatics, paraneoplastic syndromes from ectopic hormone production by small cell variants of adenocarcinoma, and disseminated intravascular coagulation (DIC).

Although men with prostate cancer can present with voiding symptoms suggesting locally advanced cancer, or with signs and symptoms suggesting metastatic cancer, currently more than 90% of men diagnosed with prostate cancer are initially detected as a result of digital rectal examination (DRE) abnormalities or of serum PSA elevations.

Digital Rectal Examination

In men with early-stage prostate cancers, physical findings, if present, usually are limited to an abnormal DRE, used for both diagnosis and staging. Palpable areas of induration, or asymmetric firmness of the gland, suggest the presence of prostate cancer, but these findings can also be caused by prostate inflammation (especially granulomatous prostatitis), by BPH, and by prostatic stones. DRE has only fair reproducibility in the hands of experienced examiners.[199] When used alone for detection of prostate cancer, DRE misses 23% to 45% of the cancers that are subsequently detected by prostate biopsies done for serum PSA elevations or for transrectal ultrasound (TRUS) abnormalities.[200–202] In addition, prostate cancers detected by DRE are at an advanced pathological stage in more than 50% of men.[203,204]

The positive predictive value of DRE (the fraction of men who have prostate cancer if the DRE is abnormal) depends on age, race, and PSA level.[205,206] African-American race, older age, and higher PSA levels are associated with a higher positive predictive value for DRE.[206] The positive predictive value of a suspicious DRE was 5%, 14%, and 29% in white men, and 8%, 37%, and 50% in black men with PSA levels of 0 to 1.0, 1.1 to 2.5, and 2.6 to 4.0 ng/mL, respectively (Table 88-2). The positive predictive value of a suspicious DRE ranged from 33% to 83% in men with PSA levels of 3.0 to 9.9 ng/mL or more.[200–202,207–211] A prostate biopsy usually is recommended for men with an abnormality on DRE that is suspicious for prostate cancer, regardless of the PSA level.

Serum Prostate-Specific Antigen

PSA is a member of the human kallikrein gene family of serine proteases encoded by genes located on chromosome 19.[212] A component

Table 88-1 TNM and AUA Staging Systems for Prostate Cancer

TNM STAGING SYSTEM

PRIMARY TUMOR (T)

- TX Primary tumor cannot be assessed.
- T0 No evidence of primary tumor
- T1 Clinically inapparent tumor neither palpable nor visible by imaging
  - T1a Tumor incidental histologic findings in ≤5% of tissue resected
  - T1b Tumor incidental histologic finding in >5% of tissue resected
  - T1c Tumor identified by needle biopsy (e.g., because of elevated PSA)
- T2 Tumor is confined within prostate.*
  - T2a Tumor involves one half of a lobe or less
  - T2b Tumor involves more than one half of lobe, but not both lobes
  - T2c Tumor involves both lobes†
- T3 Tumor extends through the prostate capsule.
  - T3a Unilateral extracapsular extension
  - T3b Bilateral extracapsular extension
  - T3c Tumor invades seminal vesicle(s)
- T4 Tumor is fixed or invades adjacent structures other than seminal vesicles.
  - T4a Tumor invades bladder neck, external sphincter, or rectum.
  - T4b Tumor invades levator muscles or is fixed to pelvic wall, or both.

NODE (N)

- NX Regional lymph nodes cannot be assessed.
- N0 No regional node metastasis
- N1 Metastasis in single lymph node, ≤2 cm
- N2 Metastasis in a single node, >2 cm but ≤5 cm
- N3 Metastasis in a node >5 cm

METASTASIS (M)

- MX Presence of metastasis cannot be assessed.
- M0 No distant metastasis
- M1 Distant metastasis
  - M1a Nonregional lymph node(s)
  - M1b Metastasis in bone(s)
  - M1c Metastasis in other site(s)

AUA STAGING SYSTEM

STAGE A: CLINICALLY UNSUSPECTED DISEASE

- A1 Focal carcinoma, well differentiated
- A2 Diffuse carcinoma, usually poorly differentiated

STAGE B: TUMOR CONFINED TO PROSTATE GLAND

- B1 Small, discrete nodule of one lobe of gland
- B2 Large or multiple nodules or areas of involvement

STAGE C: TUMOR LOCALIZED TO PERIPROSTATIC AREA

- C1 Tumor outside prostate capsule, estimated weight ≤70 g, seminal vesicles uninvolved
- C2 Tumor outside prostate capsule, estimated weight >70 g, seminal vesicles involved

STAGE D: METASTATIC PROSTATE CANCER

- D1 Pelvic lymph node metastases or ureteral obstruction causing hydronephrosis, or both
- D2 Bone, soft tissue, organ, or distant lymph node metastases

AUA, American Urological Association; PSA, prostate-specific antigen; TNM, tumor-node-metastasis.

*Invasion into the prostatic apex or into (but not beyond) the prostatic capsule is classified as T2, not as T3.

†Tumor found in one or both lobes by needle biopsy but not palpable or visible by imaging is classified as T1c.

Table 88-2 Positive Predictive Value of DRE and PSA in a Multicenter Screening Trial

DRE	PSA	PPV (%)
Abnormal	Any	21.4
Any	PSA >4	31.5
	4–10	26.1
	>10	52.9
Normal	PSA >4	24.4
Abnormal	PSA <4	10.0
	4–10	40.8
	>10	69.1

DRE, digital rectal examination; PPV, positive predictive value; PSA, prostate-specific antigen.

Data from Catalona WJ, Richie JP, Ahmann FR, et al: Comparison of digital rectal examination and serum prostate specific antigen in the early detection of prostate cancer: results of a multicenter clinical trial of 6,630 men. J Urol 1994;151:1283.

of the ejaculate, PSA is produced by columnar secretory cells in the prostate. PSA expression is regulated by androgens, becoming detectable in serum at puberty accompanying increases in luteinizing hormone and testosterone. In the absence of prostate cancer, serum PSA levels increase with age and prostate volume and usually are higher in African-American men. Cross-sectional population data suggest that the serum PSA increases 4% per mL of prostate volume, and that 30% and 5% of the variance in PSA can be accounted for by prostate volume and age, respectively.[213]

Serum PSA elevations likely occur as a result of disruption of the normal prostate architecture, permitting PSA to diffuse into the prostate parenchyma and gain access to the circulation. This can occur in the setting of both benign and malignant prostate diseases (prostatitis, BPH, and prostate cancer) and as a result of prostate manipulation (prostate massage and prostate biopsy).[214] Although the presence of some type of prostate disease is the most important determinant driving elevation of the serum PSA, an increased serum PSA *is not specific for prostate cancer*. Furthermore, not all men with prostate disease have elevated serum PSA levels.

Treatments targeting the prostate gland (for BPH or for prostate cancer) can lower serum PSA by decreasing the number of prostatic epithelial cells capable of producing PSA, and by decreasing the amount of PSA produced by each cell. Modulation of sex steroid hormone levels for treatment of BPH or prostate cancer, radiation therapy for prostate cancer, and surgical ablation of prostate tissue for BPH or prostate cancer can all lead to decreases in serum PSA. 5α-reductase inhibitor such as finasteride and dutasteride lower PSA levels by 50% after 12 months of treatment.[215] Thus, for men treated with these agents for 12 months or more, the serum PSA level should be doubled to estimate the "true" PSA value. Interpretation of serum PSA values should always take into account the presence of prostate disease, previous diagnostic procedures, and prostate-targeted treatments.

Numerous studies have documented the validity of serum PSA testing as a strategy for assessing the risk that prostate cancer is present. Routine use of serum PSA testing increases the detection of prostate cancer over that of DRE, improves the predictive value of the DRE for cancer, and leads to detection of prostate cancers at an early stage. The lead time (time by which a cancer diagnosis is advanced) with PSA screening has been estimated to be, on average, ~10 years.[216,217] As a result of the lead time associated with PSA screening, most men today are diagnosed with early-stage disease that is considered appropriate for curative intervention with radiation or surgery. The extent to which PSA screening has contributed to the decline in prostate cancer mortality that began in the early 1990s, and whether early detection of prostate cancer does more harm than good, are being debated.[218]

The serum PSA value is correlated directly with prostate cancer risk.[201] Gann and coworkers first showed that the risk of a cancer diagnosis increases incrementally and directly with PSA over the decade after a baseline measurement, even at low PSA levels (below 4.0 ng/mL), a finding that has now been confirmed by many others, including recent data from the PCPT.[219,220] These observations emphasize that the serum PSA should be used not as a dichotomous test, but rather as a test that represents a continuum of prostate cancer risk. The probability that prostate cancer is present varies according to PSA and DRE results (see Table 88-2).

The most effective method for early detection of prostate cancer is the combined use of DRE and serum PSA testing. When DRE and the serum PSA are used as screening tests for prostate cancer, detection rates are higher with serum PSA determinations than with DRE alone, and highest with a combination of both tests. Because DRE and serum PSA determinations are not always simultaneously abnormal in the presence of prostate cancer, the tests are complementary when used for prostate cancer detection. Experts disagree on the use of DRE for screening when PSA levels are very low, because in that setting, the DRE has a relatively poor positive predictive value.

The widespread use of PSA for early detection of prostate cancer has stimulated efforts to improve the sensitivity (i.e., the percentage of men correctly identified as having prostate cancer among those with the disease) and specificity (i.e., the percentage of men correctly identified as free of prostate cancer among those without the disease) of the test. Altering the serum PSA threshold value used to trigger prostate biopsy, adjusting the PSA level for the prostate volume (the PSA "density"),[221–228] monitoring the rate of change in serum PSA values over time (the PSA "velocity"),[229–231] and the selective assay of various molecular forms of PSA in the serum[232,233] have all been evaluated as methods of distinguishing prostate cancer from BPH and other prostate diseases.

Prostate-Specific Antigen Threshold for Prostate Biopsy

The choice of a serum PSA threshold value or "cut-point," above which further evaluation to rule out prostate cancer (by prostate biopsy) should be recommended historically has been a controversial issue. However, it is now widely recognized that there is virtually no serum PSA value below which prostate cancer, even an aggressive-appearing prostate cancer, can be excluded as a diagnosis.[234] Thus, there has been a greater emphasis on using serum PSA testing as part of a risk assessment algorithm that might include age, race, PSA velocity, etc.[235,236] Physicians should discuss the likelihood of a prostate cancer diagnosis, given the serum PSA level and these other factors, with those men who have chosen to undergo serum PSA testing before recommending further evaluation.

Prostate-Specific Antigen "Density"

The major source of serum PSA in men without prostate cancer is the transition zone (TZ) epithelium, not the epithelium of the peripheral zone.[237] Since BPH represents an enlargement of the transition zone, and since serum PSA levels are largely a reflection of transition zone volume in men with BPH, adjusting the serum PSA for either prostate volume (PSA density) or more specifically, the transition zone volume (PSA-TZ), has been shown to improve the detection of prostate cancer (Table 88-3). Volume adjustment of the serum PSA value is used most often to determine the need for a repeat biopsy in men with a prior negative biopsy, a clinical setting in which a missed cancer is suspected because of a persistently elevated serum PSA.[238]

Prostate-Specific Antigen "Velocity"

Carter and colleagues,[229] using frozen serum samples from an aging study cohort, demonstrated that PSA "velocity" (PSAV; the rate of

Table 88-3 Age-Specific Reference Ranges for Serum PSA and PSA Density

Age Range (yr)	Serum PSA (ng/mL)	PSA Density (ng/mL)
40–49	0.0–2.5	0.0–0.10
50–59	0.0–3.5	0.0–0.12
60–69	0.0–4.5	0.0–0.14
70–79	0.0–6.5	0.0–0.16

PSA, prostate-specific antigen.

Data from Osterling J, Jacobsen S, Klee G, et al: Free, complexed, and total serum prostate specific antigen: the establishment of appropriate reference ranges for their concentrations and ratios using newly developed immunofluorometric assays (IFMA). J Urol 1995;154:1090, with permission.

change of serum PSA in ng/mL per year on repeated testing) was higher among men destined to be diagnosed with prostate cancer, even at a time when serum PSA levels could not distinguish between men with and without the disease (Fig. 88-8). For men with serum PSA levels between 4.0 and 10.0 ng/mL at 5 years before prostate cancer diagnosis, a PSAV of 0.75 ng/mL per year or greater had a specificity of 90% percent for distinguishing men with prostate cancer in the setting of BPH, and a specificity of 100% for distinguishing men with prostate cancer and no BPH. Not only has PSAV been shown to be higher among men with prostate cancer when compared to men without prostate cancer, but PSAV also has been found to be higher in men with high-grade and high-stage prostate cancer as compared with men with lower-grade and lower-stage disease.[239,240] Furthermore, men with a PSAV above 2.0 ng/mL per year in the year before a diagnosis of prostate cancer were at an increased risk of prostate cancer death after surgical intervention when compared with men with a PSAV of 2.0 ng/mL per year or less.[241] Even when PSAV was measured 10 to 15 years before prostate cancer diagnosis (when most men had PSA levels below 4.0 ng/mL), a PSAV less than 0.35 ng/mL per year was associated with a prostate cancer-specific survival 25 years later of 92% (with a 95% confidence interval of 84% to 96%), while a PSAV greater than 0.35 ng/mL per year was associated with a prostate cancer-specific survival of 54% (with a 95% confidence interval of 15% to 82%, $P < 0.001$). All of these data suggest that PSAV is a marker of life-threatening prostate cancer and may be useful as part of the algorithm for determining the need for a prostate biopsy, rather than using absolute serum PSA levels alone.

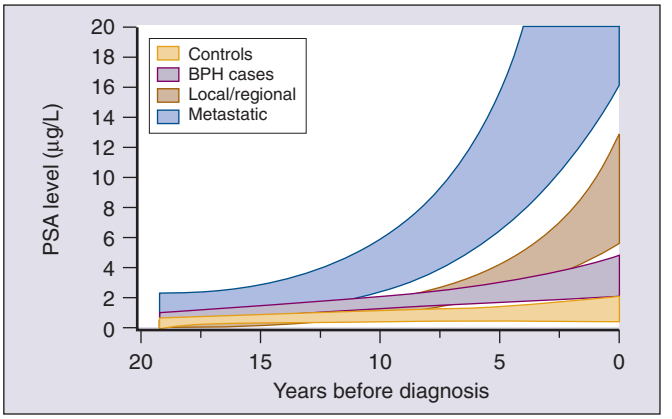

Figure 88-8 • Longitudinal increases in serum prostate-specific antigen (PSA) levels in men with and without prostate cancer. BPH, benign prostatic hypertension. (From Fromter HB, Pearson JD, Metter EJ, et al: Longitudinal evaluation of prostate-specific antigen levels in men with and without prostate disease. JAMA 1992;267:2215.)

Molecular Forms of Prostate-Specific Antigen

PSA in the bloodstream circulates in both bound and unbound forms. Most of the detectable PSA in the serum (65%–90%) is bound to α_1-anti-chymotrypsin, while the rest (10%–35%) remains unbound or "free."[212] The assays primarily used for prostate cancer detection and monitoring detect both "free" and "complexed" PSA, providing a determination of the "total" serum PSA. Newer assays that can distinguish "free" and "complexed" serum PSA have more recently been developed and approved by the U.S. Food and Drug Administration (FDA) for use in the early detection of prostate cancer.

In general, men with prostate cancer have a greater fraction of serum "total" PSA that is bound to α_1-anti-chymotrypsin, and a commensurately lower fraction of "total" PSA that is "free," than men without prostate cancer. This difference is thought to be due to the differential expression of PSA isoforms by cells in the transition zone (the zone of origin for BPH) tissue as compared with peripheral zone (the zone where most prostate cancers arise) tissue.

The percentage of "free" serum PSA appears most useful in distinguishing between men with and without prostate cancer in the setting of "total" serum PSA levels between 2 and 10 ng/mL (Table 88-4). Most urologists use "free" serum PSA determinations to help make decisions about the need for a repeat biopsy in a man with a persistently elevated serum PSA and previous negative prostate biopsies, where the possibility of a missed prostate cancer may be a concern. Measurement of "complexed" serum PSA, using a single assay, has been promoted by some investigators as a better method for assessing prostate cancer risk, in place of the two assays ("total" serum PSA and "free" serum PSA) needed for determination of percent "free" serum PSA.

Transrectal Ultrasound-Guided Prostate Biopsy

Transrectal ultrasound (TRUS) is not an accurate method for localizing early prostate cancer and is not recommended for use in prostate cancer screening. The primary role of TRUS in prostate cancer detection and diagnosis is to ensure accurate sampling of prostate tissue by prostate biopsies in men suspected of harboring cancer based on serum PSA levels and DRE.[242] This is best accomplished by targeting peripheral zone lesions that appear hypoechoic by TRUS for biopsy, along with performing systematic sampling biopsies of areas without hypoechoic lesions in the prostate periphery.

TRUS-guided prostate biopsies are performed routinely with an 18-gauge needle fired from a spring-loaded gun through a port mounted on the TRUS probe. Most commonly, in preparation for a biopsy procedure, men are administered a fluoroquinolone antibiotic and given a cleansing enema. Most urologists inject a local

Table 88-4 Probability of Cancer Based on PSA and Percent of FPSA Results

PSA (ng/mL)	Probability of Cancer (%)	FPSA (%)	Probability of Cancer (%)
0–2	1	0–10	56
2–4	15	10–15	28
4–10	25	15–20	20
>10	>50	20–25	16
		>25	8

FPSA, free prostate-specific antigen; PSA, prostate-specific antigen.

Men with nonsuspicious digital rectal examination results, any age: % FPSA can stratify risk for men with PSA of 4–10 ng/mL.

Data from Catalona WJ, Partin AW, Slawin KM, et al: Use of the percentage of free prostate-specific antigen to enhance differentiation of prostate cancer from benign prostatic disease: a prospective multicenter clinical trial. JAMA 1998;279:1542.

anesthetic around the periphery of the prostate to reduce discomfort associated with prostate biopsy. Major complications, such as bleeding and/or infection requiring hospitalization, are rare, although hematuria and hematospermia are common sequelae of the procedure.

The optimal biopsy technique, including the number and placement of biopsies for tissue procurement that will minimize the chance of missing a relevant cancer, remains controversial. Nonetheless, the best evidence available suggests that biopsies placed more laterally within the peripheral zone of the prostate may be important to exclude prostate cancer in men with elevated serum PSA values and a nonsuspicious DRE.

Screening for Prostate Cancer

There are legitimate concerns about population screening of asymptomatic men using PSA and DRE, despite the 30% decline in prostate cancer mortality between 1993 and 2003 (*http://seer.cancer.gov/faststats/*) that has been attributed in part to PSA testing.[218]

First, the lifetime risk (from age 0 to 90 years) of death from prostate cancer is 3%, and the lifetime risk of a diagnosis of prostate cancer is 17%. Thus, in the absence of markers that accurately identify those men who have life-threatening cancers, screening will result in the overdiagnosis (i.e., detection of a cancer through screening that would have otherwise remained clinically silent) and over-treatment of some men. In a recent observational study of men over age 65 years who were detected with low to intermediate risk prostate cancer in the PSA testing era, the findings suggested that 200 men would need to be treated over 12 years to prevent 1 prostate cancer death.[243] Remarkably, even though competing causes of death reduce the benefits of screening and treatment among older men, rates of screening in the elderly are higher than the rates of screening among younger men.[244] Second, screening for prostate cancer in asymptomatic men results in false-positive results prompting unnecessary prostate biopsies, and treatment of prostate cancer, by any means, can result in unwanted side effects—a poor tradeoff if the treatment results in no benefit in terms of years of life saved. Third, the costs of screening may not be justified if the societal harm of diagnosis and treatment are far greater than any health benefits obtained. All of these as yet incompletely addressed issues are considerations of any screening program and not unique to prostate cancer screening.

The PLCO (Prostate, Lung, Colon, Ovary) Trial of the National Cancer Institute and the ERSPC (European Randomized Study of Screening for Prostate Cancer) are ongoing randomized trials designed to address whether or not prostate cancer screening reduces prostate cancer mortality. At this time, no organization endorses universal or mass screening for prostate cancer (Box 88-2). The U.S. Preventive Services Task Force concluded that the evidence is insufficient to recommend for or against routine screening for prostate cancer using PSA testing or DRE.[245] This conclusion was based on good evidence that PSA testing can lead to the detection of prostate cancer at an early stage, but inconclusive evidence that early detection improves health outcomes. Specialty organizations such as the American Cancer Society (http://www.cancer.org/docroot/home/index.asp) and the American Urological Association recommend that prostate cancer screening with PSA and DRE be offered to all men over age 50 years and that the risks and benefits of screening be discussed with the patient. Although the value of PSA screening remains controversial, men who present for periodic health examinations should be made aware of the availability of the PSA test, so that they can make an informed decision about the need for routine screening. The general enthusiasm for screening in the United States suggests that most men will elect to be tested.[246]

Histopathology of Prostate Cancer

Microscopic analysis of prostate tissue by a surgical pathologist is needed for the diagnosis of prostate cancer, for determining prostate cancer stage after prostatectomy, and for histological grading, via the assignment of a Gleason score, to predict the behavior of prostate cancer (Table 88-5). Most prostate cancers are adenocarcinomas, although other types of cancers can appear. Most often, the diagnosis of prostate cancer is made using core needle biopsy specimens, which sample small amounts of prostate tissue. In many cases, needle biopsies contain only small numbers of prostate cancer cells among more plentiful noncancerous cells. Also, several prostate conditions, including acute, chronic, or granulomatous prostate inflammation, epithelial atrophy, and PIN, exhibit histological features that mimic some of those present in prostate cancers.[247] Thus, prostate cancers can be difficult to recognize in needle biopsy specimens, and difficult to distinguish from other prostate abnormalities. Most experienced prostate pathologists use a combination of architectural, cytological, and ancillary findings to make a diagnosis of prostate cancer on needle biopsy.[247–249] In addition, because normal prostate glands, but not glands present in prostate cancers, contain basal epithelial cells, immunohistochemical staining for basal epithelial cell markers, such as cytokeratins K5 and K14, can be used to help distinguish benign from malignant glands in prostate tissue samples. Also, immunohistochemical staining for AMACR, a prostate cancer biomarker discovered through cDNA microarray transcriptome profiling, can aid in prostate cancer diagnosis.[168,170,250] Neither of these immunohistochemistry reagents perfectly distinguishes prostate cancer: the absence of basal epithelial cell markers is not always diagnostic of prostate cancer, and AMACR expression is absent in some prostate cancers and present in PIN.[247] For all of these

Box 88-2. POPULATION SCREENING FOR PROSTATE CANCER

There is no proof yet that prostate-specific antigen (PSA) screening in asymptomatic men prevents prostate cancer deaths. Nonetheless, the use of serum PSA testing, along with digital rectal examination (DRE), to screen men for prostate cancer has been proven to detect prostate cancer at earlier stages. As a result, prostate cancers discovered by screening are more likely to be treated with curative intent via surgery or radiation therapy. The major concern about prostate cancer screening is the potential for overdiagnosis of prostate cancers that would be unlikely to pose a threat for morbidity or mortality. For these reasons, screening approaches for prostate cancer are still evolving, with the optimal screening test (serum PSA vs. other molecular forms of PSA), the optimal screening population (younger vs. older men), and the optimal screening interval yet to be determined.

Table 88-5 Cancer-Specific Mortality Rates*

	AGE (YR)			
Gleason Score	**50–59**	**60–64**	**65–69**	**70–74**
2–4	4%	5%	6%	7%
5	6%	8%	10%	11%
6	18%	23%	27%	30%
7	70%	62%	53%	42%
8–10	87%	81%	72%	60%

*Probability of dying of prostate cancer within 15 years of diagnosis in men with clinical stage prostate cancer treated conservatively.

Data from Albertsen PC, Hanley JA, Gleason DF, et al: Competing risk analysis of men aged 55 to 74 years at diagnosis managed conservatively from clinically localized prostate cancer. JAMA 1998;280:975.

reasons, second opinion interpretations of prostate biopsy findings, especially when foci of atypical glands suspicious for cancer are identified, are often helpful.

High-grade PIN, a lesion characterized by the proliferation of malignant-appearing prostate epithelial cells within the confines of otherwise normal glandular structures, is identified in about 5% of men subjected to prostate biopsies.[251,252] The evidence that high-grade PIN is a likely precursor to prostate cancer includes the findings that (1) high-grade PIN is more commonly present in prostates that also contain prostate cancer; (2) high-grade PIN and prostate cancer both tend to arise in the peripheral zone of the prostate and often are directly contiguous; and (3) high-grade PIN and prostate cancer express similar biomarkers and share many somatic genome abnormalities.[253,254] The notion that high-grade PIN lesions might be prostate cancer precursors has stimulated interest in possibly treating men with high-grade PIN to prevent prostate cancer.[254] Unfortunately, the natural history of individual high-grade PIN lesions is not known. Furthermore, high-grade PIN lesions, which can be recognized only by sampling prostate biopsies, are not easily monitored. These limitations have hindered the use of high-grade PIN as a response surrogate for cancer prevention drug development. Because high-grade PIN is not currently treated, the major significance of the finding of high-grade PIN, in the apparent absence of prostate cancer, by prostate biopsy is that prostate cancer may have been missed by the prostate sampling strategy used for the biopsy procedure. As serum PSA screening was first introduced, men with an elevated serum PSA and high-grade PIN by prostate biopsy seemed to have as high as a 50% chance of having prostate cancer when subjected to repeat prostate biopsies. With more widespread adoption of serum PSA screening strategies, for men with an elevated serum PSA, the chance that a second set of prostate biopsies will detect prostate cancer after an initial diagnosis of high-grade PIN on a first set of prostate biopsies has fallen to 23% to 35%, only slightly greater than the 20% chance that repeat prostate biopsies will detect prostate cancer even in the absence of an initial diagnosis of high-grade PIN.[255–257] Of interest, unlike prostate cancer, prostate inflammation, or BPH, PIN lesions are not thought to perturb prostate architecture enough to elevate the serum PSA. Recently, increasing attention has been afforded the notion that PIA lesions might be precursors to PIN and/or prostate cancer. Like PIN, PIA lesions tend to arise in the peripheral zone of the prostate, where prostate cancers arise, and some PIA cells acquire somatic genome alterations reminiscent of prostate cancer cells.[93,258] Currently, men with PIA lesions are not subjected to any kind of treatment, and the presence of PIA on an initial prostate biopsy is not thought to predict the detection of prostate cancer on repeat biopsy. The major significance of PIA in regard to the diagnosis of prostate cancer by prostate biopsy may be the propensity for such lesions occasionally to exhibit features that mimic prostate cancer.[247]

The most commonly used approach to histological grading of prostate cancer is Gleason scoring.[259] The Gleason grade refers to architectural prostate cancer patterns, numbered 1 (well-differentiated) to 5 (poorly differentiated). Because prostate cancers often are heterogeneous, Gleason scoring (sometimes referred to as the "combined" Gleason grade) is accomplished by adding the Gleason grade of the most abundant pattern to the Gleason grade of the second most abundant pattern (e.g., a Gleason score of 4 + 3 = 7). The Gleason score, when applied by an expert pathologist, is one of the best tools available for predicting the outcomes of men treated with radical prostatectomy or with radiation therapy; prostate cancers with Gleason scores of 8 to 10 are much more likely to recur after primary treatment than prostate cancers with Gleason scores of 2 to 6.[260,261] Furthermore, for prostate cancers with a Gleason score of 7, Gleason 4 + 3 = 7 appears more correlated with prostate cancer recurrence than Gleason 3 + 4 = 7. One challenge presented by Gleason grading is the variability in Gleason scores assigned to the same prostate cancers by different pathologists.[262,263] To address this challenge, Internet educational tools have been developed by expert pathologists to improve the fidelity of Gleason scoring by community pathologists.[264] Of note, since Gleason scoring applies pattern grades to the architecture of cancer within the prostate, metastatic prostate cancers detected by biopsies of metastatic deposits are not assigned a Gleason score.

Evaluation of the Extent of Prostate Cancer

The extent of prostate cancer is correlated with tumor stage, Gleason score (the sum of two Gleason grades), and serum PSA level.[265] Nomograms, incorporating clinical stage, estimated using DRE findings, the serum PSA level, and the Gleason score, have been shown to be capable of predicting both prostate cancer extent (when compared to the pathological stage evident at the time of prostate surgery) and the long-term outcome following primary tumor treatment.[266–268] D'Amico and associates[268] have suggested that men with prostate cancer can be stratified into low-risk (stages T1c to 2a, serum PSA <10 ng/mL, and Gleason score of ≤6), intermediate-risk (stage T2b, or serum PSA of 10–20 ng/mL, or Gleason score of 7), and high-risk (stage T2c, or serum PSA >20 ng/mL, or Gleason score of ≥8) groups, reporting that the fraction of men free of prostate cancer 10 years after radical prostatectomy is significantly different for the risk categories: 83% of men with low-risk prostate cancer, 46% of men with intermediate-risk prostate cancer, and 29% of men with high-risk prostate cancer. When undertaken before initiating prostate cancer treatment, risk stratification of men with prostate cancer aids in counseling such men about the expected outcome of aggressive local prostate cancer treatment, providing estimates of the chance that local treatments might be curative.

Radiographic Imaging

Although CT scanning is used routinely by radiation oncologists for prostate cancer treatment planning, no imaging technique available today has been proven to add additional useful information when used to evaluate the extent of prostate cancer in men with low and intermediate risk disease.[269] TRUS and MRI give the most accurate definition of prostatic architecture and anatomy, but current imaging technologies do not provide very precise assessments of cancer extent within the prostate or the presence of microscopic foci of prostate cancer that have escaped the confines of the prostate gland. Radionuclide bone scans detect metastatic prostate cancer in less than 1% of men with a serum PSA value less than or equal to 20 ng/mL and are not recommended for the initial evaluation of men with low or intermediate risk prostate cancer.[270] Positron emission tomography (PET) has not yet been found to be useful in the evaluation of men with prostate cancer and has no place in the prostate cancer staging.[271] New imaging technologies, including three-dimensional color Doppler, contrast-enhanced color Doppler, magnetic resonance spectroscopy, and high resolution MRI with magnetic nanoparticles, have great potential for improving the assessment of local and distant prostate cancer extent.[269,272] Cross-sectional imaging of the pelvis, by CT scan or MRI, for the purpose of detecting lymph node metastases, and radionuclide bone scans for the detection of bony metastases, should be reserved for men with high-risk prostate cancer.

^{111}In-capromab penditide, a radioimmunoconjugate featuring a monoclonal antibody to an intracellular domain of prostate-specific membrane antigen (PSMA; ProstaScint, Cytogen Corporation) has been approved by the FDA for use in the evaluation of men for treatment of clinically localized prostate cancer. There is some evidence that when ^{111}In-capromab pendetide immunoscintigraphy is used in combination with other pretreatment prostate cancer staging tools, the predictive value for presence of lymph node metastases increases.[273] However, this scan is not being used routinely today for assessment of prostate cancer extent, in large part because of frequent difficulties in scan interpretation, and because of the lack of scan sensitivity, even among men with fairly high-risk prostate cancer.

Serum Biomarker Assays and "Molecular" Staging

Increases in serum PSA and in serum prostatic acid phosphatase (PAP)[274] correlate directly with the extent (stage) of prostate cancer disease. As described earlier, the serum PSA is a useful tool for the preoperative assessment of prostate cancer extent, especially when considered along with other pretreatment parameters. Radioimmunoassays for PAP appear more sensitive, but less specific, than enzymatic assays, when used to detect serum PAP as a marker of advanced prostate cancer. Several studies have documented a correlation between the presence of advanced prostate cancer and elevations of serum PAP.[275–277] Elevated serum PAP values, and serum PAP levels in the upper half of the normal range, portend a high likelihood (>80%) of extra-prostatic cancer.[276,277] However, normal serum PAP levels are not very predictive of the absence of extra-prostatic disease. For men thought to have clinically localized prostate cancer based on the results of serum PSA, DRE, and Gleason score, serum PAP testing rarely adds additional information. The use of serum PAP testing for prostate cancer staging has declined substantially, giving way to the use of serum PSA testing.

"Molecular" staging for prostate cancer refers to the detection of circulating prostate cancer cells and/or cell fragments, either indirectly, by identifying mRNA species, such as those encoding PSA or PSMA, characteristically expressed by epithelial cells from the prostate,[278] or directly, by recovering prostate cancer cells using centrifugation/immunostaining methods.[279,280] To detect prostate lineage mRNAs or prostate cancer DNAs, polymerase chain reaction (PCR) approaches, capable of astonishing sensitivity, typically are used.

Reverse transcriptate-PCR (RT-PCR) for *PSA* mRNA in the blood has been reported to be more predictive of pathologic prostate cancer stage when compared to other pretreatment predictors such as serum PSA and Gleason score,[281] and to be an independent predictor of disease-free survival after treatment.[282] However, as many as one in four men with localized prostate cancer who underwent radical prostatectomy for cancer confined to the prostate had "positive" RT-PCR assays for *PSA* mRNA in blood specimens in one study.[281] These men would be denied aggressive treatment if the presence of circulating prostate cells indicated the presence of distant blood-borne prostate cancer metastases. In another study, 7% of men without prostate cancer exhibited "positive" RT-PCR assays for *PSA* mRNA in blood.[283] The relation between circulating prostate cancer cells, regardless of how they are detected, and the development of metastatic prostate cancer is not well understood, but is likely that the formation of metastatic prostate cancer deposits in bone and at other sites may be a relatively inefficient process, and that dissemination of prostate cancer cells into the bloodstream may be necessary, but not sufficient, for metastasis.[278,284] Until the predictive value of a "positive" RT-PCR assay for *PSA* mRNA in the blood has been established for a cohort of men with long-term follow-up after treatment for clinically localized prostate cancer, the assay will remain a investigational test.

TREATMENT OF LOCALIZED PROSTATE CANCER

Selection of Treatment Approach

Men thought to have localized prostate cancer face a number of treatment choices, including watchful waiting, radical prostatectomy, interstitial brachytherapy, and external beam radiation therapy (Box 88-3). Not all of these treatment approaches are appropriate for every man with prostate cancer. The different treatment approaches tend to be associated with different potential side effects. Also, men diagnosed with prostate cancer may have other medical conditions that can increase the chance or severity of such side effects. Prognostic factors, including prostate cancer stage, Gleason score, and serum PSA, are used to stratify men into low-, intermediate-, and high-risk groups for prostate cancer recurrence after treatment, providing some guidance as to likely treatment efficacy. Age, comorbidity, and life expectancy also should be considered in treatment selection (Table 88-6). Some prostate cancers exhibit a very indolent natural history, progressing slowly to threaten symptoms or survival. Many older men likely die *with* such cancers rather than *because* of them. The increased use of serum PSA for prostate cancer screening and early detection, particularly if applied to older men, may tend to overdiagnose such cancers. In contrast, young, healthy men with more aggressive prostate cancers may benefit from early prostate cancer detection and definitive treatment.

Since the mid-1980s, both surgery and radiation therapy for prostate cancer have improved dramatically, providing effective local control of cancer in the prostate while reducing the threat of side effects. At this point, the optimal treatment approach for men with localized prostate cancer who are appropriate candidates for surgery and radiation therapy has not been fully resolved. Comparisons between the treatment approaches remain difficult because there have been no randomized clinical trials testing differences in treatment

Box 88-3. TREATMENT OF MEN WITH CLINICALLY LOCALIZED PROSTATE CANCER

Men with localized prostate cancer have several treatment options, including watchful waiting, radical prostatectomy, interstitial brachytherapy, and external beam radiation therapy. Age, life expectancy, and medical history, as well as prostate cancer prognostic factors, such as stage, Gleason score, and serum prostate-specific antigen (PSA), typically are used to guide treatment recommendations. For example, men with a life expectancy of less than 5 years and low-risk prostate cancer (defined as stage T1 or T2, a Gleason score of 2–6, and a serum PSA value of 10 ng/mL or less) often are counseled to consider watchful waiting or radiation therapy, while men with a life expectancy of more than 20 years and low-risk prostate cancer might be offered radical prostatectomy or radiation therapy. Men with a life expectancy of more than 5 years and intermediate-risk prostate cancer (stage T2b to T2c, Gleason score of 7, or serum PSA of 10–20 ng/mL) usually are referred for radical prostatectomy or radiation therapy. Men with a life expectancy of more than 5 years and high-risk cancer (stage T3a to T3b, Gleason score 8–10, or serum PSA higher than 20 ng/mL) tend to be candidates for radiation therapy, administered along with adjuvant androgen deprivation therapy.

Table 88-6 Life Expectancy of Men (All Races) in the United States of America, by Age

	LIFE EXPECTANCY (YR)	
Age (yr)	**1989**	**2000**
50	26.4	27.9
55	22.3	23.8
60	18.5	19.9
65	15.1	16.3
70	12.1	13.0
75	9.4	10.1
80	7.1	7.6
85	5.3	5.6

Data from Arias E: United States life tables, 2000. Natl Vital Statistics Rep 2002;51:1–42.

outcomes. Furthermore, historical data offer only limited assistance in choosing between surgery and radiation therapy because each approach has improved in the time since most men were treated in case series with long-term follow-up data, and because most men treated in the past with radiation therapy tended to be older, have more substantial comorbidities, and have more aggressive (i.e., higher stage and grade) prostate cancers.

The 2007 National Comprehensive Cancer Network (http://www.nccn.org) guidelines for the management of clinically localized prostate cancer reflect the need for consideration of both life expectancy and the risk for prostate cancer recurrence in making treatment recommendations. In these guidelines, men with a life expectancy of less than 5 years and low-risk prostate cancer (defined as stage T1 or T2, a Gleason score of 2 to 6, and a serum PSA value of 10 ng/mL or less) are recommended for watchful waiting or for radiation therapy, while men with a life expectancy of more than 10 years and low-risk prostate cancer would be recommended for radical prostatectomy or for radiation therapy. Men with a life expectancy of more than 5 years and intermediate-risk prostate cancer (stage T2b to T2c, Gleason score of 7, or serum PSA of 10 to 20 ng/mL) also are recommended for radical prostatectomy or radiation therapy. Men with a life expectancy of more than 5 years and high-risk cancer (stage T3a to T3b, Gleason score 8 to 10, or serum PSA greater than 20 ng/mL) are recommended for radiation therapy and some sort of adjuvant androgen deprivation therapy, or, in certain specific cases, for radical prostatectomy. No adjuvant chemotherapy has yet been shown to benefit men with clinically localized prostate cancer.

Watchful Waiting (Conservative or Expectant Management)

Even when detected before widespread use of serum PSA for prostate cancer screening, the natural history of localized prostate cancer treated conservatively was characterized by slow progression of the disease, with few deaths within 10 years but a substantial risk of death at 15 years, especially for men with Gleason combined scores of 6 or greater.[285,286] Thus, most men with life expectancies beyond 10 years are thought to be candidates for curative therapy. No long-term studies of conservatively managed patients with prostate cancers detected by serum PSA screening are available. However, several observations suggest that conservative management may be a very reasonable option for selected men with prostate cancers diagnosed after serum PSA screening. First, the lead-time for prostate cancer diagnosis using serum PSA screening has been estimated to be 6 to 12 years.[216,287] Second, among men with palpable (stage T2) disease that was not detected using serum PSA screening, 8 years of follow-up were required to demonstrate an absolute difference of 7% in prostate cancer-specific survival in a randomized trial of surgery versus conservative management that showed an advantage for surgical treatment.[288] Thus, only a small minority of men with palpable prostate cancer benefit from surgery at 8 years. For men diagnosed with nonpalpable prostate cancer via serum PSA screening, with a lead-time of 6 to 12 years, it seems unlikely that most men age 70 years and older will derive much benefit from aggressive treatment. Such men should be offered watchful waiting as an alternative to surgery or radiation therapy. In addition, some younger men who are thought to have small-volume prostate cancer also may not benefit from aggressive treatment.

With the adoption of serum PSA screening, an estimated 20% to 30% of men detected to have nonpalpable prostate cancer (stage T1c) appear to have small-volume cancers (0.5 mL or less) that are not poorly differentiated.[204,289] Given the long natural history of prostate cancer, and the high rates of prostate cancer overdiagnosis (i.e., detection of cancer that would not have been detected without PSA testing) with serum PSA screening, especially for older men, watchful waiting should be considered in selected men with nonpalpable, serum PSA-detected, non-poorly differentiated (Gleason score of 6 or less) prostate cancers.

Most watchful waiting approaches have involved periodic general follow-up with initiation of palliative treatment as needed for symptomatic prostate cancer progression or for the appearance of cancer metastases. However, the ability to use serum PSA as a biomarker for prostate cancer activity has led to newer approaches where older men who are thought to harbor small-volume prostate cancers are followed more closely, with initiation of aggressive treatment with curative intent if and when it becomes appropriate. The challenges for these approaches are to identify men with small-volume disease who may be candidates for such an approach, and to identify which triggers can be used to change the management strategy from conservative to curative.

Epstein and coworkers[204] have presented criteria for identifying men with small-volume cancers. In their analyses, if the serum PSA "density" was less than 0.15 and there were no adverse pathologic findings detected by prostate needle biopsy (Gleason score 6 or less, less than 3 biopsy cores containing prostate cancer, and no more than 50% involvement of any biopsy core with prostate cancer), at the time of radical prostatectomy, 79% of such men had tumors of 0.5 mL or less that were organ-confined and were not high grade.[204] In contrast, if the PSA density was 0.15 or greater, or if any adverse needle biopsy findings were present (Gleason score 7 or higher, more than 2 biopsy cores containing prostate cancer, or more than 50% involvement of any biopsy core with prostate cancer), 83% of men had prostate cancers that were larger than 0.5 mL, cancers that were not confined to the prostate, or cancers that were high grade at radical prostatectomy. The predictive value of these criteria subsequently was confirmed in a prospective study.[290] When the criteria were used to identify a cohort of men (median age 67 years) with small-volume prostate cancer for a watchful waiting program, featuring serial serum PSA determinations and DREs as well as yearly surveillance prostate biopsies, some 30% of the men followed for more than 1 year were found to have adverse findings on surveillance biopsies that prompted a recommendation for curative treatment.[290] Nevertheless, 90% of the men found to have adverse prostate biopsy findings in this cohort still were thought to have curable prostate cancer when treatment was recommended.[290] The absence of prostate cancer on subsequent surveillance biopsies was strongly correlated with an absence of adverse pathology findings on future surveillance biopsies, but serum PSA determinations (including "free" PSA and PSA "velocity") were not helpful in predicting the future appearance of adverse pathology.[290] Thus, watchful waiting, conducted with curative intent, may be a reasonable approach for selected men above age 65 years with a high likelihood of harboring small-volume prostate cancer based on serum PSA and prostate biopsy criteria.

Radical Prostatectomy

Radical prostatectomy is used to treat men with clinically localized prostate cancer who have a life expectancy of at least 5 years. Although there are not specific or universally accepted age limits for radical prostatectomy, the life expectancy of men above 70 to 75 years of age is low enough that few men in this age range undergo radical prostatectomy.[291] Clearly, men with uncontrolled or acute medical conditions are not candidates for surgery. Previous pelvic surgery or radiation therapy, which can lead to increased complications, are relative contraindications to radical prostatectomy. Preoperative assessment of men for radical prostatectomy typically includes a history and physical examination, hematology studies, serum electrolyte studies (with a serum creatinine determination), a urinalysis, coagulation studies, and an electrocardiogram. Surgery for prostate cancer is usually delayed for 6–8 weeks after prostate needle biopsy to permit resolution of hematomata caused by the biopsy procedure. In anticipation of surgery, men avoid aspirin, nonsteroidal anti-inflammatory agents, or high doses of vitamin E that might promote

excess bleeding. Some men bank blood for possible transfusion if necessary. Anesthesia for radical prostate surgery has been provided using general, spinal, and epidural approaches; however most surgeons today prefer regional anesthesia, which has been reported to be associated with less blood loss and a lower risk for pulmonary emboli.[292,293]

The most common radical prostatectomy performed today uses a retropubic approach that has been perfected to better remove all cancer in the prostate and to better preserve anatomic structures essential for erectile function and urinary control.[6,7,294] Other surgical procedures for removal of the prostate gland include radical perineal prostatectomy and laparoscopic approaches to radical prostatectomy.[295–297] The radical retropubic prostatectomy proceeds via performance of a staging pelvic lymphadenectomy, division of puboprostatic ligaments, identification, ligation, and division of the dorsal vein complex to control blood loss, division of the urethra, identification and preservation of the neurovascular bundles needed for penile erection (unless wide excision of a neurovascular bundle is necessary for cancer control), division of the bladder neck and resection of the seminal vesicles, and construction of a urethrovesical anastomosis to best provide urinary continence.[298] The most common intraoperative complication is hemorrhage, although blood loss greater than 1000 mL is uncommon for most procedures.[298] Much less frequently, the obturator nerve can be injured during the pelvic lymphadenectomy, a ureter can be injured near the bladder, or the rectum can be injured during the dissection of the apex of the prostate gland. In the immediate postoperative period, complications include deep venous thrombosis and pulmonary emboli.[299] The operative mortality (death within 30 days) for radical prostatectomy is around 0.2%.[298]

Urinary Continence after Radical Prostatectomy

Urinary incontinence rates after radical prostatectomy vary greatly in different reports, with incontinence rates as high as 31% for men in the general population who underwent radical prostatectomy and as low as 10% or less for men who underwent radical prostatectomy at centers of excellence.[300–303] Some of the variation in reported incontinence rates may be attributable to differences in definitions of incontinence (stress incontinence versus more severe difficulties with urinary control), differences in the time after surgery when urinary continence was assessed (urinary control can continue to improve for as long as a year following surgery), and differences in whether incontinence was reported by treating surgeons in case series or by patients in survey questionnaires. However, surgical technique likely has significant consequences for urinary control following radical prostatectomy. Both the striated urinary sphincter musculature and smooth muscle surrounding the urethra can be injured during surgery.[298] Postoperative strictures at the site of the vesicourethral anastomosis also can affect control of urination.[304] Such strictures can be dilated, if necessary, to improve urination. Avoidance of such injuries, accompanied by modifications of the urethrovesical anastomosis, has led to improved urinary control rates by expert surgeons.[305,306] In the best case series, as many as 95% of men are completely dry 2 years after radical prostatectomy, and as many as 98% of men report no significant urinary problems.[303,307] Men with persistent or severe urinary incontinence after radical prostatectomy can be treated with periurethral collagen injections or with placement of an artificial urinary sphincter.[308,309]

Erectile Function after Radical Prostatectomy

Before 1982, most men subjected to radical prostatectomy were rendered impotent by the procedure. At that time, Walsh and Donker[6] meticulously assessed the anatomy of the nerves traversing the lateral surface of the prostate en route to the corpora cavernosa of the penis, discerning the close proximity of the nerves to vascular structures (the neurovascular bundles) visible at the time of radical prostatectomy. This revelation led Walsh and colleagues[7] to propose a modification of the radical prostatectomy procedure to preserve the neurovascular bundles in an effort to maintain erectile function postoperatively. Wide adoption of this modification has led to improvements in sexual potency rates following radical prostatectomy. As many as 91% of young men (<50 years of age) with good preoperative erectile function and low-stage prostate cancers who undergo an anatomic radical prostatectomy with preservation of both neurovascular bundles can expect recovery of potency after surgery.[310] Improvement in sexual function following surgery tends to occur gradually over at least 24 months or more.[303,311] Poor recovery of erectile function after surgery is correlated with increasing age (75% of men 50–60 years of age, 58% of men 60–70 years of age, and 25% of men 70 years of age or older were potent after radical prostatectomy in one series), poor potency before surgery, advanced prostate cancer stage (with capsular penetration or seminal vesicle invasion), and excision of neurovascular bundles.[310,312] Population studies have confirmed these predictors of erectile dysfunction after radical prostatectomy, with as many as 60% of men reporting impotence following surgery and some 42% reporting that poor sexual function was a significant problem.[301] In the best case series, 86% of men were able to have erections sufficient for sexual intercourse by 18 months.[303] Interposition grafts, from the sural nerve, have been used in attempts to repair nerves severed when wide excision of neurovascular bundles was required during radical prostatectomy, but the effectiveness of this procedure has been questioned.[313,314] Many men use seldenafil citrate (Viagra, Pfizer, Inc.) to improve sexual function following radical prostatectomy.[315]

Control of Prostate Cancer by Radical Prostatectomy

Radical prostatectomy is an effective means of treating localized prostate cancer. In a randomized trial ($N = 695$ men) comparing radical prostatectomy with watchful waiting, the odds ratio for death due to prostate cancer for men treated with surgery was 0.50 (with a 95% confidence interval of 0.27 to 0.91, $P = 0.02$)[288] (Fig. 88-9). Following surgery, serum PSA levels should fall to undetectable levels. A persistently detectable serum PSA after radical prostatectomy most often reflects the presence of disseminated cancer, occasionally indicating an incomplete resection of prostate tissues. After the serum PSA has declined to an undetectable level following radical prostatectomy, subsequent detection of PSA in the serum always indicates prostate cancer recurrence, preceding clinically significant prostate cancer progression by as many as 6 years or more.[316] Most modern case series examining outcomes of men with prostate cancer treated by radical prostatectomy feature the serum PSA as a surrogate biomarker for recurrence of prostate cancer. In such series, some 80% of men remain free of prostate cancer recurrence by 5 years following surgery.[317–321] In multivariate statistical analyses, the risk of serum PSA recurrence after radical prostatectomy has been correlated with clinical stage, Gleason score in prostate biopsies, and serum PSA values, determined preoperatively, and with pathological stage and Gleason score in the resected prostate specimen, determined postoperatively.[266,267]

Radiation Therapy

Radiation therapy has been used in the management of prostate cancer for nearly a century. Following Roentgen's discovery of the x-ray in 1895,[322] and the isolation of radium by Pierre and Marie Curie in 1898,[323] several pioneering physicians began treating prostate disorders, including prostate cancer, with radiation. In 1910, Paschkis and Tittinger inserted radium into the prostatic urethra with a cystoscope in what may be the first use of radiation for prostate cancer. Not long after, Hugh Hampton Young from Johns Hopkins

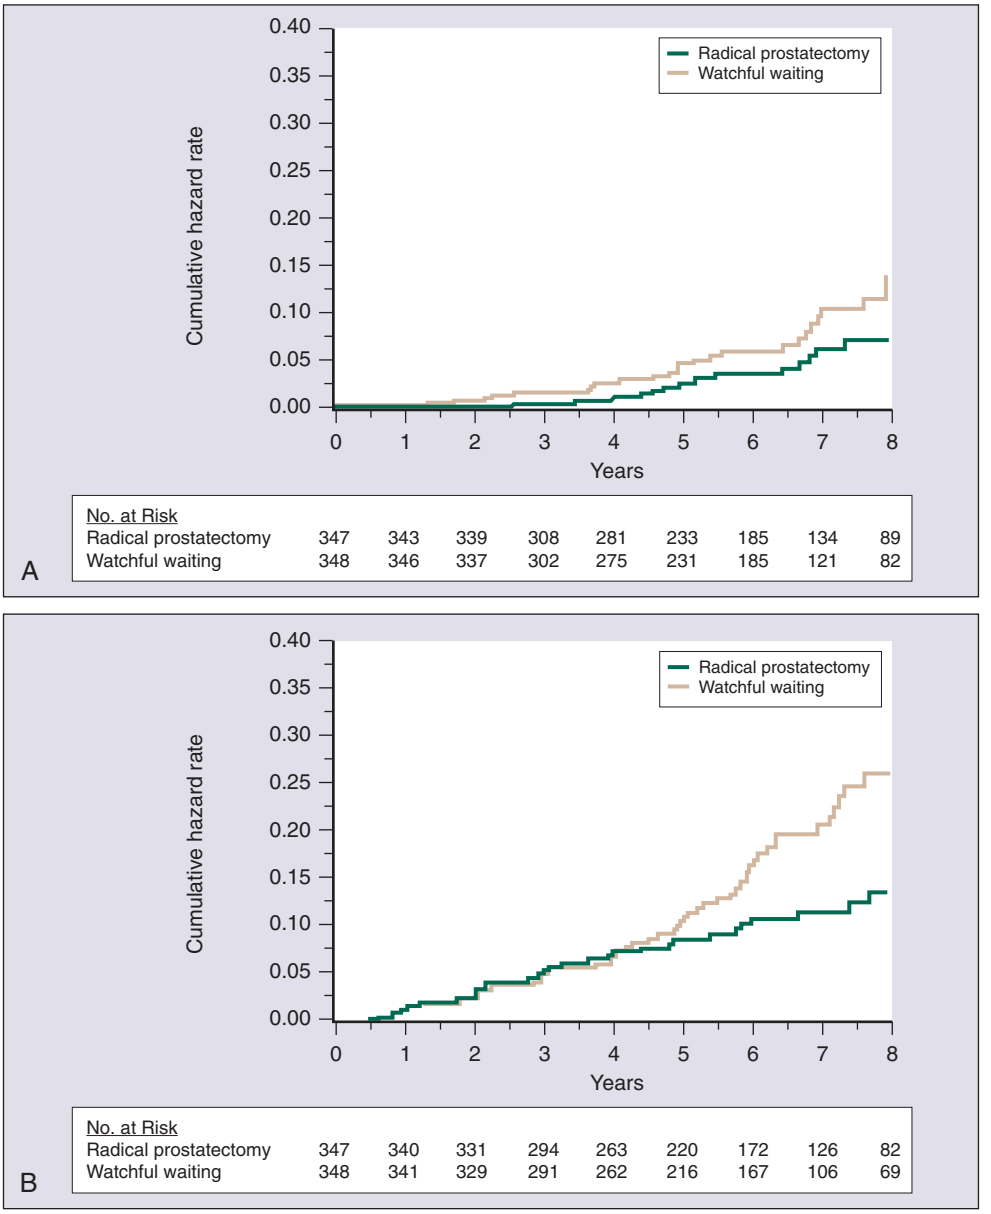

Figure 88-9 • Results of a randomized clinical trial of radical prostatectomy versus watchful waiting. **A,** Cumulative hazard rates of prostate cancer death. **B,** Cumulative hazard rates of prostate cancer metastasis. (Data from Holmberg L, Bill-Axelson A, Helgesen F, et al: A randomized trial comparing radical prostatectomy with watchful waiting in early prostate cancer. N Engl J Med 2002;347:781–789, with permission.)

reported the relatively large experience of treating prostate cancer patients with urethral and rectal radium "applicators."[324] These and other early studies revealed that even when radiation was applied in this crude manner, it could improve symptoms and kill prostate cancer. However, treatment was technically difficult for the physician and uncomfortable for the patient. In 1928, the first report on the use of externally delivered low-energy kilovoltage radiation for prostate cancer was offered by Barringer.[325] The associated dosimetry was not well worked out and, thus, men were treated until their skin turned red. These types of low-energy radiation machines were used until cobalt machines became available and provided the first opportunity to treat tumors more deeply seated in the body. The first reported series of prostate cancer patients treated with ^{60}Co0 therapy was by George and associates in 1965 and featured men with unresectable disease.[326] It was also during this time (beginning in the late 1950s) that the megavoltage linear accelerator was being developed at Stanford University.[327] The pioneering work of Bagshaw, Kaplan, Del Regato, and others, ushered in the modern era of radiation therapy for prostate cancer.[328,329]

Now men with prostate cancer have several different radiotherapeutic options, each of which can be employed with very high precision and with great effectiveness. The integration of computer-based technology for the design of three-dimensional conformal treatment plans, and use of high-energy accelerators with sophisticated dynamic shielding, allows men with prostate cancer to be treated with high doses of radiation while at the same time sparing surrounding normal tissues. In addition, the development of permanently implantable radioactive sources, along with the use of real-time imaging and treatment planning, also has provided the opportunity for sophisticated prostate brachytherapy techniques resulting in safe and efficacious treatment of men with prostate cancer.

Traditionally, men with prostate cancer referred for radiation therapy tended to be older, to be in poorer health, and to have higher-risk, more advanced tumors than those patients treated surgically. Consequently, results using less sophisticated radiation therapy techniques were less than optimal, raising concerns that radiation therapy might not be as effective as radical prostatectomy. However, with long-term results obtained across a broad range of patients, it is now

clear that radiation therapy for prostate cancer provides excellent disease-free survival, comparable to radical prostatectomy for men at similar risk of prostate cancer recurrence.

The following section provides a brief description of how men are evaluated and risk-stratified for radiation therapy, followed by a description of treatment techniques, and a review of treatment outcomes for men with low-, intermediate-, and high-risk prostate cancer. The use of radiation therapy to treat local prostate cancer recurrences after radical prostatectomy is also reviewed.

Conventional External Beam Radiation Therapy for Localized Prostate Cancer

For over three decades, external beam radiation therapy and radical prostatectomy have been widely used for the definitive management of clinically localized prostate cancer. Although there have been no large randomized trials in North America or Europe that have directly compared the two treatment modalities, retrospective comparisons are plentiful, but limited by the tendency of older men with higher prostate cancer to have been treated with suboptimal radiation doses and techniques. In general, the conventional techniques used standard radiation fields, based on bony pelvic landmarks, to define the region of clinical interest for a dose range of 65 to 70 Gy delivered to the prostate. Commonly, a four-field pelvic box with custom Cerrobend (Cerro Metal Products Company, Bellefonte, PA) blocking was used to treat the prostate, seminal vesicles, and proximal lymphatic drainage. These fields were treated to a dose of 45 to 50 Gy in 1.8- to 2.0-Gy fractions. The prostate, and sometimes the seminal vesicles plus a safety margin, were then boosted to 65 to 70 Gy. Cerrobend blocking was used to shield, if possible, the posterior wall of the rectum, anal canal, and any small bowel. In spite of its limitations, this version of external beam radiation therapy was fairly effective: although overall survival numbers generally were higher for men treated with radical prostatectomy (often younger and healthier men), cause-specific survival rates were not significantly different.[330] In an analysis of pathologically staged men with stage A2-B prostate cancer treated as part of Radiation Therapy Oncology Group (RTOG) Trial 77–06, 5- and 10-year survival rates, 87% and 63%, respectively, were comparable to age-matched controls without prostate cancer.[331] The prostate cancer-specific survival was 86%, which was similar the to outcomes of some surgical series.[332,333]

With the ready availability of serum PSA testing, current outcome comparisons focus on PSA as a marker of prostate cancer recurrence following primary treatment ("PSA relapse"-free survival). A rising serum PSA after radiation therapy for prostate cancer is correlated with the appearance of progressive or metastatic prostate cancer on further follow-up.[334] Furthermore, the rate of serum PSA rise may help distinguish between a local or distant treatment failure. Men with slow rates of serum PSA increases are more likely to have local prostate cancer recurrences, whereas men with a rapid serum PSA rise appear more likely to have distant prostate cancer metastates.[335] In 1997, the American Society for Therapeutic Radiology and Oncology (ASTRO) issued a consensus statement establishing the definition of recurrence of prostate cancer following radiation therapy as three consecutive rises in serum PSA levels ("biochemical" treatment failure) with determination made at least 3 months apart.[336] Before these criteria were formulated, treatment outcomes in different studies and case series were difficult to compare because of the lack of uniformity in defining treatment failure.

Pretreatment serum PSA levels are particularly predictive of radiation treatment outcome. In a case series of men ($N = 461$) with stage T1-T2 prostate cancer treated at M.D. Anderson Cancer Center, 5-year PSA relapse-free survival rates for men with pretreatment PSA levels of less than 4 ng/mL, 4 to 10 ng/mL, 10 to 20 ng/mL, and more than 20 ng/mL were 91%, 69%, 62%, and 38%, respectively.[337] In another study, Zietman and coworkers[338] reported 4-year PSA relapse-free survival of 65% for pretreatment PSA level below 15 ng/mL and 6% for patients with levels above15 ng/mL. The routine monitoring of serum PSA to detect cancer recurrence following primary treatment spurred interest in escalating radiation doses to improve cancer control.

Toxicity of Conventional External Beam Radiation Therapy

Dose escalation with conventional external beam radiation therapy has been limited by the toxicity of treatment (Table 88-7). Most men experience dysuria and/or diarrhea during the course of prostate cancer therapy, but these symptoms generally resolve weeks after completion of treatment. Long-term sequelae of conventional external beam radiation therapy (i.e., delivered without the use of conformal techniques) were reviewed in an analysis of 1020 patients treated in RTOG trials 75–06 and 77–06.[339] The incidence of late grade 3 or 4 urinary complications, such as hematuria, cystitis, bladder contracture, or urethral stricture, was 7.7%, with surgical intervention needed for 0.5%. Grade 3 or 4 rectal complications, such as bleeding, ulceration, proctitis, rectal/anal stricture, or chronic diarrhea, were seen in 3.3%, with surgery for bowel obstruction or perforation needed in 0.6%. Notably, the risk of complications was significantly higher when doses greater than 70 Gy were administered by these nonconformal techniques.

Data on the incidence of erectile dysfunction after external beam radiation therapy have been widely variable. Sexual function has many facets that are difficult to evaluate or quantify. A commonly used qualitative definition of sexual potency is the ability to achieve spontaneous erections sufficient for intercourse. While potency rates after radical prostatectomy have increased with use of nerve-sparing techniques, the mechanism of radiation-related erectile dysfunction appears unrelated to the neurovascular bundles. Zelefsky and colleagues[340] specifically addressed this topic by performing duplex ultrasound studies before and after prostaglandin injection to stimulate erections in men with radiation-related erectile dysfunction. A diminished peak penile blood flow rate (<25 mL/min) was evident in 63% of such men, with abnormal distensibility of the corpora cavernosa in 32%. Thus, the primary mechanism of radiation therapy-associated impotence may be vascular damage rather than nerve damage. Fisch and associates[341] demonstrated a correlation between incidence of erectile dysfunction post-radiation therapy and radiation dose to the vascular penile bulb. Men receiving more than 70 Gy to more than 70% of the bulb of the penis are at greatest risk of experiencing radiation therapy-associated erectile dysfunction. A steady decline in potency rates over time is characteristic for men treated with external beam radiation therapy. In a large series ($N = 434$) of men treated with radiation therapy at Stanford University, 86% of the men remained potent at 15 months after treatment, but

Table 88-7 Radiation Therapy Oncology Group Criteria for Late Morbidity after Radiation Therapy

Grade	Criteria
1	Minor symptoms requiring no treatment
2	Symptoms responding to simple outpatient management, lifestyle not affected
3	Distressing symptoms altering patient's lifestyle Hospitalization for diagnosis or minor surgical intervention (such as urethral dilatation) may be required.
4	Major surgical intervention (such as laparotomy, colostomy, cystectomy) or prolonged hospitalization
5	Fatal complication

only 50% were potent 6 years later, and only 30% maintained erectile function for the remainder of their lives.[342] Sildenafil administration resulted in improvement of erectile function in 74% of men with radiation therapy-associated erectile dysfunction in a study at Memorial Sloan-Kettering Cancer Center.[343] Men who do not respond to sildenafil may respond to intracavernosal prostaglandin injections.

Second malignancy after definitive radiation therapy for prostate cancer is uncommon. Using data from the Surveillance, Epidemiology, and End Results (SEER) program cancer registry, Brenner and coworkers[344] compared second malignancy risks for men ($N = 51,584$) who received radiation therapy for prostate cancer from 1973 to 1993 versus the risks for men ($N = 70,539$) who underwent radical surgery during the same time period, finding a small but significant increase in second malignancy attributable to radiation treatment. The most common radiation-induced tumors were carcinomas of the bladder and rectum, and sarcoma. The absolute risk of second malignancy for men who were treated with radiation therapy was 1 in 290. For survivors more than 10 years after treatment, the risk increased to 1 in 70.

Three-Dimensional Conformal Radiation Therapy

The advent of CT-based simulation and treatment planning and the innovation of multileaf collimators in modern linear accelerators have allowed for increased precision and accuracy in radiation therapy. Three-dimensional reconstructions of acquired CT images are generated, and target volumes (e.g., prostate and seminal vesicles) are delineated. Critical structures (e.g., bladder and rectum) to be avoided also are contoured. Computerized treatment planning software allows the iterative process of designing beam arrangements that will deliver a prescribed dose to the regions of interest and minimize dose to a given volume of a critical organ. Target volumes and normal organs are visualized in three dimensions (permitting the so-called "beam's-eye view," a portrayal of the target area as if looking straight down the path of the radiation beam). Computerized multileaf collimators shape each individual beam to conform to the shape of the target in the beam's-eye view. The treatment planning system generates a dose-volume histogram for a selected treatment plan, a graphic description of the relationship between dose administered and volume of an organ that is receiving a given dose (Fig. 88-10), which allows an objective assessment of the anticipated performance of a proposed radiation treatment plan. Since these technologies became clinically available in the 1990s, they have been used in dose escalation studies in prostate cancer.

The profound effect of radiation dose escalation on treatment outcomes for prostate cancer has been demonstrated through work from several institutions.[345–348] Men with intermediate-risk prostate cancer (serum PSA values of 10–20 ng/mL) may benefit most from dose-escalation. However, in a large cohort of men ($N = 1100$) treated with three-dimensional conformal radiation therapy (3D-CRT) at Memorial Sloan-Kettering Cancer Center, a significant benefit of dose escalation was evident regardless of the pretreatment PSA.[347] Initially, men with prostate cancer were treated with conventional radiation dose levels of 64.8 to 70.2 Gy using 3D-CRT techniques, and then the radiation dose was increased to as high as 86.4 Gy. At a median follow-up of 60 months, PSA relapse-free survivals for men with low-risk prostate cancer treated to radiation doses of 64.8 to 70.2 Gy versus 81 Gy, were 77% and 98%, respectively.[347] Men with intermediate- and high-risk prostate cancers also showed significant improvement.

Will improved treatment outcomes from 3D-CRT, evidenced by reduced numbers of men with prostate cancer relapses detected as a rising serum PSA, result in improvements in disease-free survival, freedom-from-distant metastasis, or overall survival? A randomized dose escalation trial detected a substantial improvement in prostate cancer control rates for men with prostate cancer, especially men with a pretreatment PSA higher than 10 ng/mL (Fig. 88-11).[345,349] This study involved the stratification of men ($N = 305$) with stage T1-T3 prostate cancer to undergo treatment to a total dose of either 70 Gy using conventional radiotherapeutic techniques, or to 78 Gy utilizing a six-field 3D-CRT boost after the delivery of an initial 46 Gy. Results revealed a freedom-from-PSA relapse of 64% and 70% at 6 years for the 70 Gy and 78 Gy groups, respectively ($P = 0.03$). Men who had a pretreatment PSA higher than 10 ng/mL were found to have the most significant benefit from radiation dose escalation, with freedom-from-PSA relapse rates of 62% for the 78 Gy arm and 43% for the 70 Gy arm ($P = 0.01$), a benefit not seen for men with a pretreatment PSA below 10 ng/mL. Overall survival was not significantly different between the two radiation doses, but a trend toward an improved freedom-from-distant metastasis was evident in men treated on the 78-Gy arm, 98% versus 88% at 6 years ($P = 0.056$).

Toxicity of Three-Dimensional Conformal Radiation Therapy

While the use of 3D-CRT was intended to minimize the effects of high-dose radiation on normal tissues, increased late toxicities have been noted with escalating radiation doses used in 3D-CRT.[348,350] In the Fox Chase case series, the 5-year incidence of grade 3 or 4 rectal toxicity at a dose of 75 to 76 Gy was 8%. However, after the anterior rectal wall was shielded to keep the dose to this region under 72 Gy, grade 3 or 4 rectal toxicity was evident in only 2% of patients. From the M.D. Anderson Cancer Center dose escalation case series, men who received more than 70 Gy to 30% or more of the defined rectal volume had a significantly higher risk of rectal toxicity.[351] Zelefsky and colleagues[350] reported a 1.2% actuarial risk of grade 3 or higher rectal toxicity by 5 years with 3D-CRT. Grade 2 rectal bleeding was seen in 17% of men who received 75.6 Gy or more as compared to 6% for men receiving 64.8 to 70.2 Gy. Furthermore, even if the rectum was completely shielded in each field above a dose of 72 Gy, grade 2 rectal bleeding was seen in 15% of men. As for urinary toxicity with 3D-CRT, urethral strictures have been observed in 1.5% of treated men, with a 4% incidence of stricture in men with a history of previous transurethral resection of the prostate (TURP). Grade 3 hematuria appears in as many as 0.5% of men, with grade 2 hematuria in 13% of men treated to a dose of 75.6 Gy or higher and 4% of men treated to lower total doses. Urinary incontinence is rare following treatment with 3D-CRT (<0.2% with 2% in the setting of a prior TURP).[352]

Intensity-Modulated Radiation Therapy

Intensity-modulated radiation therapy (IMRT) equipment and treatment planning software have become increasingly available, with the technology attracting interest from both academic and community cancer centers for the treatment of a variety of malignancies. The largest experience with IMRT to date has been in the treatment of prostate cancer. Via inverse planning, IMRT allows identification of the region to be treated along with surrounding critical normal organs so that radiation dose and volume goals can be prescribed for each target and structure. The treatment planning software then derives an optimized dose distribution by modifying the number, orientation, and intensity of the beams across the designated volume. This is in contrast to 3D-CRT, where beam arrangement and field shapes must be designed manually to accomplish radiation dose-volume goals, a task that typically requires multiple time-consuming iterations.

In a case series ($N = 772$) of men with clinically localized prostate cancer treated with IMRT at Memorial Sloan-Kettering Cancer Center, a reduction in late rectal toxicity was seen in comparison to 3D-CRT.[353] Most of the men (698 of the 772) were treated to a total dose of 81 Gy while the remainder received 86.4 Gy. With a median follow-up of 24 months, actuarial rate of grade 2 or higher rectal bleeding at 3 years was 4%, and only 0.5% of men experienced any grade 3 rectal toxicity (no grade 4 rectal toxicity was seen). However, despite the increased conformality of incident radiation and the decreased bladder volumes receiving high radiation doses, there was no improvement in late urinary toxicity with IMRT versus 3D-CRT, with 15% of men suffering late grade 2 urinary toxicity. Because this may be the result of high-dose radiation to the urethra, decreasing urethral doses for men with prostate cancer limited to the peripheral zone of the prostate may be a means of reducing late urinary toxicity with IMRT, but better diagnostic imaging is necessary to identify men with such cancers.

One concern with IMRT techniques, in general, is the potential for inadequate treatment at the margins of radiation fields with increasingly conformal radiation dose delivery. However, preliminary treatment outcome data obtained thus far with IMRT appear similar to those with 3D-CRT, with 3-year actuarial PSA relapse-free survival rates, using American Society for Therapeutic Radiology and Oncology (ASTRO) consensus criteria, for men with low-, intermediate-, and high-risk prostate cancer of 92%, 86%, and 81%, respectively.[353] It should be noted that planning target volume (PTV) definitions for IMRT often are the same as those used with 3D-CRT. If tighter PTV definitions are to be used, better prostate immobilization and localization techniques are likely needed. This strategy currently is being investigated in several centers with the use of electronic portal imaging (EPI), a real-time treatment set-up verification system, and of B-mode acquisition and targeting (BAT), an ultrasound-based real-time localization system.[354]

Brachytherapy

Prostate brachytherapy refers to the implantation of radioactive sources into the prostate under transrectal ultrasound (TRUS) guidance. In principle, brachytherapy offers an attractive means for radiation dose escalation and conformality in the treatment of clinically localized prostate cancer. Modern prostate brachytherapy techniques that use ultrasound or CT-based targeting, a perineal template for precise seed implantation, and computerized treatment planning

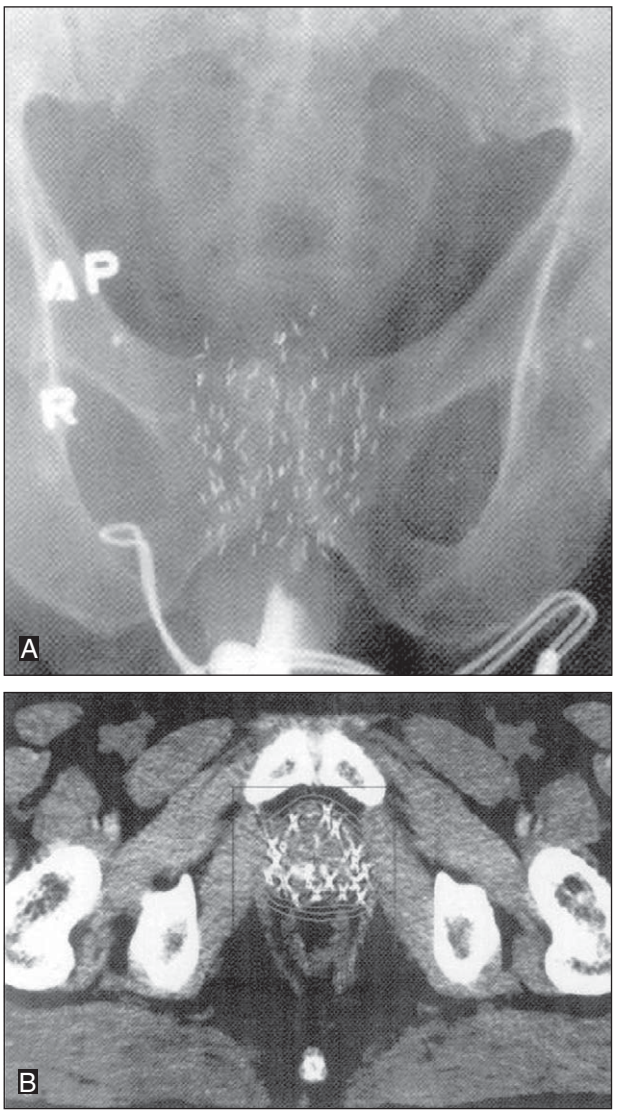

Figure 88-12 • Interstitial brachytherapy for prostate cancer. **A,** Radiograph obtained after implantation of radioactive seeds. **B,** CT image showing radioactive seed location within prostate. (From Speight JL, Roach M III: Imaging and radiotherapy of the prostate. Radiol Clin North Am 2000;38:159–177.)

have gained in popularity over the past 15 years (Fig. 88-12). For the patient with prostate cancer, this option may be most convenient, allowing a rapid return to normal lifestyle and activity. A typical brachytherapy procedure is performed in 2 hours, often under spinal anesthesia, and does not require an overnight hospital stay. Before the procedure, an ultrasound or CT-based volume study is performed and a preplan is formulated, specifying three-dimensional seed distribution to deliver a prescribed dose to the prostate and a periprostatic margin. Typically, peripherally biased seed distributions provide a relatively lower dose to the urethra. In the operating room, using spinal or general anesthesia and with Foley catheter in place, the patient is placed in the dorsal lithotomy position, a TRUS of the prostate volume is registered to approximate the prostate volume obtained from a preprocedure study (some centers use real-time intraoperative treatment planning systems to make adjustments to optimize the dose distribution because the prostate volume may be slightly different from that of the preplan), hollow needles are guided into the prostate through the perineum using a template, and radioactive sources are deposited in the prostate according to the plan as the needles are withdrawn (through use of the Mick applicator or with seeds strewn on ribbons with equal spacing). Post-treatment CT scans are then routinely done to evaluate the quality of the implant procedure.[355]

Thus far, every use of permanent brachytherapy for prostate cancer reported has been a retrospective analysis of a case series from a single institution. Comparisons among these series, or to results from external beam radiation therapy or radical prostatectomy, are fraught with difficulty due to the lack of uniformity in reporting of patient selection and treatment outcome criteria. Additionally, implantation techniques, isotopes, dosimetry, and operator experience vary widely from one prostate cancer brachytherapy series to the next. Many practitioners have recommended brachytherapy for men with low-risk prostate cancer, but have added supplementary external beam radiation therapy to brachytherapy for men with prostate cancer at higher risk for extraprostatic extension. Combinations of brachytherapy and external beam radiation therapy also have been advocated for use in all men with clinically localized prostate cancer.[356] In 1999, the American Brachytherapy Society recommended that brachytherapy using radioactive iodine or palladium might be appropriate for men with prostate cancer of clinical stage T1-T2a, with a serum PSA of 10 ng/mL or less, and a Gleason score 6 or less, and that supplemental external beam radiation therapy should be added for men with higher risk disease.[357] This recommendation was based in part on inferior outcomes reported for men with high-risk prostate cancer treated with brachytherapy.[358] It is possible that favorable outcomes may be achieved even in some men with prostate cancer and some high-risk features through the use of generous periprostatic treatment margins at the time of implant and/or the use of supplemental external beam therapy.[359–361]

In the absence of a prospective randomized trial, the routine use of prostate brachytherapy in the treatment of clinically localized prostate cancer has been based on retrospective studies with varying follow-up time. Recently, treatment outcomes for more than 2500 men with prostate cancer, treated at 11 different institutions with permanent interstitial brachytherapy, were reported.[362] The median follow-up for this group of men with stage T1 or T2 prostate cancer was 63 months, and all were treated with either ^{125}I or ^{103}Pd without use of hormonal therapy. Men with low-, intermediate-, and high-risk prostate cancer had 8-year actuarial PSA relapse-free survivals of 82%, 70%, and 48%, respectively, using ASTRO criteria. As in previous studies, the dosimetric quality of the implant was critical to outcome: for men in whom 90% of the prostate (D_{90}) received 130 Gy or more, the 8-year PSA relapse-free survival was 93%, while for men in whom the prostate D_{90} was less than 130 Gy, the 8-year PSA relapse-free survival was 76%. Three other series have reported long-term results with brachytherapy.[363–365] Ragde and associates[365] reported 12-year treatment results from a group of men ($N = 229$) with T1-T3 prostate cancer who underwent ^{125}I or ^{103}Pd implantation. Men with low-risk prostate cancer ($N = 147$) in this case series were treated with brachytherapy alone, whereas men with high-risk prostate cancer ($N = 82$) received external beam radiation therapy followed by implant. The PSA relapse-free survival was 66% for men with low-risk prostate cancer and 79% for men with high-risk prostate cancer. In light of subsequent superior results in men with low-risk prostate cancer treated with brachytherapy alone, a possible explanation for the poor performance of brachytherapy alone in this case series is that there has been significant refinement of technique and treatment planning since many of these men were treated. In another case series, men with low-risk prostate cancer treated in 1986–1987 exhibited a significantly worse progression-free survival than men treated in 1988–1990.[364]

The addition of supplemental external beam radiation therapy to brachytherapy remains somewhat controversial. Davis and coworkers examined the radial distance of extra-prostatic extension of prostate

cancer and found it to be almost always 5 mm or less, which would be within a typical brachytherapy dose distribution.[366] Thus, generous periprostatic margins in brachytherapy planning may obviate the need for supplemental external beam radiation therapy. Proponents of combination therapy point to the advantage of higher biologic doses and the ability to smooth out cold spots inherent with brachytherapy, the so-called "spackle effect." Sylvester and colleagues[367] recently reported a retrospective review of 232 men with clinically localized prostate cancer treated with either ^{125}I or ^{103}Pd brachytherapy and external beam radiation therapy administered before placement of the implant. At a median follow-up of 9.4 years, the biochemical relapse-free survival for the entire study group was 74%, with biochemical relapse-free survival for low-risk prostate cancer of 85.8%, for intermediate-risk disease of 80.3%, and for the high-risk group of 67.8%. These results compare favorably with all other surgical and/or radiation series with respect to long-term durable prostate cancer control. The RTOG is studying a similar combination therapy approach using brachytherapy and external beam radiation therapy; the results of this study will help to determine the incremental benefit of supplemental external beam radiation therapy in each risk group, as the addition of this therapy nearly doubles the cost of treatment.[368]

Relative contraindications to the use of prostate brachytherapy are large prostate size, preimplant obstructive urinary symptoms, history of prior TURP, and the presence of perineural prostate cancer invasion on prostate biopsy. Large prostate size has been perceived to be associated with a higher risk of urinary morbidity postimplant and with unsuitability for implant due to pubic arch interference. Men with a prostate volume of greater than 50 mL have been either counseled against brachytherapy or placed on androgen deprivation therapy in an attempt to reduce gland size. Nonetheless, the implantation of large prostates with radioactive seeds has been described with acceptable morbidity.[369,370] In one case series, postimplant dosimetry quality was found to be independent of prostate size or use of androgen deprivation therapy.[370] The use of the extended dorsal lithotomy position and steering of needles around the pubic arch increases the fraction of men that can be implanted with radioactive seeds by experienced radiation oncologists.[371] The correlation of preimplantation obstructive urinary symptoms and postimplantation urinary obstruction is not yet resolved. Terk and associates[372] reported that a high International Prostate Symptom Score (I-PSS), a measure of obstructive urinary symptoms, predicted postimplant urinary retention. With the use of α-blockers before and after implant procedures, others have noted no association between preimplant I-PSS and urinary obstruction.[373] A prospective study examining preimplant urinary flow rate and postvoid residual, in addition to I-PSS, showed no association of obstructive urinary symptoms with postimplant urinary retention or long-term urinary function.[374] TURP is thought to be a relative contraindication to prostate brachytherapy, because it has been associated with unacceptably high rates of urinary incontinence. This may be attributable to seed loading approaches that result in a high central dose to the TURP defect. However, by using a peripheral source loading approach to limit dose to the TURP defect to 110% of the prescription dose, the incidence of urinary incontinence may be reduced.[375] Finally, because prostate cancers exhibiting perineural invasion have been shown to be associated with inferior outcome in radical prostatectomy series, this adverse prognostic finding will likely also be associated with inferior outcome from brachytherapy.[376] Curiously, in one case series no difference in brachytherapy treatment outcome attributable to the presence of perineural invasion was evident.[377]

A phenomenon peculiar to prostate brachytherapy that deserves mention is the so-called "PSA spike." With a time of onset between 12 and 30 months postimplantation, approximately one third of men with prostate cancer treated with brachytherapy will experience a transient increase in serum PSA.[378] This spike may be due to radiation-associated prostatitis that compromises prostate architecture, permitting more PSA to appear in the serum. Such PSA spikes portend no worse long-term outcome.

Table 88-8 Physical Differences Between ^{125}I and ^{103}Pd Radioactive Seeds

	^{125}I	^{103}Pd
Year introduced	1965	1986
Photon energy (keV)	28	21
Half-life (days)	59.4	17
Initial dose rate (for monotherapy)	7 cGy/hr	18–20 cGy/hr
RBE	1.4	1.9

RBE, relative biologic effectiveness.

Another controversy for prostate brachytherapy concerns the choice of isotope and use of androgen deprivation therapy. The most common sources in use today are ^{125}I and ^{103}Pd (Table 88-8). Thus far, there have been no compelling data to support the superiority of one isotope or the other. It has been hypothesized that the higher initial dose rate of ^{103}Pd might be advantageous for the treatment of cancers with a relatively low α/β ratio (more radioresistant) such as prostate cancer; however, retrospective data for prostate cancer have been inconclusive.[379] A prospective randomized trial directly comparing ^{125}I to ^{103}Pd for prostate cancer brachytherapy is ongoing. Most of the experience with prostate brachytherapy has been with permanent low dose-rate (LDR) implants. Several centers have collected experience with temporary high dose-rate (HDR) implants for prostate cancer brachytherapy.[380–382] Although this treatment approach is not widely used, the available results appear comparable to those of permanent brachytherapy for clinically localized prostate cancer. HDR approaches have a theoretical advantage over LDR brachytherapy for the treatment of cancers with a low α/β ratio that approximates that of normal tissue. That is, a higher biologically equivalent radiation dose (BED) with HDR implants could be delivered with similar rates of morbidity as compared to LDR implants. Therefore, HDR implants would seem to be ideal for prostate cancer. Further study is needed to validate this theory.

Androgen deprivation therapy has been used with prostate cancer brachytherapy both to reduce the size of the prostate gland and to improve outcomes. Most prostate glands exhibit some decrease in volume after 3 months of androgen deprivation therapy, with an average 30% to 40% reduction and little further volume decreases.[383] About 10% of prostate glands will show no volume reduction at all in response to androgen deprivation. Decreasing the size of the prostate may reduce pubic arch interference in selected men. Blank and coworkers[384] reported that men treated with androgen deprivation therapy tended to have smaller prostates that required fewer seed implants. However, at this point there are no data to suggest that smaller prostate volumes correlate with reduced acute or late morbidity from brachytherapy. Furthermore, although prospective randomized trials have demonstrated improved survival in those men with locally advanced prostate cancer treated with external beam radiation therapy and androgen deprivation therapy, it is not clear that these results can be extrapolated to men treated with brachytherapy. A retrospective matched-pair analysis of men ($N = 60$) with prostate cancer treated at Memorial Sloan-Kettering Cancer Center showed no benefit for the addition of androgen deprivation therapy to brachytherapy for men with low-, intermediate-, or high-risk prostate cancers.[385]

Toxicity of Brachytherapy

The short- and long-term sequelae of brachytherapy for prostate cancer differ from those of external beam radiation therapy and

radical prostatectomy. Kleinberg and colleagues[386] described the morbidity outcomes of the early Memorial Sloan-Kettering Cancer Center experience with permanent transperineal brachytherapy, reporting that the most common side effects were nocturia and dysuria (80% and 48%, respectively, 2 months after implantation). By 12 months following implantation, these figures had declined (to 45% and 20%, respectively). Urinary retention is seen in 3% to 14% of men and usually lasts 1 week or less. The most bothersome late complications of prostate cancer brachytherapy are urethral stricture and urinary incontinence. Ragde and associates[387] reported a 5.1% incidence of urinary incontinence in men treated with prostate cancer brachytherapy and followed for 7 years; each of the men with incontinence had a history of TURP. Urethral stricture developed in 14.4% of the men. Others also have seen an increased incidence of urinary incontinence in the setting of a history of TURP.[388] In a cohort study of Medicare beneficiaries ($N = 2124$) who were treated with brachytherapy, urinary incontinence was noted in 6.6%, and bladder outlet obstruction requiring intervention was found in 8.3%.[389] In a more recent report from the RTOG multi-institution prospective trial (RTOG 98–05) of definitive brachytherapy alone, 23% of the men experienced urinary toxicity of a grade greater than 2.[390]

Rectal morbidity after brachytherapy includes change in bowel habits, rectal bleeding or ulceration, and fistula. Kleinberg and coworkers[386] reported that 25% of men treated with prostate cancer brachytherapy had a change in bowel habits within 2 months of implant. By 12 months postimplant, no patient had grade 2 or higher rectal symptoms. The 3-year actuarial incidence of rectal bleeding was 31% and the incidence of ulceration was 16%. With more operator experience, rates of rectal complications subsequently fell: an update of the Memorial Sloan-Kettering Cancer Center experience revealed only a 9% incidence of rectal bleeding.[391] Among Medicare beneficiaries, rectal injury not requiring colostomy was reported in 5.1% of men treated with prostate cancer brachytherapy, while colostomy was required in 0.3%.[389] Radiation proctitis was reported in 2.2%, fistula in 1.8%, and ulceration in 1.1%.[389] Generally, late rectal complications have their onset within 3 years of implant. Conservative measures usually generally result in spontaneous resolution of bleeding. In the recent RTOG trial of brachytherapy for prostate cancer (RTOG 98–05), 5% of men suffered grade 2 bowel toxicity, and no man experienced long-term grade 3 or 4 bowel toxicity.[390]

As the popularity of prostate brachytherapy for clinically localized prostate cancer grew in the 1990s, a commonly cited advantage of the treatment modality was a lower incidence of treatment-associated erectile dysfunction compared with external beam radiation therapy or radical prostatectomy. Undoubtedly, this selling point tipped the scales in favor of brachytherapy for many men faced with selecting a treatment for early-stage prostate cancer. For instance, Stock and colleagues[392] reported a 2 year potency rate of 94% after implant, while Wallner and associates[393] reported a 3-year potency rate of 86%. Studies with longer follow-up, however, have shown a continued decrease in sexual potency over time. With more long-term follow-up in other case series, only 57% of men retained potency at 5 years.[391] Even Stock and coworkers[394] subsequently reported a 6-year potency rate of 59% in their case series. Notably, their study found that 70% of men with normal erectile function before implant retained potency at 6 years, whereas men with "erectile function sufficient for intercourse" but suboptimal erections had only a 34% 6-year potency rate. Using postimplant dosimetry studies, Merrick and colleagues[395] demonstrated that dose to the penile bulb correlated with postimplant erectile dysfunction. In most men who retained potency, the dose delivered to 50% of the penile bulb was less than 50 Gy. This knowledge potentially may result in improved morbidity outcomes with technical attention to this dose threshold. Erectile dysfunction is not the sole complication of prostate brachytherapy with the potential to affect sexual quality of life, however; there have been reports of hematospermia in 28%, orgasmalgia in 15%, and alteration in the intensity of orgasm in 38% of patients.[396] These side effects tend to be transient in most men.

Recently, health-related quality-of-life instruments have become available to evaluate morbidity outcomes for prostate cancer treatments. A prospective study of health-related quality-of-life outcomes in men treated with brachytherapy, external beam radiation therapy, or radical prostatectomy was recently reported.[397] Men treated with external beam radiation therapy did not show significant changes in health-related quality of life following completion of treatment, whereas men treated with brachytherapy and radical prostatectomy had significant decreases in health-related quality of life within the first month following treatment. By 12 months after treatment, health-related quality of life had returned to baseline in each of the three treatment groups.

Proton Beam Radiation Therapy

Although proton beam radiation therapy is available only at a few centers worldwide, there has been interest in its use for prostate cancer. The unique physical properties of protons make them ideal for the treatment of disease in close proximity to critical structures. Specifically, protons deposit the majority of their energy at the very end of their linear tracks, a phenomenon termed the *Bragg peak*. The dose falls off very rapidly at depths beyond the Bragg peak, a feature that is particularly useful in the treatment of prostate cancer, to minimize rectal and bladder dose. Investigators from Loma Linda University reported their experience treating men ($N = 1255$) with T1-T3 prostate cancer.[398] Men were treated with protons alone to 74 cobalt Gray equivalents (CGE) or with photons to 45 Gy followed by proton boost to 75 CGE. The median follow-up was 62 months, and the 8-year actuarial biochemical disease-free survival rate was 73%. In a recent prospective, randomized trial of 70.2 GyE versus 79.2 GyE (combination of photons plus protons) for men ($N = 393$) with stage T1b-T2b prostate cancer and a serum PSA below 15 ng/mL, at a median follow-up of 5.5 years, 61.4% of the men treated with 70.2 GyE versus 80.4% of men treated with 79.2 GyE were free of biochemical treatment failure, supporting the concept that higher doses of radiation result in a statistically significant reduction in the risk of recurrence of localized prostate cancer.[399]

Adjuvant Endocrine Therapy and Radiation Therapy for Low-Risk Localized Prostate Cancer

Androgen deprivation therapy has been found to improve survival in randomized trials of men with high-risk prostate cancer treated with external beam radiation therapy (Fig. 88-13).[400–402] The role of androgen deprivation therapy in men with low-risk prostate cancer is unknown. D'Amico and associates reported results of a large retrospective study ($N = 1586$) of men treated with 3D-CRT plus or minus androgen deprivation therapy for low-risk, intermediate-risk, and high-risk prostate cancer.[403] In this study, the median radiation dose was 70.2 Gy and androgen deprivation therapy was used for 276 of the men for two months before radiation therapy, during treatment, and for two months after treatment was completed. With a median follow-up of 51 months, the 5-year PSA relapse-free survival for men with low-risk prostate cancer was 92% with the addition of androgen deprivation therapy versus 84% without ($P = 0.09$). Men with intermediate- and high-risk prostate cancer also faired significantly better when given androgen deprivation therapy. RTOG Trial 94–08, which completed accrual in 2001, has been designed to ascertain whether men with stage T1b-T2 prostate cancer and a serum PSA of 20 ng/mL or less benefit from the addition of "complete androgen blockade" given for four months before and concomitantly with external beam radiation therapy.

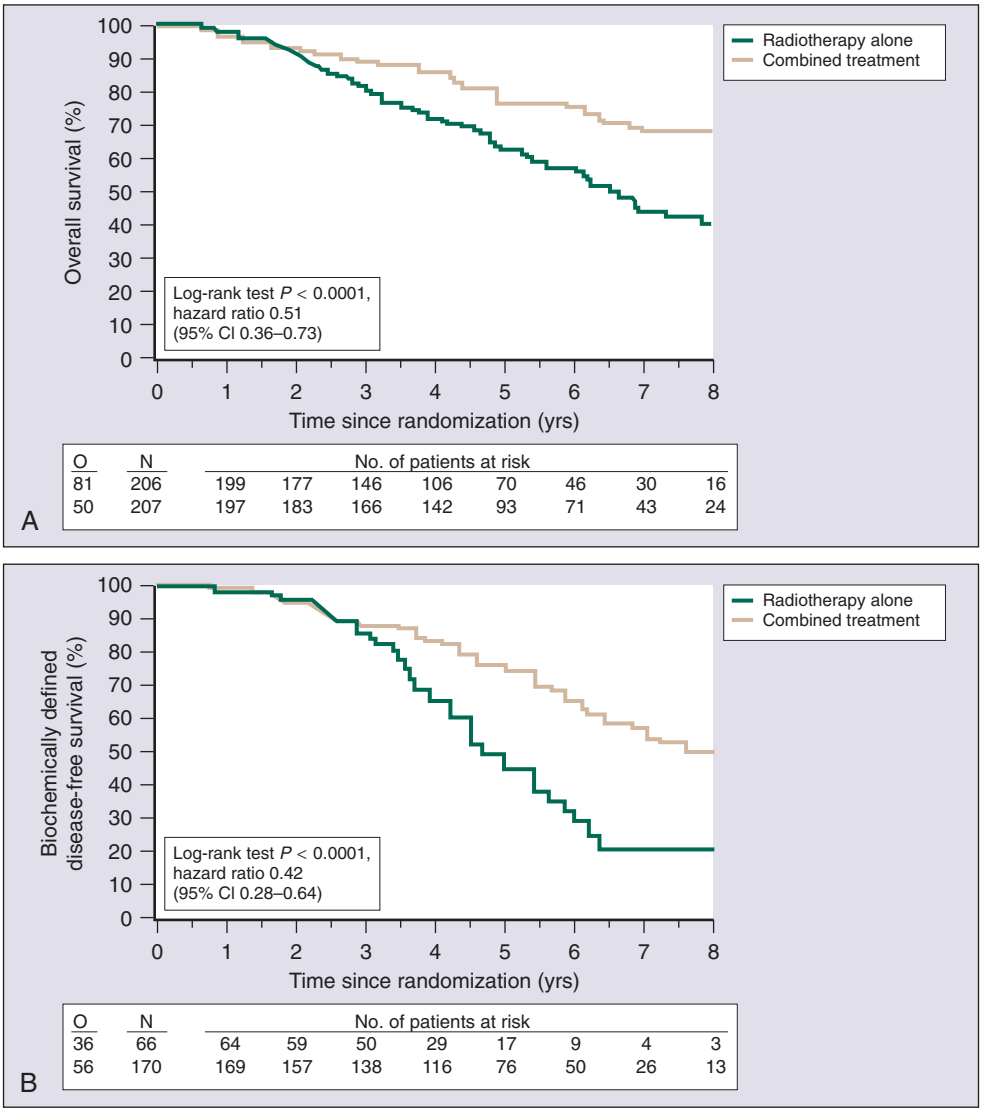

Figure 88-13 • Kaplan-Meier estimates of survival for men with prostate cancer from a prospective randomized clinical trial comparing a combination of androgen-deprivation therapy (goserelin acetate for a total of 3 years with cyproterone acetate for 1 month) and radiation therapy versus radiation therapy alone. **A,** Overall survival. **B,** Relapse-free. O, number of deaths; N, number of subjects. (From Bolla M, Collette L, Blank L et al: Long-term result with immediate androgen suppression and external irradiation in patients with locally advanced prostate cancer [an EORTC study]: a phase II randomized trial. Lancet 2002;360:103–106.)

Adjuvant Endocrine Therapy and Radiation Therapy for Intermediate- and High-Risk Localized Prostate Cancer

Men with intermediate-risk prostate cancer (clinical stage T2b, Gleason score of 7, or PSA of 10–20 ng/mL) fall at the break-point of defined prognostic subgroups in many case series reporting treatment outcomes, making treatment recommendations difficult. Although dedicated phase III trials evaluating the role and technique of radiation therapy with this group of men have not been performed, intermediate-risk men often are included in studies of radiation treatment for both men with low-risk prostate cancer and those with more advanced disease. Radiotherapeutic options for men with intermediate-risk prostate cancer include external beam radiation therapy, prostate brachytherapy, or a combination of both modalities. The need for adjuvant androgen deprivation therapy in this subset of men is debatable, but a potential benefit can be inferred from phase III clinical trials and single institution case series. One recent trial of a limited course of androgen deprivation combined with radiation (N = 206) for clinically localized prostate cancer (Gleason score > 7 or a serum PSA > 10 ng/mL or evidence of extraprostatic disease) randomized men to receive radiation therapy to a dose of 70 Gy alone or 70 Gy radiation plus 6 months of androgen deprivation therapy. At a median follow-up of 4.52 years, men treated with the combination of radiation plus androgen deprivation had a significantly higher overall survival than men treated with radiation alone (actuarial 5 year survival = 88% vs. 78% respectively).[404]

High-risk prostate cancer (clinical stage T2c-T4, Gleason score of 8–10, or serum PSA > 20 ng/mL) usually is treated with androgen deprivation therapy in conjunction with radiation therapy. The optimal duration and sequencing of androgen deprivation therapy, however, remains to be determined. Brachytherapy, usually in conjunction with both androgen deprivation therapy and external beam radiation therapy, also has been used to treat men with high-risk prostate cancer.

Adjuvant Endocrine Therapy and Radiation Therapy for Locally Advanced Prostate Cancer

Combined modality treatment using androgen deprivation therapy in conjunction with external beam radiation therapy takes advantage of separate and noncompeting modes of cell death such that cells that can survive the insult of one modality cannot survive the other or the additive/synergistic properties of the two.[405] Androgen deprivation

therapy has been used along with radiation therapy for many years in an attempt to modify the outcome of men with stage C (T3) prostate cancer.[406] Historically, the rationale for this treatment approach was that these men had an inferior outcome compared with men with earlier-stage prostate cancer treated with radiation therapy. In addition, the tumors often were quite bulky, and it was thought that a course of cytoreductive therapy might provide a more favorable geometry for external irradiation. However, the use of androgen deprivation therapy in combination with radiation was not universally accepted throughout the 1970s and 1980s. Radiation therapy techniques were improving, and the results from early case series exploring the benefit of androgen deprivation therapy before and/or during radiation therapy often were negative.[407,408]

In the early 1980s, two case series reported encouraging results with the use of androgen deprivation therapy and external beam radiation therapy to treat men with locally advanced prostate cancer.[409,410] Pilepich and coworkers[411] also found that men with histologically unfavorable prostate cancers who had been treated with androgen deprivation therapy and external beam radiation therapy as part of RTOG trial 75–06 exhibited similar disease-free survival and overall survival rates to those of men with more favorable prostate cancers who did not receive androgen deprivation therapy along with radiation therapy. More recently, phase III clinical trials have established the local control and survival benefits of androgen deprivation therapy given along with external beam radiation therapy for locally advanced prostate cancer. The advantage of androgen deprivation therapy before irradiation, as opposed to starting androgen deprivation therapy and external beam radiation therapy together, has never been established by a direct comparison.

RTOG 86–10 was a randomized phase III clinical trial of external beam radiation therapy alone (standard treatment arm) versus neoadjuvant and concomitant total androgen suppression and external beam radiation therapy (experimental treatment arm).[412] Eligible men had bulky (>25 cm^2), locally advanced prostate cancer (stage T2b-T4, N0-N1, M0). Men randomized to receive total androgen suppression were treated with goserelin acetate, 3.6 mg, every 28 days and flutamide, 250 mg, three times daily for 2 months before the start of, and during, radiation therapy. Standard radiation techniques were utilized, with 45 Gy delivered to the pelvis followed by a 20- to 25-Gy boost to the prostate. Extended fields were used to treat the lymph nodes when they were involved. A total of 471 men were enrolled and randomized to one of the two treatment arms. Analysis of the trial results revealed that men treated with total androgen suppression and radiation had a significant improvement in local control at 5 years compared with those men treated with radiation only ($P < 0.001$). A recent update of this trial, with a median follow-up over 6 years, continues to report a statistically significant difference in the 5-year probability of local treatment failure (22% vs. 35%, $P = 0.004$) as well as an increase in both disease-free survival (33% vs. 21%, $P = 0.004$) and cause-specific mortality (23% vs. 31%, $P = 0.05$), when considering the entire group, in favor of combined treatment. In subset analyses, there also was an improvement in overall survival for those men with Gleason score 2 to 6 prostate cancer (70% vs. 52%, $P = 0.015$), in favor of combined treatment. This improvement in overall survival was not seen when evaluating all men in the study. There are several possible explanations. It is possible that there may not be an overall survival benefit for men when total androgen suppression is added in this fashion and/or in this patient population as a whole. However, it is important to note that this study was limited in that it did not routinely obtain serum PSA levels from all men before entry, a parameter now recognized to be an extremely important prognostic factor and indicator of disease extension. Therefore, it is likely that there were a large number of men with elevated serum PSA levels in the range commonly associated with a high risk for micrometastatic prostate cancer. The study also included men with node-positive disease, also recognized to be a poor risk factor, for which the value of any treatment modality to overall survival can be debated. Nonetheless, this was an important study, performed in rigorous fashion, and revealing important and measurable benefits attributable to the addition of androgen deprivation therapy to external beam radiation therapy for these men with prostate cancer.

The RTOG 85–31 trial also targeted men with locoregionally advanced prostate cancer, including men who had undergone radical prostatectomy and were identified at pathologic examination as being at high risk.[402,413] The aim of this phase III trial was to evaluate the role of long-term adjuvant androgen suppression in men with high-risk prostate cancer. Men enrolled on the trial who underwent definitive radiation were those with clinical stage T3 (>25 cm^2), or T1-T2 disease and radiographic or histologic lymph node involvement. Men were eligible after prostatectomy if prostate cancer with capsular penetration and positive surgical margins or with seminal vesicle involvement was found. A total of 945 evaluable men were enrolled and followed for a median of 4.5 years. Conventional radiation therapy techniques were used to deliver a total dose of 44 to 46 Gy to the whole pelvis with a 20- to 25-Gy boost to the prostate or postoperative prostatic fossa, for a total dose of 65 to 70 Gy. Androgen deprivation therapy was accomplished using goserelin acetate, 3.6 mg, monthly, beginning the last week of radiation therapy. Actuarial projections at 5 years revealed 84% of men receiving adjuvant androgen deprivation versus the 71% of men on the observation arm who remained without evidence of local recurrence ($P < 0.0001$). The corresponding figures for freedom-from-distant metastases and disease-free survival were 83% versus 70% ($P < 0.001$) and 60% and 44% ($P < 0.0001$). The 5-year survival rate for the entire population was 75% on the adjuvant androgen deprivation arm versus 71% on the observation arm ($P = 0.52$). However, in men with prostate cancers with a Gleason score of 8 to 10, a statistically significant difference in actuarial 5-year survival of 66% versus 55% favoring the adjuvant androgen deprivation arm was evident ($P = 0.03$). The most recent update of this trial with a median follow-up of 5.6 years confirmed the statistically significant improvement in both absolute and cause-specific survival for adjuvant androgen deprivation given with external beam radiation therapy.[413]

Bolla and colleagues[400,401] published results of the European Organization for Research and Treatment of Cancer (EORTC) 22863 trial. This phase III trial enrolled 415 men with stage T3-T4 prostate cancer of any grade or stage T1-T2 World Health Organization (WHO) grade 3 prostate cancer with no evidence of nodal or metastatic disease. Men were randomized to receive external beam radiation therapy alone (control arm) or androgen deprivation therapy plus external beam radiation therapy (experimental arm). Androgen deprivation consisted of oral cyproterone acetate, 50 mg, three times daily for 4 weeks before radiation and goserelin acetate, 3.6 mg, started on the first day of radiation and continued every month for 3 years. Radiation therapy was delivered as 50 Gy to prostate and regional lymph nodes, followed by a 20-Gy boost to the prostate, for a total prostate dose of 70 Gy. A total of 401 men were studied, with a median follow-up of 45 months. Overall survival at 5 years was 79% in the androgen deprivation therapy plus external beam radiation therapy arm and 62% in the external beam radiation therapy alone arm ($P = 0.001$). The local recurrence-free survival was 97% for men treated with androgen deprivation therapy plus external beam radiation therapy versus 77% for men treated with external beam radiation therapy alone ($P < 0.001$). The relapse-free survival was reported to be 85% for combined treatment and 48% for radiation alone ($P < 0.001$). The most recent update of this trial, at a median follow-up of 66 months, confirmed the durability of these initial results with 5-year overall survival of 78% versus 62%, favoring the androgen deprivation therapy plus external beam radiation therapy arm ($P = 0.0002$).[401] Five year relapse-free survival also continued to favor the combination treatment (74% versus 40%).

The RTOG 92–02 Trial, which completed accrual in 2000, is a phase III prospective randomized trial of androgen deprivation

therapy plus external beam radiation therapy for men with locally advanced prostate cancer.[414] This study compared the efficacy of short-term androgen deprivation, as was administered in RTOG 86–10, with that of long-term androgen deprivation, similar to that used in the EORTC 22863 trial. A total of 1554 men with locally advanced prostate cancer stage T2c-T4 with serum PSA below 150 ng/mL were enrolled in the trial and followed for a median of 4.8 years. All men received 4 months of goserelin acetate and flutamide, 2 months before and during radiation therapy. Men were then randomized to receive either no further therapy (short-term androgen deprivation) or to be treated with goserelin acetate for an additional 24 months (long-term androgen deprivation). The radiation dose was 65 to 70 Gy to the prostate and 44 to 50 Gy to the pelvic nodes. At 5 years, the long-term androgen deprivation group showed significant improvement in disease-free survival of 54% versus 34% ($P = 0.0001$), in clinical local progression of 6.2% versus 13% ($P = 0.0001$), and in freedom-from-distant metastasis of 11% versus 17% ($P = 0.001$). Five-year overall survival was not significantly different between the two treatment arms (78% versus 79%). Subset analyses were performed for direct comparison of this trial to both the EORTC 22863 study and RTOG 85–31. The first subset included men with high-risk prostate cancer defined by clinical stage T3-T4 or stage T2 with a Gleason score of 8 to 10 for comparison to the results reported by Bolla and associates.[400,401] There was no overall survival difference (77% versus 80%) at 5 years but a significant advantage in disease-free survival for long-term androgen deprivation of 90% versus 86% ($P = 0.03$). A second subset included all men with Gleason score 8 to 10 prostate cancer for comparison with results from RTOG 85–31.[415] Five-year overall survival (80% versus 69%, $P = 0.02$) and disease-free survival (90% versus 78%, $P = 0.007$) were significantly better with long-term androgen deprivation.

The results of RTOG 92–02 have helped to establish the superiority of more protracted courses of androgen deprivation therapy for men with high-risk or locally advanced disease. The optimal sequencing of androgen deprivation therapy and radiation, however, has come into question. Currently it is not known whether the effects of androgen deprivation therapy on prostate cancer control were merely additive to the tumoricidal effects of radiation or were synergistic, providing an enhancement of tumor killing. Of interest in this regard, RTOG 94–13 Trial compared whole-pelvic radiation to prostate-only radiation and neoadjuvant and concomitant androgen deprivation therapy, given 2 months prior and 2 months during radiation therapy, to adjuvant androgen deprivation therapy, given after completion of radiation treatment for 4 months.[416] A total of 1295 men with prostate cancer and an estimated risk of lymph node involvement of more than 15% (based on the equation "+ lymph node = ($^2/_3$) serum PSA + (Gleason score − 6) × 10)" were randomized to one of the four treatment arms. There was no difference in outcome for neoadjuvant versus adjuvant androgen deprivation therapy; however, this may be confounded by a lead-time bias because the follow-up time for men on the neoadjuvant arm is 2 months longer than on the adjuvant arm. When comparing all four treatment arms, there was a progression-free survival advantage for whole-pelvis radiation therapy plus neoadjuvant and concomitant androgen deprivation therapy arm versus the other three arms (61% versus 45%, 49% and 47% respectively; $P = 0.005$). So far, the follow-up (median 59.5 months) is too short to adequately detect a difference in overall survival.

Risk of Pelvic Lymph Node Involvement and Determination of Radiation Field Size

Considerable effort has been directed toward defining the optimal radiation treatment volumes for men with prostate cancer. Men with high-risk prostate cancer are of particular interest in this regard because there is no universally accepted standard of care for this group of men with a defined risk of pelvic lymph node involvement. The rationale for prophylactic irradiation of pelvic lymph nodes is based on well-established surgical data that predict a rate of lymph node positivity, ranging from 5% to 50% for men with prostate cancer and one or more high-risk features.[417] Since the advent of 3D-CRT and its progressive refinement into more accurate dose delivery techniques, the debate of whether or not to treat pelvic nodes has intensified. Because a potentially higher risk of complications may be associated with whole-pelvis irradiation, it would be considered desirable not to treat such a large radiation portal if it were not beneficial. The RTOG 77–06 Trial found no advantage to pelvic radiation for men with T1/T2 prostate cancer.[418] However, this study included men estimated to be at low risk for lymph node involvement, including some proven to be pathologically lymph node-negative. RTOG 76–05, which randomized T3/T4 men to pelvis-only versus pelvic and para-aortic radiation therapy, also failed to detect an advantage for the extended radiation treatment field.[419] Of note, this trial often has been misinterpreted as suggesting that there is no role for radiation of pelvic nodes in men with prostate cancer, although it really only examined the efficacy of para-aortic radiation.

More recently, results of the phase III randomized RTOG 94–13 trial have provided further insight into the use of larger radiation fields,[416] as described previously. In brief, the study featured a 2 × 2 factorial design comparing whole-pelvic radiation to prostate-only radiation (and neoadjuvant and concomitant androgen deprivation therapy to adjuvant androgen deprivation therapy). Whole-pelvis radiation therapy consisted of a conventional four-field technique with a minimum field size of 16 × 16 cm treated to a maximum dose of 50.4 Gy. An additional 19.8 Gy was then delivered to the prostate using a conedown boost technique. Prostate-only radiation therapy was limited to the prostate and seminal vesicles, with a maximum field size of 11 × 11 cm, to a total dose of 70.2 Gy. Four-year progression-free survival (PFS) was 56% for whole pelvic radiation therapy compared with 46% for prostate-only radiation therapy ($P = 0.014$), with no difference in overall survival. There also was no significant difference in acute or late gastrointestinal or genitourinary toxicities between the two treatment approaches.

Postprostatectomy Adjuvant Radiation Therapy

Pathologic features that portend a higher risk of local recurrence are common after radical prostatectomy. A positive surgical margin is associated with a risk of approximately 50% of prostate cancer recurrence.[338,420–423] Other features associated with recurrence are extracapsular extension, seminal vesicle invasion, and Gleason score of 7 or greater. Several retrospective series have demonstrated improved PSA relapse-free survival with the addition of adjuvant radiation therapy following radical prostatectomy for men with these risk factors.[424–426] In one study of men ($N = 149$) with pathologic stage T3N0 prostate cancer and an undetectable postoperative serum PSA, adjuvant radiation therapy was given to a median dose of 64.8 Gy to some men ($N = 52$), while the remainder ($N = 97$) underwent no further treatment.[424] In a matched-pair analysis, the 5-year freedom-from-PSA relapse rate was 89% in the adjuvant radiation therapy group versus 55% for treatment with surgery alone ($P < 0.01$).

Three prospective randomized trials have been completed that tested the benefits of adjuvant radiation therapy versus observation following radical prostatectomy in men with prostate cancer and poor pathologic features. The EORTC has published clinical trial results revealing an improvement in biochemical relapse-free survival and locoregional progression-free survival for the men with pT3 tumors or pT2/T3 prostate cancer and positive surgical margins treated with adjuvant radiation therapy.[401] In a second study targeting the same patient population conducted by the Southwest Oncology Group (SWOG), men with prostate cancer who received adjuvant radiation not only enjoyed better biochemical and local control, but also appeared likely to have better metastasis-free survival and overall survival, although these improvements were not yet statistically

significant even at a median follow-up of 10 years.[427] Nonetheless, men treated with adjuvant radiation therapy were less likely to need hormonal therapy at 5 years (10% vs. 21%, $P < 0.001$). Avoidance of androgen deprivation therapy is likely of significant clinical benefit, reducing or delaying significant morbidity, including hot flashes, diminished bone density, sexual dysfunction, cognitive dysfunction, and overall reduced quality of life. Finally, a third randomized trial comparing adjuvant radiation and observation after prostatectomy, which enrolled only men with pT3 disease regardless of surgical margin status, was reported by the German Cancer Study Group.[428] As with the other two studies, men treated with adjuvant radiation experienced a superior biochemical relapse-free survival with median follow up of only 3.3 years. Thus, overall, data available today provide a convincing case for adjuvant radiation treatment after prostatectomy. However, it is clear that not all men benefit from such treatment. A more precise way to stratify men for adjuvant radiation therapy is needed: one such group may be men with positive surgical margins after radical prostatectomy.

Salvage Radiation Therapy after Radical Prostatectomy

Salvage radiation therapy refers to the use of radiation therapy postprostatectomy in the setting of recognized prostate cancer recurrence. As many as 27% to 53% of men who undergo radical prostatectomy for prostate cancer will have a detectable PSA within 10 years of surgery.[316] Subsequently, approximately 25% of men who undergo radical prostatectomy will be treated with salvage radiation therapy for recurrent prostate cancer.[429] In the setting of persistent or rising serum PSA following radical prostatectomy, it is important to rule out distant metastatic prostate cancer with bone scan, chest radiography, and CT scan of the abdomen and pelvis, prior to the initiation of salvage radiation therapy. Partin and coworkers[430] correlated the rate of serum PSA rise with likelihood of local versus distant relapse after surgery. A serum PSA rise of 0.75 ng/mL/yr was associated with local recurrence. In 1999, an ASTRO consensus panel concluded that treatment of men with local prostate cancer recurrence after radical prostatectomy and a preradiation therapy serum PSA below 1.5 ng/mL was more likely to be successful.[431] In addition, doses above 64 Gy were recommended in the salvage setting. Several studies have demonstrated a Gleason score greater than 7 to be associated with a low likelihood of successful salvage after prostate cancer recurrence postprostatectomy.[432,433] Cadeddu and colleagues[433] reported no men free of PSA relapse treated with salvage radiation therapy after prostatectomy for prostate cancers with Gleason scores of 8 or above. Similarly, Song and associates[432] found only 2 of 14 men with Gleason score of 8 or above to be prostate cancer-free at the time of analysis. These results indicate that men with recurrent prostate cancer and a Gleason score of 8 or greater are unlikely to benefit from salvage radiation therapy due to the likelihood of microscopic systemic prostate cancer metastases.

However, the largest multi-institution retrospective series to date ($N = 501$ men) has provided a clearer view of the likelihood of benefit for various subgroups of men with local prostate cancer recurrence after prostatectomy.[434] In this study, predictors of a poor response to salvage radiation included Gleason score of 8 to 10, preradiation PSA level higher than 2 ng/mL, PSA doubling time after prostatectomy of 10 months or less, negative surgical margins, and seminal vesicle invasion. Nonetheless, a significant fraction of men with one or more of these negative prognostic features still experienced a durable response to salvage radiation, particularly if the radiation was given prior to a PSA level of 2 ng/mL. Even for the group of men with the worst combination of prognostic features, a Gleason score of 8 to 10 and a preradiation PSA of 2 ng/mL or higher, salvage radiation produced a progression-free survival of 12% at 4 years. While these results hint at marked benefit to salvage radiation therapy after prostatectomy, the study itself was retrospective and may have been confounded by selection bias. Prospective studies are needed to determine definitively whether patients with one or more poor prognostic features derive benefit from salvage radiation. However, given the available data and considering the limited morbidity of this treatment, especially with IMRT, it is reasonable to consider salvage radiation for postprostatectomy patients with PSA recurrence regardless of prognostic factors.

The role of androgen deprivation therapy concomitant with radiation therapy given as an adjuvant to surgery as salvage for prostate cancer recurrence following surgery has not been established. In the RTOG 85–31 Trial, a subgroup of men with pathologic T3N0 prostate cancer who underwent radical prostatectomy received adjuvant radiation therapy to a dose of 60 to 65 Gy and then were randomized to immediate androgen deprivation or androgen deprivation initiated at the time of PSA relapse.[435] At 5 years, 65% of men treated with immediate androgen deprivation versus 42% of men treated with delayed androgen deprivation were free of PSA relapse. There are no prospective trials examining the addition of androgen deprivation therapy to salvage radiation therapy for local prostate cancer recurrence after prostatectomy. Taylor and coworkers[436] reported a benefit to the addition of androgen deprivation therapy to salvage radiation therapy in a retrospective case series. In this series, adjuvant androgen deprivation therapy was given to men who received salvage radiation therapy for a median duration of 24 months. At 5 years, 81% of men receiving androgen deprivation therapy (versus 54% not treated with androgen deprivation) were free of PSA relapse. In contrast, Song and colleagues[432] reported identical median disease-free survivals of 26 months for men treated with or without concurrent androgen deprivation therapy along with salvage radiation therapy for prostate cancer recurrence. The 1999 ASTRO Consensus Panel concluded that there was insufficient evidence to support routine use of androgen deprivation therapy with postprostatectomy radiation therapy.[431]

Toxicity of Postprostatectomy Radiation Therapy

In general, men receiving radiation therapy postprostatectomy experience little in the way of additional morbidity. The incidence of urinary incontinence does not seem to be increased, and erectile function does not seem to be worsened in men treated with adjuvant radiation therapy after prostectomy.[437,438] Bastasch and associates[439] reported that 100% of men who were potent after nerve-sparing radical prostatectomy remained potent after adjuvant IMRT. Despite these promising reports, side effects remain possible. Katz and coworkers[440] noted that 19% of men experienced grade 2 or 3 genitourinary toxicity (hematuria or urethral stricture), and 12% of men experienced grade 2 bowel toxicity (with no grade 3 or higher toxicity noted), following salvage radiation with 3D conformal techniques.

SYSTEMIC TREATMENT OF METASTATIC CANCER

Natural History of Metastatic Prostate Cancer

Over the past decade, widespread and routine clinical use of serum PSA testing has changed not only screening and diagnosis of prostate cancer, but virtually all aspects of prostate cancer management.[441,442] Current estimates of prostate cancer incidence by stage illustrate a major prostate cancer stage migration with a categorical shift toward less advanced cancer at the time of diagnosis. Similarly, outcome data from large cohorts and from contemporary large-scale prospective randomized clinical trials reveal that time-to-progression and survival from prostate cancer have changed substantially over the past decade. Previously collected outcome data must be scrutinized and considered in the context of more contemporary findings before making treatment recommendations or designing new clinical trials. For example, for men with newly diagnosed metastatic prostate cancer who have not received androgen suppression therapy (stage D2

disease; sometimes referred to as "hormone-naïve"), randomized prospective trials conducted before the serum PSA testing era consistently have shown a median time-to-progression ranging from 12 to 18 months, and a median survival ranging from 24 to 30 months. Men with limited metastatic prostate cancer (appendicular skeleton and/or nonvisceral soft tissue metastases) tended to have a median survival of 52 months, whereas men with extensive bony metastases and/or visceral disease had a median survival of 24 months. Also, the distribution of men with prostate cancer according to extent of disease in the earlier studies typically included as many as 80% with extensive metastatic disease, while more contemporary studies often have less than 50% of men in this category. In a case series, the median metastasis-free survival of men with recurrent prostate cancer after radical prostatectomy at the Johns Hopkins Hospital who underwent routine yearly follow-ups, with serial serum PSA determinations and bone scans, from the time of biochemical relapse following surgery, was more than 6 years.[316] One explanation for the relatively long survival of these men may be that the overwhelming majority who developed distant metastasis had limited metastatic disease, most likely due to an increased lead-time in diagnosis of metastatic prostate cancer resulting from intensive follow-up featuring serum PSA assays.

This lead-time effect also is apparent in men who suffer prostate cancer progression following initial androgen deprivation therapy. The survival of men with androgen-independent (sometimes called *hormone-refractory*) prostate cancer in chemotherapy trials conducted over a decade ago ranged between 6 and 12 months, whereas in more contemporary studies, median survival has ranged between 15 and 20 months. Furthermore, a large and increasing proportion of men with metastatic prostate cancer who progress after initial androgen deprivation therapy are first identified because of rising serum PSA values without other evidence of prostate cancer progression. Not unexpectedly, survival for men with serum PSA increases as the only manifestation of prostate cancer progression is significantly longer than for men with evidence of radiologic and/or clinical progression (i.e., new findings on physical examination and/or cancer-related symptoms) in addition to rising serum PSA levels (Table 88-9).

Table 88-9 Prognostic Factors for Men with Androgen-Independent Prostate Cancer Treated with Chemotherapy

Prognostic Factor	Significance
Performance status	Definite: seen in virtually all studies
Baseline hemoglobin	Possible: seen in some studies (associations detected using multivariate analysis of uncontrolled clinical trials; not shown to be correlated with survival in randomized trials)
Liver metastases (metastasis to other visceral sites)	
Baseline serum acid phosphatase, alkaline phosphatase, lactate dehydrogenase	
Time from initiation of androgen-deprivation therapy to initiation of chemotherapy	
Response to chemotherapy (reduction in measurable cancer deposits and/or ≥50% decline in serum PSA for ≥4 wk)	
Baseline serum PSA	
Extent of disease (on bone scan)	Equivocal: more data needed
Continuation of androgen-deprivation therapy	

PSA, prostate-specific antigen.

Endocrine Approaches to Prostate Cancer Treatment

The dependence of prostate cancer cells on androgens for growth and differentiation has been well recognized for at least five decades[443] (Fig. 88-14). Testosterone, produced by Leydig cells in the testes upon stimulation by LH, is converted to DHT by the action of 5α-reductase.[10] DHT, a more potent androgen than testosterone, binds to intracellular androgen receptors to activate the expression of target genes.[11,12] Androgen deprivation therapy for prostate cancer involves maneuvers that reduce circulating testosterone to levels around or below levels present in castrated men (<50 ng/mL). Forced reduction of testosterone levels by castration, or via gonadal suppression, triggers a wave of apoptosis in both normal and neoplastic prostate cells, with little or no acute effect on nonandrogen target tissues, providing one of the most effective systemic palliative treatments known for solid organ cancers. Unfortunately, despite the magnitude of the initial beneficial treatment response, prostate cancer inexorably evolves to androgen-independence.[21] As of yet, no therapeutic maneuver has been shown to prevent this sequence of progression.

Strategies for Androgen Deprivation

Currently, the general consensus is that a reduction in testosterone produced by the testes represents the best standard approach to androgen deprivation therapy for prostate cancer (Box 88-4). This can be accomplished by surgical removal of the testis (bilateral orchiectomy), by inhibition of the synthesis and release of pituitary gonadotropins by gonadotropin-hormone-releasing hormone analogues (GnRH or LHRH analogues and LHRH antagonists), or by the administration of pharmacologic doses of estrogens.

Bilateral orchiectomy results in a rapid decline of testosterone to 5% to 10% of normal values and remains the treatment of choice for severely symptomatic patients. Although the suppression of testosterone production associated with LHRH analogues is comparable to bilateral orchiectomy, the nadir of serum testosterone levels is not reached until after 3 to 4 weeks of treatment. The LHRH analogues, highly potent LHRH agonists, initially stimulate LH release by the pituitary, but on chronic administration subsequently suppress LH and testosterone production.[444,445] Thus, LHRH analog treatment also is associated with an initial rise in LH and in serum testosterone in virtually all patients. This brief elevation of testosterone levels has been reported to be associated with a flare of the prostate cancer, manifested by an increase in pain in symptomatic patients, or by more worrisome consequences of prostate cancer progression, including epidural cord compression and urinary obstruction.[446] Longer-acting depot preparations of LHRH analogues (administered monthly, every 3 or 4 months, or yearly) are available for clinical use. Clinical trials comparing bilateral orchiectomy to a variety of LHRH analogues have revealed comparable short- and long-term efficacy in patients with metastatic prostate cancer. Because of convenience, and the ability to avoid surgery, LHRH analogues have become the most widely used method for reducing serum testosterone.

New LHRH antagonists have been introduced to achieve a reduction in serum testosterone without the brief flare associated with initial stimulation of pituitary gonadotropin secretion and testicular androgen production associated with LHRH analogues. These agents appear to be generally as effective as LHRH analogues, achieving a faster suppression of gonadal androgen production to the castrate range with comparable long-term sustained reductions of serum testosterone and no evidence of flare reactions.[447] The efficacy of LHRH antagonists as treatments for prostate cancer, in comparison to bilateral orchiectomy or to LHRH analogues, has not been fully evaluated. Nonetheless, because LHRH agonists can lower the serum testosterone rapidly, like bilateral orchiectomy, these agents may well offer an attractive alternative to the LHRH analogs for the treatment of men with symptomatic prostate cancer for whom a flare reaction might threaten significant morbidity.

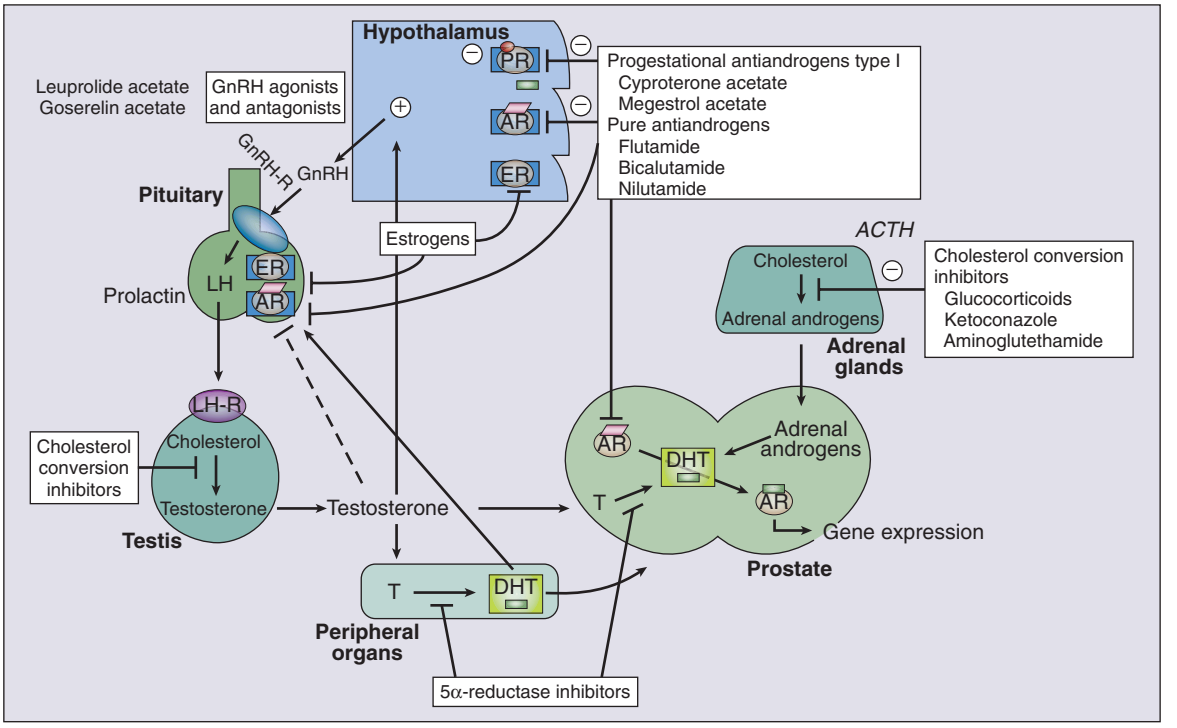

Figure 88-14 • Sites of action of different treatments that affect androgen action. ACTH, adrenocorticotropic hormone; AR, androgen receptor; DHT, 5α-dihydrotestosterone; ER, estrogen receptor; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PR, progesterone receptor; T, testosterone.

The administration of pharmacologic doses of synthetic estrogens represented the earliest strategy for drug treatment of prostate cancer.[448] Initial studies using diethylstilbestrol (DES) revealed a dose-dependent suppression of serum testosterone to the castrate range. When used for prostate cancer progression, DES provided clinical benefits comparable to those achieved with bilateral orchiectomy. In a clinical trial conducted by the Veterans Administration Cooperative Urological Research Group (VACURG Study 1), men with prostate cancer treated with DES had a prostate cancer-specific survival comparable to men treated by bilateral orchiectomy.[448,449] However, men in this study treated with DES (at a dose of 5 mg daily) suffered a high incidence of cardiovascular deaths.[450] A subsequent clinical trial (VACURG Study 2) evaluated different daily doses of DES (0.2 mg, 1.0 mg, and 5.0 mg) versus placebo.[448,449] Results suggested that the 1.0 mg daily DES dose was as effective as the 5.0 mg daily dose in terms of prostate cancer deaths, but was associated with a lower incidence of fatal cardiovascular complications. Subsequent analyses of men treated with DES at a daily dose of 1 mg revealed that testosterone often was not adequately suppressed, especially in younger patients with initially normal gonadal function.[448,449,451] All of these findings led to the recommendation that DES, at a 3-mg daily dose (known to result in effective long-term suppression of testosterone comparable to bilateral orchiectomy), constituted an effective prostate cancer treatment despite the fact that the safety and efficacy of this DES dose, relative to lower or higher doses, remain untested in prospective randomized clinical trials. With the ready availability of LHRH analogues, synthetic estrogens are not currently used for prostate cancer treatment.

Accumulated data from prospective randomized clinical trials in men with metastatic prostate cancer have revealed comparable efficacy of the various forms of androgen deprivation therapy, regardless of the outcome measure used, including rates of subjective and/or objective improvement, time-to-cancer-progression, or survival. However, in 1984, after leuprolide acetate, the first commercially available LHRH analog in the United States, was shown to be comparable to DES in treatment efficacy but associated with fewer serious complications, particularly congestive heart failure and thromboembolic events, DES was virtually abandoned in favor of LHRH analogues for the initial treatment of metastatic prostate cancer. Goserelin acetate, another commercially available LHRH analogue,

Box 88-4. SYSTEMIC TREATMENT OF MEN WITH METASTATIC PROSTATE CANCER

Androgen deprivation therapy, usually accomplished via the administration of luteinizing hormone-releasing hormone (LHRH) agonists, remains the standard treatment approach for men with symptomatic metastatic prostate cancer. In certain cases, antiandrogens are used to prevent the flare reaction associated with initiating LHRH agonist treatment.

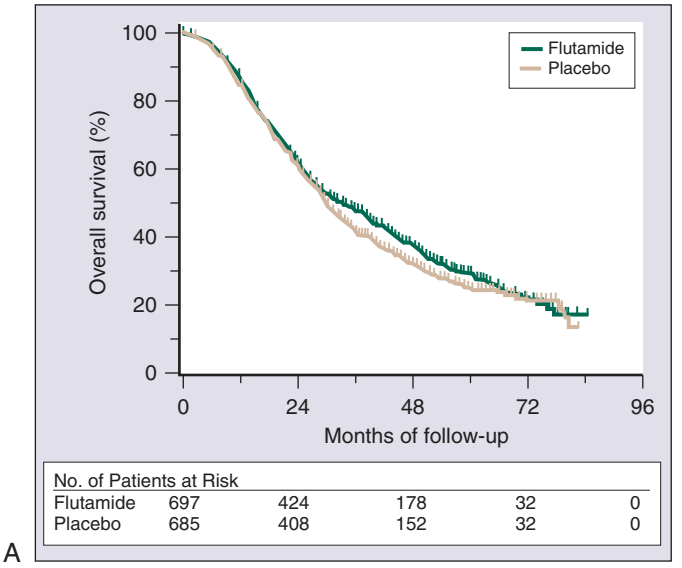
With the widespread use of serum prostate-specific antigen (PSA) testing as a monitoring tool for prostate cancer relapse after surgery or radiation therapy, a major new challenge has confronted physicians who treat prostate cancer: many men with recurrent prostate cancer have no symptoms attributable to the disease and no evident metastatic cancer deposits that can be detected by radiographic imaging. Which of these men should be considered for treatment, and when should treatment be initiated? Although these issues have not been fully resolved, available data indicate that the time between surgery or radiation therapy and PSA relapse, the Gleason score at the time of primary treatment, and the PSA doubling time are predictive of the risk and timing of overt metastatic prostate cancer. Men at high risk for progressive metastatic prostate cancer are likely the best candidates for systemic treatment.

also has been found to be comparable to bilateral orchiectomy in men with metastatic prostate cancer.

Anti-Androgens and 5α-Reductase Inhibitors

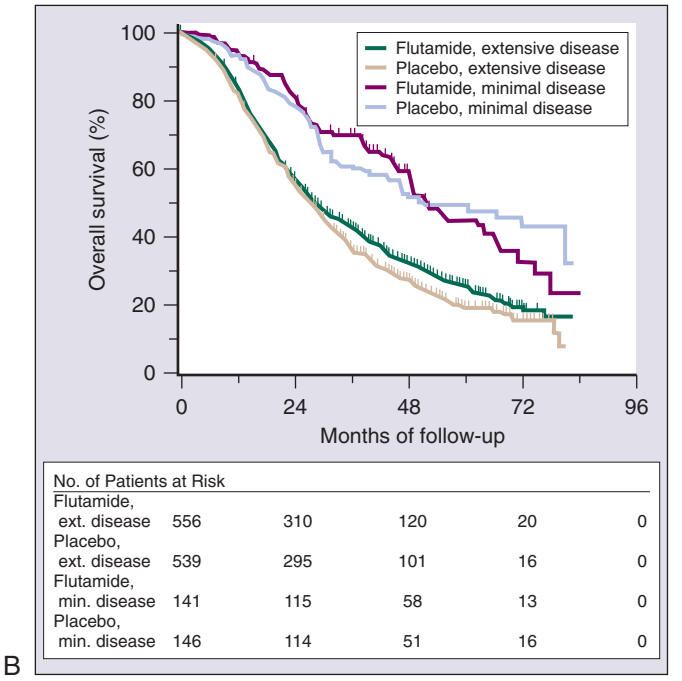
Anti-androgens compete with androgenic hormones for binding to the androgen receptor, blocking transcriptional activation of androgen target genes.[21] Anti-androgens have been used as adjuncts to androgen deprivation therapy (so-called "complete" or "maximal" androgen blockage) and as single agents, in an attempt to preserve sexual function. However, anti-androgen monotherapy is not without side effects: approximately 50% of men treated with bicalutamide at a 150-mg daily dose develop gynecomastia, and although libido often can be maintained, fewer men remain potent.[452] Bicalutamide monotherapy has been reported to provide similar survival outcomes to bilateral orchiectomy in men with nonmetastatic advanced prostate cancer (stage T3 and T4).[452] Nonetheless, anti-androgens used alone appear inferior to androgen deprivation therapy in prospective randomized clinical trials in men with metastatic prostate cancer.[452] The efficacy of anti-androgens used earlier in the natural history of prostate cancer (as adjuvant therapy for men with high-risk prostate cancer treated with radical prostatectomy or as treatment for men with a rising serum PSA after failure of cancer control with primary therapy) remains to be established. Flutamide, bicalutamide, and nilutamide are the nonsteroidal anti-androgens available currently in the United States.

Although DHT is a more potent androgen than testosterone, 5α-reductase inhibitors have not been found to be particularly effective in the treatment of metastatic prostate cancer when used alone.[183] A combination of the type 2 5α-reductase inhibitor finasteride and the nonsteroidal anti-androgen flutamide has been explored in clinical trials; the results obtained thus far do not suggest any striking advantage for combination treatment.[453] Dutasteride, an inhibitor of both type 1 and type 2 5α-reductases, has not been fully tested against prostate cancer.



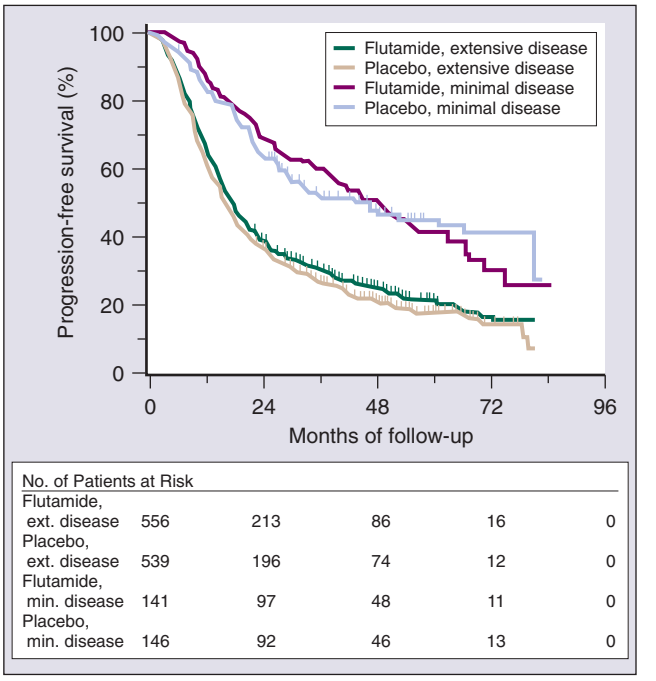
"Complete" Androgen Blockade

A substantial amount of basic research has been devoted to enhancing the understanding of critical mechanisms involved in the hormonal control of prostate cancer growth, and the emergence of androgen-independent prostate cancer.[21] Prostate cancers contain populations of cancer cells that are heterogeneous with regard to androgen dependency and sensitivity. In the 1980s, Labrie and colleagues[454,455] hypothesized that prostate cancer cells could adapt to the low levels of androgens present after androgen deprivation therapy, some produced by the adrenals, and support prostate cancer growth. To neutralize the effects of adrenal androgens, a combination of bilateral orchiectomy (or LHRH analogues) and a nonsteroidal anti-androgen was promoted as "complete" androgen blockade. The initial reports of the efficacy of this treatment combination prompted the conduct of a unprecedented number of clinical trials to assess the possible advantages of "complete" androgen blockade for men with metastatic prostate cancer: 7987 men with metastatic prostate cancer were entered onto 27 prospective randomized clinical trials comparing the efficacy of bilateral orchiectomy (or LHRH analogues) alone (monotherapy) to almost every possible combination of bilateral orchiectomy (or LHRH analogues) and anti-androgens.[456] A comprehensive review of all studies reported thus far has revealed that 24 of the 27 studies reported no significant differences in survival, while only 3 demonstrated modest, statistically significant, improvements in favor of "complete" androgen blockade.[456] Even for the occasional trial showing an apparent benefit for "complete" androgen blockade, there was a lack of consistency when considered in the context of other trials. For example, flutamide resulted in a survival advantage in one trial in combination with an LHRH analogue, whereas nilutamide did not; and nilutamide resulted in a survival advantage in one trial in combination with bilateral orchiectomy, whereas flutamide did not. For each of the trials hinting at a benefit for "complete" androgen blockade, at least one, and as many as five, similarly designed trials found no evidence for the benefit. Taken together, the large collection of clinical trial data testing the efficacy of "complete" androgen blockade suggest that any potential benefit of "complete" androgen blockage is likely minimal and of negligible clinical significance.



The first published large-scale prospectively randomized clinical trial of "complete" androgen blockade was the National Cancer Institute (NCI)-sponsored trial INT-0036.[142] Men ($N = 603$) with stage D2 prostate cancer were randomly assigned to receive daily subcutaneous injections (1 mg/day) of leuprolide acetate and the nonsteroidal anti-androgen flutamide versus leuprolide acetate and placebo. The median overall survival with "complete" androgen blockade was 36 months, while the median survival with monotherapy was 28 months ($P = 0.035$). While the NCI INT-0036 trial clearly showed a benefit to the treatment combination, several explanations other than the "complete" androgen blockage hypothesis have been proffered to account for the trial results. One argument was that the difference in favor of combination treatment could have been an attenuation of the LHRH analogue flare reaction by the anti-androgen.[457] In support of this contention, men randomized to receive combination treatment exhibited a trend toward more favorable pain control, improvement in performance status, and reduction in PAP, as compared to men treated with monotherapy, that was evident during the first 12 weeks of treatment.[142] However, this notion is not supported by the results of another study that discerned no difference in survival between men randomized to receive leuprolide acetate with 2 weeks of flutamide treatment versus leuprolide acetate alone.[458] A second argument for the superiority of combination treatment in the NCI INT-0036 trial was that noncompliance with the daily leuprolide acetate injection regimen might result in inadequate gonadal suppression, providing the opportunity for an advantage for the combination of daily leuprolide and flutamide. Because routine evaluations of serum testosterone were not included on the study, this argument could not be effectively excluded. To address these issues, a confirmatory trial, using bilateral orchiectomy rather than leuprolide acetate for androgen deprivation, was conducted (the NCI INT-0105 trial).

Bilateral orchiectomy represents the optimal method of reducing testosterone for testing the "complete" androgen blockade hypothesis because it is not associated with a flare reaction and/or compliance difficulties. The NCI INT-0105 clinical trial prospectively randomized men ($N = 1387$) with stage D2 prostate cancer to treatment with bilateral orchiectomy with flutamide versus bilateral orchiectomy with a placebo[141] (Fig. 88-15). The trial was designed to have sufficient power to detect a 25% or better advantage in survival attributable to combination treatment. However, at a median follow-up time of ~50 months, and with 70% deaths occurring by the date of final analysis, the trial failed to detect a survival advantage to "complete" androgen blockade, finding a median survival of 33 months for men treated with combination therapy versus 30 months for men treated with orchiectomy alone (hazard ratio = 0.91 for combination treatment, with a 90% confidence interval of 0.81–1.01, $P = 0.14$). Although a slightly greater fraction of men in the bilateral orchiectomy ± flutamide trial (20%) than in the leuprolide ± flutamide trial (13%) had minimal metastatic prostate cancer, men in the two trials otherwise had very similar characteristics with regard to age and other demographic features.[141,142]



The EORTC conducted a clinical trial ($N = 327$) comparing goserelin acetate plus flutamide to bilateral orchiectomy in men most of whom had stage D2 prostate cancer.[459–462] Although an initial analysis of trial results, at a median follow-up time of 30 months, had disclosed no significant survival differences, a later analysis showed a 7-month improvement in median survival ($P = 0.04$) in favor of combination treatment. (Data from Eisenberger MA, Blumenstein BA, Crawford ED, et al: Bilateral orchiectomy with or without flutamide for metastatic prostate cancer. N Engl J Med 1998;339:10036–10042.)

(DAPROCA) conducted a virtually identical study, with the same treatment arms and approximately the same number of patients.[463] This trial, which was completed at about the same time as the EORTC trial, revealed a longer overall survival with bilateral orchiectomy, although the difference was not statistically significant.[463] The reason for the discordant results is not clear: both studies recruited similar patient populations. A combined analysis of both studies, undertaken to enhance statistical power, failed to detect significant differences between "complete" androgen blockade and bilateral orchiectomy.[464]

Several studies have examined the use of cyproterone acetate, a steroid anti-androgen, in combination with androgen deprivation therapy, and none reported significant survival benefits attributable to combination treatment.[465–469] In fact, in a meta-analysis, there appeared to be a trend toward decreased survival for men treated with cyproterone acetate as part of a "complete" androgen blockade regimen.[470] The use of cyproterone acetate for "complete" androgen blockade is not recommended.

In 1995, the Prostate Cancer Trialists' Collaborative Group (PCTCG) reported the results of a meta-analysis from 22 randomized trials comparing "complete" androgen blockade to androgen deprivation alone for a total of 5710 men with prostate cancer[471] (Fig. 88-16). To accomplish an intention-to-treat analysis, complete data for each man treated were requested from the investigators for each trial. Hazard ratios were calculated separately for every trial, based on the raw data, and then combined for all of the trials using log-rank statistics. This analysis revealed a 2.1% difference in survival in favor of "complete" androgen blockade (a 6.4% reduction in annual risk

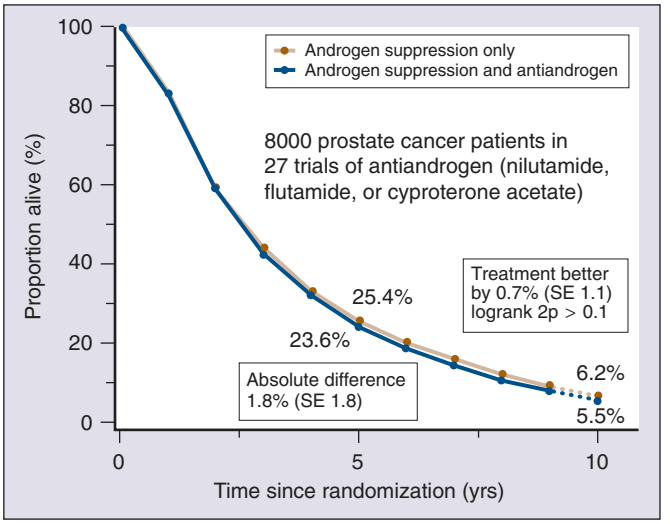

Figure 88-16 • A meta-analysis of survival from metastatic prostate cancer with maximal androgen blockade versus androgen deprivation alone. (From Prostate Cancer Trialists Cooperative Group: Maximum androgen blockade in advanced prostate cancer: an overview of the randomised trial. Lancet 2000;355:1491–1498.)

of death) that was not statistically significant. The results were independent of the androgen deprivation strategy used or the anti-androgen selected for the combination. The Agency for Health Care Policy and Research (AHCPR; results published on the Web (http://www.ahcpr.gov/clinic/index.html#evidence; AHCPR report No.99-E012) also conducted a meta-analysis based on all published "complete" androgen blockade clinical trials. This meta-analysis found no difference in 2-year survival rates (hazard ratio = 0.970 with a 95% confidence interval of 0.866–1.087). Only 10 of the 27 trials reported 5-year survival data, in addition to the 2-year survival figures, and the combined results of these ten trials suggested a minimal 5-year survival difference in favor of "complete" androgen blockade of uncertain clinical significance (hazard ratio = 0.871 with a 95% confidence interval of 0.805–0.9887).

Androgen deprivation therapy and anti-androgens are associated with a number of side effects, whether given alone or in combination, including hot flashes, loss of libido, loss of bone and muscle mass, fatigue, anemia, gynecomastia, and other symptoms. When the impact of such side effects were prospectively evaluated and compared to the beneficial impact of treatment, using a quality-of-life questionnaire, men treated as part of the NCI INT-0105 trial reported an improvement in quality of life attributable to treatment.[472] However, the improvement was more pronounced for men treated with bilateral orchiectomy than for men treated with "complete" androgen blockade, with men receiving "complete" androgen blockade reporting a higher frequency of diarrhea and worsening emotional functioning.[472] The quality-of-life benefit resulting from bilateral orchiectomy for treatment of metastatic prostate cancer appeared to be offset by the addition of anti-androgen treatment, primarily because of an increased incidence of side effects.

A key feature of the "complete" androgen blockade hypothesis was that adrenal androgens might contribute to prostate cancer growth in the absence of gonadal androgens. In fact, Labrie and associates[473,474] suggested that suppression of gonadal androgen production might be associated with an increased expression of enzymes, like 17β-hydroxysteroid dehydrogenase and 5α-reductase, in the prostate and elsewhere, capable of converting weak adrenal androgens (androstenedione and dehydroepiandrosterone) into testosterone and DHT, attributing as much as 30% to 50% of the intracellular pool of androgens to adrenal origin. At this point the role of adrenal androgens in the progression of metastatic prostate cancer is not established. On the other hand, new insights into the diverse molecular mechanisms associated with prostate cancer progression in the face of androgen deprivation therapy, with myriad alterations in androgen receptor function, activation of cell proliferation, loss of apoptosis, increase in tumor angiogenesis, modulation of tumor invasion and metastasis by the extracellular matrix, and maintenance of immune tolerance, have suggested that there is likely considerable heterogeneity in the androgen-independent prostate cancer phenotype.[21] With all of these mechanisms possibly contributing to androgen-independent prostate cancer progression, it is not entirely surprising that the "complete" androgen blockade treatment approach proposed by Labrie and coworkers was not associated with a clinically significant survival benefit.[454]

Optimal Timing for Initiation of Androgen Deprivation Therapy

Although there is a general belief that immediate initiation of androgen deprivation therapy for men with metastatic prostate cancer may improve quality of life, there is no compelling evidence of a reduction in survival resulting from deferring treatment until symptomatic progression has occurred. Effects of the timing of androgen deprivation therapy on the survival of men with metastatic prostate cancer has become a more critical issue recently since an increasing number of men are recognized very early to have recurrent or metastatic prostate cancer because of increases in the serum PSA. The VACURG Study 1, testing the benefits of androgen deprivation therapy achieved by administration of DES, even though conducted decades ago, provides valuable insights into the effect of timing of androgen deprivation therapy on survival from metastatic prostate cancer. In the trial, men with advanced prostate cancer were randomized to initial treatment with bilateral orchiectomy plus a 5-mg daily dose of DES, bilateral orchiectomy plus a placebo, 5 mg DES per day alone, or placebo alone, with results indicating no significant differences in survival among the different treatment groups.[448,449] However, men on the placebo arm who subsequently were crossed over to another treatment arm at the time of progression had a comparable survival to men initially treated on one of the other treatment arms, suggesting that immediate initiation of androgen deprivation therapy was without marked benefit.

The Medical Research Council also evaluated immediate versus deferred androgen deprivation therapy for advanced prostate cancer.[475] In their study, men with prostate cancer ($N = 934$ men; 434 men with and 500 men without prostate cancer metastasis) were randomized to either early androgen deprivation or to androgen deprivation initiated for symptomatic prostate cancer progression. Follow-up procedures were not strictly defined in the trial, relying on the discretion of the treating physicians, and 5% of the men who died of prostate cancer never received androgen deprivation therapy, while 10% or the men were not treated until they suffered a pathologic bone fracture or spinal cord compression. Using death from prostate cancer as a study endpoint for the men who had metastatic prostate cancer, no significant difference was detected between the early (65% prostate cancer deaths) versus late (69% prostate cancer deaths) treatment groups. In an initial report of trial results, the group of men with nonmetastatic prostate cancer appeared to have fewer deaths (32%) when treated with early androgen deprivation therapy than when treatment was delayed (49%). However, of the men in this group who died in the delayed treatment arm, 54% never received endocrine therapy. In a more recent report, reflecting greater follow-up time, no statistically significant differences were evident for men with prostate cancer treated with early versus delayed androgen deprivation therapy.

The Eastern Cooperative Oncology Group carried out a randomized prospective trial of immediate androgen deprivation therapy versus observation in men ($N = 98$) who underwent radical

prostatectomy and were found to have lymph node metastases.[476] After a median of 7.1 years of follow-up, a significant difference in survival, favoring immediate androgen deprivation therapy, was detected. This finding was surprising because a fairly large difference in survival was evident within a relatively short period of observation. In the trial, prostate cancer-specific survival in the observation group was 78% at 5 years. This is quite low compared to rates seen in men with prostate cancer and microscopic lymph node metastasis treated with radical prostatectomy alone. Furthermore, in a nonrandomized case series ($N = 790$) from the Mayo Clinic, representing the largest retrospective collection of data on men with lymph node-positive prostate cancer treated by radical prostatectomy, with almost three decades of follow-up, a survival advantage in favor of immediate androgen deprivation was seen only for men with prostate cancers that were diploid, and this survival advantage did not become apparent until 10 years after surgery.[477] In that case series, men with aneuploid prostate cancers and lymph node metastases subjected to radical prostatectomy did not appear to benefit from immediate adjuvant androgen deprivation therapy. When men with diploid prostate cancers ($N = 57$) were treated similarly and followed for 10 years, there was also no improvement in survival attributable to adjuvant androgen deprivation therapy, but at 15 years of follow-up 14 men with diploid prostate cancers were alive, 12 who had received early androgen deprivation therapy and 2 who had not ($83.2 \pm 4.1\%$ vs. $48.5 \pm 13\%$). Thus, the finding of a benefit to early androgen deprivation therapy was based on the experience with 14 men of 790 men with lymph node-positive prostate cancer who underwent radical prostatectomy.

Why are the ECOG study results, indicating a benefit for early androgen deprivation therapy, different from other data suggesting only a marginal benefit to immediate initiation of treatment? In an editorial that accompanied publication of the ECOG study findings, one concern raised was that this study never realized its projected accrual goal of 240 patients.[478] This fact may be critically important, because the outcome of patients with prostate cancer nodal metastasis is extremely variable and difficult to predict. This problem could have been minimized if a sufficient number of men with prostate cancer were randomized to the different treatment arms. Unfortunately, the ECOG trial was relatively small and might have been affected by imbalances of factors that were not identified at the time the study began. In support of this concern, the fact that 50% of the men in the observation arm had progressed by 5 years, with 22% deaths, suggested that this control group most likely represented a collection of men with poor-risk and/or high-grade prostate cancers.[476]

Intermittent Androgen Deprivation Therapy

Intermittent androgen deprivation therapy has the promise of reducing the impact of treatment-associated side effects while still maintaining some benefits from treatment. Additionally, findings from one group of animal model studies has suggested that intermittent reductions in testosterone levels, versus continuous androgen deprivation, might actually delay prostate cancer progression to androgen-independence.[479] In these preclinical experiments, androgen-dependent cancer carried subcutaneously in mice was treated by bilateral orchiectomy once the tumors grew to 3 g. After the tumors had regressed 30%, they were transplanted into intact mice and then treated again by bilateral orchiectomy once the tumors had again grown to 3 g. This treatment cycle was continued until the cancer became androgen-independent. For comparison, mice carrying 3-g cancers were treated with a single cycle of androgen deprivation. Remarkably, androgen-independent cancer progression occurred 51 days after one-time bilateral orchiectomy versus 147 days for mice cycled through intermittent androgen deprivation. The mechanism for this difference, attributed to a superiority of intermittent androgen deprivation as cancer treatment, has not been fully elucidated. However, other preclinical animal model studies have yielded conflicting results. When rats carrying a transplantable androgen-dependent prostate cancer were treated with immediate bilateral orchiectomy, with continuous high- or low-dose DES, or with intermittent high- or low-dose DES, rats treated with continuous androgen deprivation survived 38%to 50% longer than rats treated with intermittent androgen deprivation.[480] These uncertainties from preclinical studies suggest the clinical use of intermittent deprivation therapy must be carefully evaluated in well-designed clinical trials before routine use in clinical practice. The efficacy and safety of intermittent versus continuous androgen deprivation is currently under scrutiny in clinical trials.

"Second-Line" Endocrine Treatment

During the past several years it has become evident that men suffering with prostate cancer progression after initial androgen deprivation therapy represent a heterogeneous group with varying degrees of residual sensitivity to hormonal manipulations. Kelly and colleagues described the "flutamide-withdrawal" syndrome, later found also to be associated with other anti-androgens, characterized by an improvement seen in 20% to 25% of men on discontinuation of anti-androgen treatment.[481–483] This phenomenon occurred both for men who initially were treated with "complete" androgen blockade and for men who had received anti-androgens at some other time. The clinical observation of an "anti-androgen withdrawal" syndrome prompted a renewed interest in the biology of the androgen receptor in prostate cancer cells. A variety of AR alterations have been described in prostate cancers progressing after initial hormone manipulations, and *AR* mutations, encoding androgen receptors with altered ligand specificity, also have been detected for which anti-androgens can act as agonists.[145,146,148]

Among the agents reported to cause beneficial treatment responses (a drop in the serum PSA or other response) after adequate androgen deprivation treatment are bicalutamide (20%–24%), megestrol acetate (8%–13%), DES (26%–66%), ketoconazole with hydrocortisone (27%–63%), and glucocorticoids alone (18%–22%).[484] PC-SPES, a multi-component herbal mixture with estrogenic properties, was reported to produce treatment responses in men with androgen-independent prostate cancer.[485] However, many PC-SPES lots were contaminated with prescription drugs, including DES, coumadin, and indomethacin, and as a result, PC-SPES is no longer available.[486] Responses to second-line hormonal manipulations usually are brief, with median durations of benefit ranging from 3 to 4 months.

Clinical Approach to Men with Androgen-Independent Prostate Cancer

Most men with androgen-independent prostate cancer demonstrate a rising PSA as the first manifestation of prostate cancer progression following androgen deprivation. In a prospective evaluation of men ($N = 282$) who had received first-line androgen deprivation therapy and suffered cancer progression, an increase in serum PSA levels occurred approximately 6 months before any other clinical (radiologic or bone scan) evidence of worsening cancer.[487] However, for men initially treated with androgen deprivation based only on a rising serum PSA (and no clinical evidence of prostate cancer metastases), the time interval between subsequent serum PSA increases, indicating androgen-independent prostate cancer progression, and the appearance of clinically significant metastases is not known, although the serum PSA level at initial presentation, the rate of serum PSA rise, the Gleason score at the time of prostate biopsy or surgery, the clinical stage at presentation, and the response to androgen deprivation treatment are likely of prognostic significance.[488] When the appearance of androgen-independent prostate cancer is suspected for men treated with androgen deprivation therapy, a determination of the serum testosterone (to ensure that androgen deprivation has been adequately accomplished), serum PSA, PAP, and alkaline

phosphatase, hematology and serum chemistry studies, radiographic imaging (including a bone scan), and a history and physical examination often are undertaken.

For years it has been suggested that discontinuation of androgen deprivation in men who have not undergone bilateral orchiectomy may adversely affect prostate cancer progression and survival.[436] The administration of exogenous testosterone and its derivatives is known to produce a significant prostate cancer flare with severe pain and neurologic, urologic, and coagulation complications in a small proportion of men.[489–491] In a retrospective analysis of men ($N = 205$) with androgen-independent prostate cancer who were treated with chemotherapy, there appeared to be no difference with respect to prostate cancer progression and survival in men with prior bilateral orchiectomy as compared with men treated with gonadal androgen suppression that was discontinued at least 4 weeks before chemotherapy.[492] Of course, many of the men treated with gonadal suppression likely never achieved normal serum androgen levels. Until the issue of whether discontinuation of gonadal suppression might compromise survival from androgen-independent prostate cancer has been resolved, maintenance of gonadal androgen suppression is recommended. Also, because stopping anti-androgen treatment at the time of prostate cancer progression can result in decreases in serum PSA levels, and in occasional symptomatic benefits or objective improvements in soft tissue and bone metastasis, men taking anti-androgens along with androgen deprivation therapy should be encouraged to discontinue these agents for at least 4 to 8 weeks before considering other treatment maneuvers.[493]

Bisphosphonates

Bone metastases, accompanied by destruction of bone architecture and accompanying pain, fracture, and spinal cord compression, arise commonly as part of prostate cancer progression. Furthermore, androgen deprivation therapy causes osteopenia/osteoporosis, with some 19.4% of men treated with androgen deprivation for at least 5 years reported to suffer pathologic bone fracture.[494] Such skeletal complications, whether arising as a result of prostate cancer itself or of prostate cancer treatment, may accelerate life-threatening prostate cancer progression.[495]

Bisphosphonates promote bone ossification and have established benefits for the treatment of osteoporosis, hypercalcemia of malignancy, and cancer bone metastasis.[496–499] For men with prostate cancer, almost any of the available bisphosphonates can treat osteoporosis associated with androgen deprivation. In one trial, men ($N = 47$) with prostate cancer and no bone metastases who required treatment with leuprolide were randomized to receive hormonal therapy alone or with pamidronate (60 mg every 12 weeks) and monitored for bone mineral density via dual-energy x-ray absorptiometry (DEXA) of the lumbar spine and proximal femur, and trabecular bone density via quantitative computed tomography of the lumbar spine.[500] Results indicated that while androgen deprivation therapy decreased bone mineral density at all sites, the addition of pamidronate to hormone treatment prevented this complication. However, in the setting of established prostate cancer bone metastases, only zoledronic acid (4 mg every 3 weeks) has demonstrated benefit sufficient for regulatory agency approval. In a placebo-controlled trial for men with progressive prostate cancer and bone metastasis ($N = 643$), zoledronic acid therapy reduced skeletal complications by 22% (38% with zoledronic acid vs. 49% with placebo), with improvements in time-to-first skeletal complication and pain.[501,502] The superiority of zoledronic acid over the other bisphosphonates for this indication may be a consequence of drug effects on both osteoblasts and osteoclasts.[503] Preclinical models have hinted that bisphosphonate treatment of early-stage prostate cancer might reduce or delay the appearance of bone metastases, and clinical trials of bisphosphonates for the prevention of bone metastasis have been initiated.[504] In addition to the efficacy of zoledronic acid in preventing skeletal complications of metastatic prostate cancer, a single infusion of the drug prevented osteoporosis associated with a year of androgen deprivation therapy in a randomized controlled trial.[505] Bisposphonate treatment has been associated with occasional but significant side effects, including renal dysfunction and osteonecrosis of the jaw.[506]

Bone-Targeted Radionuclides

The contribution of osteoblast action to the pathogenesis of prostate cancer bone metastases has stimulated interest in radioemitting calcium mimetics as treatments for progressive prostate cancer with skeletal involvement. ^{89}Sr, given as ^{89}SrCl, provides some pain palliation, without survival prolongation, for men with prostate cancer and symptomatic bone metastases.[507] A β-emitter with a $t_{1/2}$ of 50.5 days, ^{89}Sr accumulates in metastatic bone lesions. The most clinically significant toxicity of ^{89}Sr is myelosuppression, with nadir blood counts 4 to 6 weeks after administration. This limits ^{89}Sr therapy to men with adequate blood counts, precluding retreatment until after at least 6 months or so, and all but eliminating opportunities for other concurrent treatments. Nonetheless, in a provocative randomized clinical trial, men ($N = 72$) with androgen-independent prostate cancer and bone metastases who had responded to an induction chemotherapy regimen and received ^{89}Sr in addition to doxorubicin enjoyed an improvement in survival when compared to men treated with doxorubicin alone.[508] Newer bone-targeted radiopharmaceuticals, including ^{188}Re-hydroxyethyldidene diphosphonate (^{188}Re-HEDP), which emits both β and γ particles and has a $t_{1/2}$ of 16.9 hours, and ^{153}Sm-ethylene diamine tetramethylene phosphonate (^{153}Sm-EDTMP), which emits both β and γ particles and has a $t_{1/2}$ of 46.3 hours, may palliate painful bone metastases with less myelosuppression than ^{89}SrCl.[509,510]

Treatment of Androgen-Independent Prostate Cancer

The tendency for prostate cancer to progress after androgen deprivation therapy poses the greatest threat of morbidity and mortality. For men with symptomatic metastatic prostate cancer despite adequate androgen deprivation therapy, randomized clinical trials have demonstrated that systemic treatment with mitoxantrone and corticosteroids tends to reduce bone pain and improve quality of life, but not to prolong survival.[511–513] However, in 2004, two randomized clinical trials showed that docetaxel, alone or in combination with estramustine, improved the survival of men with metastatic androgen-independent prostate cancer in comparison to mitoxantrone and corticosteroids.[514,515] As a consequence of these two clinical studies, the role of systemic chemotherapy in prostate cancer treatment is now well established, and vigorous clinical research is now ongoing to improve the outcomes achievable with taxane chemotherapy.[516] In addition, new avenues of treatment, including prostate cancer immunotherapy, have progressed to advanced phases of clinical assessment (Box 88-5).

Docetaxel

Both paclitaxel, from the bark of the Pacific yew tree (*Taxus brevifolia*), and docetaxel, from the leaves of the European yew tree, disrupt microtubule function, required for chromosome segregation at mitosis in eukaryotic cells, and promote apoptosis.[517,518] Nonetheless, the mechanism(s) by which these drugs act against prostate cancer cells is not clear. Prostate cancers tend to have very low growth fractions, as compared to many normal cells and most other cancers, yet prostate cancer cells remain sensitive to taxane drugs. One possibility is that microtubule function may be needed for other critical cell processes, such as for nuclear-cytoplasmic shuttling of critical regulatory proteins, essential for prostate cancer cell viability.[519]

Although both paclitaxel and docetaxel have shown promising activity against prostate cancer in early clinical trials, only docetaxel

Box 88-5. CHEMOTHERAPY FOR MEN WITH ANDROGEN-INDEPENDENT METASTATIC PROSTATE CANCER

Despite adequate androgen deprivation therapy, prostate cancer tends to progress to threaten morbidity and mortality. For men with metastatic androgen-independent prostate cancer, docetaxel chemotherapy, with or without estramustine, has been proven to prolong survival. Because the addition of estramustine to docetaxel produces an increase in cardiovascular side effects, without a clear benefit in prostate cancer survival, docetaxel, given every 3 weeks at a dose of 75 mg/m^2, along with a corticosteroid, has become the standard systemic treatment for metastatic prostate cancer progressing after androgen deprivation therapy. New docetaxel combinations, with a variety of agents, are under active development in clinical trials.

has been subjected to large-scale trials testing effects on survival for metastatic androgen-independent prostate cancer. Docetaxel, given every 3 weeks (75 mg/m^2) to men with prostate cancer in a small trial ($N = 35$), was associated with a 46% serum PSA response rate.[520] In a series of clinical trials featuring weekly docetaxel (35–40 mg/m^2), serum PSA response rates ranged from 41% to 64%.[521–525] The addition of estramustine to docetaxel appeared also to produce significant benefits in early studies, both for serum PSA responses (45%–74%) and for measurable disease responses (11%–57%).[526–530]

One of the two large randomized trials featuring docetaxel (TAX-327) assigned men with androgen-independent prostate cancer ($N = 1006$) to one of three treatment arms, directly comparing two different schedules of docetaxel (30 mg/m^2 given weekly or 75 mg/m^2 given every 3 weeks) and prednisone against mitoxantrone and prednisone[514] (Fig. 88-17). In the trial, the median survival was 18.9 months for men treated with docetaxel (75 mg/m^2 every 3 weeks) and prednisone, and only 16.5 months for men treated with mitoxantrone and prednisone, a difference that was statistically significant ($P = 0.009$). Weekly docetaxel treatment, with a median survival of 17.4 months, did not provide as compelling a benefit. Along with the survival improvement, docetaxel given every 3 weeks also resulted in a better serum PSA response rate (45% versus 32%) and better pain control (35% versus 22%) than mitoxantrone and prednisone ($P < 0.01$). The other randomized trial (SWOG 99–16) targeted a similar group of men ($N = 770$) and compared treatment with docetaxel and estramustine to treatment with mitoxantrone and prednisone.[515] Again, an improvement in median overall survival was evident for the docetaxel and estramustine regimen (17.5 months versus 15.6 months, $P = 0.02$). In both of the trials, docetaxel chemotherapy was associated with more side effects, including edema, gastrointestinal symptoms, neuropathy, and nail changes, than mitoxantrone treatment, and the combination of docetaxel and estramustine was also associated with a higher incidence of cardiovascular events. The additional complications, and uncertain benefit, accompanying the addition of estramustine to docetaxel has led to the establishment of docetaxel chemotherapy, given every 3 weeks, along with prednisone, as the standard-of-care for men with metastatic androgen-independent prostate cancer. To build on the success of docetaxel against metastatic androgen-independent prostate cancer, several docetaxel combinations—with calcitriol, bevacizumab, and a number of other agents—are being tested in phase 3 trials.[516] In addition, docetaxel itself is being tested in the adjuvant therapy setting. In one phase 2 study, men ($N = 77$) at high risk for serum PSA recurrence following radical prostatectomy were treated with 6 cycles of docetaxel (35 mg/m^2, days 1, 8, 15 every 28 days).[531] With a median follow-up of more than 29 months, the median time-to-PSA recurrence was 15.7 months.

Immunotherapy

The mechanistic basis for prostate cancer immunotherapy is that prostate cancer cells contain antigens that can be recognized by immune cells allowing for selective prostate cancer cell killing.[532,533] T-cells respond to small peptides derived from intracellular proteins that are presented on specialized molecules at the surface of cancer cells. Prostate cancer cells can be recognized by virtue of containing new proteins, formed as a result of somatic gene mutations and translocations, or of expressing lineage proteins, representing prostate cell differentiation. Several such prostate lineage antigens, including PSA, prostate-specific acid phosphatase (PAP), prostate-specific membrane antigen (PSMA), NKX3.1, and others, have become attractive targets for vaccine immunotherapy.[534,535] Unfortunately, prostate cancer cells, and most other cancer cells, tend to evade destruction by immune cells by promoting antigen-specific tolerance, a state in which T cells that could kill cancer cells are inactive and respond poorly to stimuli, including vaccination.[536] The major

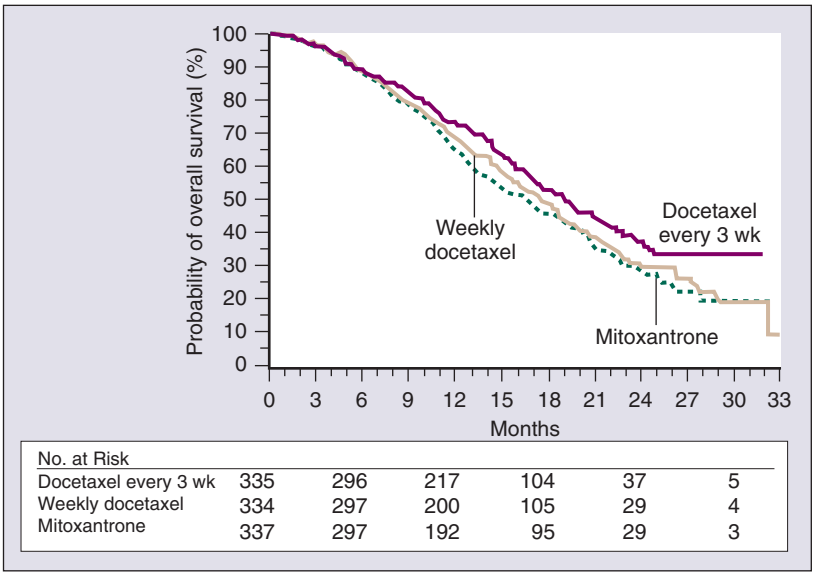

Figure 88-17 • Results of a randomized clinical trial of docetaxel, given at two different dosing schedules, and prednisone versus mitoxantrone and prednisone for men with androgen-independent metastatic prostate cancer. (Data from Tannock IF, de Wit R, Berry WR, et al: Docetaxel plus prednisone or mitoxantrone plus prednisone for advanced prostate cancer. N Engl J Med 2004;351:1502–1512.)

vaccine strategies explored clinically have featured the delivery of prostate cancer antigens to antigen-presenting cells (APCs), such as dendritic cells (DCs) in the skin, which have the capability of stimulating specific T cells to attack prostate cancer cells. However, the clinical experience to date with prostate cancer vaccine immunotherapy has suggested that T-cell tolerance may constitute a significant barrier to treatment success: although measurable immune responses can be elicited by vaccination using a variety of vaccine strategies, these responses only occasionally are accompanied by disease responses.[535] New immunotherapy approaches, featuring strategies to undermine T-cell tolerance, may increase the efficacy of vaccine approaches for prostate cancer.[536,537]

Two immunotherapy approaches have reached phase 3 clinical trials and merit attention. In one strategy, DC vaccines have been created using immature DC precursors recovered from blood mononuclear cells via leukapheresis and loaded with PA-2024, a recombinant protein consisting of PAP fused to GM-CSF.[538,539] In phase 1 and 2 clinical trials of this immunotherapy approach, men with androgen-independent prostate cancer tolerated DC treatment well, exhibited immune responses to PA-2024 after vaccination, and showed a median survival of 29 weeks, with serum PSA responses in 3 men. Phase 3 trials of APC-8015, targeting men with asymptomatic metastatic androgen-independent prostate cancer, with a primary endpoint of objective time-to-progression, have been completed and submitted for regulatory agency approval. A second strategy has featured the use of vaccines created from prostate cancer cells, genetically modified to increase immunogenicity by secretion of GM-CSF.[540] The first clinical application of this strategy for prostate cancer involved genetic modification of autologous prostate cancer cells recovered at radical prostatectomy with *GM-CSF* cDNA.[541] In a phase 1 trial ($N = 8$ men) of irradiated GM-CSF-secreting autologous prostate cancer cell vaccines, 7 of the vaccinated men exhibited delayed-type hypersensitivity (DTH) reactions against unnmodified autologous tumor cells and serum antibody responses to several proteins from prostate cancer cells. To overcome technical problems with generating sufficient numbers of vaccine cells from prostate cancer cells recovered at the time of surgery, prostate cancer vaccine cells have been created by genetic modification of the prostate cancer cell lines LNCaP and PC-3 to permit high level secretion of GM-CSF.[542] In phase 2 studies of this vaccine approach, men with androgen-independent metastatic prostate cancer have been treated with various doses and dose-schedules of GM-CSF-secreting LNCaP/PC-3 vaccines. After a median of 15 months of follow-up, the median survival had not been reached. Also, some 43% of the men had stable or improved bone scans. A phase 3 trial of this vaccine approach, randomized against treatment with docetaxel, for men with androgen-independent metastatic prostate cancer, has been started.

SUMMARY

Although mortality from prostate cancer has declined over the past few years, demographic trends, such as the general aging of the population, suggest that prostate cancer will remain one of the most common health threats for men in the developed world. Widespread implementation of prostate cancer screening using serum PSA has resulted in a changing character of prostate cancer at its initial presentation, with younger men being diagnosed at earlier stages than ever before. The use of serum PSA testing for disease activity monitoring has changed the character of prostate cancer throughout the rest of its natural history, with healthier men having less prostate cancer at later stages of the disease. These changes have put new demands on improving prostate cancer treatment, whether minimizing the morbidity of local prostate cancer treatment or increasing the efficacy of systemic prostate cancer treatment. In the very near future, large clinical studies of prostate cancer prevention, of the benefits of prostate cancer screening, of systemic adjuvant therapies given along with primary local prostate cancer treatment, of systemic chemotherapy for androgen-independent prostate cancer, and of a variety of new agents, will provide new insights of critical importance to prostate cancer care. Ultimately, new biomarkers, new imaging strategies, and new prevention and treatment approaches may hold the secret to eradicating prostate cancer morbidity and mortality.

89 Cancer of the Penis

Daniel J. Culkin, Sreenivas Vemulapalli, and C. Scott Manatt

SUMMARY OF KEY POINTS

- Penile carcinoma is a rare disease in North America and Europe.
- Penile carcinoma is more common in Africa and South America.
- Greater than 95% of malignant lesions are squamous cell carcinoma (SCC).
- Treatment for SCC is surgical with partial or radical penectomy.
- Treatment often must include inguinal and/or pelvic lymphadenectomy.
- Advanced disease is treated with surgery, chemotherapy, and radiation therapy.
- Five-year survival rates for node-negative disease are favorable.

INTRODUCTION

Penile carcinoma comprises less than 1% of all male malignancies in North America. It is most commonly diagnosed in the sixth decade of life, and as many as 30% of new cases demonstrate advanced disease at the time of initial presentation. SEER (statisitics, epidemiology, and end result) data reveal that more than 95% of the lesions are squamous cell carcinoma (SCC). Generally, lesions start as superficial neoplasms of the prepuce or glans penis and then progress to local invasion of the corpora cavernosa with subsequent development of metastases to the inguinal lymph nodes. The most important prognostic factor for survival remains stage of disease at presentation. Age greater than 65, presence of node-positive disease, and African-American ethnicity have been found to be independent predictors of decreased survival.[1] Early detection and treatment are essential for improved oncologic outcomes and quality of life for patients.

EPIDEMIOLOGY

Geographic Variation

Penile cancer is exceedingly rare in North America and Scandinavia and is far more prevalent in South America, Asia, and Africa. The incidence of SCC of the penis is estimated at 1/100,000 in Western countries.[2,3] In contrast, the incidence has been estimated as high as 17% in Brazil and between 10% and 20% in Africa and Asia.[4,5] Despite geographic differences, the overall incidence has been decreasing worldwide.[3,6,7]

ETIOLOGY

Various factors including an intact prepuce, poor hygiene, presence of sexually transmitted disease, radiation exposure, and cigarette smoking have been linked to the development of penile cancer.

Circumcision

The association of phimosis and penile carcinoma is well established.[8,9] Neonatal circumcision seems to protect against penile carcinoma, because the incidence is essentially zero among this male cohort.[10] In Israel the rate of neonatal circumcision is nearly 100% and the incidence of penile carcinoma is closer to 1/1,000,000 than 1/100,000.[11] The risk of penile cancer in uncircumcised men and in men who undergo postperinatal circumcision are equal and approach three times that of men circumcised in the neonatal period.[12] However, presence of the foreskin alone is not the only risk factor for development of penile cancer. Circumcision rates in Finland and Denmark are much lower than seen in North America, although the incidence of penile cancer is similar.[7,13,14] Furthermore, recent studies show the incidence of penile intraepithelial neoplasia to be quite high in neonatally circumcised men.[15] Ultimately, associated factors such as hygiene, history of sexually transmitted disease, and sexual promiscuity may play an equal or greater role than the presence of the foreskin in the etiology of penile cancer.

Infection

The carcinogenic effect of smegma and the bacteria *Mycobacterium smegmatis* are probably less relevant than once believed in the etiology of penile carcinoma.[16–18] Current investigations implicate the human papilloma virus (HPV), specifically HPV types 16 and 18, in the development of some cases of penile carcinoma.[1] Several studies have demonstrated the presence of HPV DNA from penile cancer specimens in as many as 71% of patients.[19–21] However, other studies have shown much lower detection rates of HPV DNA.[12,22–25]

Warty carcinoma is a subtype of penile SCC that is morphologically distinct.[26] Warty carcinoma seems to be more strongly associated with HPV infection and tends to display a less aggressive clinical phenotype than standard penile SCC.[22,26,27]

Bezerra and colleagues found HPV DNA in 30% of penile carcinoma specimens from 82 patients but demonstrated no significant difference in lymph node metastasis and 10-year survival between HPV^+ and HPV^- groups.[26] These findings suggest that different etiologic pathways may be relevant depending on the type of penile carcinoma diagnosed. The association between penile carcinoma and other sexually transmitted diseases has not been established, nor has any substantive correlation been made between this disease and alcohol consumption or illicit drug usage.[12]

Radiation and Cigarette Smoking

Other factors that seem to play a role in the development of penile carcinoma are ultraviolet (UV) radiation and cigarette smoking. The

former is supported by the increased incidence of cases in men treated with UV light—a phototherapy for psoriasis.[28] Several recent population-based studies have found an increased incidence of penile carcinoma in smokers.[29]

Hygiene

The very low incidence of penile carcinoma in countries such as Denmark and Finland where perinatal circumcision is uncommon supports the notion that proper hygiene and early education in these matters provides equal protection against this disease process.[7] In situations in which hygiene may become an issue because of behavioral or neurologic disorders that limit self-care, circumcision may still be warranted.

PATHOLOGY

Penile carcinoma is one of many pathologic processes that have visible dermatologic signs identified on the genitals. Vigilance on the part of health care providers is essential to early diagnosis because of the myriad benign and premalignant lesions that may imitate or precede penile carcinoma.

Leukoplakia

Leukoplakia presents in diabetic men as perimeatal, blanched plaques or scaled areas that can extend into the urethral meatus. The microscopic appearance is consistent with acanthosis, parakeratosis, and hyperkeratosis and is often seen in close proximity to malignant lesions. This lesion may arise in response to recurrent inflammation or irritation. Treatment of leukoplakia includes excision and biopsy with careful follow-up for the development of possible malignancy. Successful therapy with bleomycin for extensive lesions has been reported in the literature.[30]

Balanitis Xerotica Obliterans (Lichen Sclerosis)

Balanitis xerotica obliterans (BXO) is lichen sclerosis et atrophicus of the penis. First diagnosed in 1928, this disorder can affect the glans, prepuce, and urethra. BXO is associated with SCC of the penis in 2.3% to 5.8% of cases.[31,32] The natural history of BXO is highly variable. Some patients will have an indolent chronic affliction that produces few early symptoms. Others may present with diffuse disease only weeks after onset. The patient often presents with areas of ivory-colored, sclerotic plaque on the glans or inner prepuce and may complain of pruritus. Other symptoms may include phimosis, dysuria, painful erections, or a burning sensation with erection. If untreated, these lesions will spread and coalesce, becoming less pliable and more fibrotic. Sexual intercourse will often result in fissures, blisters, and bleeding. Continued progression of disease can result in contraction of the frenulum and fibrotic phimosis. Topical steroids or circumcision for advanced disease are recommended treatments for BXO. Routine follow-up is important secondary to the rare, but potential malignant transformation of these lesions.[31,33,34]

Carcinoma in Situ

Carcinoma in situ (CIS) of the genitals has different names depending on the location of the lesion. A sharply demarcated, shiny, raised erythematous plaque of the glans or mucosal surface of the prepuce is called erythroplasia of Queyrat (EQ). Bowen's disease (BD) describes the same histologic entity but presents as red, scaling patches on the keratinized genital surfaces such as the penile shaft, scrotum, or perineum.[35,36] These lesions are definitely considered premalignant or malignant because of a progression rate to SCC of 10% to 30%.[37–39] EQ and BD tend to occur in older men, with the most common diagnosis in the fifth decade. BD typically involves the epithelial cell layers of hair follicles with a very similar histologic appearance to EQ. When found on the penis, this lesion often appears as a scaling plaque without notable erythema and signifies the presence of CIS. Only about 1 lesion in 10 will progress to invasive carcinoma, a rate that is comparable to EQ.

Histologically, these lesions demonstrate diffuse changes throughout the squamous epithelial cell layers including keratinocyte hyperplasia, nuclear atypia with many mitoses, proliferation of enlarged hyperchromatic cells, multinucleated cells, and loss of polarity within most cells. Presence of inflammatory cell infiltration and increased density of microvasculature is common. Similar to invasive penile carcinoma, links to HPV infection have been investigated and have revealed a correlation with many of the same viral strains.[40] A small study of EQ identified DNA from HPV type 8 in every sample of penile CIS, whereas this viral DNA was not identified in any samples of BD lesions.[41] In addition, HPV type 16 was found in more than 80% of these samples.[41]

Bowenoid Papulosis

Bowenoid papulosis (BP) is markedly different from EQ and BD in presentation, demographics, and clinical course. Men who have BP are much younger than their EQ counterparts with a mean age of almost 30 years of age.[42] These lesions are groups of scaling, erythematous papules typically seen on the keratinized skin of the penile shaft. Histologically the cellular morphology mimics CIS, but the keratinocytes tend to be slightly more differentiated than those seen in CIS. In addition, histologic sections of Bowenoid papules demonstrate that the more atypical-appearing cells tend to be found among the top epithelial cell layers and in the upper portion of the sweat glands. A physician must combine the clinical presentation and the histologic findings to arrive confidently at the diagnosis (Box 89-1).[42]

Buschke-Lowenstein Tumor (Verrucous Carcinoma)

Commonly known as verrucous carcinoma or giant condyloma acuminatum, Buschke-Lowenstein (B-L) tumors are very similar in appearance to benign condyloma venereatum. Unlike their benign counterparts, B-L tumors tend to invade tissue and cause significant damage. This can be seen histologically. The rete pegs of these lesions are often seen penetrating deeply into surrounding tissue. This aggressive behavior is in contrast to the very well-differentiated cells that compose B-L tumors; cellular anaplasia is very atypical in these specimens. A viral etiology seems to play a role in the development of B-L tumors. Investigators have found associations with HPV

Box 89-1. BOWENOID PAPULOSIS: A DIAGNOSTIC DILEMMA

Bowenoid papulosis resembles carcinoma in situ. The physician needs to be aware of the differences in clinical presentation for these two lesions. The physician will need tissue biopsies to distinguish these lesions histologically.

The etiology of BP is still unclear. Investigations into the viral etiology of BP have provided increasing evidence to support a link to HPV subtypes.[6,14,18,39,165–172] Progression of BP to squamous cell carcinoma has been reported in lesions with high-risk HPV strains.[29,45,173] There have been other reports of malignant conversion as well.[174] Spontaneous regression has also been reported.[175,176]

Recently, treatment for BP has consisted primarily of topical therapy including 5-FU, imiqimod cream, and cidofovir in immunocompromised patients.[177–179] Historically these lesions have been surgically excised, and results with laser and other forms of ablative therapy have been mixed.[43,180] Often topical and extirpative therapy can be used in combination with good results.

strains 6 and 11.[43] Despite the local tissue destruction commonly found with these tumors, metastatic progression of the tumor does not occur. Therefore, local control is the primary objective. Thus, control may require partial or total penectomy.[44] To date, no large-scale trials of topical or radiation therapies have shown efficacy, and most data can be derived from isolated case reports of various treatment modalities.[45,46] A report of B-L tumor regression after treatment with intralesional injections of interferon-α suggests that local nonexcisional therapies directed at viral etiology may hold promise for future therapies.[47] Use of systemic chemotherapy with bleomycin, methotrexate, and cisplatin has been reported to achieve regression of B-L lesions. However, given the known toxicities of these agents, this approach is rarely indicated for this disease.[48] Currently, CO_2 laser ablation is the method of choice for local control of this lesion.[49,50]

Nonsquamous Malignancies

Nonsquamous cell carcinoma of the penis is rare and the tumors compose less than 5% of penile tumors. The most common malignancy is sarcoma. Other histologic penile tumors that have been reported are melanoma, basal cell carcinoma, and lymphoma. With the increasing prevalence of human immunodeficiency virus and acquired immunodeficiency syndrome (AIDS), the incidence of Kaposi's sarcoma is rising, and genital lesions can be found in nearly 20% of patients with AIDS-related Kaposi's sarcoma. Only a very small percentage of these patients will present with a penile lesion. The gross appearance is of erythematous nodules with sharp margins found most often on the glans penis.[51] Standard therapy involves conservative measures such as local excision, laser ablation, or palliative irradiation.[52]

Basal cell carcinoma of the penis most often can be found on the penile shaft, with only a fraction of cases reported on the prepuce or glans.[53] Appearance of this tumor on the scrotum or perineum is even less common.[54,55] The typical appearance of basal cell carcinoma of the penis is a well-circumscribed lesion with clear borders and central pitting. Given the slow rate of growth and lack of metastasis, local excision is often curative.[53,55,56]

In contrast, melanoma of the penis carries a very poor prognosis. Almost 40% of patients present with regional lymph node metastasis.[57] Two of every three lesions are found on the glans. Wide, local excision with a 3- to 5-cm margin is the treatment of choice for lesions less than 1.5 mm Breslow depth.[58] Bilateral inguinal lymph node dissection has been the standard of care for lesions thicker than 1.5 mm.[57]

Tumors that are far more unusual have been reported in the literature as case reports. These tumors include penile schwannoma, plexiform neurofibroma, vascular hemangioendothelioma, leiomyosarcoma, rhabdomyosarcoma, epitheloid sarcoma, Ewing's sarcoma, mucoepidermoid carcinoma, and synovial sarcoma.[59–66] Generally, the prognosis of these tumors is similar to the reported outcomes of these malignancies when they are identified in more typical anatomic locations.

Extramammary Paget's disease is a very rare penoscrotal neoplasm, and distinguishing this lesion from EQ or BD is clinically impossible. Histologically, it is diagnosed by the presence of large, clear-staining cells with hypochromatic nuclei within the epidermis called Paget's cells. This disease is seen in older men and appears as a well-demarcated, erythematous, eczematous lesion. Metastasis to regional lymph nodes occurs very rarely. It is considered the etiology of adenocarcinoma in situ of the epidermis. This entity arises from pluripotent intraepidermal cells undergoing malignant transformation during apocrine differentiation.[67] Clinical suspicion for underlying genitourinary malignancies should be very high, in that 16% to 33% of patients with penoscrotal Paget's disease have concurrent internal genitourinary carcinoma.[67–69] Historically, patients with extramammary Paget's disease were evaluated extensively for occult pulmonary and gastrointestinal malignancy. However, retrospective analysis of patients with penoscrotal Paget's disease reveals that 92% of those with associated malignancy have genitourinary pathology.[67] Treatment generally consists of wide local excision that typically requires coverage of the defect with skin grafting or tissue flaps.[67] Mohs' micrographic surgery has been recommended as the therapy of choice because of the very high incidence of positive margins using standard surgical techniques.[70] Nonexcisional treatments have been described, but these isolated reports do not provide enough data to evaluate for efficacy.[69] Recurrence in these patients is very common, and close follow-up is mandatory.

Metastatic Tumors

Secondary tumors of the penis from metastatic nongenital primary malignancies are rare with only 460 cases reported in the literature.[71] Metastatic tumors to the penis are most often found in the presence of advanced systemic carcinoma. The index of suspicion for penile metastasis should be high in patients who have a known malignancy and subsequently suffer from priapism or complain of a new penile lesion. The common presentation of penile metastases is multiple nodules along the penile skin with occasional ulcerations that have a similar appearance to a syphilitic chancre. These lesions typically are not painful. Almost 50% of patients will have extensive involvement of the corpora cavernosa, which accounts for the common presentation of priapism.[72] The primary tumors that most frequently metastasize to the penis are prostate, bladder, urothelial, renal cell, testis, and rectal carcinomas.[71,72] The prognosis is dismal, with less than 6-month survival for these patients. Treatment should be systemic chemotherapy or local radiation therapy, with surgical treatment reserved for palliation. Partial and total penectomy with negative margins have been reported to render effective palliation.[73]

INVASIVE SQUAMOUS CELL CARCINOMA

Pathology and Natural History

Over 95% of primary penile tumors are SCC. Unfortunately, fewer than half of patients will have superficial disease at the time of diagnosis.[74] This malignancy can arise in any location on the penis, but the lesions of the glans account for nearly half of squamous cell penile carcinomas. Tumors of the prepuce account for more than 20% of penile SCC, and almost 10% of patients will have lesions on both the glans and the foreskin.[74]

Metastasis of penile carcinoma occurs first in the superficial inguinal lymph nodes, and the risk of metastatic disease is related to tumor size. Small tumors found only on the glans or prepuce are rarely metastatic at diagnosis.[75] Large tumors that involve more than 75% of the penile shaft have a very high risk of nodal spread.[76,77]

SCCs of the penis are graded using the Broder scale to quantify the degree of tumor cell differentiation (Table 89-1). Half of all lesions are either grade I or II at initial diagnosis. Histologically these tumors have a hyperkeratotic dermis with cords of carcinoma cells extending into deeper tissue layers, with intercellular bridges, keratin, and keratin pearls prominent throughout the specimen. More than 50% of tumors that first arise on the penile shaft tend to be high-grade carcinoma. By contrast, only 10% of preputial SCC demonstrates poorly differentiated histology.[76]

Other grading systems have been developed to improve the reproducibility of the Broder classification. Factors that influence grading in these systems are the number of mitotic cells per high-power field, degree of keratinization and cellular atypia, and the infiltration of inflammatory cells into the tumor (Fig. 89-1). Each parameter is assigned a score, and these are then summed to give a grade. Application of this system revealed 80% survival among patients with low-grade tumors.[6] Another technique for correlating histology and survival classifies tumors based upon superficial spread, vertical

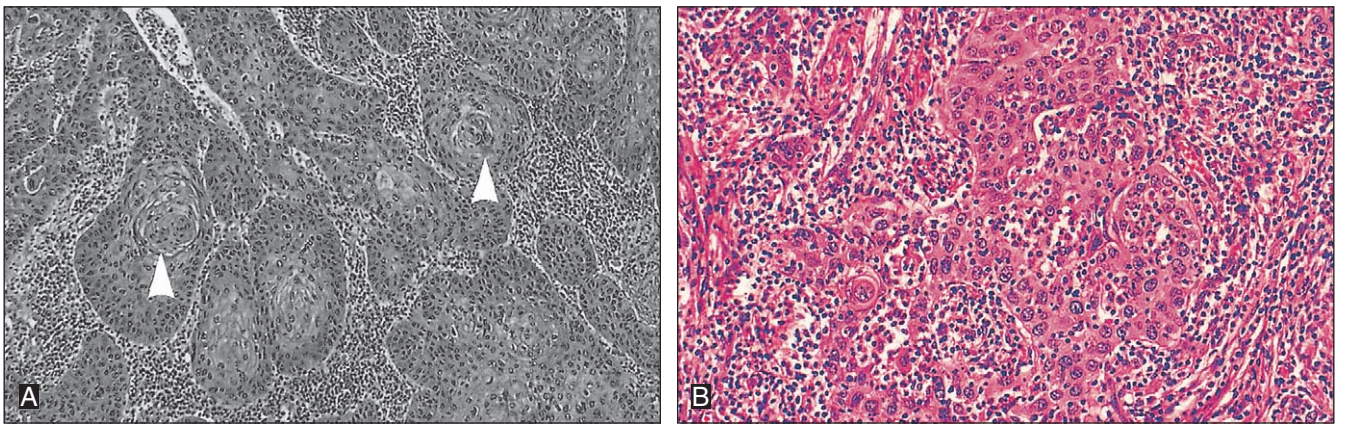

Figure 89-1 • Squamous cell carcinoma. **A,** Irregular nests of neoplastic cells invade the underlying tissue. Note the foci of keratinization (*arrowheads*). **B,** At the point of the deepest invasions, the squamous carcinoma cells are nonkeratinizing and exhibit considerable pleomorphism with large vascular nuclei. Note the associated intense inflammation often seen in invasive carcinoma.

growth, verrucous features, and multicentricity. These categories revealed metastatic disease in 42% with superficial disease and 82% with vertical tumor growth.[78] Other features studied for prognostic significance include ulcerative versus exophytic appearance. Exophytic tumors have a high degree of keratinization on histologic examination with cells that appear fairly well differentiated. Conversely, ulcerative penile malignancy more often has a poorly differentiated appearance and has a higher incidence of lymph node involvement.[4,78]

The natural history of this disease includes invasion and destruction of local tissues with eventual invasion of the corpora and urethra (Fig. 89-2). Metastatic spread occurs as the tumor invades into the lymphatic network of the prepuce and penile skin. These empty to the base of the penis and then to both inguinal node beds. This anatomy has complicated efforts to develop reliable sentinel node biopsy techniques. Once lymph has entered either superficial inguinal nodal chain, it drains into the deep inguinal nodes found below the fascia lata and medial to the femoral vein. The lymphatic system for the glans, urethra, and corpus spongiosum has a variable drainage to either the superficial or deep inguinal nodes. Lymphatic drainage from these structures very rarely goes to the external iliac lymph node complex. Metastatic disease in distant sites such as the liver, lungs, and bones are late signs of advanced disease and carry a poor prognosis.[79] Fortunately, fewer than 5% of patients have evidence of distant metastases at diagnosis.[80,81]

Table 89-1 Broder Classification for Grading of Squamous Cell Carcinoma

Grade	Histologic Features
I	Cells well differentiated with keratinization
	Prominent intercellular bridges
	Keratin pearls
II–III	Increased mitotic activity
	Fewer keratin pearls
IV	Marked nuclear pleomorphism
	Many mitoses
	Necrosis
	Lymphatic and perineural invasion
	Absence of keratin pearls
	Deeply invasive

Clinical Manifestations

Generally, penile carcinoma is a disease of older men in their sixth and seventh decades. Clinical suspicion in younger patients is warranted, because such cases have been reported in the literature.[29,45,77] These lesions may vary in presentation from the innocuous-appearing induration (Fig. 89-3) with slight erythema to the obviously malignant fungating penile tumor that leads to autoamputation (Fig. 89-4). Pruritus of the prepuce or a burning sensation may be an early symptom of this tumor, and careful inspection may reveal a lesion on the prepuce or glans. This lesion may then progress to a papule or mass, which can be found in nearly half of cases. Phimosis may make early identification of these lesions difficult, if not impossible, and patients often delay evaluation by a physician for an average of 1 year as a result.[82] By this time, a chronic malodorous discharge will often drain from under the prepuce. Further delay leads to bleeding from invasion of the deeper penile structures, as well as urethrocutaneous fistula and distortion of basic phallic morphology.[83]

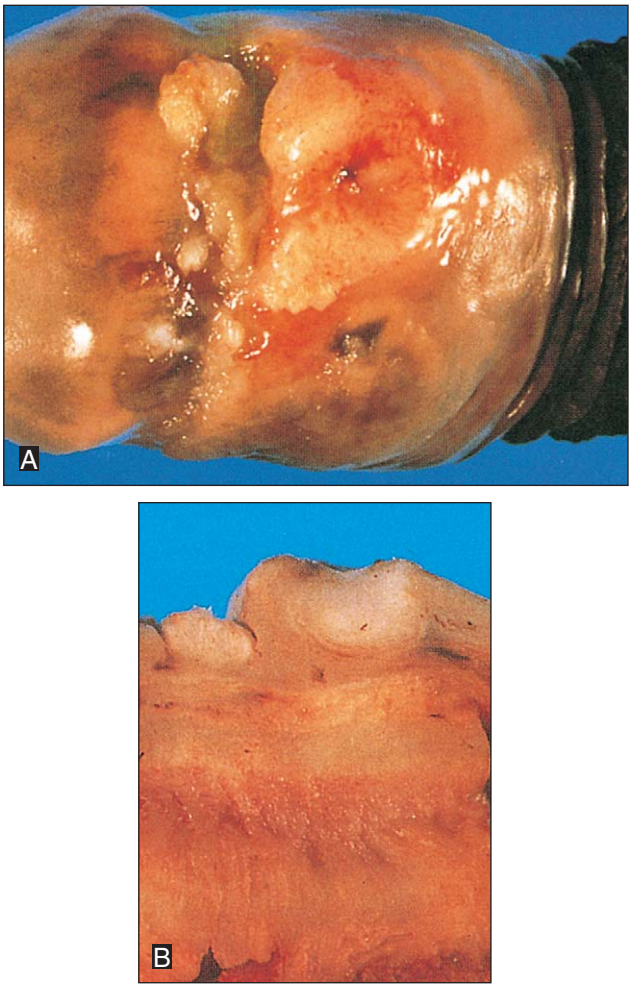

Figure 89-4 • Squamous cell carcinoma. **A,** This resection specimen shows a small lesion arising in the coronal sulcus. **B,** Cut sections from the specimen demonstrated two small nodules of invasive tumor.

Inguinal lymphadenopathy is a common finding at diagnosis, with nearly 60% of patients having palpable inguinal lymph nodes. Many of these patients have concomitant infections that are responsible for the inflammation of the inguinal nodes, and this adenopathy will subside with appropriate treatment. More ominously, one in five patients with clinically negative inguinal lymph nodes will have microscopic evidence of metastatic disease.[79]

Staging and Prognosis

Although many historical staging systems have been used, current staging of penile carcinoma follows the American Joint Committee on Cancer system, which incorporates tumor invasion, local node involvement, and the presence of distant metastases (TNM) to stratify patients based upon prognosis (Table 89-2).[84]

Unlike renal cell carcinoma or prostate cancer in the era of prostate-specific antigen, the importance of physical examination in the setting of a suspected penile malignancy cannot be overstated. A thorough evaluation will provide valuable information regarding the size and location of the tumor as well as the possibility of corporal involvement. Inguinal lymphadenopathy must be noted at the time of diagnosis, because this immediately affects the ensuing treatment algorithm. Inflammation is a confounding variable on physical examination, because it is a probable cause for a worrisome inguinal examination. Consequently, the overall sensitivity and specificity of a careful physical examination of the inguinal region is poor.[85,86] Inflammatory changes also decrease the accuracy of assessing tumor invasion of the corpora. As a result, some investigators are using magnetic resonance imaging (MRI) to improve detection of corporal involvement, but this modality has not become standard of care.[87]

Table 89-2 American Joint Committee Staging System for Penile Carcinoma (TNM Classification)

Classification	Description
TUMOR	
Tx	Primary tumor cannot be assessed.
T0	No primary tumor is present.
Tis	Carcinoma in situ is present.
Ta	Noninvasive verrucous carcinoma is present.
T1	Tumor invades subepithelial connective tissue.
T2	Tumor invades corpus cavernosum or spongiosum.
T3	Tumor invades urethra or prostate.
T4	Tumor invades other adjacent structures.
NODE	
Nx	Regional nodes cannot be assessed.
N0	No regional lymph node metastases are present.
N1	Metastasis exists in a single superficial inguinal node.
N2	Metastasis exists in multiple or bilateral superficial inguinal nodes.
N3	Metastasis exists in deep inguinal or pelvic lymph nodes; unilateral or bilateral.
METASTASIS	
Mx	Distant metastases cannot be assessed.
M0	No distant metastases are present.
M1	Distant metastases are present.

Clinical suspicion of penile malignancy and information gleaned from physical examination must be confirmed by pathologic diagnosis. These tests usually include tissue cultures and special stains so as to exclude infectious etiologies. Small lesions confined to the glans or foreskin can be sampled via circumcision or excisional biopsy. Large lesions are often subjected to biopsy at the time of definitive treatment, and initial diagnosis is made via frozen-section histology.

The management of inguinal lymphadenopathy has been a troublesome issue, because a significant percentage of these patients do not have metastatic disease. It is undesirable to subject patients without metastatic disease to the morbidity of bilateral superficial lymphadenectomy. Consequently some investigators have proposed cytologic aspiration or computed tomography-guided biopsy of suspicious nodes to aid in the decision to excise lymph nodes. Others use ultrasound guidance for needle aspiration of lymph nodes, citing the ability of good ultrasonographers to reliably show changes in nodal architecture such as hypoechogenicity or heterogeneity that suggest the presence of malignancy.[86] The considerable false-negative rate with aspiration cytology limits the clinical utility of this procedure.[88,89] As noted previously, the lack of predictable lymph drainage patterns has also limited the clinical application of sentinel lymph node biopsy for penile malignancy.[90] Also, because this is an uncommon malignancy, sufficient numbers are rarely available to assess the marker characteristics of these tests.

Conservative approaches for the management of inguinal nodes have unacceptably high risks. Only 5% of patients with proven nodal metastases who are treated with expectant management are still alive after 3 years.[91] By contrast, patients with node-negative disease have a 77% survival rate at 5 years.[91,92] The most important prognostic factor predicting nodal involvement is the depth of invasion of the primary tumor. Superficial disease or T1 lesions have a very low rate of metastases to the inguinal region. This is not true for penile carcinoma that has invaded Buck's fascia and involves the corpora. Nearly half of patients with T2 disease will have histologically positive lymph nodes, and the percentage increases with increasing stage, so that more than two thirds of patients with T4 disease have nodal metastasis.[93]

Extent of nodal involvement also has prognostic significance. Five-year survival decreases in conjunction with increasing number of involved lymph nodes. Patients without nodal involvement have an excellent 5-year survival rate of 95%, but only 81% of those with up to three positive nodes will be alive during the same period. Patients with more than three malignant lymph nodes have a 50% mortality, and no patients with pelvic disease are alive at 5 years.[94] A meta-analysis of several series confirms these findings, with a 93% 5-year and 84% 10-year survival for node-negative patients, but only 62% to 65% survival for N1 and N2 patients over the same time span.[95]

Undoubtedly the most reliable method for determining regional node status is the ilioinguinal lymphadenectomy. As noted previously, this invasive procedure is not without significant morbidity.[94,96,97] Consequently, efforts are being made to identify other methods of determining who will benefit most from the procedure so as to limit unnecessary morbidity. Some investigators have suggested that combining the tumor grade with the TNM staging provides better estimation of those at risk for nodal metastases.[93,98]

TREATMENT AND RESULTS

Historically, the foundation of therapy for penile carcinoma has been surgical excision of both the primary tumor and regional lymph nodes. These patients must be counseled preoperatively to minimize negative emotional and psychologic reaction postoperatively.[99] Furthermore, if medically feasible, attempts to incorporate organ-preserving techniques such as Mohs' micrographic surgery or laser ablation into treatment protocols should be considered. Ongoing research to develop less disfiguring treatments are being investigated to maintain or improve outcomes while minimizing the need for complete penile reconstruction.

Treatment of the Penile Tumor

Circumcision is an excellent form of therapy for small Tis or T1 lesions limited to the prepuce. Intraoperative use of frozen-section pathology to determine negative surgical margins is critical to ensure an optimal result. When the malignancy is located on the glans or penile shaft, nonextirpative therapies should be explored in an effort to provide excellent opportunity for a cure without severe disfigurement. 5-Fluorouracil (5-FU) has been applied as a topical chemotherapy in the treatment of CIS of the penis with acceptable results.[100] Limitations include patient compliance due to the long course of therapy (3–7 weeks) and local skin irritation. The gold standard for these lesions is partial penectomy. The recurrence rate for this procedure is from 0 to 8% with negative margins.[101,102] Other surgical techniques include limited local excision and Mohs' micrographic surgery. Lont and colleagues describe penile preservation surgery for T1 and small T2 lesions. The lesion was excised, and the bed was coagulated using laser. The local recurrence rate was 22% at 5 years for microscopically tumor-free margins.[103]

Mohs' micrographic surgery requires microscopic inspection of surgical margins to permit complete excision of the lesion, and initial studies report an 80% cure rate at 5 years. This technique has been used in conjunction with other therapies with good results.[104] The complication rate is very low.[105] Mohs' surgery, however, typically requires multiple procedures and specially trained surgical staff.[106,107] In certain cases, wide local excision of the tumor with skin grafting or skin advancement for coverage can provide a normal appearance without jeopardizing cancer control.[108]

Surgical Therapy in Advanced Penile Cancer

If the primary tumor is large enough to have infiltrated 75% of the penile shaft, it is unlikely that the required 2-cm margin will be achieved while leaving adequate penile length to urinate with sufficient hygiene. In such cases, a total penectomy or complete corporal body resection with a perineal urethrostomy is indicated. More aggressive tumors that appear to invade the surrounding bony structures mandate local bone resection in addition to penectomy and perineal urethrostomy.

The typical patient with advanced penile malignancy will often have associated infections that require treatment and lymph node beds that will require staging. Evaluation of the nodal involvement allows for more accurate stratification of those patients who are likely to have recurrence with conventional therapy. Biopsies of bulky pelvic nodes can be performed with computed tomography or ultrasound guidance, or by open incisional techniques. The literature does not support any suggestion that pelvic lymphadenectomy is curative, but the pathologic information from the dissection allows precise staging and identifies those patients who may benefit from adjuvant treatments. Given the poor long-term survival for patients with known pelvic nodal metastases, experimental protocols that include combinations of chemotherapy and irradiation are advisable in this high-risk cohort. The problem once again is that these patients are a subset of a rare malignancy, and meaningful numbers in these research studies are difficult to attain.

Superficial Inguinal Lymphadenectomy

The presence of metastatic lymph node disease has been shown to be an important predictor of survival. Patients with T2–4 disease and clinically negative or minimally palpable inguinal nodes should undergo a modified superficial inguinal lymphadenectomy (ILND). Frozen-section pathology is a critical intraoperative tool to identify patients who need more extensive nodal excision. Several retrospective reviews have shown that the incidence of noncontiguous or "skip" metastases is almost negligible when fewer than two involved nodes are found in the superficial lymph node bed.[99–113] Consequently, if more than two lymph nodes are found to be involved with

metastatic disease on frozen section, the lymph node dissection must be expanded to include the deeper lymph node chains as well. In addition, patients with T1 penile malignancy but poorly differentiated histology should be offered superficial ILND given the higher incidence of nodal metastasis among this group. Controversy exists regarding the timing of ILND, but some data suggest benefit to early intervention.[82]

Technical considerations for superficial ILND include preservation of the areolar adipose layer superficial to Scarpa's fascia. This decreases the likelihood of flap necrosis and epidermolysis by leaving most of the saphenous vein lymphatic drainage intact. Anatomic boundaries of dissection are confined anteriorly by Scarpa's fascia and posteriorly by the fascia lata; the superior-inferior limits are from 2 cm cephalad to 10 cm caudad to the inguinal ligament. Careful adherence to proper surgical guidelines for superficial ILND is important, because many current series have demonstrated that this procedure when performed properly is effective treatment of limited node involvement.[114–117] Furthermore, the modified superficial ILND seems to have refined the inguinal lymph node dissection with resultant decrease in morbidity.[118] Postoperative sequelae of superficial ILND are lymphedema, deep venous thrombosis, and wound complications. The estimated morbidity of this procedure including all complications is less than 15%.[101]

Sentinel Lymph Node Biopsy

Complications from morbidity associated with inguinal lymph node dissection can be significant when they occur. There appears to be a survival advantage in immediate lymphadenectomy for those patients with tumor-positive nodes.[119,120] However, only about half of patients with *clinically* positive nodes will have nodes positive for cancer after dissection. This can lead to overtreatment of patients without metastases and place these patients at unnecessary risk for significant morbidity.[119] Sentinel lymph node biopsy was introduced to combat this problem (Box 89-2); however, reproducibility of the technique was found to be poor because of difficulty identifying the position of the sentinel node. In addition, the false-negative rate was unacceptably high.[119] Horenblas and colleagues introduced a promising new technique called dynamic sentinel lymph node biopsy.[121] The technique comprises lymphoscintigraphy the day before surgery for lymph node mapping. During surgery a γ-ray detection probe and blue dye are used to identify the sentinel nodes. If the nodes are found to be positive for tumor, further lymph node dissection is carried out. If the nodes are histologically negative, no further dissection is necessary. Morbidity from this procedure is low.[121,122] In a recent series Horenblas and colleagues report that size of metastasis in the sentinel lymph node is important. They found that 80% of patients with micrometastatic disease in the sentinel lymph node had no further lymph node involvement.[121] The dynamic sentinel lymph node biopsy technique continues to be refined. If it is confirmed to be reliable with further studies, it will be a valuable tool in identifying those patients that require minimal or no lymph node dissection.

Along similar lines of research, McDougal and coworkers report on an imaging procedure using lymphotrophic nanoparticle-enhanced MRI with ferumoxtran-10 for staging of lymph nodes in patients with penile cancer.[123] This technique has been used successfully to detect metastatic nodal disease in other primary cancers. Seven patients with penile SCC and planned ILND were enrolled in the study. The patients were imaged with MRI before and 24 hours after infusion of ferumoxtran-10. They then underwent ILND, and the pathology results were compared to the imaging results. This imaging technique was found to accurately diagnose benign and malignant nodes. The sensitivity was 100%, the specificity was 97%, the positive predictive value was 81.2%, and the negative predictive value was 100%.[123] The negative predictive value was significant, because this showed that all patients with positive nodes were identified, and there were no false negatives.[123] Although the series is small, these preliminary data exceed the accuracy of other current modalities.[123] If these findings are confirmed with larger studies, lymphotrophic nanoparticle-enhanced MRI will be a valuable tool for staging penile cancer patients in the future.

Box 89-2. SENTINEL LYMPH NODE BIOPSY

Sentinel lymph node biopsy for penile carcinoma is controversial. There is ongoing research on techniques to best achieve reproducible results. Some techniques seem promising. However, larger studies will be necessary before a consensus can be reached.

Radical Inguinal Lymph Node Dissection

This procedure is currently performed essentially as it was originally described by Daseler and associates in 1948.[124] The limits of the dissection are from the sartorius muscle to the adductor longus in a lateral to medial direction, and from the inguinal ligament inferior to the apex of the femoral triangle. The initial incision is through the tensor fascia lata over the adductor longus, with ligation of the greater saphenous vein, and then carried medially to the border of the sartorius muscle. A requirement for the deep nodal dissection includes incision of the femoral vascular sheath so as to excise the extensive lymphatic networks that completely encase these vessels.

Reconstructive options to cover the exposed femoral vessels include rotation of a sartorius muscle flap as mentioned earlier. This procedure involves dissecting the sartorius tendon from the anterior superior iliac spine and suturing it to the inguinal ligament over the femoral vessels. Ulcerated and matted nodes often result in wide excision of the overlying skin with at least a 3-cm margin. Rotated myocutaneous gracilis, rectus abdominis, or tensor fascia lata flaps can be used to augment coverage and assist healing. Local control of these advanced lymph nodes is critical, because progression of the disease can lead to vascular erosion and hemorrhage. Surgical treatment often requires careful dissection and control of the femoral vessels. Advanced and erosive disease may mandate resection of part or all of the femoral vein wall as well as venous thrombectomy.

As would be expected, complications of the deeper nodal excision are more frequent and severe than those encountered with the superficial and modified procedures. The relative incidence of flap necrosis and large lymphoceles requiring percutaneous drainage is 2% to 5%.[125] The incidence of wound infections, lower extremity and scrotal edema, lymphocele, seroma, and thrombophlebitis ranges from 2% to 13%.[89,103,116,125–129] Improvements in surgical techniques and postoperative care have decreased the severity and incidence of complications, but postoperative morbidity after deep ILND continues to be a significant clinical problem.[118,125,130]

Pelvic Lymphadenectomy

Pelvic lymphadenectomy may be done simultaneously with a superficial ILND or as a staged procedure. The dissection can be performed open or laparoscopically.[131] This procedure excises the nodal chains from the common iliac vessels down to the internal and external perivascular iliac nodes, and from the lateral pelvic sidewall to the bladder medially. The posterior limit of dissection is the obturator nerve. To date, pelvic lymphadenectomy has value only as a staging procedure. The survival of patients who undergo this excision is less than 5% after 5 years.[132,133]

Chemotherapy for Advanced Penile Carcinoma

Single-Agent Therapy

Historically, chemotherapeutic agents have been applied in the treatment of penile carcinoma in combination with surgical or radiation therapies. The most commonly used agents that have proven

Table 89-3 Selected Reports of Single-Agent Chemotherapy for Penile Cancer

Drug and Regimen	No. of Patients	Response (%)*
Bleomycin		
3–20 mg/m^2/day continuous infusion *or* 10–30 mg/m^2 every day or weekly boluses	14	21 (4)
Methotrexate		
Various treatment schedules	8	38 (3)
or 250 mg/m^2 every 2–4 wk *or* 30–40 mg/m^2 weekly	13	61 (8)
Cisplatin		
70 or 120 mg/m^2 every 21 days	14	21 (3)
or 50 mg/m^2 on days 1 and 8 for 28 days	26	15 (4)

*Number of patients responding is given in parentheses.

cytotoxic effects in penile carcinoma are bleomycin, methotrexate, and cisplatin. These drugs have been reported in several combinations in small series with variable doses and medication schedules. As single-agent chemotherapy, these medications have produced only modest results in patients with advanced disease (Table 89-3).[134–137] The vast majority of patients who showed any regression of disease had a partial response; and, in the report on methotrexate activity by Sklaroff and Yagoda, the median duration of remission in partial responders was 3 months.[135] However, two patients did have responses that lasted more than 12 months. Investigation into cisplatin yielded similar results, with the duration of partial response 1 to 3 months and a median survival of only 5 months.[137]

Dose-dependent side effects of bleomycin were pneumonitis and pulmonary fibrosis, with elevated risk when dosing was greater than 400 units.[135] Patients undergoing treatment with methotrexate most frequently had mucositis as the primary adverse reaction. Infrequent side effects of methotrexate were pneumonitis, hepatic insufficiency, myelosuppression, renal insufficiency, skin rashes, and sepsis.[135] The most debilitating effect of cisplatin single-agent treatment was nausea and vomiting.[137] Other significant toxicities of cisplatin therapy were nephrotoxicity that led to cessation of treatment in 8% of patients, as well as ototoxicity, myelosuppression, and neuropathy.[137]

Combination Chemotherapy

The intent of combination chemotherapeutic regimens is to optimize cytotoxicity while increasing the range of activity of treatment and reducing the probability of inducing tumor drug resistance. In a small series, an 80% response rate with 40% complete response was achieved in five patients treated with cisplatin and 5-FU before lymphadenectomy.[138] Another small series had similar success, with one complete response and five partial responses in six patients who subsequently underwent surgical or radiation treatments.[139] In this series all six patients eventually had progression of their disease, but median time to progression was 1 year and median survival was 16 months. However, another small study reported on a similar regimen with 5-FU and cisplatin that resulted in only a 25% response rate in eight patients.[140] The variability in outcomes may be a result of chance given the small sample sizes in each study, or may be related to different modes of delivery of chemotherapeutic medicines or patient selection. Nevertheless, these results suggest that this combination has significant activity in the treatment of penile SCC despite the lack of a durable response.

Another trial of combination chemotherapy used cisplatin, bleomycin, and methotrexate that resulted in a 72% response rate in 10 of 14 patients, with the vast majority having a partial response.[141] The patients underwent leucovorin rescue after treatment with methotrexate. The average duration of response was nearly 6 months, and one patient continued to be disease-free at 2 years. In this study a small percentage of patients received the bleomycin and cisplatin through local-regional infusion into pelvic arteries. In addition, Huang and coworkers reported three of three responders with exclusively intra-arterial administration of all three agents.[142] Reported toxicities were similar to those seen with single-agent treatment with these agents.

These results led to a larger multi-institutional prospective study of methotrexate, bleomycin, cisplatin combination therapy in 45 patients by the Southwest Oncology Group.[143] These investigators were able to achieve a 32.5% response rate, with 5 of 13 responders showing a complete response. However this regimen resulted in 11% treatment-related mortality primarily due to pulmonary complications, with an additional 17% of patients experiencing life-threatening toxicity. The unacceptable level of toxicity prevented further clinical trials of this regimen.

The combination of vincristine, bleomycin, and methotrexate was investigated in patients with advanced penile malignancy, and a 53.8% response rate was reported.[144] In 13 patients with bulky inguinal metastases that were deemed unresectable before chemotherapy, 5 had sufficient response to undergo postchemotherapy radical excision. Two of the five enjoyed long-term disease-free survival longer than 5 years. Toxicities were less severe than other regimens, with fever, cutaneous hyperpigmentation, and pulmonary fibrosis reported.

The activity of chemotherapeutic agents in treatment of advanced penile carcinoma indicates that combination chemotherapy should contribute to multimodality approaches in the management of penile carcinoma. As with chemotherapeutic investigations of other malignancies, identification of active combinations while minimizing toxicity remains the objective. More intensive efforts should be directed toward refining combination chemotherapies for penile SCC. This could be accomplished through multi-institutional, collaborative, international studies.

Chemotherapy with Surgery

No large studies of preoperative chemotherapy in penile cancer patients exist, but reports of patients who have received chemotherapy before surgical treatment can be gleaned from the published literature on chemotherapy for advanced disease. By combining the published series on cisplatin-based chemotherapy, 35 patients with fixed inguinal nodes can be identified who received chemotherapy and then subsequently underwent excisional surgery.[139–141,144,145] Nearly 70% of patients from these series showed some response to chemotherapy, with 23% demonstrating a durable response, and the treatment allowed complete resection of tumor in 15. Of these patients, 8 had long-term survival in excess of 12 months and as long as 10 years. Another study in 27 patients with T1 lesions resulted in 85% penile preservation after treatment with vinblastine, bleomycin, and methotrexate followed by surgical excision or ablation with CO_2 laser. Furthermore, 44% of those treated had no pathologic evidence of disease, and an additional 34% had partial response to this combination therapy.

In another small series, Pizzocaro and Piva treated 12 patients with a postoperative adjuvant chemotherapy regimen consisting of vinblastine, methotrexate, and bleomycin.[146] Only 1 of these 12 patients relapsed during a median follow-up of 42 months. In addition, 5 patients with unresectable bulky inguinal disease were treated with this chemotherapeutic regimen. Subsequently, 3 patients who exhibited a partial response underwent radical lymphadenectomy and continued to be disease-free at 20 to 72 months after surgery. Two minimal responders could not have radical surgery, and they died of the disease within 1 year.[146] Encouraged by these findings, the same group then reported on 26 patients who had fixed inguinal nodes. Ten of these patients were treated with radiation therapy, with or without chemotherapy, and 16 received neoadjuvant chemotherapy.

Radiation therapy made it possible for only one patient to later have lymphadenectomy, and all of these patients died of their disease within 3 years. In dramatic contrast, 10 (56%) of those who were treated with neoadjuvant chemotherapy responded sufficiently to have subsequent node excision, and 5 (31%) were found to be disease-free on 5-years follow-up.[147]

Since then, Roth and colleagues designed a more extensive adjuvant chemotherapeutic regimen including 5-FU, cisplatin, mitomycin, bleomycin, and methotrexate. Eight patients with penile carcinoma received eight intra-arterial infusions over 48 hours.[148] All but one patient had previous resection of disease with pathologic confirmation of nodal involvement, or were found to have recurrence in the inguinal region on follow-up. Three patients had a complete response; three had a partial response, with one demonstrating stable disease. Two of three patients with complete response had long-term disease-free survival for more than 5 years.

Clearly, the use of chemotherapeutic regimens to permit patients with bulky nodal disease to undergo surgical resection, or as an adjuvant after lymphadenectomy, has been shown effective in some patients. Yet these data tend to be hidden within other reports, because no large-scale prospective trials have been designed to assess optimal timing and regimens for the adjuvant chemotherapeutic treatment of penile SCC in conjunction with surgical excision. Again, given the rarity of this disease in many countries, compiling enough cases to perform such a study is certainly a daunting task that emphasizes the need for multi-institutional and international collaboration to determine the optimal therapy for advanced disease.

Radiation Therapy in Penile Cancer

An alternative to topical or extirpative therapy for penile cancer is radiation therapy via interstitial brachytherapy or external-beam radiation. Radiation therapy has been reported in many series as a single-agent treatment for both primary penile tumors and metastatic lymph node disease.[80,94,127,149–154] Crook and associates reported the use of interstitial brachytherapy for penile carcinoma and reported a 93% disease-free rate for patients with T1 and T2 lesions and a 100% cure rate for patients with well-differentiated tumors.[155] This treatment has been the therapy of choice for small, clinically localized penile cancer in France, with a 74% penile conservation rate and only 11% local failure for tumors smaller than 2 cm.[156] The success rates from other reports have varied from 65% to 80% for superficial lesions.[117,120,152,153,157,158]

In more advanced penile malignancy, treatment with radiation therapy has an unacceptably high rate of tumor recurrence that is between 20% and 40%.[152,157,159] Furthermore, radiation therapy for tumors larger than 4 cm often results in a nonfunctional penis or significant active residual disease. Both outcomes defeat the purpose of organ-preserving therapy, which is to adequately treat the disease while maintaining function.[153,158] In choosing radiation treatment rather than surgical extirpation of the primary lesion, the patient must realize that the tumor may progress to lymph nodes or distant metastases despite treatment, thus precluding the opportunity for cure. The complete response rate for external-beam radiation therapy has been reported as 56% with local failure rate of 40%.[94,149] Fortunately, in some cases excision of local recurrence after irradiation can provide local control.

Complications from radiation treatment for penile malignancy can vary from relatively benign telangiectasias and catarrhal reactions seen in more than 90% of patients, to more troublesome urethral strictures in 20% to 35%, and meatal stenosis in 15% to 30%.[80,150,154] In addition, tissue changes in response to radiation treatment often lead to necrosis that is clinically similar to the appearance of residual tumor and results in severe impairment of organ function. Nevertheless, given the undeniable activity of radiation therapy in penile carcinoma, particularly in early-stage disease, this modality will continue to be an integral part of integrated organ-sparing therapy for penile cancer.

Chemotherapy with Radiation

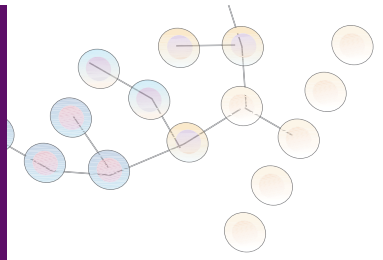
Several small series of combination chemotherapy and radiation regimens demonstrate response rates superior to those reported for radiation therapy alone.[160–162] Modig and coworkers found similar survival rates between 19 patients treated with bleomycin and radiation and a similar cohort of patients who underwent surgery.[160] Most efforts in organ-preserving therapy have involved bleomycin and irradiation, because bleomycin is a known radiosensitizer and most treated patients have had relatively low-stage tumors. A series of 47 patients with penile carcinoma ranging from T1 to T3 disease were treated with bleomycin and 45 or 58 Gy of radiation for a period of 5 to 6 weeks with little overall toxicity. Results from the two arms of this study demonstrated that 2 of 7 (18%) treated with 45 Gy required further tumor excision, whereas 4 of 40 (10%) patients who received 58 Gy subsequently underwent surgical salvage.[163] However, smaller studies do not support these findings; treatment of 10 patients with a similar dose of bleomycin and 60 Gy external-beam radiation administered in three equal doses resulted in one treatment-related death with moderate to severe toxicity in 8 patients. Worse, only 4 patients ultimately achieved organ preservation.[164]

Unquestionably, the published literature supports the notion that penile SCC is sensitive to chemotherapy. Currently no conclusive data exist to suggest that one chemotherapeutic regimen is superior to the myriad combinations that have been investigated. Yet, many other agents other than bleomycin, 5-FU, methotrexate, and cisplatin have not been evaluated for activity in treatment of penile malignancy. In addition, the significant toxicity of the commonly used therapy of bleomycin, methotrexate, and cisplatin, and the heretofore unknown side effect profiles of other chemotherapeutic combinations demand further investigation into other regimens that ultimately have superior outcomes in terms of morbidity as well as response rate and overall mortality.

The gold standard of therapy for penile carcinoma remains early detection with local tumor control if feasible. Treatment guidelines based upon pathologic stage are shown in Table 89-4. Patients at high risk for relapse should strongly consider neoadjuvant therapy. Currently the small numbers in the reported series and the different combinations and administrations investigated limit the ability to draw firm conclusions about multimodality therapy for penile carcinoma. However, the data do suggest that preoperative administration of chemotherapy that includes cisplatin will allow 40% of patients with local-regional dissemination of malignancy to proceed with surgical resection with good probability of negative margins, and will result in long-term disease-free survival in as many as 20%. Other combinations such as vinblastine, bleomycin, and methotrexate do not seem to achieve comparable response rates. Combinations of bleomycin and radiation therapy seem to hold promise for organ-preserving treatment in carefully selected subjects.

Table 89-4 Stage-Based Guidelines for Treatment of Penile Carcinoma

Penile Cancer Stage	Guidelines for Treatment
pT1, pT2	Partial penectomy, superficial ILND, frozen-section confirmation; deep ILND if frozen-section evaluation of superficial nodes is positive
pT3	Total penectomy, superficial and deep ILND
T4	Initial treatment with neoadjuvant chemotherapy followed by salvage lymphadenectomy if possible
N2–N3	Enroll in postoperative neoadjuvant chemotherapy or radiation treatments



ILND, inguinal lymphadenectomy.

90 Testicular Cancer

Charles J. Ryan, Eric J. Small, and Frank M. Torti

SUMMARY OF KEY POINTS

Incidence
- One percent of all male malignancies, accounting for 6000 to 8000 new cases a year in the United States
- Most common malignancy among men aged 15 to 35
- Seminoma: 40% of all germ cell tumors
- Nonseminoma: 60% of all germ cell tumors, with embryonal elements most frequent

Differential Diagnosis
- Testicular torsion, hydrocele, varicocele, spermatocele, epididymitis (can coexist with germ cell tumors)
- Other malignancies: lymphoma, metastases from prostate cancer, lung cancer, or melanoma (generally in older age group)

Diagnosis and Staging Evaluation
- Complete history and physical examination
- Bilateral testicular ultrasonography
- Tumor serum markers (lactate dehydrogenase [LDH], β-human chorionic gonadotropin [β-HCG], and α-fetoprotein [AFP])
- Hemogram, chemistry studies including renal function
- Computed tomography (CT) of chest, abdomen, and pelvis
- Additional imaging studies as appropriate (e.g., imaging of brain in patient with pure choriocarcinoma)
- Radical (inguinal) orchiectomy (transscrotal biopsy or orchiectomy should be avoided)

Primary Therapy

Seminoma
- Localized disease is curable with orchiectomy and low-dose adjuvant radiotherapy or single-dose carboplatin to lymph nodes in 98% of patients.
- Locally advanced disease (stage II) is curable with orchiectomy and radiation therapy to involved areas in 85% to 95% of patients with minimal to moderately bulky disease.
- Metastatic disease (stage III) or bulky locally advanced disease is curable in 90% with combination chemotherapy.
- Postchemotherapy retroperitoneal lymphadenectomy can prevent subsequent relapse in selected patients.

Nonseminoma
- Clinically localized disease is curable with orchiectomy alone in 60% to 80%.
- Risk of relapse is decreased with retroperitoneal lymphadenectomy, although in selected patients surveillance without surgery is a possible option.
- Adjuvant combination chemotherapy after lymphadenectomy may further decrease risk of relapse but does not impact on survival.
- Nonbulky locally advanced (stage II) disease is cured with surgery alone in 40% to 60% of cases.
- Moderate to bulky nodal disease requires combination chemotherapy.
- Metastatic disease (stage III), or bulky locally advanced disease is curable in 80% of cases with combination chemotherapy.
- Postchemotherapy retroperitoneal lymphadenectomy can prevent subsequent relapse in selected patients.

Effective Second- and Third-Line Therapies
- Chemotherapy salvage rates are about 80% for patients who have failed surgical or radiation therapeutic treatments.
- Second-line chemotherapy for patients who have failed prior chemotherapy are curative in 20%–75%.
- High-dose therapy with autologous bone marrow transplant/peripheral stem cell transplant (PSCT) possibly curative in 15% to 20% of those in whom second-line therapy has failed

INTRODUCTION

Although testicular cancer accounts for only 1% of all male malignancies, the understanding and study of this disease are important for a variety of reasons. The evolution of therapy for germ cell tumors (GCTs) has been deliberate and thoughtful, and has resulted in cures of 85%. GCT therapy serves as a model for the treatment of curable cancers and is particularly notable because GCT occurs in young men who are entering their most productive years. Nonetheless, challenges in the management of GCTs remain. Because of their young age, patients who have been cured are at risk of delayed, treatment-induced toxicity. Furthermore, an 85% cure rate also implies that 15% of patients with GCTs will not be cured and will ultimately succumb to their disease. An understanding of staging and risk assessment is crucial if (1) patients with good-risk features are not to be overtreated and exposed to undue toxic risks, and (2) patients with poor-risk features are to receive adequate (curative) therapy.

EPIDEMIOLOGY

Incidence

GCTs account for 1% of all male malignancies and it is estimated that 7500 new cases were diagnosed in the United States in the year 2007.[1] Approximately 400 men in the United States died in the year 2002 as a consequence of germ cell tumors, despite their overall curability. Although GCT is an uncommon malignancy, it is the most common malignancy among men aged 15 to 35. Seminoma accounts

for 40% of all GCTs, whereas nonseminoma germ cell tumors (NSGCTs) account for 60%. Although occasionally GCTs occur in children (generally yolk sac tumors) and in men over 70 (generally spermatocytic seminoma), by and large it is a malignancy of early adulthood, with the incidence of seminoma peaking in the 25- to 45-year-old group; the highest incidence of nonseminoma occurs in a slightly younger group of men (15- to 30-year-old group).[2] Although the incidence of germ cell neoplasms in African American men is one fourth that of white men, African Americans have a higher disease stage at diagnosis than white men.[3] Bilateral tumors occur in 2% to 4% of patients.[4]

Etiology

Although risk factors for the development of this disease are largely unknown, a history of cryptorchidism seems to be related to the development of GCT. The risk of developing GCT is 10- to 40-fold higher in cryptorchid testes, and it is anticipated that 12% of all GCTs arise in cryptorchid testes. Conversely, from 1% to 5% of boys with a history of an undescended testicle will go on to develop GCT. The risk is highest (at approximately 5%) when a cryptorchid testis is retained intra-abdominally, falls to 1% if retained in the inguinal canal, and seems to fall further if the undescended testis is surgically placed in the scrotum (orchiopexy) before 6 years of age. However, one fourth of GCTs arising in patients with a history of cryptorchidism occur in the normal, descended testicle, suggesting that systemic sequelae of cryptorchidism (i.e., testicular atrophy) is of greater etiologic importance than local or anatomic abnormalities.[5,6] Further, males exposed to tobacco smoke in utero have a higher incidence of cryptorchidism,[7] although a direct link between tobacco smoke and testis cancer has not been observed.

In patients with testicular feminization syndrome and intra-abdominally retained gonads, a 40-fold increase of GCT is seen. In phenotypically female but genotypically male patients, this syndrome may be mistaken for ovarian cancer.[8]

Although the association between cryptorchidism and the development of GCT is indisputable, it is prudent to recall that a history of cryptorchidism is absent in nearly 90% of men with GCT. The contribution of orchitis, testicular trauma, or irradiation to the genesis of GCT is unknown, but it has been postulated that the final pathway common to all of these associations is testicular atrophy with increased follicle-stimulating hormone (FSH) drive. There is growing support for the concept of transplacental damage to the fetal gonad by maternal estrogen levels as a contributing causative agent of germ cell cancer.[9]

Extragonadal GCTs seem to arise as a consequence of the malignant transformation of residual midline germinal elements, usually in the mediastinum or retroperitoneum, but occasionally in other locations such as the sacrococcygeal region and the pineal gland.[10] Whether these residual germinal elements are a consequence of abnormal germ cell migration is not known, and other factors that may contribute to the development of extragonadal GCT have not been identified.

Molecular Biology

The cytogenetic and molecular biology of GCT has only recently begun to be understood. Most interest has focused on changes involving chromosome 12. The isochromosome of the short arm of chromosome 12, i(12p), has been reported in up to 90% of GCT patients,[11,12] and in cases in which the isochromosome is not seen, excess genetic material is typically found on the p arm of chromosome 12.[13] Although it is occasionally found in gastric cancer, i(12p) is nearly a pathognomonic feature of GCT of all histologic types, whether of gonadal or extragonadal origin. This cytogenetic abnormality has been reported in carcinoma in situ tissue, suggesting it is an early marker, if not a cause, of germ cell tumorigenesis.[14] In patients with mediastinal GCT, in whom there is an increased incidence of hematologic malignancies, often acute myeloid leukemia, i(12p) can be found in both the mediastinal GCT tissue and in the leukemic cells,[15] suggesting a common clonal origin for both. Similarly, i(12p) is found in malignant tissue of diverse histologies that has developed from the malignant transformation of teratoma, which is a component of nonseminomatous germ cell cancers.[16] The presence of i(12p) has been utilized diagnostically in patients with midline carcinomas of unknown origin,[17] allowing, in one series, a definitive diagnosis of GCT in 28% of patients, and also serving as a marker of chemotherapy sensitivity (within the group of patients with midline malignancies of uncertain histogenesis).[18] The presence of three or more copies of i(12p) has been correlated with poor prognosis GCT.[19] Other changes in chromosome 12 are seen in GCT. Deletions of the terminal portion of 12q have been observed in up to 44% of patients with GCT, as well as in several GCT cell lines, suggesting the possibility of a tumor suppressor gene in this area.[20]

The gene or genes on i(12p) that may be involved in carcinogenesis have not been identified, although the oncogene c-Ki-ras-2, which is located on i(12p), has been implicated in GCT cell lines.[21] The cyclin D2 gene has received much attention in normal testicular development as well as in the pathogenesis of GCT. It has an important role in cellular proliferation, and its expression is tightly regulated throughout the cell cycle. It facilitates passage of cells though the G1 cell-cycle checkpoint. The gene is located on the short arm of chromosome 12, and it is overexpressed in nearly all GCTs. Cyclin D2 is therefore a candidate GCT oncogene.[20] Activated mutations in the proto-oncogene c-kit have also been isolated from seminoma specimens.[22] c-kit encodes a transmembrane receptor tyrosine kinase that seems to have a role in normal spermatogenesis, and it is expressed in early fetal germ cells up to 12 weeks of gestation, but not beyond. In addition, it has also been detected in carcinoma in situ (CIS) and seminoma cells, reflecting a possible role in GCT oncogenesis.[22,23] Epidermal growth factor receptor has also been found to be overexpressed in approximately 25% of the β-HCG-expressing component of mixed GCTs.[24] Epidermal growth factor receptor is a plasma glycoprotein that after binding to its ligand activates protein tyrosine kinase activity. This leads to activation of a cascade of biochemical and physiologic responses that are involved in the mitogenic signal transduction of normal as well as malignant cells.

HISTOLOGY AND NATURAL HISTORY

Overview of Histology

Most primary testicular cancers are of germinal origin and are felt by some to be the malignant counterparts of normal embryonic development. In this model, the normal embryonic development counterpart of seminoma is the spermatocyte, whereas pluripotential early cleavage stage tissues are the counterpart of embryonal cell carcinoma. More differentiated malignancies find their normal tissue counterparts in tissues derived from the developing embryo, such as the embryo itself (teratoma), the yolk sac (yolk sac tumors), and the placenta (choriocarcinoma.)

A commonly used histologic classification of testicular neoplasms is derived from the Armed Forces Institute of Pathology classification schema of Dixon and Moore,[25] which recognizes pure seminoma, as well as four other categories, each of which may occur with or without seminoma elements: (1) embryonal carcinoma, (2) teratoma, (3) teratoma with foci of embryonal carcinoma and choriocarcinoma (also termed teratocarcinoma), and (4) choriocarcinoma with and without embryonal elements.

The World Health Organization international classification divides tumors into those of single histologic type (seminoma, spermatocytic seminoma, embryonal carcinoma, choriocarcinoma, teratoma, and yolk sac tumors) and those of more than one type, in which the listing and estimation of relative proportion of each type

Table 90-1 Comparison of Two Classifications of Germ Cell Tumors

Extragonadal	1–5	20–35

GCT, germ cell tumor.

is required.[26] The major important differences between these two schemas is the recognition by the World Health Organization schema of yolk sac tumors (endodermal sinus tumors) and spermatocytic seminoma as distinct categories (Table 90-1). Representative photomicrographs of various GCTs can be seen in Figure 90-1.

Testicular cancers that are of nongerminal origin include specialized gonadal stromal neoplasms as well as sarcomas. These, in addition to adenocarcinoma (of the rete testis), and secondary (nonprimary) malignancies such as acute leukemia, lymphoma, carcinoma, and melanoma make up less than 5% of testicular neoplasms. The frequency and natural history of specific histologic subtypes are discussed in the following sections and summarized in Table 90-2.

Overview of Natural History

The natural history of GCT is largely defined by lymphatic spread to the retroperitoneal lymph nodes early in the disease, with hematogenous dissemination developing later. Thus, virtually all GCTs with pulmonary or visceral metastases will have concomitant retroperitoneal lymph node involvement. Pure choriocarcinoma is an exception, characterized by early hematogenous dissemination to lungs, brain, and viscera. The more aggressive biology of nonseminomatous GCT is evidenced by the approximately 60% to 70% of individuals with nonseminomatous GCT who will have nodal or other metastatic involvement at presentation, compared with 25% in individuals with pure seminoma. These figures are somewhat biased, because people with clinical stage I seminoma (confined to testis) do not routinely undergo pathologic staging with a retroperitoneal lymph node dissection (RPLND), whereas pathologic staging is often undertaken in similar nonseminomatous patients.

Seminoma usually spreads to first-station para-aortic nodes, although (as with nonseminomatous GCT) pelvic nodes may be involved if the scrotal sac has been violated, either by the primary tumor or in the case of trans-scrotal exploration by inguinal surgery. Whereas nodal involvement is less common in seminoma than in NSGCT, ureteral obstruction seems to occur more commonly than in nonseminomas, because of either bulky disease or more diffuse sheetlike spreading. It is extremely unusual for seminomas to present with hepatic or pulmonary metastases; when they do, it is virtually always in the setting of retroperitoneal nodal involvement. The presence of nonpulmonary visceral metastasis (e.g., bone or liver) portends an adverse prognosis.

The distribution of retroperitoneal lymph node metastases in nonseminomatous GCT has been described by Ray and colleagues[27] and Donohue and associates[28] and provides the basis for the specific surgical and therapeutic approaches described in the following section. Figure 90-2 diagrams the anatomy and distribution of retroperitoneal lymph node involvement in GCT. A right-sided testicular primary is most frequently found to have interaortocaval nodal metastases, followed (in order of decreasing frequency) by the precaval and preaortic nodes. Contralateral nodal involvement occurs in 15% of patients, but in virtually every case with contralateral involvement, ipsilateral nodes were also involved. Left testis tumors most frequently have nodal spread to the left para-aortic, preaortic, and interaortocaval nodes, in that order. Suprahilar nodal involvement does not occur in patients with microscopic or low burden infrahilar disease (stage B1), whereas 25% of patients with gross infrahilar disease have been found to have positive suprahilar nodes.[27] Other nodal metastases are rare, but can occur in the external iliac and obturator nodes if the primary tumor invades the epididymis or extends up the spermatic cord, or in inguinal lymph nodes if the tumor extends through the tunica vaginalis to involve the scrotum, or if trans-scrotal exploration has been used.[29]

Seminoma

Seminomas account for 40% of all GCTs. The three distinct histologic patterns that have historically been described are classic seminoma, anaplastic seminoma, and spermatocytic seminoma. However, a clinical distinction can only be made between classic seminoma and spermatocytic seminoma, and the histologic definition of anaplastic seminoma (more than five mitotic figures per high-power field, cellular anaplasia, and tissue disruption) is of historic interest only, in that neither response to therapy nor survival are adversely affected by the presence of anaplastic features.[30]

Classic seminoma usually presents in the fourth or fifth decade. It is localized to the testes (stage I) in approximately 70% of patients and is metastatic to lymph nodes (generally stage II) in 25%.[31] Metastases to lymph nodes occurs in an orderly sequential fashion along

Figure 90-1 • Representative histology of germ cell neoplasms. **A,** Classic seminoma. Note uniform cells, with central, well-delineated nuclei. Occasional clear spaces represent areas of glycogen deposition (H&E, ×50). **B,** Seminoma with giant syncytiotrophoblast cells. This histologic pattern may be seen in HCG-positive seminomas. Fibrovascular septae with a lymphoid infiltrate are a typical feature of seminoma (H&E, ×25). **C,** Spermatocytic seminoma. Distinguished histologically from classic seminoma by relative lack of fibrovascular septae and lymphoid infiltrate, as well as by marked variation of cell size, but not shape (H&E, ×100). **D,** Embryonal carcinoma. Compared with seminoma (**A**), note cellular and nuclear pleomorphism and syncytial pattern (loss of cellular borders) (H&E, ×50.) **E,** Mixed germ cell tumor, with seminoma and embryonal carcinoma elements. Note fibrovascular septae with lymphoid infiltrate characteristic of seminoma and islands of embryonal carcinoma (H&E, ×25). **F,** Immature teratoma. Note primitive neural differentiation (H&E, ×25). **G,** Choriocarcinoma. The two cell types required for diagnosis are present. Syncytiotrophoblastic cells (giant cells with hyperchromatic nuclei and abundant eosinophilic cytoplasm) are seen in the upper right quadrant. Cytotrophoblasts (sheets of cells with single nuclei and abundant clear cytoplasm) compose the midportion of this photomicrograph. Hemorrhagic infiltrate at the bottom of the photomicrograph is common in choriocarcinoma (H&E, ×25). **H,** Yolk sac tumor, microcystic pattern (H&E, ×25). (Courtesy of Dr. Noel Weidner, Department of Pathology, University of California, San Francisco.)

draining lymph node chains. Visceral metastases are present at presentation in less than 5% of patients, and in general occur late in the course of the disease. Seminomas tend to appear homogeneous, with little necrosis or hemorrhage on gross inspection. Microscopically, they consist of sheets of uniform cells with large central hyperchromatic nuclei and clear or granular cytoplasm, which are divided by thin fibrous septations. Although lymphocytic infiltration and occasional giant cells may be seen, neoplasms in which any teratomatous or embryonal elements are seen are by definition not considered to be pure seminomas.[25] Spermatocytic seminoma represents approximately 5% of all seminomas and warrants special consideration. It generally occurs in the sixth decade. Although it is more likely to be bilateral than typical seminoma (6% vs. 2%), it is nonetheless a fairly indolent malignancy in which metastatic events are distinctly uncommon.[32] Spermatocytic seminoma can be histologically distinguished from classic seminoma by the relative lack of compartmentalization of sheets of cells by fibrous septae, by the marked variation in cell size, and by the absence of lymphocytic infiltration.

Embryonal Carcinoma

Pure embryonal carcinomas account for over 60% of NSGCTs, although foci of embryonal elements may be found in a large majority of NSGCTs. Embryonal carcinoma occurs in 20- to 30-year-olds and is a highly malignant tumor characterized by rapid and bulky growth. In addition to lymphatic spread, these tumors are characterized by hematogenous spread of cancer cells, particularly to lung and liver. Over 60% of patients with embryonal carcinoma have metastases at presentation, and the likelihood of occult nodal metastases in clinical stage I (confined to testis) tumors is a function of the proportion of the tumor that is composed of embryonal carcinoma.[33] Furthermore, embryonal carcinoma has been reported to have the highest rate of venous invasion, lymphatic invasion, and tunica (capsular) invasion in both stage I and II tumors.[30] Embryonal carcinomas exhibit focal necrosis and hemorrhage, and microscopically are quite variable. Cellular features of embryonal carcinoma correlate with its more aggressive behavior and include anaplastic cells with embryoid features. Large pleomorphic nuclei, mitotic figures, and multinucleation are common as well. Stroma varies from loose to thick and fibrous.[25]

Teratoma and Teratocarcinoma

Mature teratoma has elements of one or more of the three germinal layers that are fully differentiated. Pure teratoma is uncommon and makes up less than 5% of GCTs in adults. Over 75% of nonseminomas have been reported to have variable amounts of teratomatous elements, so that "pure" teratomas must be sampled carefully to exclude undifferentiated foci. The term teratocarcinoma refers to teratomas in combination with other elements, although some pathologists reserve the term for the combination of teratoma and embryonal carcinoma. When a teratoma has cellular and active stroma with mitotic figures, it is referred to as immature teratoma. Teratomas and teratocarcinomas are composed of solid and cystic spaces on cut surface, with areas of hemorrhage and necrosis. A histologic mix of fully differentiated cartilage, muscle, or epithelial tissue and malignant embryonal elements is seen. Predominant teratomatous features account for one third of teratocarcinomas, whereas approximately two thirds are mostly composed of nonteratomatous elements.[25] Mature teratoma is the least aggressive of the nonseminoma GCTs, although up to 30% of adult patients with clinical stage I teratoma treated with orchiectomy alone will subsequently relapse, suggesting that pure teratomas should not be exempted from the usual clinical and pathologic staging of GCT or from the usual subsequent therapeutic interventions.[34] The natural history of teratocarcinomas lies somewhere between that of mature teratoma and embryonal carcinoma, but for practical (diagnostic and therapeutic) purposes, teratocarcinomas can be grouped with embryonal cell carcinomas. The likelihood that residual or recurrent masses after treatment are composed of mature teratoma is increased in patients with more extensive teratomatous elements at presentation later in the chapter.

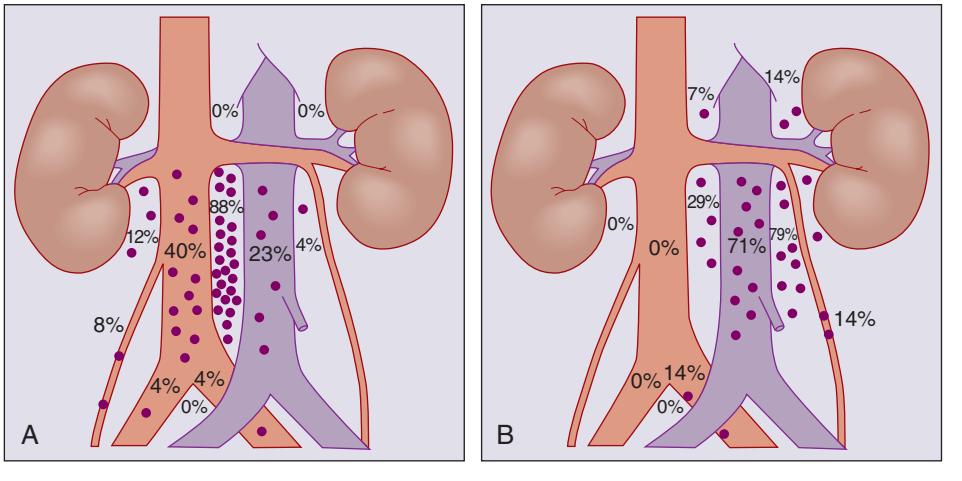

Figure 90-2 • Distribution of retroperitoneal nodal metastases in early-stage nonseminoma germ cell tumor. **A,** Right. **B,** Left. (From Donohue JP, Sachary FM, Maynard BR: Distribution of modal metastases in nonseminomatous testic cancer. J Urol 1982;128:315, with permission.)

Choriocarcinoma

Choriocarcinoma is the most aggressive of the nonseminoma GCTs, with early hematogenous dissemination to lungs, liver, brain, and other visceral sites. Pure choriocarcinoma is exceedingly rare, accounting for less than 0.5% of all testicular malignancies, but focal areas of choriocarcinoma are seen in approximately 12% of embryonal and teratocarcinomas.[35] Because advanced-stage disease at diagnosis is common, pure choriocarcinoma has a particularly poor prognosis. If pure choriocarcinomas are excluded, the specific histologic subtype of NSGCT does not have an influence on survival. The microscopic diagnosis of choriocarcinoma requires the presence of two cell types: syncytiotrophoblastic cells (giant cells with multiple hyperchromatic nuclei and abundant eosinophilic cytoplasm) and cytotrophoblasts (sheets of cells with single nuclei, abundant clear cytoplasm, and well-defined borders) arranged in papillary or pseudovillous patterns.[25]

Yolk Sac Tumors

Also known as endodermal sinus tumors, pure yolk sac tumors occur rarely, accounting for 1% of GCTs in adults. More commonly, yolk sac tumors in adults are found in combination with other tumor types, occurring in up to 70% of GCTs. In one series of 459 patients with stage I and II testicular cancer, the most common histology observed was a mixed one consisting of embryonal carcinoma plus yolk sac tumor and teratoma. Furthermore, the presence of teratoma and yolk sac tumor seemed to be associated with a large primary tumor size.[35] While pure yolk sac tumors are conventionally considered to be more aggressive with early hematogenous distribution,[30] recent histologic reviews have suggested that patients in whom yolk sac tumor elements are present are at lower risk of relapse than patients in whom they are absent. However, the relatively high frequency with which yolk sac tumors and embryonal carcinoma are found together (50% of all tumors in some series) and the extremely rare occurrence of pure yolk sac tumors (1%) make this a difficult conclusion to substantiate.[36] Yolk sac tumors occur more commonly in children, in whom they seem to be a less aggressive histologic subtype.[37] The histology of yolk sac tumors, though characteristic, may be observed in several common patterns. These include a papillary pattern in which Schiller-Duval bodies (a fibrovascular core with a circle of cells around it, vaguely reminiscent of a glomerulus) can be seen, as well as microcystic, glanduloalveolar, and solid patterns.

Stromal Cell Tumors

Derived from the stromal and supporting cells surrounding germ cells, stromal cell tumors consist of Leydig cell tumors, Sertoli cell tumors, and granulosa cell tumors. As a group they account for 3% to 4% of primary testicular tumors but constitute nearly 20% of childhood testicular tumors. Although by and large they are benign, up to 10% may metastasize.[38] Histologic features seem to be useful in predicting the risk of disseminated disease, and management generally consists of orchiectomy and clinical staging with CT scan, without use of RPLND. These tumors may be estradiol-secreting; gynecomastia occurs in 30% of Sertoli cell tumors and 15% of Leydig cell tumors.

Secondary (Metastatic) Neoplasms

Although the large majority of testicular neoplasms in young men are GCTs, in men over 60 years of age only 25% of malignancies will be of germinal origin. Testicular malignancies in this age group are predominantly composed of lymphomas,[39] although metastases to the testicles, primarily from prostatic adenocarcinoma, lung carcinoma, and melanoma primary tumors must also be considered.

CLINICAL MANIFESTATIONS

The most common presentation of testicular cancer is testicular swelling (73% in one series of 450 patients).[35] A commonly held misconception is that testicular cancers are by and large painless and that painful testicular masses need not be evaluated for malignancy. In fact, testicular pain is a presenting feature of 18% to 46% of patients with GCT.[35] Acute pain may be associated with torsion of the neoplasm, infarction or bleeding in the tumor, as well as with epididymitis. Signs and symptoms indistinguishable from acute epididymitis have been observed in up to one fourth of patients with testicular neoplasms. Less commonly presenting symptoms will include gynecomastia in HCG-producing tumors such as choriocarcinoma (10%), back or flank pain from metastatic disease (10%), and infertility in less than 5% of tumors. Approximately 25% of patients with advanced disease have symptoms referable to their metastases, such as back pain.[40] This is frequently the presenting symptom in patients with primary retroperitoneal GCT. Pulmonary symptoms including shortness of breath, chest pain, and hemoptysis are rare but can occur in patients with advanced pulmonary disease or primary mediastinal GCT.

The physical examination of the testicles is performed by fully palpating all areas of the testicle between thumb and fingers. Testicular masses are firm to hard, and generally the scrotal sac is normal in appearance unless there is a large mass causing distension. The man with a testicular mass must of course have a careful and complete physical examination, including examination for lymphadenopathy, intra-abdominal masses, hepatomegaly, bone tenderness, and pulmonary abnormalities.

The constellation of elicited symptoms and physical examination findings can offer a clue to the histology of a testicular mass. For example, it has been reported that pain more commonly occurred in patients who had embryonal carcinoma elements in their tumors than in those without that histologic feature (56% vs. 37%; $P < 0.02$). The same study reported a significantly higher incidence of testicular swelling when the primary tumors contained teratoma or yolk sac tumor elements.[35] Primary tumors from patients with seminoma tend to be larger and more homogeneous, with diffuse involvement of the testicle, whereas embryonal and teratomatous elements tend to form smaller, discrete masses. Rapidly growing tumors, particularly those with extranodal dissemination, should raise the possibility of choriocarcinoma. These observations are of course no substitute for the appropriate clinical staging and histopathologic evaluation.

In addition to malignancy, the differential diagnosis of a testicular mass includes testicular torsion, hydrocele, varicocele, spermatocele, and epididymitis. Benign hydroceles tend to extend along the spermatic cord and can be transilluminated. However, it is prudent to recall that a small percentage of testicular cancers are associated with hydroceles. Varicoceles occur in the venous pampiniform plexus of the spermatic cord and result in what has been classically described as a "bag of worms" on palpation. Spermatoceles are found in the posterior, superior portion of the scrotum and also transilluminate. As noted previously, testicular cancer is perhaps most often mistaken for epididymitis, which is marked by a swollen, extremely tender testicle with occasional fever and pyuria. Delays in treatment of testicular cancer of up to 9 months have been observed as individuals are treated for presumed epididymitis. Thus, the clinical diagnosis of epididymitis should prompt a careful physical examination as well as ultrasonographic examination of the scrotum, particularly in those patients who fail to respond to a 10-day course of antibiotics.

EVALUATION OF THE PATIENT: DIAGNOSIS, CLINICAL STAGING, AND RISK ASSESSMENT

Diagnosis: Testicular Ultrasonography

The initial evaluation of a testicular mass is ultrasonographic evaluation (Fig. 90-3). Testicular ultrasonography is a sensitive and specific

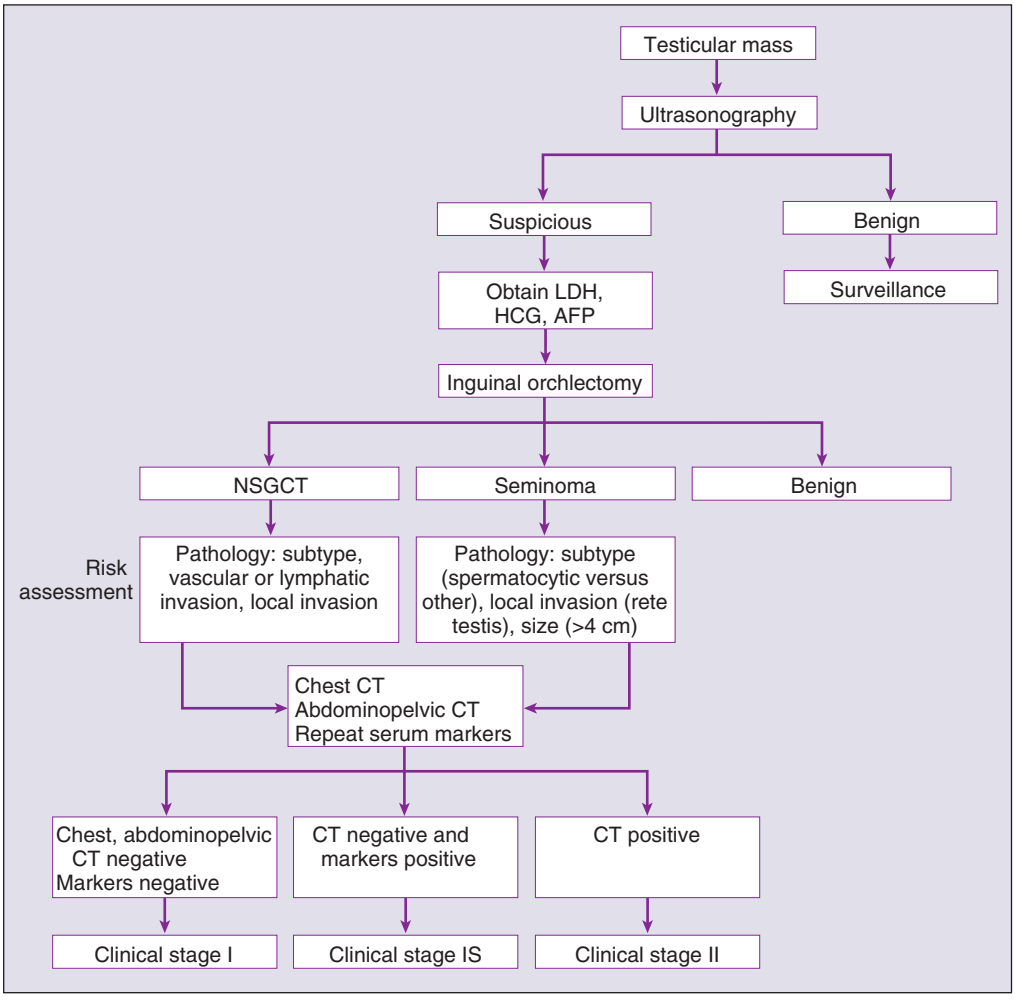

Figure 90-3 • Diagnosis of patients with testicular germ cell tumor.

test that can discriminate between a testicular neoplasm and nonmalignant processes included in the differential diagnosis such as testicular torsion, hydrocele, varicocele, spermatocele, and epididymitis. Thus, the demonstration of hypoechoic or heterogeneous masses on ultrasonographic examination should prompt a thorough subsequent evaluation as described later. Similarly, a negative ultrasonogram fairly reliably establishes the absence of intrascrotal GCT.[41] Both testes should be examined carefully, in that 2% to 4% of patients will harbor bilateral lesions.[28] Extragonadal GCTs are a distinct clinical entity constituting from 1% to 5% of all GCTs; in these patients scrotal ultrasonography will be negative.

Diagnosis: Orchiectomy

Any patient with a testicular mass or abnormal ultrasonography, or both, should have testicular carcinoma ruled out by a unilateral radical transinguinal orchiectomy. Orchiectomy is the definitive procedure for both pathologic diagnosis and local control of the primary tumor and in some cases may be a curative procedure. Furthermore, important predictive factors can be identified with routine histologic techniques that are crucial to risk assessment strategies used in the clinical management of these patients.[31,34,35,42–44] The removal of suspicious testicles by inguinal orchiectomy should be undertaken even in patients in whom a diagnosis of disseminated GCT has been made by biopsy of a metastatic site, because the testes seem to be chemotherapy sanctuaries for cancer cells.[45]

Orchiectomy delay for up to two cycles of chemotherapy is occasionally indicated, when control of metastatic disease must be obtained urgently. There seems to be a blood-testis barrier, so that viable GCTs can persist in the testis despite complete eradication of cancer from metastatic deposits by chemotherapy. Orchiectomy should therefore always be performed once control of metastatic disease is achieved.[46,47] Patients with a diagnosis of extragonadal GCT with normal testicular examinations and ultrasonograms need not undergo orchiectomy. Trans-scrotal orchiectomies or needle biopsies are absolutely contraindicated, in that they have been associated with up to 24% incidence of local recurrence or spread to inguinal lymph nodes.[29]

CLINICAL STAGING AND RISK ASSESSMENT

The first step after the histologic confirmation of a GCT is to determine the extent of the disease (staging) so that appropriate therapy can be undertaken. An assessment of risk of metastases (in the case of local disease) or response to systemic therapy (in the case of advanced disease), utilizing the results of histopathologic, biochemical, and radiographic evaluations, should be an integral element of the staging process; such assessment is discussed in detail for each stage.

Tumor Markers

Tumor markers have become a fundamental component of the laboratory evaluation of individuals with suspected testicular neoplasms, offering diagnostic, staging, and prognostic information, as well as measuring disease progression and response to therapy. Thus, along

with the usual laboratory studies obtained on persons with suspected GCT, preorchiectomy levels of β-HCG, AFP, and LDH are mandatory.

HCG is a glycoprotein of 45,000 MW. It consists of two covalently linked subunits, an α-subunit shared by luteinizing hormone (LH), FSH, and thyroid-stimulating hormone, and a unique β-subunit (β-HCG), which can be readily measured in serum. Whereas it is normally produced at high levels by the placenta, low levels are detectable in normal nonpregnant adults, including some men. HCG elevations are seen in neoplasms other than GCTs, including prostate, bladder, ureteral, and renal cancers.[48] Spurious elevations have been noted in persons using marijuana.[49] Some patients who have undergone systemic therapy develop *cis*-platinum (cisplatin)-induced testicular atrophy in the remaining testis, resulting in lower levels of testosterone, with a compensatory hypersecretion of LH to stimulate Leydig cell secretion of testosterone. Although HCG and LH are not immunologically cross-reactive, very high levels of LH may spuriously elevate measured HCG levels. When necessary, measurement of HCG levels 2 weeks after the administration of depotestosterone should rule out this possibility. The biologic half-life of serum HCG is approximately 24 hours. In GCTs, HCG is produced by syncytiotrophoblastic cells in embryonal carcinoma, choriocarcinoma, and seminoma. Extremely high levels of HCG are generally associated with choriocarcinoma. Although seminomas are generally felt to be marker-negative, the incidence of HCG-positive seminoma varies from 5% to 40%. In general, these HCG elevations do not exceed a level of 100 mIU/mL, and probably do not connote a worse prognosis.[50–54]

AFP is a glycoprotein that is the major serum protein of the fetus. It is also an oncofetal protein, found not only in patients with nonseminomatous GCT, but in pregnant women (fetal hepatic production), in patients with hepatocellular carcinoma, and occasionally, at somewhat lower levels, in patients with cirrhotic livers demonstrating nodular regeneration or in patients with hepatitis. Its biologic half-life is 4 to 6 days. AFP elevations are most commonly seen in embryonal carcinoma and yolk sac tumors, with reports of up to 89% of tumors with yolk sac elements demonstrating elevated AFP.[35] Pure seminomas and pure choriocarcinomas do not produce AFP. Thus, in the absence of hepatitis or other causes of AFP, by definition the presence of an elevated AFP in a histologically pure seminoma identifies the presence of nonseminomatous elements and mandates that the management proceeds accordingly.

LDH is a nonspecific marker that seems to be related to tumor burden and that can serve as both an indicator of response to treatment and a predictor of prognosis. Interestingly, the gene that encodes LDH isoenzyme 1 maps to chromosome 12, and the serum level of LDH isoenzyme 1 has been shown to correlate with the number of copies of i(12p) in the tumor, a fairly specific genetic marker of germ cell malignancies. Furthermore, the presence of three or more copies of i(12p) has been correlated with a worse prognosis.[19]

Overall, approximately 85% of nonseminomas will have an elevation of either AFP or β-HCG.[48,55,56] Approximately 15% are marker-negative. AFP elevation alone is elevated in 40% of nonseminomatous GCTs, and β-HCG elevation alone is seen in 50% to 60%. It is important to note that up to 30% of patients with early-stage nonseminomatous GCT will have normal serum markers, so the absence of marker elevation should not influence the decision to perform an orchiectomy. The incidence of serum marker elevation as a function of tumor histology is shown in Table 90-3.

Even though most seminomas and as many as 30% of nonseminomatous GCTs are marker-negative, AFP, LDH, and β-HCG levels should always be checked before and after orchiectomy. The correct interpretation of serum marker levels requires that the biologic half-life of AFP and HCG be taken into account. Thus, the persistence of elevated AFP or β-HCG levels higher than predicted by the half-lives of these glycoproteins after orchiectomy implies residual (occult) disease. The converse, however, is not true: normalization of markers after orchiectomy does not ensure the absence of occult disease. In fact, as many as 60% of patients with nonseminomatous GCT believed on clinical grounds to be confined to the testis (stage I) with normalization of markers after orchiectomy will have involvement of retroperitoneal lymph nodes with tumor.[34,42–44] The management of clinical stage I cancers reflects this fact and is discussed later in the chapter.

In patients with advanced disease, serum markers can also be used as a measure of response to therapy. Patients with retroperitoneal adenopathy who have been treated by lymphadenectomy should normalize their markers; failure to do so implies residual or recurrent disease. The response of advanced GCT to chemotherapy can also be monitored by a fall in serum markers. However, in this situation, unlike the postorchiectomy or post-RPLND setting, tumor debulking is not instantaneous. Thus, the use of known half-lives to calculate the expected decay of levels of serum tumor markers is more difficult. A 10-fold decrease in the HCG level over a 3-week period has been empirically observed to be consistent with disease eradication. Other investigators have shown that a durable complete response to chemotherapy could be predicted with a high degree of accuracy by the ratio of the HCG level measured on day 22 (after one cycle of chemotherapy) to the day 1 HCG level. In this schema, if the HCG level failed to normalize after one cycle of chemotherapy (day 22), and if the ratio between day 22 and day 1 was greater than 1 : 200 (0.005), an incomplete response could be predicted in 94% of patients. Conversely, if the day 22 HCG value was within normal range, or if the ratio between day 22 and day 1 was less than 1 : 200, a durable complete response could be predicted in 91% of patients.[57] Other reports have noted that observed half-life decays of greater than 7 days for AFP, and greater than 4 days for HCG after treatment with chemotherapy, are associated with poor outcome and probably correlate with the emergence of drug-resistant disease. Likewise, reappearance of serum marker elevation after therapy is an invaluable method of detecting early relapse, often predating any radiologic evidence of relapse or recurrence. On occasion, tumor lysis with chemotherapy will result in transient "flares" or rises in serum markers followed by a subsequent

Table 90-3 Germ Cell Tumors and Serum Markers

Histology	Marker Negative (%)	Elevated HCG Alone (%)	Elevated AFP Alone (%)
Seminoma	90	10 (usually <100 IU/mL)	0 (if +, by definition, NSGCT)
All NSGCT	15	50–60	40
Embryonal		0	10–40
Yolk sac tumors		Rare	80–90 (alone or with elevated HCG)
Choriocarcinoma (or syncytiotrophoblast elements		>90 (level can be very high)	0

AFP, α-fetoprotein; HCG, human chorionic gonadotropin; NSGCT, nonseminoma germ cell tumor.

decline. The prognostic implications of such a flare are not well understood.

Measurements of AFP and β-HCG offer an excellent tool for monitoring disease progression and response to therapy, so that the subset of nonseminomatous GCT patients who are marker-negative requires particularly careful clinical scrutiny. Although the vast majority of seminomas are marker-negative, in general their phenotype is less malignant and their responsiveness to therapy is extremely high, making the usual absence of biochemical markers of disease less troublesome.

Radiologic Evaluation

The goal of routine postorchiectomy radiographic studies is to detect evidence of spread to the retroperitoneum and lungs. Accordingly, all individuals with GCT should undergo CT of the chest, abdomen, and pelvis. Although some investigators have reported a 10% higher detection of metastatic disease by chest CT (compared with chest radiography), the value of the increased sensitivity of tomography has been disputed. In one series of 120 patients staged with both chest radiograph and whole-lung tomograms, tomography led to a change in therapy in only one patient (0.8%). Nonetheless, although interval changes in the size of pulmonary nodules as a response to therapy can be monitored with a chest radiograph, many investigators recommend that the radiographic evaluation of pulmonary nodules for the purpose of initial staging, final documentation of response to therapy, and subsequent follow-up, should consist of a chest CT. Caution is warranted in the interpretation of chest CT scans of persons who have received bleomycin, because subclinical pulmonary fibrosis may have the appearance of metastatic nodules. A comparison of chest CT scans before and after chemotherapy is usually all that is required for the distinction of progression of pulmonary nodules from bleomycin effects, obviating the need for biopsy.

The standard method of staging retroperitoneal disease in a person with testicular cancer consists of abdominal and pelvic CT scanning. In those with nonseminomatous GCT, abdominopelvic CT understaging (e.g., false negatives) occurs in as many as 50% of patients, whereas overstaging (e.g., false positives) occur in approximately 10% of patients.[42–44] The sensitivity and specificity of abdominal CT for detecting lymph node metastases in patients with clinical stage I disease (testis-only disease) has been recently evaluated.[58] Using a cutoff of 10 mm or larger, a sensitivity of 37% and a specificity of 100% were observed, whereas using a 4-mm cutoff enhances sensitivity to 93% but decreases specificity to 58%.

The exact incidence of occult retroperitoneal lymph node metastases in patients with seminoma who have normal CT is not known, because these patients are typically treated with radiation therapy, and do not undergo surgical exploration. Nonetheless, an estimated incidence of occult nodal metastases of 10% to 25% is generally accepted.[31,59]

More recently, ^{18}Fluor-labeled deoxycglucose–positron emission tomography (FDG-PET) has been used to identify viable cancer in residual postchemotherapy masses. Sensitivity and specificity of 88% and 95%, respectively, have been reported, along with high positive and negative predictive values (90% and 96%) in two multicenter trials.[59] By contrast, the utility of FDG-PET in the initial staging of GCT patients is less clear. Several reports comprising more than 110 patients evaluated the accuracy of FDG-PET compared to CT scan staging in patients with stage I and II GCTs. Sensitivity and specificity were reported as 73% to 94% and 40% to 78%, respectively. Moreover, FDG-PET was unable to detect mature teratomas as well as lesions smaller than 5 mm in diameter.[60,61] Hence, FDG-PET is not routinely used or recommended as initial staging for stage I–II GCTs.

In summary, the major limitation of CT imaging is that although gross nodal disease can usually be detected, this is not the case for microscopic metastases. For this reason an assessment of the risk of occult retroperitoneal nodal involvement based on histopathologic features is of importance.

Other imaging modalities such as head CT and bone scan are not routinely undertaken except as warranted by symptoms. One exception to this rule is for choriocarcinoma, in which an increased incidence of brain metastases mandates a CT of the head before proceeding with chemotherapy.[62]

Similarly, in persons with serum marker-positive GCT who have relapsed by serum markers, but have a negative physical examination and a negative imaging evaluation consisting of an ultrasonogram of the contralateral testicle and abdominopelvic and chest CT, it is not unreasonable to complete the evaluation with a head CT and a bone scan.

Staging

Several schemas are incorporated in the current staging of GCT. Because lymphadenectomy is almost never undertaken as a primary therapeutic modality in seminoma it is staged clinically and radiographically. Until recently, the standard treatment of nonseminomatous tumors has included a RPLND, so that most patients with nonseminomatous GCT were pathologically staged. Because as many as 80% of patients with carefully staged clinical stage I nonseminomatous GCT tumors have been found to be free of retroperitoneal disease, many patients with clinical stage I nonseminomatous GCT are offered observation in lieu of lymphadenectomy. A clear distinction must be made in these—and in all patients with nonseminomatous GCT—between clinical stage and pathologic stage. The development of an international consensus GCT risk classification schema (see section on advanced disease) has allowed the use of prognostic groupings as the basis of a revised staging classification. This revised (1997) TNM American Joint Committee on Cancer/Union Internationale Contre le Cancer (AJCC/UICC) classification (Table 90-4) continues to rely on anatomic disease extent, allows for the pathologic classification of lymph nodes, but for the first time also takes into account serum tumor markers. Patients who have only serologic marker evidence of disease after orchiectomy are now classified as stage I-S.

In general, stage I (or A) refers to tumors confined to the testis, with no evidence of nodal or pulmonary parenchymal involvement. Stage II (or B) denotes tumors with retroperitoneal lymph node metastases. Stage II patients are further subdivided by the relative tumor burden. In seminoma patients this is clinically defined by the size of nodal involvement detected by imaging studies, whereas in nonseminomatous GCT this is usually but not always a pathologic diagnosis. Stage IIA (or B1) implies minimal but definite nodal involvement, generally of a microscopic nature; IIB (or B2) refers to macroscopic disease, or a larger number of microscopic metastases, whereas IIC (or B3) indicates bulky retroperitoneal nodal disease. Stage III (or C) refers to disease that has spread beyond the retroperitoneum, usually to supradiaphragmatic lymph nodes, pulmonary parenchyma, or other sites including liver, bone, or brain. Some staging schemas, particularly those for seminoma, distinguish between stage III (supradiaphragmatic lymph nodes) and stage IV (any extranodal metastases, including pulmonary parenchyma, bone, and brain) (Table 90-5). The distinction of hepatic, central nervous system, and osseous metastases is not without merit, because patients with metastases to these regions clearly have a worse prognosis.

MANAGEMENT OF LOW-STAGE DISEASE

The management of clinical stage I GCT is in part dependent on an assessment of the risk of occult nodal metastases. This assessment is in turn based on clinicopathologic features of the primary tumor, including serum marker elevation, size and extent of disease, and histologic features. Pure seminoma and NSGCT are considered separately.

Table 90-4 TNM Classification of Testis Tumors

PRIMARY TUMOR (pT)

The extent of primary tumor is classified after radical orchiectomy.

pT	Primary tumor cannot be assessed (if no radical orchiectomy has been performed TX is used).
pT0	No evidence of primary tumor (e.g., histologic scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma in situ)
pT1	Tumor limited to testis and epididymis without vascular/lymphatic invasion Tumor may invade into tunica albuginea but not tunica vaginalis.
pT2	Tumor limited to testis and epididymis with vascular/lymphatic invasion, or tumor extending through tunica albuginea with involvement of tunica vaginalis.
pT3	Tumor invades spermatic cord with or without vascular/lymphatic invasion.
pT4	Tumor invades scrotum with or without vascular/lymphatic invasion.

REGIONAL LYMPH NODES (N)

Clinical

NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension; or multiple lymph nodes, none more than 2 cm in greatest dimension
N2	Metastasis with a lymph node mass more than 2 cm or less than 5 cm in greatest dimension; or multiple lymph nodes, any one mass more than 2 cm but not more than 5 cm in greatest dimension
N3	Metastasis with a lymph node mass more than 5 cm in greatest dimension

PATHOLOGIC CLASSIFICATION OF REGIONAL LYMPH NODES (pN)

pNX	Regional lymph nodes cannot be assessed.
pN0	No regional lymph node metastasis
pN1	Metastasis with a lymph node mass 2 cm or less in greatest dimension and 5 or fewer positive nodes, none more than 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass, more than 2 cm but not more than 5 cm in greatest dimension; or more than 5 nodes positive, none more than 5 cm; or evidence of extranodal extension of tumor
pN3	Metastasis with a lymph node mass more than 5 cm in greatest dimension

DISTANT METASTASIS (M)

MX	Distant metastasis cannot be assessed.
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonregional lymph node or pulmonary metastasis
M1b	Nonpulmonary visceral metastasis

SERUM TUMOR MARKERS (S)

SX	Marker studies not available or not performed
S0	Marker study levels within normal limits
S1	LDH < 1.5 × normal and HCG (mIU/mL) < 5000 and AFP (ng/mL) < 1000
S2	LDH 1.5–10 × normal or HCG (mIU/mL) 5000–50,000 or AFP (ng/mL) 1000–10,000
S3	LDH > 10 × normal or HCG (mIU/mL) > 50,000 or AFP (ng/mL) > 10,000

N indicates the upper limit of normal for the LDH assay

STAGING GROUPING

Stage 0	pTis	N0	M0	S0, SX
Stage I	pT1–4	N0	M0	SX
Stage IA	pT1	N0	M0	S0

Clinical Stage I Seminoma

Risk Assessment

A histologic diagnosis of pure seminoma implies an excellent prognosis. Pure seminoma is exquisitely sensitive to radiation therapy and can be readily sterilized by relatively low doses (20 to 35 Gy) of external-beam irradiation.[63] Consequently, prognostic factors are difficult to analyze in patients with early-stage seminoma because treatment failures are uncommon.

Prognostic factors that have been postulated as predictors of outcome include DNA ploidy status, mitotic rate, DNA S phase percentage, presence of syncytiotrophoblasts, degree of lymphocytic infiltration of the primary tumor, and the expression of β-HCG and low-molecular-weight keratin on immunohistochemical analyses. However, none of these factors has been confirmed in prospective trials.[30,64,65] The utility of serum markers in seminoma patients is limited to the identification of nonseminomatous elements by an elevated AFP, even in the face of a histologic diagnosis of pure

Table 90-5 Royal Marsden Clinical Staging Schema for Seminoma

Stage	Definition
I	Confined to testis
IIA	Abdominal nodal disease: <2 cm
IIB	Abdominal nodal disease: 2–5 cm
IIC	Abdominal nodal disease: >5 cm
III	Supradiaphragmatic nodal disease
IV	Extranodal disease

seminoma. Ten percent of pure seminoma patients will have an elevated β-HCG. Preorchiectomy elevations of β-HCG do not connote a worse prognosis in stage I seminoma patients.[51–54,65]

Approximately 20% of unselected patients with seminoma who are managed with surveillance will relapse. A pooled analysis of data from four surveillance series identified size of primary tumor (>4 cm) and rete testis invasion as independent predictors of relapse. Other data sets suggest that the risk of relapse in patients who lack the adverse prognostic features of older age (>34 years), size of tumors 6 cm or larger, and small vessel invasion have a relapse rate of approximately 6%.[66] Although previous studies suggested that patients younger than 30 years old were at higher risk of relapse, this was not observed in this pooled analysis. An increased incidence of pelvic nodal involvement is also seen in patients who have had previous inguinal surgery, or in whom the primary tumor has invaded scrotal skin. Scrotal skin involvement also predisposes to relapse in the hemiscrotum.[67,68] Finally, tumor invasion of the spermatic cord increases the risk of relapse in the inguinal orchiectomy scar.[69]

Treatment

Cancer confined to the testis is the most common presentation of seminoma, accounting for nearly 70% of all patients with this diagnosis. For the last half century, the traditional management of these patients after an orchiectomy has consisted of radiation therapy to the para-aortic and pelvic (retroperitoneal) lymph nodes. Recent surveillance studies (see later discussion) suggest that approximately 15% to 20% of clinical stage I seminoma patients will in fact have occult retroperitoneal disease, indicating that the common practice of nodal irradiation is not unreasonable.

Conventional radiation fields for clinical stage I seminoma treat the para-aortic nodes from the diaphragm at the level of the T10 vertebral body down to the lower border of the L4 vertebral body, including the ipsilateral common iliac and external iliac nodes. If pelvic nodes may be involved, the field is extended to include the ipsilateral inguinofemoral lymph nodes. Spermatic cord involvement necessitates a radiation field that covers the entire inguinal orchiectomy scar, whereas scrotal skin involvement mandates radiation to the hemiscrotum.[69]

The results of adjuvant radiation therapy in clinical stage I seminoma patients have been reviewed. Most centers treat patients with 25 to 35 Gy to the retroperitoneal nodes in 15 to 20 fractions over 3 to 4 weeks. In more than 2000 patients reported, the cause-specific 5-year survival is 97%. Most relapses occur within 2 years, and almost always within 5 years of treatment. Failures within the radiated fields are extraordinarily uncommon; most relapses occur in the mediastinum, supraclavicular and cervical lymph nodes, or lung. Isolated recurrences may respond well to radiation therapy, although most radiation failures can be salvaged with systemic chemotherapy since the advent of cisplatin-based chemotherapy. Prophylactic mediastinal and supraclavicular irradiation has been used as a means of reducing relapses in these regions but has not been shown to confer a survival advantage.

The side effects of the low doses of radiation therapy required for the treatment of stage I seminoma are mild and include mild nausea, possibly peptic ulcer disease, transient oligospermia, and a modest but measurable increase in the risk of subsequent (secondary) malignancies. The possibility of reducing both early and late radiation-associated toxicity, coupled with the availability of salvage therapy with excellent results, is the impetus behind the evaluation of lower doses of radiation as well as surveillance as a therapeutic option in clinical stage I seminoma. For example, the use of 26 Gy to the para-aortic region with the omission of iliac irradiation results in a relapse rate of 3.7% with only 0.8% isolated ipsilateral iliac responses, and has been advocated by some to be appropriate therapy.

A trial conducted by the Medical Research Council (MRC) in Great Britain in conjunction with the European Organization for Research and Treatment of Cancer (EORTC) randomized 625 patients with stage I seminoma to therapy with 20 Gy in 10 fractions over 2 weeks or 30 Gy in 15 fractions during 3 weeks after orchiectomy. Interim results suggest that short-term morbidity (lethargy and decreased work capacity) is slightly higher in the patients receiving 30 Gy, although all differences resolve by 12 weeks. At 61 months of follow-up there was no difference in relapse rates.[70] These data suggest that 20 Gy may be reasonable in this setting.

Several large studies have evaluated the role of surveillance in persons with stage I seminoma, with similar results.[71–75] The cumulative risk of relapse within the first year is 5% to 10%, 10% to 15% in the second year, and 15% to 20% by the third year. As noted previously, two adverse prognostic factors can identify patients at high risk of relapse: tumor larger than 4 cm and rete testis involvement. In a pooled analysis, the 5-year relapse-free survival for patients with no or one risk factor was 83% to 88%, whereas patients with two adverse factors had a 5-year relapse-free survival of 69%.[76] These data have allowed an estimation of the frequency of occult nodal metastases in clinical stage I seminoma. The most common site of relapse has been the para-aortic lymph nodes. At relapse, salvage therapy with either radiation or systemic therapy is extremely successful, resulting in a cause-specific survival identical to historical experience with conventional radiotherapy (95% to 100%).[71–75] There is no consensus regarding the optimal follow-up protocol for seminoma patients undergoing surveillance. In general, patients are seen at 3- to 4-month intervals for 3 to 4 years, every 6 months for another 2 to 3 years, and then annually. At each visit, a clinical assessment, chest radiography or chest CT, serum markers, and CT of the abdomen and pelvis are obtained, although ongoing studies seek to determine if a lower frequency of scans may be equivalently effective.[74]

Two major studies have been conducted to determine the efficacy of single-agent carboplatin administered as an adjuvant therapy for stage I seminoma. The MRC of Great Britain conducted a comparative trial in which 1477 patients with stage I seminoma (excluding those with T4 primary tumors) were randomized to therapy with radiation ($N = 904$) administered in a dog-leg or para-aortic field at a dose of 20 to 30 Gy versus a single dose of carboplatin ($N = 573$) administered at an area under the curve of 7. After 3 years of follow-up, the relapse-free rates were similar in both groups—95.9% vs. 94.8% for those receiving radiation therapy versus carboplatin, respectively. Furthermore, quality-of-life parameters such as lethargy and work absence were more significant in the radiation therapy arm.[77] Criticisms of this study include a lack of stratification by risk factors among patients as well as the lack of an arm that included observation, the inclusion of which would have given insight into the margin of benefit for any adjuvant therapy versus none. In the second study, a "risk-adapted" approach was used in which carboplatin (area under the curve of 7 for two cycles) was administered to patients with either rete testis invasion (11%), a primary tumor size of 4 cm or

greater (42%), or both (16%). Patients without these risk factors underwent surveillance. A total of 314 patients were enrolled, and 214 (36%) received carboplatin. Of the 100 patients undergoing surveillance, 6 (6%) relapsed compared to 7 (3.3%) of those who received carboplatin. Interestingly, 9% of the patients with rete testis invasion relapsed compared with 0.8% of those with tumor size of 4 cm or larger. All patients who relapsed were salvaged with standard etoposide plus cisplatin chemotherapy.[78]

Taken together, these trials suggest that in certain settings (large tumors, rete testis invasion) single-agent carboplatin may be an effective alternative to radiation therapy and that chemotherapy is associated with low toxicity and certain benefits compared with irradiation. A definitive trial in which surveillance, carboplatin, and radiation therapy are compared in patients stratified by tumor stage is unlikely to be performed because of sample size limitations.

Clinical Stage I Nonseminoma

Risk Assessment

Controversy over the optimal management of clinical stage I nonseminomatous GCT has prompted a search for prognostic factors that can be used to predict the risk of occult nodal involvement. Histologic subtype, local tumor extension, and vascular or lymphatic invasion have all been shown to correlate with occult nodal metastases (pathologic stage IIA) or a high risk of relapse (summarized in Table 90-6).

Several studies have identified histologic evidence of vascular or lymphatic invasion in the primary tumor as a predictor of either relapse or occult nodal involvement in clinical stage I patients who were followed after orchiectomy with surveillance, or treated with RPLND. In patients with clinical stage I NSGCT, the Testicular Cancer Intergroup Study observed venous or lymphatic invasion in 23.6% and 9.2% of specimens, respectively, compared with 55% and 45%, respectively, of specimens from patients with clinical stage II disease. Not only was vascular invasion more common in node-positive patients than in node-negative patients, but in node-negative patients treated with orchiectomy and RPLND alone, relapse was noted in 10 of 168 (6%) patients who demonstrated no vascular invasion, compared with 12 of 62 (19.4%) if vascular invasion were present.[48] Other studies[36,47,49,62,63,65] have confirmed the significance of vascular or lymphatic invasion as a predictor of occult nodal metastases or relapse, either alone or in combination with other variables. A British study of 259 clinical stage I nonseminomatous GCT patients identified invasion of veins or lymphatics, along with two histologic features (presence of embryonal carcinoma and absence of yolk sac tumor) as four factors most predictive of relapse. If three or four features were present, the likelihood of relapse or occult nodal involvement was 58%; patients with two positive risk factors had a 24% chance of relapse, whereas patients with zero or one risk factor relapsed only 9% of the time.[47] A Swedish/Norwegian study identified vascular invasion, absence of AFP before orchiectomy, or high T stage as predictive factors that identified high-risk clinical stage I nonseminomatous GCT patients.[79] In a Danish study, patients with vascular invasion had a risk of relapse of 36%, compared with patients with no vascular invasion, whose relapse rate was 13%.[63]

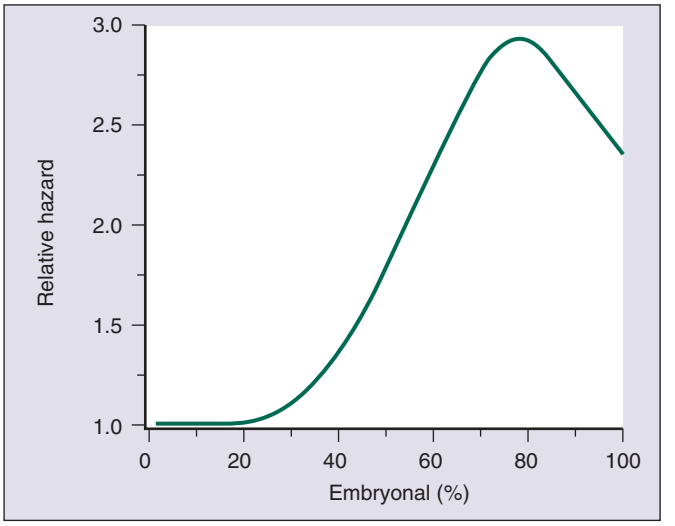

Figure 90-4 • Relationship between percentage of embryonal carcinoma in the primary orchiectomy specimen and relative risk of recurrence. (Data from Sesterhenn IA, Weiss RB, Mostofi FK, et al: Prognosis and other clinical correlates of pathologic review in stage I and II testicular carcinoma: a report from the testicular cancer intergroup study. J Clin Oncol 1992;10:69.)

Several series have demonstrated an association between the presence of embryonal carcinoma in the primary tumor and an increased risk of lymph node metastasis. In 321 patients with either stage I or II nonseminomatous GCT who were treated with orchiectomy and lymphadenectomy, the Testicular Cancer Intergroup Study demonstrated that the risk of relapse remained low until the percentage of embryonal carcinoma exceeded 30% to 40% (Fig. 90-4). However, in this series the percentage of embryonal carcinoma was not found to be a significant prognostic factor after adjustment for either vascular invasion or nodal stage.[48] Another large series of 292 patients with clinical stage I NSGCT from Indiana University suggested that embryonal carcinoma-predominant tumors were both more likely to have occult positive lymph nodes (32% vs. 15.6%) and also considerably more likely to relapse after RPLND (21% vs. 3%).[33]

The absence of yolk sac elements is believed to be a marker of poor prognosis in patients with stage I NSGCT. The confirmation by the Testicular Cancer Intergroup Study that AFP production is linked to yolk sac histology[48] suggests that the identification of AFP negativity as a marker of poor prognosis in stage I NSGCT[62] is a reflection of the fact that yolk sac tumor histology seems to confer some benefit to these patients.[47] Fung and colleagues[41] have confirmed in their series of 60 nonseminomatous GCTs the importance of vascular invasion as a negative prognostic marker but have also identified tumors with less than 50% teratoma as having a higher likelihood of relapse.

Local extension of tumor into paratesticular structures also seems to be predictive of higher relapse rates. Although some studies have noted higher relapse rates in patients with invasion of any structures outside the testis (rete testis, tunica albuginea, epididymis, or spermatic cord), others have noted that tumor involvement of only certain paratesticular structures carried an increased risk of relapse.[80] Thus, Sesterhenn and associates[35] reported a 42% versus 16% relapse rate after RPLND in stage I and II patients with and without tunica

albuginea involvement. Other studies have suggested that involvement of the rete and epididymis, but not the tunica albuginea or spermatic cord, were associated with a higher risk of relapse. Recent studies suggest that negative immunohistochemical staining with an antibody against the Ki-67 receptor, a marker of tumor proliferation, identifies a good-risk population with a negative predictive value for occult nodal involvement of 88%, although this has not been confirmed by others.[81]

Many other factors have been shown to have no prognostic value. Interestingly, increased levels of preorchiectomy β-HCG and AFP, the size of the primary tumor (in contrast to seminoma), and the side of the primary (right vs. left) are not generally predictive of the risk of relapse after orchiectomy.[80]

Treatment

Clinical stage I NSGCTs account for approximately 50% of all NSGCTs. Pathologic staging reduces this number to approximately 40%. The evolution of improved surgical technique, the increased capacity for judicious surveillance, and the advent of highly successful systemic chemotherapy have all served to make the management of clinical stage I NSGCT a controversial one.

RETROPERITONEAL LYMPH NODE DISSECTION. Before the advent of cisplatin-based chemotherapy, it was recognized that radical RPLND offered the potential of cure, even to NSGCT patients with nodal metastases. This dissection is a full, bilateral procedure in which all lymphatic, neural, and connective tissue is removed from a field demarcated by the crus of the diaphragm superiorly, to the bifurcation of the common iliacs inferiorly, and bordered laterally by the ureters.

After RPLND, clinical stage I NSGCT patients are restaged as either pathologic stage I or pathologic stage IIA (microscopic nodal involvement). In the era before cisplastin, survival rates were 93% for pathologic stage I and 75% for pathologic stage IIA patients. Since the advent of cisplatin-based chemotherapy, which is used in this setting as either salvage or adjunctive therapy, the long-term survival rate approaches 100% for patients with pathologic stage I tumors, and 96% for patients with pathologic stage IIA tumors.[82]

A large prospective trial by the Testicular Cancer Intergroup Study enrolled 195 pathologic stage II NSGCT patients (including 64 patients with pathologic stage IIA) who were randomized after RPLND to observation or immediate adjuvant chemotherapy.[82] For patients with pathologic stage I NSGCT, at a median follow-up of 45 months, 28 patients (10.5%) had recurrent disease and six had died, two of drug- resistant cancer. At the time of report, 98% of patients were alive and disease-free.

Patients with pathologic stage IIA disease who are treated with orchiectomy and RPLND only will have a relapse rate as high as 30% to 40%,[82] although some investigators have reported relapse rates in the 10% range in carefully selected pathologic stage IIA patients. Regardless of surgical cure rate, in the cisplatin era, the overall survival of patients with pathologic stage IIA NSGCT treated initially with orchiectomy and RPLND is in the 96% to 99% range.[83–85] The integration of chemotherapy into treatment schemas for stage II NSGCT is discussed later.

In experienced hands, a full RPLND is associated with low morbidity and mortality, but loss of ejaculatory function occurs in 65% to 100% of patients.[28,83,86] It has been stressed that disruption of these fibers results in retrograde ejaculation but not in loss of potency, libido, or ability to have an orgasm.[83] The high incidence of ejaculatory dysfunction after full RPLND, coupled with an understanding of the pattern of nodal involvement in patients with low-volume disease, has led investigators to modify the traditional full RPLND. Extensive experience with full RPLND has allowed accurate mapping of nodal involvement in patients with low- and moderate-volume disease.[36–38] As described previously, this work has shown that (1) suprahilar metastases are exceedingly rare in patients with low-volume retroperitoneal disease, and (2) patients with minimal volume retroperitoneal disease almost always have unilateral retroperitoneal disease. Patients with left-sided primaries characteristically have nodal metastases to the upper left periaortic zone, while patients with right-sided primaries have involvement of the interaortocaval and precaval regions. These observations led to modifications of the traditional full RPLND in patients with low-volume retroperitoneal disease, whereby a suprahilar dissection was eliminated, and a limited dissection template was utilized, depending on the side of the primary. For right-sided lesions dissection is limited on the left by the lateral margin of the aorta to the bifurcation, and for left-sided tumors the right margin is the right renal hilum and the vena cava to the bifurcation.[83] The templates for right and left modified RPLND are illustrated in Figure 90-5. The benefits of a modified RPLND in this group of patients were shorter operative time, shorter postoperative ileus, and a significant reduction in ejaculatory dysfunction (30% to 40% dysfunction after a right modified RPLND, and 60% to 70% dysfunction after left modified RPLND). Furthermore, modification of the traditional full RPLND in patients with minimal retroperitoneal disease does not have an adverse effect on outcome, yielding surgical cure rates of approximately 90% in pathologic stage I patients, 70% in pathologic stage IIA patients, and an overall long-term survival rate approaching 100%.[83]

The most recent modification in technique for RPLND in patients with low-stage NSGCT is the nerve-sparing dissection described by Donohue and associates.[86,87] In this procedure, postganglionic sympathetic fibers from lumbar ganglia are prospectively identified and preserved before lymphadenectomy, with the intent to stage and treat in a standard fashion, while preserving normal ejaculatory function. One hundred percent of 73 patients with clinical stage I disease who underwent a nerve-sparing lymphadenectomy at Indiana University had normal postoperative ejaculation. The distribution of pathologic stages and relapse pattern was no different from what has been described with full or modified RPLND. Of 73 clinical stage I patients, 14 (20%) were found to have occult nodal metastases. The relapse rate was 7% in the 61 pathologic stage I patients, and 28% in the 14 pathologic stage IIA patients. All patients who suffered a relapse were salvaged with platinum-based chemotherapy.[83,86] (The characteristic relapse pattern after RPLND is discussed later and contrasted with the relapse pattern in similar patients who are not treated with an RPLND.) Thus, the nerve-sparing RPLND seems to be diagnostically and therapeutically as efficacious as more morbid full and modified retroperitoneal lymphadenectomies. Overall, approximately 30% of clinical stage I NSGCTs are found to have occult nodal involvement at RPLND and are classified as pathologic stage IIA. The use of adjuvant chemotherapy in these patients is discussed in the section on the treatment of stage II nonseminoma.

Alternatives to Retroperitoneal Lymph Node Dissection

ADJUVANT RADIATION THERAPY. Some investigators have suggested that clinical stage I NSGCT patients believed to be at high risk of relapse could potentially be treated with adjuvant chemotherapy or radiation therapy rather than RPLND.[29,65] Although NSGCT is less radiosensitive than seminoma and requires considerably higher radiation doses (45–55 Gy), radiation therapy nonetheless may occasionally be required under unusual circumstances. The results of radiation therapy alone in clinical stage I NSGCT have been reviewed.[28] Although overall survival rates from 70% to 90% have been reported, the advent of highly effective chemotherapy has largely obviated the role of radiation therapy in the treatment of clinical stage I NSGCT.

ADJUVANT CHEMOTHERAPY. As many as 50% of patients with high-risk clinical stage I NSGCT are subsequently found to have nodal involvement. As discussed later, some of these patients will go on to receive chemotherapy after RPLND or in the salvage setting. It has therefore been suggested that chemotherapy might serve as

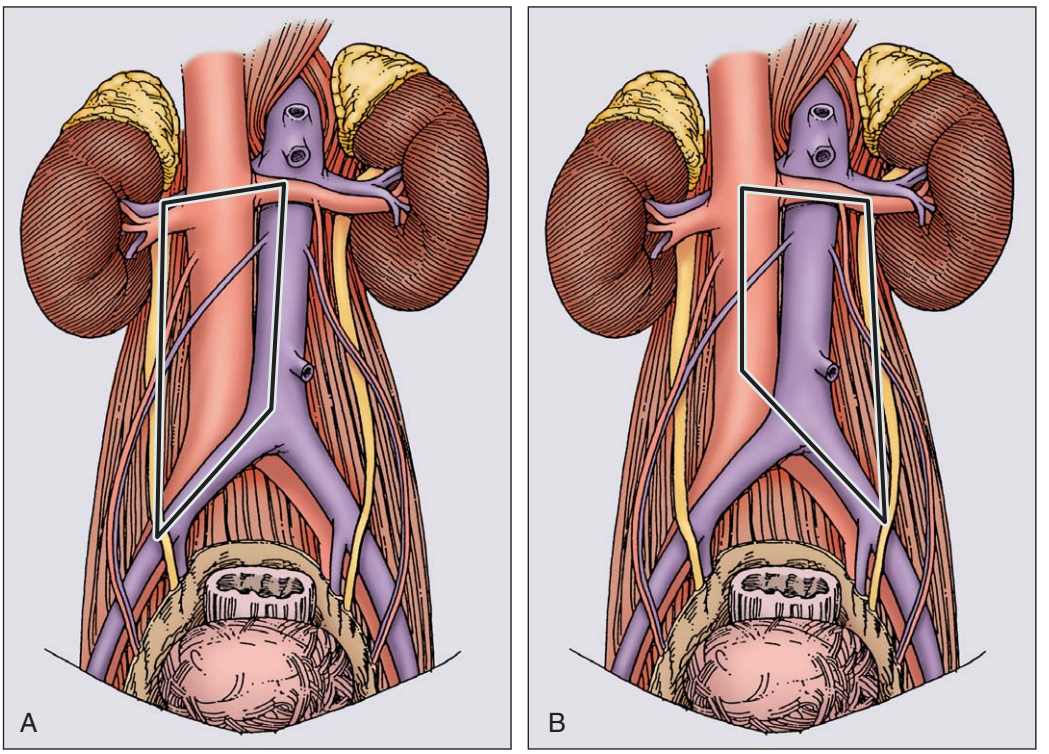

Figure 90-5 • Templates for modified retroperitoneal lymphadenectomy. **A,** Right modified RPLND; **B,** left modified RPLND. (Adapted from Foster RS, Donohue JP: Surgical treatment of clinical stage A nonseminomatous testis cancer. Semin Oncol 1992;19:166, with permission.)

effective primary adjunctive therapy after orchiectomy, thereby sparing patients an RPLND. Several investigators have used two cycles of cisplatin, etoposide, and bleomycin (PEB) in lieu of an RPLND, and have reported very low relapse rates (generally <5%) in patients with median follow-ups as long as 4 to 6 years.[88–90] More recent studies have used a risk-adapted approach, thus sparing patients with very good prognoses the potential toxicity of chemotherapy. One study administered two cycles of carboplatin, etoposide, and bleomycin (CEB) to stage I patients with either vascular invasion in the primary tumor, more than 80% embryonal component, or a preorchiectomy AFP of higher than 80. In this cohort of 76 patients there were no GCT relapses after treatment with CEB, with only one patient requiring resection of a growing teratoma.[91] These results must be balanced with the concern that the use of primary chemotherapy may expose as many as 50% of patients to unnecessary chemotherapy. Although adjuvant chemotherapy for stage I NSGCT in lieu of an RPLND may be used with increasing frequency on the basis of these data, it is not considered a standard of care in the United States.

SURVEILLANCE. The development of extraordinarily effective chemotherapy for disseminated NSGCT has also resulted in an effort to minimize "up-front" treatment for clinical stage I NSGCT. The strategy of surveillance after orchiectomy, followed by systemic therapy at the first sign of relapse, is based on the observation that only 20% to 40% of clinical stage I patients have occult nodal involvement, the belief that the majority of these patients can thus be spared the morbidity associated with RPLND, and confidence in chemotherapy as a curative "salvage" modality for those patients who do relapse.

Surveillance programs for patients with a negative initial staging evaluation have been evaluated primarily in nonrandomized studies.[92,93] A summary of published results from nearly 600 patients who underwent surveillance after orchiectomy revealed a relapse rate of approximately 30%, but an overall disease-free survival rate of more than 95%.[94] The MRC (UK) has reported on a prospective evaluation of surveillance in 373 clinical stage I NSGCT patients. Whereas the 5-year relapse-free rate was 73%, salvage surgical and chemotherapeutic interventions yielded an overall 5-year survival of 98%.[95] These data have been interpreted to suggest that the strategy of surveillance yields equivalent results to RPLND in carefully selected clinical stage I NSGCT patients.[84]

Successful surveillance requires strict adherence to selection criteria and surveillance methodologies. Most centers rely on serum markers, physical examinations, and chest radiographs obtained every 1 to 2 months, as well as CT scan of the abdomen and pelvis every 3 or 4 months the first year, every 6 months the second year, and yearly thereafter. Eligibility criteria must include a compliant and motivated patient, in whom rigorous clinical staging (negative exam, serum markers, chest radiograph or CT, and abdominal/pelvic CT) has been undertaken. Most studies have excluded patients with locally advanced tumors (e.g., spermatic cord, scrotal sac involvement), and it has been suggested that patients at high risk for nodal metastases based on the risk assessment schemas outlined previously should not undergo surveillance alone. Patient compliance with intensive surveillance programs remains a recognized problem, and successful surveillance mandates rigorous patient selection.[93]

The use of adjuvant chemotherapy in patients with stage I disease has become an area of some controversy. In one large Spanish study, a risk-adapted approach was applied to the selection of patients for chemotherapy following orchiectomy.[78] Patients with vascular invasion or invasion of local structures received two cycles of BEP, whereas those without these risks underwent surveillance. A relapse proportion of less than 1% in the first 2 years, compared with a relapse rate of 19% (71 of 358) in the patients undergoing surveillance again suggests that the use of chemotherapy in this setting prevents relapse, but does not address specifically the question of the proportion of patients who were unnecessarily exposed to the risks of chemotherapy.

Characteristically, relapses after RPLND for clinical stage I (pathologic stage I or IIA) NSGCT are either serologic or occur in the chest, although some series have reported from 4% to 6% of relapses occurring in the retroperitoneum.[93,96] Isolated retroperitoneal

nodal relapses in the absence of elevated markers or other sites of relapse are exceedingly rare. Furthermore, relapses more than 2 years after RPLND are extraordinarily uncommon.[82] By contrast, most relapses in clinical stage I patients who have selected orchiectomy alone followed with surveillance are identified by tumor markers and by and large occur in the retroperitoneum. Although some investigators have made the observation that the majority of these retroperitoneal relapses occur with bulky disease,[93] there is no evidence to suggest that overall survival is affected. Additionally, surveillance patients seem to be at risk for relapse for a longer period than patients treated with RPLND. Even though most relapses occur within the first year of instituting surveillance (median, 3–4 months), late relapses in the third to fifth year do occur.[72] These patterns of relapse, along with consideration of the morbidity involved with each therapeutic alternative, have formed the basis of debate regarding the relative merits of surveillance versus immediate RPLND in clinical stage I NSGCT patients.

As long as staging, treatment, and surveillance guidelines are strictly observed, nearly 100% of clinical stage I NSGCT patients can be cured, whether surveillance or RPLND with or without adjuvant chemotherapy are used. Each patient with clinical stage I NSGCT must be informed of these alternatives and allowed to choose the methods of management most suited to his wishes and needs (Fig. 90-6).

Stage II Seminoma: Treatment and Results

The Royal Marsden Hospital clinical staging system (see Table 90-5) divides stage II (abdominal) seminoma patients into subgroups on the basis of tumor bulk, as follows: IIA, smaller than 2 cm; IIB, from 2 to 5 cm; and IIC, larger than 5 cm. Historically, radiation therapy has been used for all stages of seminoma, allowing a retrospective analysis of failure rates and survival rates as a function of tumor mass. More recent series generally report better outcomes, perhaps because the era of CT scanning has allowed more precise definition of nodal margins and tumor volume.[97] Reviews of recent collected series have found recurrence rates generally less than 5% in patients with masses less than 5 cm in size (stages IIA and IIB); 80% to 90% will be cured with standard abdominal radiation therapy alone. The use of salvage chemotherapy or radiation therapy (or both) in patients with masses smaller than 5 cm who relapse after initial radiotherapy results in a cause-specific survival of 95% to 100%.[31] Radiation therapy is therefore recommended for small-volume (<5 cm) retroperitoneal disease. The radiation field is generally limited to the infradiaphragmatic lymph nodes as in stage I disease. Relapses, when they occur, have largely been reported to occur outside the radiation field,[98] although relapse in the mediastinum or supraclavicular nodes is a distinctly unusual event,[99] and when it occurs, salvage with radiation therapy or chemotherapy is successful.[76] Thus, supradiaphragmatic radiation therapy is not warranted in these patients.

By contrast, failure rates of around 10% are reported in patients with masses between 5 and 10 cm, although some series have reported relapse rates as high as 40%.[100] The relapse rate after radiation therapy alone in patients with masses greater than 10 cm is unacceptably high, at approximately 35%.[31] Cure rates with radiation therapy alone for patients with stage IIC seminoma range from 30% to 60%, although an overall cause-specific survival of up to 90% can be expected with salvage chemotherapy.[100] Two major problems are

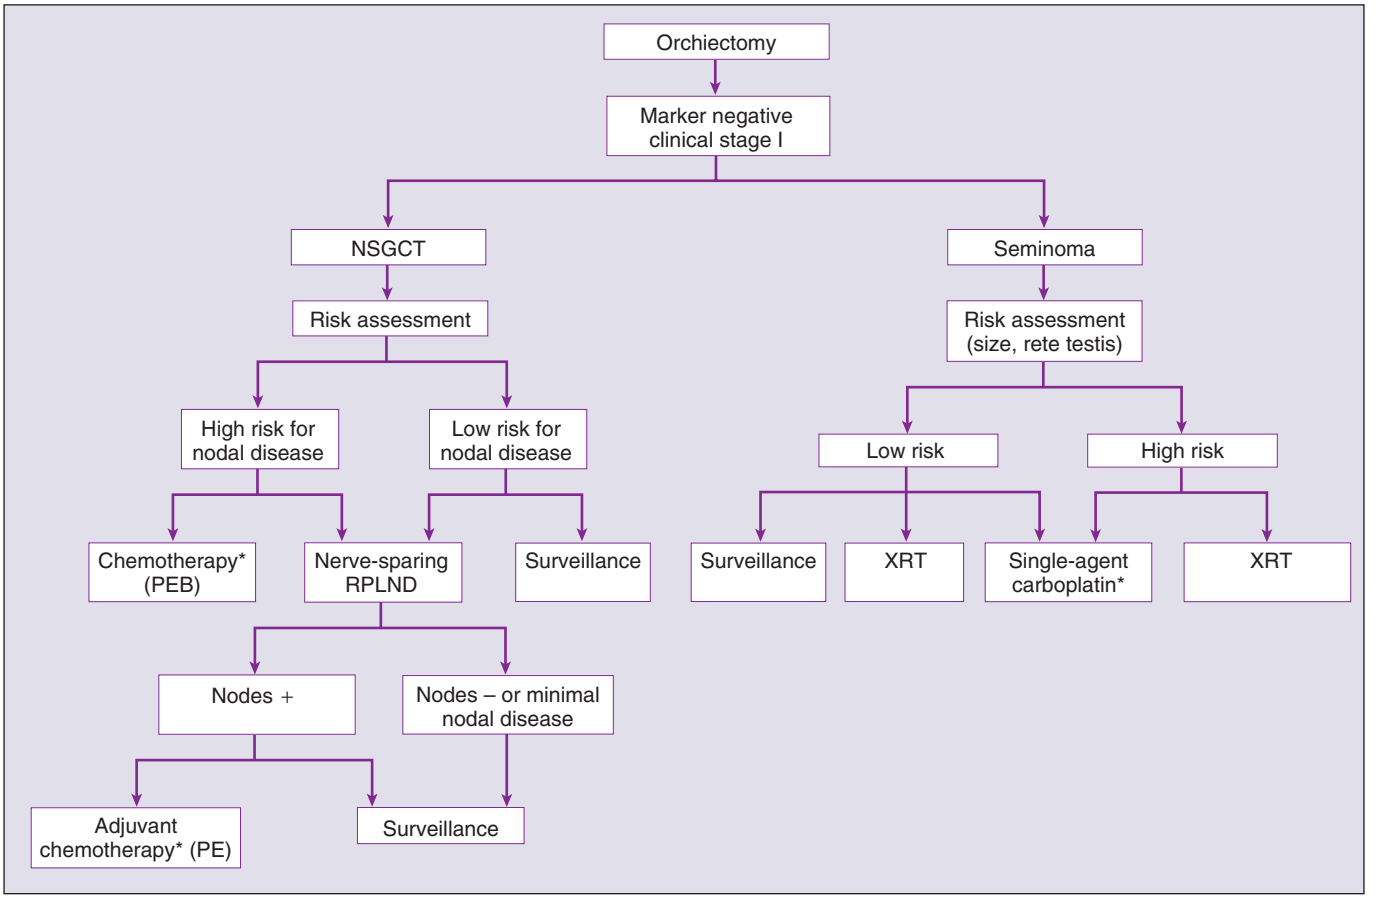

Figure 90-6 • Therapeutic options for patients with clinical stage I germ cell tumors. NSGCT, nonseminoma germ cell tumor; PE, platinum, etoposide; PEB, platinum, etoposide, bleomycin; RPLND, retroperitoneal lymph node dissection. *Investigational.

associated with the use of radiotherapy alone for stage IIC seminoma. The first is a risk of mediastinal or supraclavicular relapse in as many as 20% of patients.[99] In general, the degree of marrow compromise in patients receiving infra- and supradiaphragmatic irradiation makes supradiaphragmatic radiation therapy an impractical solution to the problem. Second, it has been suggested that the radiation fields required for treating large masses, even if shrinking-field techniques are used, make renal toxicity difficult to avoid.[101] As a consequence, it is generally recommended that stage IIC seminoma patients (masses >5 cm), and especially patients with masses larger than 10 cm be initially treated with chemotherapy (Fig. 90-7). This approach is discussed in the following section; results in cure rates are from 85% to 95%.[100,101]

STAGE II Nonseminoma

Risk Assessment

The identification of factors uniformly associated with a higher risk of relapse in node-positive NSGCT patients after RPLND has not been possible. The Testicular Cancer Intergroup Study randomized 195 patients with completely resected retroperitoneal disease to observation or two cycles of adjuvant-based chemotherapy. Among the patients randomized to observation, approximately 50% subsequently relapsed.[102] Recurrence rates were higher among patients with advanced nodal stage: 40% for patients with microscopically positive nodes, 53% for nodes less than 2 cm, and 60% for nodes larger than 2 cm. Although these differences were not statistically significant, this study was probably underpowered to detect clinically significant differences. Other series have supported an association between greater nodal involvement and higher relapse rates. Patients with substantial retroperitoneal nodal involvement or extracapsular extension treated with RPLND but no adjuvant chemotherapy have a greater than 50% risk of relapse.[80] By contrast, some series report significantly lower relapse rates (from 0 to 20%) than reported in the Williams trial, for patients with minimal nodal involvement who received no adjuvant therapy.[103–105] The impact of histologic type on risk of relapse after RPLND in stage II NSGCT was confirmed by the Testicular Cancer Intergroup Study pooled data from stage I and II patients, which demonstrated that the presence of embryonal carcinoma clearly increased the risk of recurrence, although histology was not retained as a significant predictor of relapse after correction for vascular invasion or nodal involvement.[82] Although earlier reports from the same group had suggested that vascular invasion was not a predictor of relapse in stage II NSGCT, a later study[35] reported that in node-positive patients, 24% of patients without vascular invasion relapsed, compared with a 63.5% relapse rate among patients with documented vascular invasion.

Treatment of Clinical Stage II Patients

RETROPERITONEAL LYMPH NODE DISSECTION FOLLOWED BY ADJUVANT CHEMOTHERAPY. Stage IIA and IIB NSGCT patients have minimal or moderate retroperitoneal lymphadenopathy. This category includes patients with clinical stage I NSGCT who are found to harbor occult nodal involvement at RPLND (pathologic stage IIA). The standard primary treatment for clinical stage IIA and B patients is RPLND (Fig. 90-8).

Before the advent of cisplatin-based therapy, the observed high rate of relapse after RPLND in patients who were lymph node-positive was the basis of the use of adjuvant chemotherapy. Before the late 1970s this treatment included drugs such as bleomycin, vinblastine, and dactinomycin.[106] Although it was acknowledged that over 50% of patients would be treated unnecessarily, the poor prognosis at relapse mandated this approach. Improvements in chemotherapy for systemic disease led to the use of platinum-based therapy in the adjuvant setting.[107] An international study by Williams and coworkers[106] was published in 1987, in which 195 patients with completely resected retroperitoneal disease (108 patients with pathologic stage II NSGCT) were randomized to either immediate adjuvant chemotherapy consisting of two cycles of cisplatin, vinblastine, and bleomycin (PVB) or vinblastine, dactinomycin, bleomycin, cisplatin, and cyclophosphamide (VAB-6) or no adjuvant therapy followed by chemotherapy at the time of relapse. With a median follow-up of 4 years, 49% of the patients in the observation arm relapsed, compared with 6% in the adjuvant therapy arm. Patients in the observation arm who relapsed were treated with salvage chemotherapy. Because of effective salvage therapy, the overall survival (97%) was the same in both arms. Two conclusions arose from this study: (1) that the deferral of adjuvant treatment was appropriate and (2) that a brief course of cisplatin-based therapy can prevent relapse. Although this report included patients with a mixed group of stage II tumors, ranging from microscopic nodal involvement (N1) to grossly involved lymph nodes greater than 2 cm (N2b) and nodes with capsular penetration (N3b), no subgroup was identified in which adjuvant chemotherapy was mandatory, or with so favorable an outcome that adjuvant therapy was not necessary. Nevertheless, as noted, and despite the results of this study, nodal stage is believed

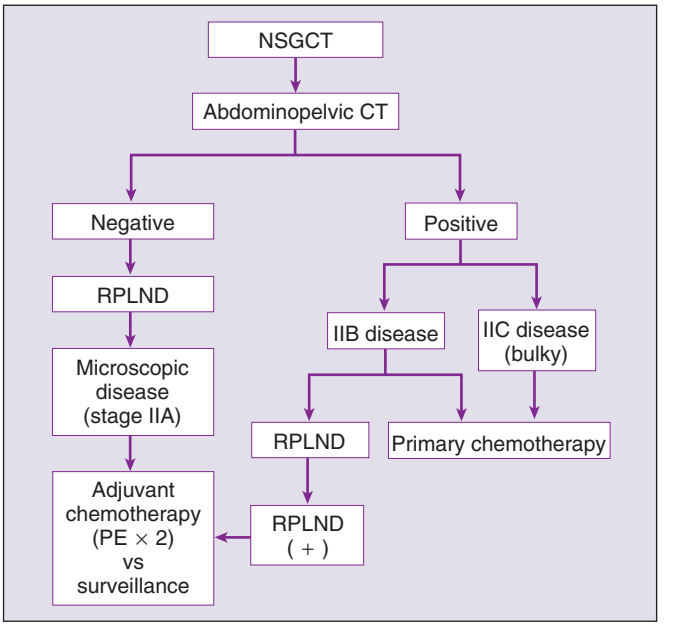

Figure 90-8 • Therapeutic options for patients with clinical stage II germ cell tumors, nonseminoma (NSGCT). PE, platinum, etoposide; RPLND, retroperitoneal lymph node dissection.

by some to have value in predicting relapse.[105,107] For this reason, most centers recommend adjuvant chemotherapy over surveillance in patients with moderate retroperitoneal lymph node involvement (i.e., stage IIB disease), but an option for patients with minimal microscopic disease is surveillance after RPLND, in that true pathologic stage IIA patients are at a very low risk of relapse (0 to 10%). Other reports support these data.[96] A recent series reported 11 relapses (22%) in 50 NSGCT patients with low-volume nodal metastases who were managed expectantly after RPLND. Most relapses consisted of marker elevation. Five of the patients who suffered relapse had elevated markers before RPLND. The relative risk (RR) of relapse in patients with persistent marker elevation before RPLND (8.0) suggests that chemotherapy, and not RPLND, should be the treatment of choice in such patients.[101] These data support earlier observations of a high relapse rate of patients with rising markers following orchiectomy (Stage IS disease).[108]

Nonrandomized series have confirmed the high overall disease-free survival rate (98% to 100%) observed with adjuvant chemotherapy administered after RPLND. Earlier studies used either PVB or one of the VAB regimens. However, studies in the late 1980s demonstrated that the substitution of etoposide for vinblastine produced equivalent survival, with substantially less toxicity when used for patients with advanced disease.[109] Consequently, several centers have tested the substitution of etoposide for vinblastine in the adjuvant setting as well. Bleomycin was omitted in two of these studies.[110–112] Survival in all these series was 99% to 100%, with follow-up ranging from 30 to 72 months.

Taken together, these data demonstrate that excellent long-term survival can be achieved with RPLND followed by either observation (with salvage chemotherapy at relapse) or adjuvant chemotherapy. The disadvantage of adjuvant therapy is that it unnecessarily subjects approximately 50% of the patients (those who would have been cured with RPLND alone) to chemotherapy. Surveillance after RPLND avoids this problem, but it requires half the patients to endure the psychologic trauma of recurrent disease and further requires that patients adhere to a frequent follow-up schedule, which is often difficult in this population of patients. (In the Williams and coworkers' study,[106] for example, 25% of the patients made six or fewer follow-up visits.) Finally, patients who do not receive adjuvant therapy will probably require more extensive chemotherapy for relapsed disease than had they been treated in the adjuvant setting. The excellent results of Motzer and coworkers[112] suggest that two cycles of etoposide and cisplatin may be adequate in the adjuvant setting, yet a chemotherapy-naive relapsed patient would probably receive either four cycles of etoposide and cisplatin or three cycles of PEB.

PRIMARY CHEMOTHERAPY. Patients who have clinical stage IIC NSGCT have traditionally been grouped with those who have stage III disease when therapeutic options are being considered, and they are usually treated with systemic chemotherapy. The rationale for this approach includes the excellent results of chemotherapy in "good-risk" disseminated disease, which includes individuals with clinical stage IIC NSGCT, as well as the increased morbidity associated with RPLND for patients with bulky disease.[113]

The excellent response of advanced disease to systemic therapy on the one hand, and the possibility of cure without an RPLND in selected clinical stage I patients on the other, are the basis for the experimental use of systemic chemotherapy without an RPLND in persons with clinical stage II NSGCT.[114] Two centers, the M.D. Anderson Cancer Center (MDA) and the Royal Marsden Hospital (RMH), have reported on the use of primary chemotherapy in clinical stage II NSGCT patients.[114,115] Postchemotherapy RPLND was required in only 22% to 30% of these patients. Analysis of the clinical and histologic features of the 50 MDA patients suggested that patients with tumors larger than 5 cm had the highest frequency of postchemotherapy RPLND (33%), although this number did not reach statistical significance. At the RMH, 17% of 58 stage IIA patients (nodes <2 cm) required RPLND, compared with 39% of 64 stage IIB patients. In the MDA series the most important predictor of the need for postchemotherapy RPLND was the presence of teratomatous elements in the primary tumor (36% incidence of need for RPLND in these patients, compared with only 8% of patients with embryonal tumors with or without seminoma; $P = 0.014$). A 96% complete response rate with primary chemotherapy followed selectively by an RPLND was reported by MDA, whereas the 5-year actuarial survival probability for the RMH patients was 95%, with a median follow-up of 5.5 years. These series suggest that primary chemotherapy may be a therapeutic option for stage II NSGCT, obviating the need for surgery in 70% to 80% of patients. Patients particularly suited for this approach seem to be those with masses smaller than 2 cm, and with no teratomatous elements in their primary orchiectomy specimens. The risks of persistent disease or progression of residual teratoma for as long as 10 years after apparent clinical eradication of stage II GCT (or both) have been cited as reasons for using this approach with caution.[116,117] The degree of retroperitoneal lymphadenopathy at which patients are directed toward primary chemotherapy rather than primary RPLND varies among institutions and is, in part, based on the experience of the treating surgeon. The approach at the University of California, San Francisco (UCSF) is to perform primary RPLND in all patients with clinical stage IIA and in most patients with stage IIB disease. For some stage IIB patients with more extensive and/or bilateral retroperitoneal disease, which would not be amenable to a modified or nerve-sparing RPLND (generally masses >3 to 5 cm in size), primary chemotherapy is offered with a "good-risk" regimen such as PEB for three cycles or PE for four cycles. The role of adjunctive surgery after chemotherapy in disseminated disease is discussed later in this chapter.

MANAGEMENT OF ADVANCED DISEASE

The functional definition of advanced GCT includes those stages of tumor in which locally directed therapy (radiation therapy for seminoma, RPLND for NSGCT) offers unacceptably poor results. Thus, for NSGCT and for most investigators, lymph nodes larger than 2 cm define advanced disease, whereas in seminoma, bulky IIC disease (generally masses >5 cm) is considered advanced disease. Stages III and IV are considered advanced by definition.

The greatly improved prognosis for disseminated GCT patients is largely attributable to a dramatic improvement in chemotherapy. The introduction of cisplatin into combination chemotherapy regimens in the 1970s and 1980s resulted in markedly superior response rates, as well as long-term survival, as compared with the previous gold standard of bleomycin and vinblastine. Einhorn and colleagues, and the Southeastern Cancer Study Group (SECSG), demonstrated the utility of PVB and further refined their regimen by showing in randomized trials that lower dosage of vinblastine and the elimination of maintenance therapy did not affect response rates or long-term survival.[118,119] Simultaneously, investigators at Memorial Sloan-Kettering Cancer Center (MSKCC) built upon the combination of vinblastine and bleomycin in their series of VAB protocols, by first adding dactinomycin, and then cisplatin.[120] Most recently, the discovery of etoposide as an active agent in advanced GCT led to the substitution of etoposide for vinblastine in the PVB regimen. A randomized trial comparing the etoposide-containing regimen (PEB) to PVB found that use of PEB resulted in an overall identical response rate, complete response rate, and 2-year survival rate, while significantly reducing the toxicity (primarily neuromuscular) associated with PVB,[106]essentially making PVB obsolete (Table 90-7).

Chemotherapy with PVB, PEB, or VAB-6 will result in a complete response in approximately 80% of patients with advanced GCT and long-term cures in 70%. By the same token, however, 20% to 30% of patients will relapse and may ultimately die from their disease, stressing the importance of improving outcomes for high-risk patients as well as developing effective salvage strategies. Studies of pretreat-

ment clinical characteristics have sought to identify prognostic features that can be prospectively used to segregate this diverse group of advanced GCT patients into poor and good prognostic subsets. Proper identification of the subset of patients who are destined to relapse or fail to achieve a complete response to standard therapy is critical, so as to offer these "poor-risk" patients more aggressive investigational therapies aimed at improving response and cure rates. By contrast, "good-risk" patients are largely adequately treated with conventional therapy. Although the toxicities of these regimens are by and large manageable, they may account for considerable morbidity and on occasion even mortality. Thus, studies of pretreatment prognostic features have also sought to identify the "good-risk patient" cohort, for whom the investigation of less toxic but equally efficacious treatment is appropriate.

Risk Assessment

Several classification systems have been proposed as a means of distinguishing between "good-risk" and "poor-risk" advanced GCT patients. In general, prognostic factors are first identified by a retrospective statistical analysis of the relationship of the risk feature to outcome (generally complete response or survival). Although the specific clinical parameters used to define prognosis vary somewhat in these classification schemas, the pretreatment tumor burden has consistently been identified as an important predictive factor. Different researchers have defined tumor mass by size, number, and location of metastases. Other proposed pretreatment clinical features influencing prognosis in advanced GCT include histology (i.e., seminoma vs. nonseminoma), primary site, serum markers, and site of metastases.[121]

When these schemas were tested prospectively on independent data sets, they seemed to classify good-risk patients equally well but yielded markedly different complete-response rates in the poor-prognosis groups.[71,72] To address this issue a common classification system was developed by the International Germ Cell Cancer Collaborative Group (IGCCCG).[73] The IGCCCG database included 5202 patients with NSGCT and 660 patients with seminoma, and was divided into a test set and a validation set. Prognostic factors for progression-free survival and survival were examined, and prognostic groups for seminoma and NSGCT were developed. The major independent prognostic factors for progression-free survival and overall survival were identified and used to establish prognostic groupings. For NSGCT the independent high-risk factors identified were presence of mediastinal nonseminomatous primary tumor, presence of nonpulmonary visceral metastases (e.g., liver, bone, brain), and increased levels of tumor markers including β-HCG, AFP, and LDH (Table 90-8). For seminoma patients, generally a group considered to carry a more favorable prognosis, the only significant prognostic factor was the presence of nonpulmonary visceral metastases.

This risk assessment schema has been validated both on the IGCCCG validation set and on an independent data set.[74] In this system, good- and intermediate-prognosis patients have a testis or retroperitoneal primary, no nonpulmonary visceral metastases, and low serum tumor markers. Intermediate-prognosis patients are the same as good-prognosis patients except that they have intermediate serum tumor markers. Poor-prognosis patients have a mediastinal primary or nonpulmonary visceral metastases or high levels of serum tumor markers. Five-year overall survival for the good-, intermediate-, and poor-prognosis categories with current regimens is 92%, 80%, and 48%, respectively (see Table 90-8). By definition, seminomas are never poor prognosis. Seminomas are segregated into only good and "intermediate" prognosis cases (any primary site, but with the presence of nonpulmonary visceral metastases), with a 72% 5-year survival.[73]

Several studies have confirmed the post-therapy rate of decline in marker concentration as a predictive marker of outcome in GCT patients. A recent study re-examined this issue in the context of the IGCCCG risk classification system. After adjusting for risk status, satisfactory marker decline (which was defined as a calculated half-life of ≤7 days for AFP and ≤3.5 days for HCG) predicted an improved complete-response proportion, 2-year event-free, and 2-year overall survival.[75]

Treatment of Good-Risk Advanced Germ Cell Tumors

All risk assessment schemas that were used before the development of the IGCCCG classification system were equally able to accurately identify a subgroup of good-prognosis testis cancer patients who had a high likelihood of obtaining a sustained complete response when treated with platinum-based therapy. In general, this group was made up of patients with marker elevation only, or small-volume infradiaphragmatic and/or supradiaphragmatic disease, and without visceral involvement.[72] Because it is not likely that the extraordinarily high cure rate for this group of patients can be improved upon, most efforts have been aimed at optimizing treatment with less toxic regimens that will have equal efficacy.

Trials evaluating (1) the elimination of bleomycin, (2) a reduction in the number of chemotherapy cycles administered, or (3) the substitution of carboplatin for cisplatin have been undertaken. In evaluating the results of these trials, several caveats hold. First, most of these trials have not used the new IGCCCG prognostic classification but instead have relied on different risk assessment schemas, making

Table 90-8 International Consensus Advanced Germ Cell Tumor Prognostic Classification Schema

Nonseminoma	Seminoma
GOOD PROGNOSIS	
56% of nonseminomas	90% of seminomas
5-year PFS, 89%	5-year PFS, 82%
5-year survival, 92%	5-year survival, 86%
Testis or retroperitoneal primary	Any primary site
and	*and*
No nonpulmonary visceral metastases	No nonpulmonary visceral metastases
and	*and*
Good markers (all of the following):	Normal AFP, any HCG, any LDH
AFP < 1000 ng/mL	
HCG < 5000 IU/L (1000 ng/mL)	
LDH < 1.5 ∞ upper limit of normal	
INTERMEDIATE PROGNOSIS	
28% of nonseminomas	10% of seminomas
5-year PFS, 75%	5-year PFS, 67%
5-year survival, 80%	5-year survival, 72%
Testis or retroperitoneal primary	Any primary site
and	*and*
No nonpulmonary visceral metastases	Nonpulmonary visceral metastases
and	*and*
Intermediate markers (any of the following):	Normal AFP, any HCG, any LDH
AFP ≥ 1000 and ≤10,000 ng/mL	
HCG ≥ 5000 IU/L and ≤50,000 IU/L	
LDH ≥ 1.5 × N and ≤10 × N	
POOR PROGNOSIS	
16% of nonseminomas	No seminoma patients classified as poor prognosis
5-year PFS, 41%	
5-year survival, 48%	
Mediastinal primary	
or	
5 Nonpulmonary visceral metastases	
or	
Poor markers (any of the following)	
AFP > 10,000 ng/mL	
HCG > 50,000 IU/L (10,000 ng/mL)	
LDH > 10 × upper limit of normal	

AFP, α-fetoprotein; HCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; N, normal; PSF, progression-free survival.

comparison between trials problematic. Second, most etoposide-containing regimens used in the United States (PEB, PE) administer a total of 500 mg/m^2 of etoposide (100 mg/m^2, days 1–5), whereas one European counterpart of these regimens administers 120 mg/m^2 on days 1 to 3, for a total of 360 mg/m^2.

Finally, the inclusion (or exclusion) of patients with advanced seminoma from good-risk trials has been inconsistent. IGCCCG data suggest that although seminoma is clearly a good-risk tumor, it should be evaluated in separate trials. In those series wherein individuals with advanced-stage seminoma were considered separately from NSGCT, platinum-containing regimens, including VIP (ifosfamide, cisplatin, and etoposide), PEB, EP, and VAB-6, result in roughly comparable survival rates of around 90%.[73]

Results of Clinical Trials in Patients with Good Prognosis

As discussed previously, etoposide may be substituted for vinblastine in the PVB regimen, resulting in an improvement in the toxicity profile, without loss of effectiveness. Using the Indiana University staging system the SECSG reported on a randomized trial of four cycles of PVB versus four cycles of PEB, with complete-response rates of 97% and 96%, respectively.[122] (Interestingly, the same study demonstrated PEB to be superior to PVB in the treatment of poor-prognosis advanced GCT patients.) A subsequent randomized trial by the SECSG demonstrated that in good-prognosis patients, three cycles of PEB are as efficacious as four cycles, with complete-response rates of 97% and continuous complete remission rates of 92% in either regimen.[123] The EORTC conducted a prospective randomized 2 × 2 factorial trial in IGCCC good-prognosis patients, which compared three versus four cycles of therapy as well as PEB administered over 5 days (cisplatin 100 mg/m^2 daily × 5 and etoposide 100 mg/m^2 daily × 5) or over 3 days, but with the same total dose (cisplatin 50 mg/m^2 on days 1 and 2, etoposide 165 mg/m^2 on days 1–3).[124] Three cycles of PEB were equivalent to four, and no difference was detected in outcome between the 3- and 5-day schedules. By contrast, a multicenter phase III trial randomized patients to the "Indiana regimen" (cisplatin 20 mg/m^2 days 1–5, etoposide 100 mg/m^2 days 1–5, and bleomycin 30 units days 1, 8, and 15 of each 21-day cycle) administered three times, versus four cycles of a regimen used by the MRC/EOTRC (cisplatin 100 mg/m^2 on day 1, etoposide 120 mg/m^2 days 1–3, and bleomycin 30 units on day 1 of each 21-day cycle). Although there was no statistically significant difference in response proportion between the two groups, overall survival was significantly better for those patients receiving the higher dose etoposide (Indiana) regimen, prompting the early termination of the study.[124] These studies have established three cycles of PEB using 100 mg/m^2 cisplatin and 500 mg/m^2 etoposide as the standard of care and as a benchmark for other good-risk GCT trials.

The relatively high incidence of clinically apparent pulmonary toxicity from bleomycin,[124] observed in as many as 20% of patients, and a small but real bleomycin-related death rate of 2% to 4% (albeit data are largely from the era before routine monitoring of respiratory function) has been the impetus behind the evaluation of regimens for good-risk GCTs that delete bleomycin.

A randomized study conducted at MSKCC compared standard therapy for GCT (three cycles of VAB-6) to four cycles of a two-drug regimen of etoposide and cisplatin (EP) in 170 good-risk patients as defined by the MSKCC risk criteria. Complete-response rates of 92% and 95% (not statistically significant) were observed in the EP and VAB-6 arms, respectively. Whereas patients treated with EP had significantly less emesis, magnesium wasting, neutropenia, and thrombocytopenia, relapse-free and overall survival were similar in both arms.

Although most investigators agree that three rather than four cycles of PEB are adequate in good-risk patients, the role of bleomycin continues to be debated, in part as a result of the heterogeneity of the risk assessment schemas and regimens used. Nevertheless, several published trials now support the inclusion of bleomycin in good-risk chemotherapy regimens. One study conducted by the

Eastern Cooperative Oncology Group (ECOG) compared three cycles of (U.S.) PE to the "benchmark" three cycles of (U.S.) PEB.[125] An interim analysis revealed an increased number of relapses, progressive disease, and likelihood of death for the two-drug combination (durable complete-response rate was 86% for PEB vs. 70% for PE), resulting in early termination of the study. Further, an EORTC study randomized 450 patients to four cycles of (European) PE or four cycles of (European) PEB, and found a significantly higher complete-response rate (95% vs. 87%) in the three-drug combination.[126] In aggregate, these data suggest that the deletion of bleomycin results in inferior outcomes in a three-cycle, good-risk regimen. Whether four cycles of (U.S.) PE is adequate therapy, however, is unknown—of the two previously noted trials using four cycles of PE as a comparator, the EORTC trial used European PE, containing less etoposide,[126] and the MSKCC trial compared PE to a nonbenchmark regimen, VAB-6.[127] In general, the current consensus is that three cycles of PEB or four cycles of EP (with 500 mg/m^2 of etoposide per cycle) are equivalent in terms of efficacy. The decision to eliminate bleomycin in lieu of treatment with a fourth cycle must be weighed against the potential for greater hematologic toxicity and time required to deliver the fourth cycle.

Carboplatin, a cisplatin analogue with less nephrotoxicity and neurotoxicity than cisplatin, has also been evaluated in good-risk GCTs. By contrast, the substitution of carboplatin for cisplatin in the two-drug regimen EP is inferior, as suggested by the results of a randomized trial of four cycles of EP given every 3 weeks versus four cycles of EC (etoposide plus carboplatin) given every 4 weeks, in good-risk patients (MSKCC criteria). Although the complete-response rates were similar (88% to 90%), unfavorable events (incomplete response or relapse) were more common in the EC arm (24% vs. 13%; $P = 0.04$), and EP patients had a superior event-free and relapse-free survival (87% vs. 76%).[81] Whether or not this difference was due to the difference in frequency of administration of each regimen (every 3 weeks for EP vs. every 4 weeks for EC) was addressed by an MRC/EORTC study, which randomized patients to receive either four cycles of European PEB (in which bleomycin was given on day 1 of each cycle only, as opposed to the usual three times per cycle) given every 3 weeks, or the same regimen, also given every 3 weeks, with the substitution of carboplatin for cisplatin. The carboplatin regimen was inferior with respect to the complete-response rate (87.3% vs. 94.4%) and with respect to 3-year survival (90% vs. 97%).[128] This combination of studies, therefore, has definitively demonstrated that carboplatin results in inferior outcomes for good-risk GCT patients.

In summary, although there has been a difference in the classification schemas used to identity good- versus poor-prognosis advanced GCT patients, all are able to identify a good-prognosis subset of patients, in whom the likelihood of a complete response to chemotherapy is in the 90% to 95% range and in whom long-term survival can be expected in 85% to 90% of patients. Three cycles of PEB or four cycles of PE are currently deemed acceptable approaches in this group of patients. There is no role for substituting carboplatin for cisplatin.

Poor-Risk Advanced Germ Cell Tumors

The outlook for poor-risk patients is grim, with only 38% to 62% of patients achieving a complete response and more than 25% of patients dying of the disease within 2 years of diagnosis.[129] Thus, whereas the major concern in good-risk patients has been the reduction of toxicity, the major objective of clinical investigation in poor-risk patients continues to be an improvement in efficacy, with less concern for reducing toxicity. An equally important goal has been the accurate pretreatment identification of poor-risk patients, so that patients are not incorrectly classified as poor risk, and thereby exposed unnecessarily to the toxicity of these regimens. The use of post-treatment variables, in particular the rate of decline of the serum markers AFP and HCG, may also serve to identify the patient for whom standard induction chemotherapy is destined to fail.[83]

Results of Clinical Trials in Patients with Poor Prognosis

The results of clinical trials conducted in patients with poor-risk GCTs have been summarized.[84] Until recently, most trials have included only small numbers of patients in single-armed phase II trials, rendering generalized interpretation difficult. The extraordinarily wide range of reported complete-remission rates (38% to 92%) is probably more a reflection of the diversity of the risk assessment schemas used than of actual differences in efficacy of the regimens themselves.

Clinical trials in poor-prognosis patients have by and large relied on either or both of two approaches. The first has been to exploit agents that have been demonstrated to be efficacious in the salvage setting, such as etoposide, paclitaxel, and ifosfamide, whereas the second has evaluated the role of dose escalation.

The earliest study which specifically identified therapy outcomes in a poor-risk patient population was the SECSG study that randomized GCT patients to receive four cycles of either PVB or PEB. A subset analysis of poor-risk patients demonstrated that PEB resulted in a higher complete-response proportion than PVB (68% and 38%, respectively, using the Indiana risk criteria).[106] This study established four cycles of PEB as a benchmark against which other high-risk GCT trials could be compared.

The appreciation of the activity of etoposide in the treatment of GCT (as in the PEB regimen) led to several trials where etoposide was used in an induction regimen. The Southwest Oncology Group (SWOG) undertook a randomized comparison of standard PVB to a PVB regimen in which etoposide was substituted for bleomycin (termed VPV) in high-risk patients. This study demonstrated that the inclusion of etoposide did not improve the frequency of disease-free status (disease-free survival; 64.5% with PEV vs. 73% with PVB).[13] Furthermore, some investigators have challenged the validity of the risk criteria used, given the high disease-free survival rate obtained with PVB.[128] The observation that the combination of VIP could salvage some patients for whom induction therapy with PVB or PEB had failed led to the use of the VIP regimen as primary induction therapy for poor-risk GCT patients.[85] A randomized trial comparing standard induction therapy (PEB) with the VIP regimen normally used in the salvage setting (see Table 90-8) found no statistically significant difference in patients rendered disease-free (51% vs. 57%), in relapse rate (17% vs. 14%), or in overall survival or progression-free survival (53% vs. 56%).[86] Furthermore, the VIP regimen was associated with increased (primarily hematologic) toxicity, and thus cannot be routinely recommended as initial therapy for high-risk patients.

The apparent dose-response relationship for cisplatin in the 75- to 120-mg/m^2 range in GCT patients[87] prompted several trials that tested the hypothesis that further dose escalation would result in improved efficacy in the high-risk subset. A randomized comparison of a high-dose regimen (consisting of etoposide added to PVB with twice the standard dose of cisplatin) to standard PVB therapy for the therapy of high-risk GCT patients was undertaken by the National Cancer Institute.[131] Although this trial demonstrated an apparent improvement in outcome (albeit with significant ototoxicity), a subsequent randomized trial conducted by the SECSG and the SWOG comparing PEB to cisplatin dose-intense PEB in high-risk patients failed to demonstrate increased efficacy.[86]

Another approach tested in poor-risk GCT patients has been the use of alternating non-cross-resistant therapy. The EORTC compared four cycles of PEB to four cycles of alternating cycles of PEB and PVB, and could show no advantage to the alternating regimen.[132] A similar approach developed by the MRC/EORTC consisted of initial treatment with bleomycin, vincristine, and cisplatin (BOP) followed by a VIP-like regimen. Preliminary results from a randomized trial comparing PEB to BOP-VIP suggested no difference in

outcome (complete-response rate, 59% and 58%; durable complete response, 50% and 52%).[133] Several other alternating regimens have been studied, including POMB-ACE, which alternates cisplatin, vincristine, methotrexate, and bleomycin (POMB) with actinomycin, cyclophosphamide, and etoposide (ACE). This regimen has been reported to yield a survival higher than expected in IGCCCG-defined poor-risk patients (75% at 3 years, vs. 50% expected), and in patients with primary mediastinal disease (73% 5-year survival vs. 40% expected),[134,135] A second regimen, BOP-CISCA-POMB-ACE, which alternates bleomycin, vincristine, and cisplatin (BOP); cisplatin, cyclophosphamide, and doxorubicin (CISCA); cisplatin, vincristine, methotrexate, and bleomycin (POMB); etoposide, dactinomycin, and cyclophosphamide (ACE) has been reported to result in a 3-year progression-free survival greater than expected in the IGCCCG-defined poor-risk patients (67% vs. 50%). A recent European study evaluated a multidrug combination known as C-BOP/PEB (cisplatin, vincristine, bleomycin, and carboplatin, followed by one cycle of vincristine and bleomycin and three cycles of PEB in both intermediate- and poor-risk patients. In a study of 66 patients, 29 of whom were poor risk, the complete-response rate was 68.2% and the 1-year progression-free survival was 82% (95% confidence interval 72.5% to 91.1%).[136] These encouraging results merit prospective evaluation versus PEB × 4 in appropriately matched patients.

The demonstration of the efficacy of high-dose chemotherapy (HDCT) with autologous hematopoietic stem cell support in the salvage treatment of relapsed or cisplatin-insensitive GCT formed the basis for treatment of selected high-risk GCT patients with HDCT earlier in their course, as part of their induction therapy, rather than reserving it as salvage. During the same time period, carboplatin had been shown effective in the treatment of GCT, first as single-agent salvage therapy[137] and then in combination with etoposide and bleomycin as induction therapy for poor-risk NSGCT.[138] These observations, along with the potential for dose escalation with carboplatin, led to its use in dose-intensity trials for high-risk tumors as well. In these trials, patients generally received one to two cycles of standard induction therapy followed by HDCT. Reasonable complete-response rates of 56% to 70%, and durable complete-response rates of 46% to 64% have been described.[139] Several phase II trials and a retrospective analysis comparing poor-risk patients to historical controls suggested that first-line HDCT is well tolerated and initially suggested that this approach may confer a potential survival advantage in poor-risk patients when compared with historical controls treated with standard therapy.[140–143]

To address this question an intergroup study comparing two cycles of PEB followed by HDCT with tandem SCT with four cycles of PEB alone as first-line therapy for patients with poor-prognosis GCT was conducted. Seventy-nine percent of the 219 patients enrolled had IGCCCG poor-risk disease, whereas 21% had intermediate-risk disease. Overall 2-year survival was 68% in the poor-risk cohort and 84% in the intermediate-risk cohort. No difference in overall survival was detected comparing the PEB × 4 group versus the PEB × 2 plus HDCT. Subset analysis of the kinetics of tumor markers revealed a relationship between the degree of change of tumor markers to overall outcome. Kinetics of marker change were defined as "satisfactory" (a decline in elevated markers to normal by the start of cycle 3 or a decrease with a half-life ≤7 days for AFP and ≤3.5 days for β-HCG) versus "unsatisfactory" (half-life of >7 days for AFP or >3.5 days for β-HCG). In this analysis, time to treatment and overall survival were greater in the "satisfactory" arm (63% 1-year durable complete responses vs. 49% [unadjusted *P* value 0.02]). Further, although overall survival at 2 years was superior in the "satisfactory" decline group (83% vs. 68%; $P = 0.03$), there was no difference in this outcome comparing standard therapy with PEB × 4 with the high-dose approach.[128] The results of this trial suggest that there is no benefit to the use of HDCT with stem cell transplantation as induction therapy in high- or intermediate-risk patients, although its use in the salvage setting continues to be defined.

To summarize, a review of available data suggests that there is currently no evidence that any approach other than PEB × 4 is appropriate for poor-risk patients (Fig. 90-9). Every effort should be made to enroll and treat patients with poor-prognosis GCT on clinical trials.

Unique High-Risk Germ Cell Tumors: Brain Metastases and Extragonadal Disease

A mediastinal primary or the presence of nonpulmonary visceral metastasis in patients with NSGCT defines high-risk patients in the IGCCCG Consensus Risk Classification. This is corroborated by a review of nearly 800 patients by the MRC, which has reported 3-year survivals for 86 patients with liver, bone, or brain metastases of 52%, compared with a 3-year survival of 89% in 709 patients without metastases at one of these sites.[42] Two clinical scenarios that warrant special consideration are those involving extragonadal primary tumors and GCT brain metastases.

Extragonadal Germ Cell Tumors

As discussed previously, it is generally accepted that extragonadal GCTs are a consequence of malignant transformation of residual midline germinal elements, generally found in the retroperitoneum or mediastinum. From 1% to 5% of GCTs are of extragonadal origin, and most but not all occur in men. As previously noted, all patients with extragonadal GCT should undergo the standard evaluation for GCT patients, including bilateral testicular ultrasonography to rule out an unsuspected testicular primary.

Extragonadal GCT of nonseminomatous histology appears to be associated with Klinefelter's syndrome. In one series of 22 consecutive patients with nonseminomatous extragonadal GCT, 18% were found to have karyotypically defined Klinefelter's syndrome. Hematologic malignancies have been observed to develop in approximately 10% of persons with the disease, usually within 2 years.[144] A common origin of the two malignancies is postulated based on a shared karyotypic abnormality (i12p).[145]

Seminomas account for approximately 30% to 40% of all these tumors. They seem to be somewhat slower growing than their nonseminomatous counterparts, and approximately 60% to 70% of patients with mediastinal seminoma will have metastases at the time of diagnosis (compared with 85% to 90% in nonseminomatous extragonadal GCT).[10] Although the lungs and intrathoracic structures are the most common site of metastases, these tumors not uncommonly will demonstrate osseous metastases. Extragonadal seminoma, like its counterpart of gonadal origin, is exquisitely radiosensitive, and approximately 60% of patients can be cured with radiation therapy. Cisplatin-based chemotherapy, however, is generally considered to be the superior modality, with complete-response rates of 67% to 89% reported.[10]

Nonseminomatous extragonadal GCTs make up 60% to 70% of all extragonadal GCTs. In contrast to extragonadal seminoma, local treatment with radiation therapy has been unsuccessful and chemotherapy is far less efficacious. A compilation of 158 cases of nonseminomatous extragonadal GCT noted an overall response to cisplatin-based therapy of 54% (range, 38% to 68%), and a long-term disease-free survival rate of 42% (range, 22% to 58%).[33] The optimal chemotherapy regimen is undefined; certainly these patients are in the poor-prognosis category, and when possible should be enrolled on appropriate clinical trials. Mediastinal NSGCTs frequently demonstrate resistance not only to primary but also to salvage therapy. A multivariate analysis of prognostic features in 283 heavily pretreated GCT patients subsequently treated with HDCT as salvage therapy demonstrated that a mediastinal site of origin clearly imparted an adverse prognosis.[146] Surgical resection of mediastinal tumors either before or after chemotherapy can lead to beneficial outcomes and should be attempted whenever possible.[147]

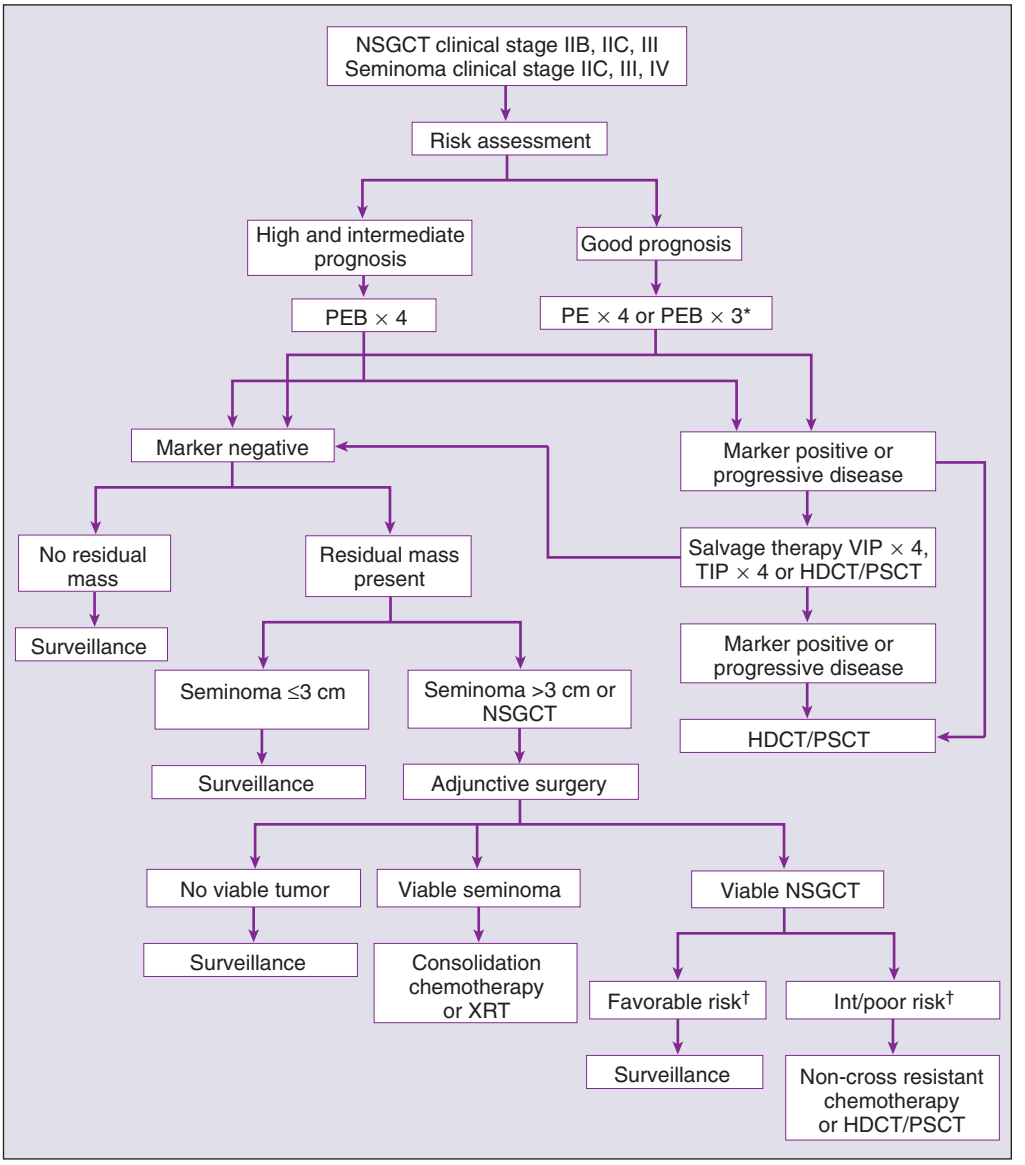

Figure 90-9 • Treatment algorithm for patients with advanced germ cell tumor. HDCT/PSCT, high-dose chemotherapy/peripheral stem cell support. *At UCSF, three cycles PEB unless pulmonary toxicity. †Adverse factors: >10% residual viable cells, incomplete resection, IGCCCC risk group per Table 90-8. Favorable risk, 0 adverse factors; intermediate risk, 1 adverse factor. Poor risk, ≥2 adverse factors.

Brain Metastases

Brain metastases occur in fewer than 5% of patients with GCTs, most frequently in patients with choriocarcinoma or yolk sac elements. The presence of brain metastases is a marker of a particularly poor prognosis. An MRC series of 795 patients included 16 patients with central nervous system involvement, in whom the 3-year survival was 37%.[42] Before the advent of etoposide-based therapy, the early data published by the Indiana University group reported an overall survival of only 31.8% for patients with brain metastases and suggested that the brain was a sanctuary from PVB and that a subset of patients could be cured if aggressive multimodality therapy using surgery, radiation therapy, and chemotherapy was used.[148] Patients with brain metastases as part of their initial presentation have a better prognosis than those who develop brain metastases.[149] Other centers have advocated combined chemotherapy and radiotherapy, with long-term disease-free intervals,[150] or high-dose intravenous methotrexate, along with intrathecal methotrexate, although these approaches have not superceded the de facto standard of care of the combination of radiation therapy and chemotherapy.[151] Taken together, these data make it reasonable to conclude that unlike most malignancies, the presence of GCT central nervous system metastases should not preclude therapy with curative intent.

RISK ASSESSMENT OF RESIDUAL MASSES AFTER CHEMOTHERAPY: THE NEED FOR ADJUNCTIVE SURGERY

The advent of platinum-based chemotherapy has resulted in complete responses in a large percentage of patients with advanced GCT. Furthermore, a number of patients with partial responses can be converted surgically into complete responders. However, surgery is unnecessary in some of these patients, because their postchemotherapy residual masses may not reveal any malignant cells on histologic review. Thus, the identification of patients likely to have residual malignancy is of importance.

Residual Masses in Seminoma

Residual masses after systemic therapy for advanced seminoma are observed in 60% to 85% of patients, whereas 15% to 45% of patients will have normal radiographic evaluations after systemic therapy.

Residual masses after chemotherapy for advanced seminoma most typically result in obliteration of radiographic planes identified on CT. These findings usually represent a dense scirrhous response that merges with the great vessels and other retroperitoneal structures.[152] These "masses" are in fact usually not discrete or well defined, generally are not easily resected, and occur in 40% tp 60% of patients. Only 20% to 30% of patients will have discrete residual masses, which are usually larger than 3 cm and in fact resectable.[152,153] The morbidity associated with attempted resections of these masses, in particular the scirrhous, ill-defined type, has prompted an evaluation of features predictive of residual active seminoma.

Motzer and colleagues[152] made the observation that nearly half (42%) of patients with residual abnormalities larger than 3 cm were found to have viable malignancy, whereas no patient with a normal imaging study or residual mass smaller than 3 cm who then underwent exploratory surgery was found to have viable tumor. The authors concluded that seminoma patients with residual abnormalities smaller than 3 cm should not undergo surgical exploration, whereas attempts to excise masses larger than 3 cm should be undertaken. Other groups have maintained a more conservative posture, performing serial CT scans and performing surgery only at the point of progressive disease.[153] More recently, FDG-PET has been shown to be a useful predictor of viable tumor in postchemotherapy masses in patients with pure seminoma, correctly predicting 96% of residual masses ≤3 cm, and 100% of masses >3 cm. This study demonstrated a superior positive predictive value (100% vs. 50%) and negative predictive value (97% vs. 91%) compared with assessment of residual mass size (≤3 cm or >3 cm).[59]

A prospective study of 56 FDG-PET scans of 51 patients who were followed for clinical recurrence or who underwent surgical resection demonstrated that in all 19 cases with residual lesions >3 cm and confirmed active disease, the PET scan was positive in all 7 patients with residual disease and was negative in all 12 patients without. Further, no false positives or false negatives were reported in tumors this size. Other groups suggest caution in the use of PET scan in these settings based on a positive predictive value for PET scans of only 67%, whereas PET scans that were positive corresponded to patients whose surgical specimens demonstrated only fibrosis, necrosis, or inflammation.[154]

Residual Masses in Nonseminoma

As many as 60% to 70% of patients with advanced-stage NSGCT will be rendered clinically free of disease with platinum-based therapy, and an additional 10% to 20% of patients observed to have residual masses after systemic therapy can be subsequently rendered free of disease surgically. Most investigators agree that, except in rare circumstances, adjunctive surgery is not indicated in the presence of persistently elevated serum tumor markers. (The role of surgery in marker-positive patients is reviewed in the section on salvage therapy.) By contrast, the recommendations for adjunctive surgery in postchemotherapy NSGCT patients in whom serum markers have normalized vary considerably.

Viable malignant GCT cells are found in the surgical specimens of approximately 15% of patients with residual masses after chemotherapy, although some series have reported residual malignancy in as few as 3% of patients.[122] Teratoma or fibrosis and necrosis are found in approximately 50% and 35% of patients with residual masses, respectively.[155,156] It is fairly clear that the histology of resected postchemotherapy masses carries significant prognostic implications. Patients with residual carcinoma in their specimens have an overall long-term survival of approximately 60% to 70%, whereas survival for patients with necrosis/fibrosis is in the 85% to 90% range.[157–159] The presence of viable GCT cells in completely resected specimens has been termed a "surgical complete response." A recent retrospective report from an international study group of 238 patients with viable GCT cells in resected postchemotherapy masses indicated 5-year progression-free survival and 5-year overall survival rates of 64% and 73%, respectively. Three factors were reportedly associated with improved progression-free and overall survival: complete resection of residual masses, fewer than 10% malignant cells in the resected specimen, and initial IGCCC good-risk group classification. These data suggest that complete and aggressive resection of residual masses is warranted. Interestingly, for patients with residual cancer in their resected specimens, in this nonrandomized retrospective analysis, an improved 5-year progression-free survival (69% vs. 52%) was seen in patients who underwent postoperative chemotherapy compared with postoperative surveillance alone. Overall survival was not statistically different, perhaps because those patients who underwent surveillance received adequate salvage therapy at the time of relapse.[160] Whereas teratoma in the residual mass may be histologically benign, the rationale for aggressive and complete early debulking of teratomas includes (1) the risk of local complications as well as growth into unresectable lesions, (2) the risk of late recurrence, and (3) the risk of malignant transformation into non-germ-cell malignancies such as sarcomas and carcinomas.[16] The association of teratoma and late relapse is discussed in the section on late consequences of therapy. Because the diagnosis of residual teratoma is usually made by excisional biopsy, it has not been possible to compare the outcome of patients with known teratoma that has not been resected with that of patients in whom the teratoma was excised. Nonetheless, most series have reported an overall survival of 85% or higher in those patients who were found to have teratoma in their postchemotherapy resected specimen.[155]

Preoperative variables have been evaluated for their usefulness in predicting postoperative histologic diagnosis (and potentially as a means of deriving guidelines for patients in whom chemotherapy after resection could be avoided).[155,156,161] Several series have identified the size of the residual retroperitoneal mass, size of prechemotherapy mass, and/or the extent of shrinkage as predictive factors able to identify a group of patients at lower risk for postchemotherapy teratoma or malignancy. Some[156] but not all[155,161] studies have demonstrated that the presence of teratomatous elements in the prechemotherapy biopsy specimens is predictive of teratoma or malignancy in the postchemotherapy specimen. Prechemotherapy serum markers (high LDH, low AFP) were also identified by logistic regression as predictors of an increased likelihood of finding only necrotic debris.[155] Despite the predictive value of some of these variables, no single variable or group of variables seems to be consistently sufficiently predictive to allow the identification of patients in whom resection can be avoided. Thus, two separate studies have reported the risk of a false-negative prediction (the likelihood of finding residual carcinoma or teratoma in patients predicted to have only necrosis/fibrosis) to be approximately 20%.[155,162] The identification of patients in whom postchemotherapy resection can be avoided remains controversial.[163] When postchemotherapy lymphadenectomy is undertaken, bilateral (non-nerve-sparing) RPLND is recommended.

Most investigators have recommended the resection of residual pulmonary nodules. From 10% to 30% of specimens have been reported as malignant, teratoma has been observed in 26% to 60%, and the fraction of specimens containing only necrosis and fibrosis has ranged from 14% to 64%.[163,164] In some series, as many as one fifth of patients undergoing resection of pulmonary nodules required bilateral thoracotomies. In a series of 39 patients undergoing 47 procedures, the pathology at resection could not be correlated with prechemotherapy size of the nodule, with size of residual nodule, or with extent of shrinkage.[155] Similarly, in the same report the pathology of residual mediastinal masses in 17 patients was not associated with prechemotherapy size or with percentage of shrinkage, although the size of the residual mass seemed to be more strongly correlated with histology.[155] Furthermore, in patients who undergo resection of more than one tumor site, several studies have suggested that histology from the earlier procedure (e.g., RPLND) will be predictive of the histology from the later procedure (e.g., thoracotomy) only 53% to 65% of the time.[164–166] Thus, although as few as 10% of residual

pulmonary nodules may harbor malignancy, the 25% to 60% incidence of teratoma, and the inability to predict which nodules will contain only fibrosis and necrosis, mandates strong consideration of surgical removal of all postchemotherapy residual masses.

SALVAGE THERAPY

Whereas 80% of patients with NSGCT can currently be cured with platinum-based therapy, 20% will ultimately die of their disease because of either failure to achieve a complete response with induction therapy or relapse after becoming disease-free with primary therapy. Before the initiation of salvage therapy, the diagnosis of relapsed or primarily refractory GCT must be clearly established. In particular, false-positive serologic data and the detection of falsely positive radiographic studies of the chest, as described previously, must be ruled out. Persistent or slowly growing masses, particularly in the absence of serologic progression, may represent benign teratoma.

Chemotherapy

Etoposide and ifosfamide are single agents with demonstrated activity in the salvage therapy of GCT, with response rates of 20% to 50% in patients previously treated with cisplatin, although currently they are rarely used as monotherapy. Particularly intriguing is a report that oral etoposide has a response rate of 28% in patients with refractory GCT whose prior combination chemotherapy treatment included etoposide.[167]

Salvage combination chemotherapy regimens have generally included etoposide, ifosfamide, or both. Before the acceptance of etoposide as a standard agent in primary induction therapy, etoposide and platinum-containing regimens resulted in long-term disease-free survival of approximately 20%.[168] Ifosfamide-containing salvage regimens for patients previously exposed to etoposide have either substituted vinblastine for etoposide (VeIP), with approximately 30% to 40% of patients achieving a complete response, but continued to utilize etoposide if the patient had been previously treated with vinblastine,[169] or simply continued to use etoposide (VIP), regardless of prior etoposide treatment (see Table 90-7). The use of etoposide combined with ifosfamide (as in the VIP regimen; see Table 90-7) resulted in a complete-response rate of 33% (including surgical resection of residual masses) in patients previously treated with PVB.[130,170]

Indiana University also reported on the results of salvage VeIP in 84 patients with refractory GCT, 77 of whom had been previously treated with etoposide-containing regimens. The overall complete response rate was 52%, and the authors reported a 33% long-term disease-free survival with a median follow-up of 17 months.[170] The MSKCC experience with salvage therapy consisting of the VAB-6 regimen, EP, or other cisplatin-based regimens suggested roughly equal complete-response rates of 25% to 36%, regardless of regimen used, with an overall durable complete-response rate of 23%.[171] In this setting, VeIP results in an 83% complete-response rate, and 54% of patients remain alive and continuously disease-free. For patients with relapsed or recurrent seminoma this is clearly the most appropiate initial salvage therapy.[172] More recently, a salvage regimen using paclitaxel, ifosfamide, and cisplatin has demonstrated significant activity, resulting in complete responses in 70% of patients who had experienced a relapse after a prior complete response to standard regimens.[173] In this series 50% of patients with a late relapse (>2 years) GCT achieved a complete response.[174] The combination of gemcitabine and oxaliplatin has demonstrated significant activity in patients with platinum-refractory disease, with a partial response rate of better than 40%.[175] Another new regimen consisting of epirubicin plus cisplatin resulted in complete responses in 30% of GCT patients who had received at least one prior cisplatin-containing regimen.[176]

Taken together these studies suggest that salvage chemotherapy has moderate to good activity in patients with a relapse after treatment with curative intent. The optimal salvage regimen is not established, and direct comparison of regimens is precluded by the diverse patient selection criteria of prior studies.

High-Dose Chemotherapy

The use of HDCT with autologous bone marrow transplant or autologous peripheral stem cell transplant (PSCT) as salvage therapy for relapsed or refractory GCT has been extensively explored.[177] The rationale for this approach includes the fact that GCTs are extremely chemosensitive and therefore potentially may demonstrate a dose-response relationship; that GCT patients are generally young and otherwise healthy, and can withstand the rigors of HDCT; and that bone marrow involvement with metastatic GCT is distinctly uncommon. Initial trials with HDCT used cyclophosphamide, etoposide, or thiotepa. Cisplatin, though certainly the most active single agent in the treatment of GCT, is poorly suited for dose intensification because of neurotoxicity, ototoxicity, and nephrotoxicity. Carboplatin, by contrast, is better suited for use in HDCT regimens, because (1) its major toxicity is hematopoietic and (2) it is an active agent in the treatment of germ cell neoplasms. A high-dose carboplatinum and VP-16 regimen pioneered by Indiana University and Vanderbilt University resulted in an overall disease-free survival rate of 60% and has become a skeleton that other investigators have modified, often by the addition of an alkylating agent such as cyclophosphamide or ifosfamide.[178] These results compare favorably with those observed after standard-dose salvage chemotherapy with VeIP and suggested that early HDCT may be beneficial in patients with relapsed GCTs.

Several novel HDCT salvage regimens have been reported, including induction with paclitaxel, ifosfamide, and cisplatin therapy followed by high-dose carboplatin, etoposide, and thiotepa,[179] as well as sequential dose intensive paclitaxel, ifosfamide, carboplatin, and etoposide.[180] From 25% to 50% of patients seem to achieve durable remissions, so that the curative potential of HDCT as salvage (and frequently third-line) therapy is fairly well established. However, preliminary reports from a randomized trial of four cycles of salvage VIP/VeIP compared to three cycles of VIP/VeIP followed by a single treatment of HDCT indicated no difference in response rates. Whether this trial will translate into survival differences, or if more conventional double ("tandem") treatments with HDCT/PSCT are required, remains to be determined.[181] Treatment-related mortality of HDCT/PSCT has declined over the years to levels usually less than 5% to 10%. Nevertheless, HDCT in this setting remains imperfect.

Surgery

In general, resection of residual masses after chemotherapy in NSGCT patients should be reserved for patients in whom serum tumor markers have normalized. Nonetheless, this approach has recently come under question. Several centers have reported on the results of surgical resection of solitary residual masses in highly selected patients with persistently elevated serum markers who were believed to be refractory to platinum (after either primary or salvage therapy). In one series of 15 patients, nearly half (7) obtained lasting complete remissions. The clinical features associated with a likelihood of successful outcome included a retroperitoneal site and/or an elevated AFP only (all 5 patients with elevated preoperative HCG levels subsequently relapsed).[182] A second report indicated a 37% "cure" rate in patients undergoing resection of residual masses in the setting of elevated serum markers.[183] High concentrations of tumor markers within residual tumors, and not systemic disease, may account for such findings.[184] Absolute conclusions regarding the role of salvage surgery cannot be drawn from such a small number of patients, and it must be borne in mind that this is a highly select group of patients. For example, the patients reported in one series accounted for only 4% of all patients who failed to achieve a complete response to

induction therapy at that institution over a 10-year period.[182] Nonetheless, these data suggest that in very carefully selected chemorefractory patients, surgical resection of residual masses, despite the presence of positive serum markers, may be appropriate.

RISK ASSESSMENT IN PATIENTS WITH RELAPSED OR REFRACTORY GERM CELL TUMOR

An analysis of the clinical features of responding versus nonresponding patients may serve to identify the subset of patients likely to benefit from each one of the salvage modalities discussed previously, as well as to identify those patients suited for novel therapeutic approaches.

Most clinical trials utilizing standard-dose salvage chemotherapy have observed that survival or response (or both) are considerably lower in primarily refractory patients, compared with patients who have had a prior response to chemotherapy.[169] MSKCC reported on 124 patients who were treated with salvage therapy. Patients who had relapsed after a prior complete response had a 2-year survival rate of 36%, compared with a 9% survival rate in patients with prior incomplete response to induction chemotherapy.[171] Similarly, the median survival for relapsed GCT patients treated with VIP at Indiana University was 10.7 months if the previous best response to chemotherapy was either an incomplete response or a complete response of less than 2 months' duration, compared with 26 months in patients who had experienced previous complete responses lasting more than 2 months.[169] Other features observed to be predictive of improved survival or response (or both) in some[169,171] but not all series[185] include lower tumor burden. Patients with extragonadal primary sites do poorly.[171] In a review of 203 patients treated with VIP or VeIP at three institutions, four independent prognostic factors have recently been identified: (1) incomplete response at induction, (2) extragonadal origin, (3) presence of lung metastases, and (4) elevated serum marker level (HCG > 1000 IU/L, AFP > 1000 ng/mL). Patients with either marker elevation or extragonadal origin and at least one other poor prognostic feature had a complete response rate of 4%, with no long-term cures, whereas patients with testicular tumors and nonelevated markers were observed to have a complete-response rate of 62% and a 3-year survival of 43%.[186]

HDCT seems to be able to overcome primary cisplatin resistance in some patients, although patients with refractory mediastinal GCTs do not seem to benefit from this approach. In the series of 40 patients with recurrent or refractory germ cell cancer treated with HDCT and autologous bone marrow transplant at Indiana University, 3 of 6 patients who obtained prolonged remissions were primarily refractory to cisplatin, whereas none of the 11 patients with extragonadal GCT obtained a complete remission.[170] Other centers have reported a complete-response rate of approximately 15% in platinum-refractory patients.[187] A multivariate analysis of risk factors in 310 patients treated with HDCT as salvage therapy at four centers in the United States and Europe reported that mediastinal NSGCT, primary platinum resistance, progressive disease before HDCT, and high HCG levels before HDCT (>1000 IU/L) had independent (adverse) prognostic significance.[146] This risk assessment schema has held true in subsequent HDCT trials. In general, patients with more than two adverse features have a poor outcome, with virtually no patient achieving a continuous remission, with median survival limited to less than 1 year.[179,181]

Patients who experience disease progression after HDCT or other second-line therapy do poorly. They often receive further chemotherapy and/or surgery. No single-agent or combination has yet demonstrated significant activity in this subset of patients. Several studies have shown response rates of 11% to 26% for single-agent paclitaxel.[188] Other agents such as gemcitabine and oral etoposide have also been reported to produce responses of 7% to 19%.[189] Chronic oral etoposide has also been used as maintenance treatment for patients at high risk of relapse or progression after salvage chemotherapy and as a palliative regimen for those patients with cisplatin-refractory disease.[190] The ECOG evaluated the combination of paclitaxel-gemcitabine in patients whose disease had progressed after conventional salvage second-line therapy or during initial cisplatin-based therapy. A response rate of 21% was reported. Despite response proportions of 10% to 20%, in general, complete responses are rare in these settings, and long-term survival is uncommon.[190] Regardless of regimen, integration of surgery as a component of post-HDCT seems to be important.[191]

LATE CONSEQUENCES

Testicular cancer is a unique malignancy in its curability. Long-term follow-up of patients treated with chemotherapy suggests that the long-term relapse-free survival for complete responders is in the range of 80% to 90%.[192] Nonetheless, once a complete remission is obtained, patients remain at risk for two types of adverse late consequences: relapse, including contralateral primary testicular neoplasms, and toxicity from therapy.

Germ Cell Tumor Relapse

After obtaining complete remission, 8% to 15% of GCT patients will relapse, usually within the first 2 years after treatment.[192] The timing of a relapse does not seem to be dependent on histology, extent of disease, or induction regimen used.[193]

Late recurrences, defined as relapses occurring more than 24 months after diagnosis, have been reported in 1.5% to 4% of patients achieving a complete response.[193,194] The majority of late relapses occur longer than 5 years from diagnosis. Nearly 50% of relapses were retroperitoneal and 35% intrathoracic (including the mediastinum). Proposed mechanisms for late relapses include the development of second primary lesions, growth of an occult contralateral testicle tumor that is not affected by chemotherapy because of the blood-testicular barrier, the "reactivation" of quiescent carcinoma, or malignant degeneration of mature teratoma. The latter argument is the most favored, in that teratomatous elements are observed in either the orchiectomy or relapse specimens in most patients. Teratomatous elements were present in the orchiectomy specimens of 66% of 21 NSGCT patients with a late relapse reported in three series.[193–195] Nonetheless, this theory does not account for the 33% of late-relapse NSGCT patients who did not have teratoma described in their orchiectomy specimen (perhaps a microscopic focus was missed), or the seven pure seminoma patients in these series who experienced a late relapse.

A late relapse should be treated aggressively as a de novo malignancy. Outcomes in this setting are a reflection of the underlying histology at the time of relapse. Patients with teratoma who are treated surgically have excellent long-term outcomes, whereas the complete-response rates to chemotherapy alone for those who relapse with viable GCT are approximately 50%,[196] and the median survival in this setting is approximately 24 months according to one recent series.[174] Approximately 70% of seminoma patients can be rendered free of disease with chemotherapy, radiation, or both.

Contralateral Testicular Cancer

Contralateral testicular cancer (CLTC), including synchronous neoplasms, has been reported to occur in 2% to 4% of patients. A Dutch tumor registry study of 1909 men with testicular cancer, with a median follow-up of 7.7 years, reported a 15-year actuarial risk of a CLTC of 2.4%.[197] The overall excess risk compared with the general population was 40-fold. This study also demonstrated that testicular cancer patients treated with chemotherapy (primarily PVB) had a significantly reduced risk of a contralateral tumor, compared with

those patients treated with radiation therapy or surgery alone, and that this risk reduction lasted for a period of at least 5 years. Supporting data come from the MRC trial of adjuvant carboplatin versus radiation therapy in patients with stage I seminoma, in which two CLTCs (4%) occurred among the 573 carboplatin-treated patients, compared with 10 cases (11%) among the 904 (11%) patients treated with radiation therapy.[77] Nevertheless, preorchiectomy chemotherapy in clinical stage II patients fails to completely eradicate all of the intratesticular cancer[45] and fails to completely prevent the recurrence of a CLTC.[198] Thus, despite the potential for the reduction of risk of a CLTC by the use of chemotherapy, it must be assumed that all men with testicular cancer are at a small but real risk of a CLTC.

Early Detection of Recurrent Germ Cell Tumor

The optimal schedule for follow-up of patients with GCTs in complete remission varies from center to center but in general consists of intensive follow-up during the first 12 months after completion of therapy (physical examinations, determination of serum marker levels, and chest radiograph every 4 to 6 weeks, with CT scans every 2–3 months), and a slightly diminished intensity of follow-up with scans every 4 months during the second year after therapy. During the third through fifth years, this evaluation is generally undertaken every 6 months. After 5 years guidelines are less well established, although most authors agree that the incidence of late recurrence mandates lifetime follow-up with at least an annual history and physical evaluation as well as tumor markers and chest radiography. In the United States the National Comprehensive Cancer Networks (NCCN) has published consensus guidelines on the timing and type of testing required for surveillance.

Toxicity

Although the acute toxicities of the various therapeutic modalities used in the treatment of GCT are fairly self-apparent and well understood, only recently have the chronic toxic costs of treatment begun to be appreciated. Just as it was only in the 1990s that we learned of the toxic consequences of therapies used in the 1970s and 1980s, an understanding of the potential late consequences of today's therapeutic maneuvers must enter into risk assessment strategies, and accentuate the need for defining low-risk populations in whom less treatment is appropriate. The acute and chronic toxicities associated with surgery, radiation therapy, and chemotherapy have been reviewed and are summarized next.

Acute Toxicities

The acute surgical morbidity of orchiectomy is minimal, similar to that seen with simple inguinal hernia repair. The surgical complications specific to retroperitoneal lymphadenectomy (apart from the usual general complications of major intra-abdominal surgery), which include retrograde ejaculation, have been described earlier in this chapter. It is generally appreciated that RPLND after radiation therapy or combination therapy is more technically demanding, and probably more morbid, because these patients have not only been debilitated by chemotherapy or radiation therapy but are also patients with bulkier tumors, greater invasion of normal tissue, and greater likelihood of fibrosis and/or necrosis of both residual malignant and surrounding nonmalignant tissue.[199]

The acute toxicities from radiation therapy are largely dose-dependent and are less of an issue in seminoma patients who usually are treated with 25 to 30 Gy. Nonetheless, acute gastrointestinal toxicity consisting of nausea, vomiting, and diarrhea has been described in as many as 50% to 100% of patients.[200] Changes in total dosage, equipment used, and treatment planning have largely relegated radiation nephritis, pneumonitis, and bone marrow suppression to historical archives.

The acute toxicities associated with chemotherapy for GCT have been extensively discussed and largely represent the toxicities anticipated from the individual chemotherapeutic agents composing these regimens. Advances in antiemetic agent development, the use of growth factors, and improvement of supportive measures have mitigated some of these toxicities. Nonetheless, specific acute toxicities that bear mention in context of the chemotherapy used for the treatment of GCT include myelosuppression, renal toxicity, pulmonary toxicity, and neuromuscular toxicity.

Myelosuppression is mild to moderate in PVB-, PEB-, or EP-treated patients and somewhat more severe with VAB-6. Considerably more myelosuppression occurs with VIP than with PEB.[85] The importance of timely administration of chemotherapy on outomes for patients with metastatic disease, even in the face of myelosuppression, has been demonstrated.[201] The frequency of myelosuppression that occurs with this therapy, coupled with the necessity of on-time chemotherapy have led the NCCN to issue guidelines that recommend the prophylactic use of growth factors during chemotherapy for GCT.

Nephrotoxicity associated with platinum-containing regimens is perhaps less severe in this group of young, generally otherwise healthy men, than in an older group of oncologic patients. Nonetheless, the potential for chronic renal insufficiency (as well as for peripheral neurotoxicity and/or ototoxicity), the occasional incidence of urinary obstruction by tumor masses, and the need for platinum-containing salvage regimens (VIP or high-dose carboplatin) in as many as 20% of patients mandates careful monitoring of renal function. In general, as noted previously, carboplatin should not be substituted for cisplatin[129,140] unless mandated by impaired renal function.

A recent review of the literature suggests that the incidence of thromboembolic events in GCT patients undergoing chemotherapy can be as high as 8%, the vast majority of which (83%) are venous and 17% arterial. Liver metastases and the administration of high dose of dexamethasone as antiemetic therapy were identified as risk factors for the development of thromboembolic complications.[202] Despite this, prophylactic anticoagulation is not routinely administered to GCT patients receiving chemotherapy, given the relatively low overall incidence of thromboembolic events.

The acute pulmonary toxicity of bleomycin is manifested as noninfectious pneumonitis. As many as 20% of GCT patients treated with bleomycin-containing regimens will develop clinically apparent pneumonitis, and some published series report mortality rates due to pneumonitis of 3% to 4%. This is a dose-related complication, with a markedly increased incidence at cumulative doses greater than 400 units, although toxicity may occur at lower doses. Although the single-breath-diffusing capacity for carbon monoxide (DLCO) is the most common test used to monitor for pulmonary toxicity of bleomycin, its utility remains controversial.[203,204] Despite this controversy, it seems reasonable to assess each patient's pulmonary function clinically before each bleomycin dose and with a DLCO before commencing each new cycle. Measured DLCO may be expressed as a percentage of the predicted DLCO. Bleomycin-stopping rules using a greater than 10-point drop in this percentage have been recommended.

Neuromuscular toxicity associated with PVB has been attributed to cisplatin (peripheral sensory neuropathy, ototoxicity) and vinblastine (peripheral neuropathy, paralytic ileus, myalgias).[124] Peripheral sensory neuropathy and possibly autonomic dysfunction after cisplatin administration have been well described and will not be further addressed. A randomized comparison of PVB to PEB reported that 8% of patients receiving vinblastine, as opposed to 2% receiving etoposide, had severe abdominal cramping, and 14% of PVB-treated patients developed severe myalgias. Four percent of patients treated with PEB (as opposed to 11% of PVB-treated patients) developed severe paresthesias.[155] These data have resulted in the substitution of PEB for PVB as front-line therapy for advanced GCT. Nonetheless, because GCT patients continue to receive cisplatin-based therapy, and vinblastine is used in the salvage VeIP regimen, the potential for neuromuscular toxicity must be appreciated.

Chronic Toxicities of Radiation Therapy

The chronic toxicities associated with modern radiation therapy techniques for GCT are not known. Much of the available information regarding chronic toxicities is derived from late follow-up reports of patients treated on orthovoltage equipment, or using dated techniques, or both. Further, field size has direct implications on the nature of long-term toxicities observed. For example, the relative risk of myocardial infarction was increased 3.7-fold for patients who received mediastinal irradiation, whereas irradiation confined to the infradiaphragmatic areas was not associated with an increased risk of myocardial infarction.[205] Nonetheless, it must be assumed that the potential for some of these toxicities persists even with modern techniques. Although only minimal late nephrotoxicity and peripheral neurotoxicity have been described with radiation therapy,[206] more common late toxicities include chronic peptic ulceration in 5% to 10% of patients,[124] and of greatest concern, the development of delayed non-germ cell malignancies, which are discussed later. Several studies have suggested that testis cancer patients may be at an increased risk of developing a second, non-germ cell malignancy with long-term follow-up, although the relative impact of chemotherapy (vs. radiotherapy) is unknown.[197,207]

Chronic Toxicities of Chemotherapy

Renal, vascular, cardiac, neurologic, and reproductive toxicities as well as the risk of secondary malignancies compose the major long-term toxicities of chemotherapy. The chronic renal toxicity associated with cisplatin administration has been reviewed.[208] Most studies suggest that the acute deterioration of renal function observed after cisplatin may be irreversible and may persist beyond 12 months, although overt renal failure is generally not observed. Presumed renovascular hypertension has been observed in as many as 24% of men after cisplatin-based therapy, although it is not known if this is a consequence of chemotherapy or of increased surveillance.

Chronic vascular toxicities associated with chemotherapy include Raynaud's phenomenon, vascular occlusive events, and potential alterations in cholesterol metabolism. The most common vascular toxicity in GCT patients treated with chemotherapy is Raynaud's phenomenon, occurring in 23% to 49% of patients, usually within a year of treatment.[208] Although the exact cause in this setting is unknown, it seems to occur after treatment with bleomycin alone, and in combination with vinblastine, but the addition of cisplatin may double the incidence. Symptoms of Raynaud's phenomenon abate in approximately 50% of patients. The possibility of a relationship between platinum-based therapy and the less than 5% incidence of fatal major vascular occlusive events involving coronary, cerebral, or peripheral arterial circulation has been raised.[208]

The cardiovascular toxicities associated with chemotherapy agents are a cause of increased concern. Although previous follow-up studies of survivors of metastatic GCT have reported a low prevalence of major cardiac events, ranging from 0% to 3%, recent studies with longer median follow-up times have observed higher prevalence of major cardiac events of up to 6%, including myocardial infarction, angina pectoris, and myocardial ischema. In part this may be explained by the presence of an unfavorable cardiac risk profile (hypertension, obesity, and an elevated serum level of total cholesterol with a decrease of high-density lipoprotein cholesterol level), which has been observed in patients who have received chemotherapy.[209,210] The mechanism behind this increased cardiovascular risk profile is unknown. Although the use of PEB chemotherapy increases the risk of cardiovascular disease in general by approximately 1.5-fold, it does not seem to increase the risk of myocardial infarction. In contrast, PVB chemotherapy increases the risk of both cardiovascular disease and myocardial infarction.[205]

The chronic reproductive toxicities associated with chemotherapeutic treatment of GCT include oligo- and azoospermia and Leydig cell dysfunction.[208,211] The exact role of chemotherapy in this process is often unclear in the individual patient, because many men are hypofertile at the time of diagnosis of GCT, and as many as 80% will be oligospermic following orchiectomy.[208,212] Many men also demonstrate Leydig cell dysfunction after orchiectomy, indicated by elevated LH and FSH levels in the face of normal testosterone levels. In one series only 11% of men treated with orchiectomy alone or orchiectomy plus radiation therapy had residual oligospermia or Leydig cell dysfunction.[211] By contrast, combination chemotherapy seems to have a profound impact on spermatogenesis and Leydig cell function. The same study reported azoospermia in 27% and Leydig cell dysfunction in 86% of patients after treatment with chemotherapy. Sperm counts generally increase in the second and third year after therapy, and return to normal in about 50% of men. Approximately 25% of men are permanently azoospermic, and it seems that Leydig cell dysfunction may persist at 3 to 9 years after therapy.[213] These deleterious effects of chemotherapy on gonadal function seem to be similar for all regimens evaluated thus far. The only exception may be short-course (two cycles) PEB, wherein the gonadotoxic effects may be reversible in nearly all patients. Nonetheless, oligospermic and even azoospermic patients have been able to father children, and approximately one third of men treated with chemotherapy are able to father healthy children.[208]

Secondary Malignancies

In a Danish tumor registry group of more than 6000 patients, in which it is likely that most were treated with radiation therapy, the relative risk of second solid malignancies is approximately 2, with a latency period of 10 or more years.[214] A Dutch tumor registry study of 1909 patients with testis cancer confirmed these results, reporting a lifetime relative risk of a secondary malignancy of 1.6 and of all gastrointestinal malignancies (the most common site of origin of secondary solid malignancies) of 2.9, with the greatest risk (RR 6.5) occurring more than 9 years after therapy. The 15-year actuarial risk of developing a second cancer was 9.8%.[197] Although it has been suggested that the risk of leukemia in patients treated with modern radiation therapy techniques does not seem to be elevated,[185] the Dutch series suggests that the relative risk of leukemia after radiation therapy, though not as high as seen after chemotherapy, remains elevated at 5.2.[197] The latency period was shorter than with solid tumors, with the highest risk occurring at around 5 years. The combination of radiation therapy and chemotherapy resulted, in this study, in significantly higher risks of solid malignancies (RR 9.5) and leukemia (RR 66.7) than if either modality was used alone.[197] Kaldor and colleagues summarized the incidence of second malignancies in 17,730 testis cancer patients identified from 11 population-based tumor registries.[215] These authors found that survivors of testis cancer experienced 30% more tumors than expected for the general population, with a statistically significant increase in the likelihood of developing sarcoma (RR 3.0), melanoma (RR 1.8), non-Hodgkin's lymphoma (RR 2.7), and leukemia (RR 1.7). No information regarding the type of treatment delivered for the initial testis tumor was available in the study. Wanderas and colleagues examined the risk of subsequent non-germ cell tumors in 2006 Norwegian testis cancer survivors who were followed for an average of 12.5 years after diagnosis of testis cancer.[216] The relative risk for developing a second non-germ cell malignancy in this population was 1.65 when compared with the general population, and the cumulative risk of developing such a tumor was 7.8% after 15 years of follow-up. There was an increased risk of colorectal, gastric, hepatobiliary, lung, and bladder cancers, as well as melanoma and sarcoma. The highest relative risk for developing a second non-germ cell tumor was seen in patients treated with either irradiation alone or with irradiation plus chemotherapy. Bokemeyer and Schmoll reported a cumulative incidence of 1.38% for the development of a secondary tumor in 1025 patients followed for an average of 61 months after treatment for testis cancer.[217]

Travis and colleagues reported the results of a regression analysis of the relative risks of second solid malignancies in testicular cancer

survivors collected from 14 population-based tumor registries in North America and Europe encompassing the outcomes of over 40,000 testicular cancer survivors. In this analysis it was determined that the risk of developing any second solid tumor over a 40-year time period (e.g., by age 75 for a patient diagnosed at the age of 35) was 36% and 31% for survivors of seminomas and nonseminomas, respectively, compared with 23% for the general population.[218]

The risk of secondary leukemias after chemotherapy for the treatment of GCT is small but real. Alkylator-associated leukemias have occurred when these agents were used in the treatment of GCT.[124] More recent series suggest that acute leukemias are unlikely to occur after treatment with standard doses of PVB.[197] Though uncommon, etoposide-associated acute leukemias have been described, occurring in approximately 0.5% of patients. From a combined total of 881 GCT patients treated on protocol at Indiana University and MSKCC, a total of four patients developed acute myeloid leukemia. All occurred in patients treated with high cumulative doses of etoposide (2 g/m^2 in all patients but one, who received 1.3 g/m^2) and were diagnosed from 2 to 4 years after treatment.[219,220] Two other centers have reported a total of six leukemias out of a total of 322 patients treated with etoposide (and none in a group of 318 men receiving platinum-based therapy without etoposide), with a somewhat higher cumulative risk (3.5% to 4.7%) of developing leukemia at 5 years.[207] Bearing in mind that even the "easiest" adjuvant regimen consisting of two cycles of etoposide and cisplatin contain 1 g/m^2 of etoposide, careful and considered use of etoposide-containing regimens is warranted as further information accumulates.

Taken together, these data suggest that secondary malignancies are an expected late occurrence in patients with treated testicular cancer, with a relative risk of between 1.38 and 2.0. Treatment regimens including radiation therapy may have a higher association with secondary solid tumors, whereas chemotherapy may be more likely to result in secondary leukemias. These risks, though quite small compared with the impact of not undergoing therapy, must nevertheless be considered in the therapeutic decision-making process, and be discussed with each GCT patient.

CANCER OF THE CERVIX

SUMMARY OF KEY POINTS

Incidence
- An estimated 11,150 new cases of invasive cervical cancer are anticipated in 2007 in the United States, with 3670 deaths projected.
- From 75% to 80% are squamous cell carcinomas.
- Since the advent of cytologic screening in the 1940s, the incidence of cervical cancer has been decreasing; however, a steady increase in the incidence of preinvasive disease of the cervix has occurred.

Etiology
- Associated risk factors include race, early age at first coitus, multiple sexual partners, multiparity, lower socioeconomic standing, cigarette smoking, history of sexually transmitted diseases, immunosuppression, and oral contraceptive use.
- Strong association with human papillomavirus (HPV)
- HPV serotypes 16, 18, 31, 33, 45, and 56 account for more than 80% of all invasive cervical cancers.

Evaluation and Staging
- Screening for cervical cancer historically has been done with the Papanicolaou (Pap) smear and pelvic examination.
- Testing for DNA of high-risk oncogenic HPV may be used to triage atypical smears and to reduce the frequency of cytologic screening.
- Biopsies should be performed of gross lesions.
- Patients without gross lesions but with abnormal cytology should undergo colposcopy with directed biopsies and endocervical curettage (ECC) or brushing.
- Once a diagnosis of cancer is made, the patient requires a complete history and physical examination, including bimanual and rectovaginal examination, as well as supraclavicular and groin lymph node examination.
- Cervical cancer is staged clinically, not surgically.
- Assignment of stage of disease may be influenced by findings from chest and skeletal radiography, excretory urography (intravenous pyelogram [IVP]), barium enema, cystoscopy, and proctoscopy.
- Results of computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), or other imaging modalities do not influence assignment of International Federation of Obstetrics and Gynecology (FIGO) stage, but may be important in directing therapy.

Primary Therapy
- High-grade dysplasia or carcinoma in situ may be treated with excisional cone biopsy (i.e., cervical conization performed with loop electrosurgical excision procedure [LEEP], or cold-knife).
- Stage Ia1 (microinvasive cervical cancer with depth of invasion 3 mm or less and 7 mm in width or less) without lymph-vascular invasion is managed with conservative surgery (i.e., excisional conization or extrafascial hysterectomy).
- Stage Ia2 lesions (invasion of more than 3 mm depth, and lesion up to 7 mm wide) or Ia1 lesions with lymph-vascular invasion are managed with modified radical hysterectomy.
- Stage Ib lesions and stage IIa lesions may be managed with radical hysterectomy or radiation therapy with equivalent probability of cure but different morbidities. Selected surgical patients with adverse risk factors may benefit from adjuvant postoperative radiation or chemoradiation.
- Patients with stage IIb to IVa generally are treated with radiation therapy with concurrent chemotherapy.

Therapy for Recurrent Disease
- Disease that recurs centrally in the pelvis after radiation may be treated with radical exenterative surgery.
- Locally recurrent disease after surgery is generally treated with radiation therapy or chemoradiation.

INTRODUCTION

Cancers of the cervix, vulva, and vagina represent the major malignancies of the lower female genital tract. With the exception of the endocervix, this portion of the genital tract is available for physical examination, including direct visual inspection and palpation. Currently, cytologic screening and surveillance by Papanicolaou (Pap) smear, testing for the presence of oncogenic strains of the human papillomavirus (HPV), colposcopy, and a variety of confirmatory biopsy techniques are capable of diagnosing preinvasive disease or very early-stage invasive disease that can be treated with a high probability of cure.

Improvements in diagnostic imaging and assessment of disease extent before therapeutic intervention and more routine use of integrated, multimodality therapy together offer the opportunity for better outcomes for women with invasive local or regional disease.

Squamous cell carcinomas are the dominant histologic type in all three sites, with many tumors associated with oncogenic strains of

HPV. In the last decade, improved understanding of HPV biology, the epidemiology and natural history of HPV infection, and early studies on HPV-directed vaccines offer hope that the incidence of invasive disease could decrease in the decades ahead. In the future, anticipated use of HPV-targeted vaccines in the pediatric population offers the potential to reduce dramatically worldwide morbidity and mortality associated with this group of diseases.

EPIDEMIOLOGY

For 2007, the American Cancer Society estimates that 11,150 cases of invasive cervical carcinoma and approximately 3670 cervical cancer deaths will occur in the United States, representing only 1.5% of the projected 270,600 annual cancer deaths in American women. A much larger population of American women (approximately four-fold) will be diagnosed with cervical dysplasia that will never develop into invasive neoplasia.

Although cervical cancer is the third most common gynecologic malignancy in the United States, it ranks as the most common gynecologic malignancy worldwide and is the second most common cancer in women in the world, with an estimated 500,000 cases in 2003. Marked disparity in incidence exists between countries where routine gynecologic care and Pap smear screening are available, and countries in Latin America, the Caribbean, and Africa, where cervical cancer is the most common cause of cancer-related death in women.[1]

It has long been appreciated that the incidence of invasive cervical carcinoma is related to sexual activity. Early age at first intercourse, multiple sexual partners, a history of venereal infection, and other parameters of sexual activity have long been recognized as factors associated with the development of invasive cervical cancer. Women from lower socioeconomic strata, and black and Hispanic populations have an increased frequency of disease. Incidence rates in the United States are estimated at 8.1 new cases per 100,000 white women each year as compared with 11 per 100,000 in African-American women and 14.4 per 100,000 in Hispanics.

Molecular epidemiologic studies have demonstrated that correlation of sexual activity with cervical carcinoma is related to transmission of the epithelial trophic and oncogenic HPV.[2–4] Most HPV infections are transient, resulting in no changes or low-grade intraepithelial lesions (cervical intraepithelial neoplasia; CIN 1) that will be spontaneously cleared in most young women.[5,6] Development of high-grade intraepithelial lesions will occur in a small minority of women, usually within 24 months.[7] High-grade lesions (CIN 2/3) may progress to invasive cervical cancer if not treated.[8,9]

Cases of CIN 2/3 that progress to invasive cancer will do so over a period of 8 to 12 years, which has been referred to as the *detectable preclinical phase*.[10–13] Thus the opportunities for early detection and intervention are abundant. However, an estimated one half of the invasive cervical cancers diagnosed in the United States are found in women who have never been screened, and an additional 10% are diagnosed in women who have not been screened within the preceding 5 years.[14]

Based on a comprehensive review of available evidence, the American Cancer Society convened an expert panel in 2001 through 2002 to formulate detailed guidelines for the initiation of screening, screening intervals, discontinuation of screening, screening in the context of prior hysterectomy, and use of various screening tests.[15] A synopsis of their recommendations is found in Table 91-1.

HUMAN PAPILLOMAVIRUS BIOLOGY

HPV is a double-stranded DNA virus in the Papovaviridae family (Fig. 91-1). This virus, constituted of approximately 8000 nucleotides, encodes seven early genes and two late genes, as well as having a small, untranslated region. Approximately 100 different serotypes with limited DNA homology have been identified. Although the identification of high-risk subtypes of HPV has been important in defining potential therapeutic targets for the prevention of cervical carcinoma, HPV infection has not adequately explained all of the biologic features of preinvasive disease and progression to invasive disease. Studies in sexually active college women demonstrated that infection with HPV is extremely common, occurring in up to 50% of women who become sexually active between the ages of 16 and 21 years, with the first abnormal Pap smear appearing in only a subset of women 1 year after infection. These infections typically are associated with low-grade dysplastic lesions and usually are transient. Persistent infection with associated high-grade dysplastic lesions is seen in only a small proportion of infected women (perhaps 1% or 2%). Biologic and/or immunologic cofactors that allow the persistence of HPV infection in a small subset of women remain unclear. Epidemiologic studies suggest that co-infection with herpes simplex virus type II (HSV), long-term oral contraceptive use, cigarette smoking, and high parity may increase the risk of persistent infection, carcinoma in situ (CIS), and invasive disease.[16,17] Whereas long-term epidemiologic studies undertaken since appreciation of the role of

Table 91-1 American Cancer Society Guideline for Screening by Cytology for the Early Detection of Cervical Neoplasia and Cancer

- Cervical cancer screening should begin ~3 yr after the onset of vaginal intercourse and no later than age 21 yr*
- Women who are age 70 or older with an intact cervix and who have had 3 or more documented, consecutive, technically satisfactory normal/negative cervical cytology tests and no abnormal/positive cytology tests within the 10-yr period before age 70 may elect to cease cervical cancer screening†
- Screening with vaginal cytology tests after total hysterectomy (with removal of the cervix) for benign gynecologic disease is not indicated. The presence of CIN 2/3 is not considered benign. Women with a history of CIN 2/3 or without documentation of the absence of CIN 2/3 should be screened until three documented, consecutive, technically satisfactory normal/negative cervical cytology tests and no abnormal/positive cytology tests with a 10-year period are achieved†
- After initiation of screening, cervical screening should be performed annually with conventional cervical cytology smears or every 2 years using liquid-based cytology; at or after age 30, women who have had three consecutive, technically satisfactory normal/negative cytology results may be screened every 2–3 years‡

*Age 21 to initiate screening is a guideline for circumstances in which sexual history is not available because providers do not ask, or because patients are unable or unwilling to provide a history regarding consensual or nonconsensual intercourse. It also is intended to protect victims of sexual abuse.

†Women who have a history of cervical cancer or in utero diethylstilbestrol exposure, or are immunocompromised (including human immunodeficiency virus positive [HIV$^+$]) should continue screening unless severe comorbid or life-threatening illnesses are present.

‡More frequent screening may be advisable in women with in utero DES exposure, and women who are HIV$^+$ or are immunocompromised by organ transplantation, chemotherapy, or prolonged corticosteroid treatment.

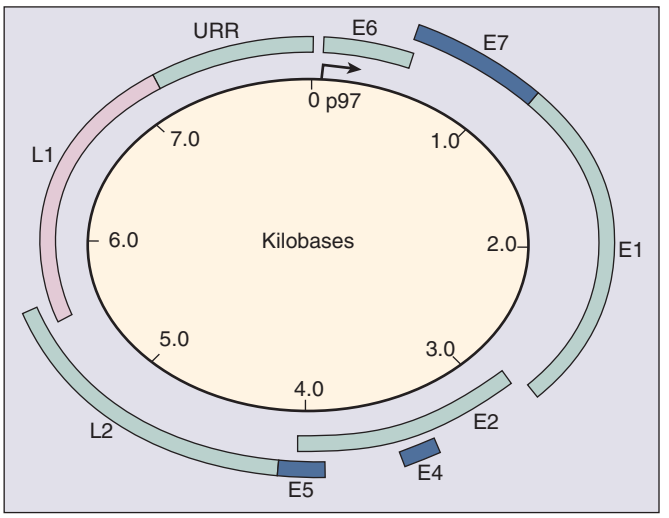

Figure 91-1 • Human papillomavirus (HPV) genome. The HPV virus is a double-stranded DNA virus in the Papovaviridae family. This virus, constituted of approximately 8000 nucleotides, encodes seven early genes and two late genes, as well as having a small, untranslated region. Approximately 100 different serotypes with limited DNA homology have been identified. (From Parker MF, Sausville EA, Birrer MJ: Basic biology and biochemistry of gynecologic cancer. In Hoskins WJ, Perez CA, Young RC [eds]: Principles and Practice of Gynecologic Oncology, 2nd ed. Philadelphia, Lippincott-Raven, 1997, Fig. 3.6.)

HPV remain incomplete, it is known that in the large majority of women, the period between HPV infection, dysplasia, and then invasive carcinoma typically is years to decades, offering the potential for screening and early intervention to change the natural history and morbidity associated with this disease.[18–22]

Molecular epidemiologic studies have divided HPV serotypes into high-, intermediate-, and low-risk subtypes for the development of cervical neoplasia.[23] Low-risk subtypes have been associated with venereal warts (condylomata acuminata), whereas intermediate- and high-risk subtypes have been associated with cervical dysplasia and invasive carcinoma. Recent worldwide review of HPV typing demonstrated that 87% of squamous cell carcinomas had an identifiable HPV genome associated with the tumor as compared with 76.4% of adenocarcinomas. HPV-16 was the predominant type, associated with between 46% and 63% of the squamous carcinomas, whereas HPV-18 was associated with 10% to 14% of squamous cell carcinomas. Sixteen other HPV types were associated with the remaining 25% of cases, including HPV-45, -31, and -33. Most epidemiologic studies have demonstrated a higher incidence of HPV-18 (37% to 41%), followed by HPV-16 (26% to 36%) in women with adenocarcinoma of the cervix. Several authors have shown a positive association between the presence of certain HPV subtypes and prognosis. Barnes and colleagues[24] showed that, among invasive carcinomas, HPV-18 is associated with poorly differentiated histology and higher incidence of nodal metastases. Similarly, Walker[25] reported that HPV-18-associated cancers were more likely to recur than were HPV-16-associated cancers. By contrast, HPV-16 was associated with large cell keratinizing tumors, and these tumors were less likely to recur.[26] Lombard[27] demonstrated HPV-18-associated tumors to have a relative risk of death 2.4 times greater than that observed for patients with HPV-16-associated tumors and 4.4 times greater than that for patients with a tumor associated with another HPV type.

The mechanism by which these epithelial trophic viruses cause neoplasia has been defined through an elaborate collection of experiments that have focused on the role of the E6 and E7 early genes. Virally encoded E6 binds to the p53 protein, leading to targeting of this cellular checkpoint protein for proteosomal destruction. The E6 protein product also enters the nucleus and interacts with the other important nuclear proteins. The second virally encoded protein, E7, sequesters the retinoblastoma gene product (Rb) releasing the RB-associated E2F transcription factor, which results in the initiation of a number of nuclear events important in driving the cell through the cell cycle. Recent studies also have suggested that p21 is sequestered and inactivated by the E7 protein. Elimination of the p53 and Rb checkpoint results in dysregulated cell growth and dysplasia. In addition, the E7/E6 proteins both independently lead to mitotic instability, with abnormality in chromosomal segregation during mitosis and increased chromosome instability. This may explain, in part, the long latency period between HPV infection and carcinoma. Loss-of-heterozygosity studies and other molecular events have defined chromosomal changes and changes in other oncogenic proteins that are neither primary nor secondary effects of HPV infection, but are due instead to co-infection or other non-HPV factors. Although data suggest that HPV infection may be critical in initiating the neoplastic transformation, it is not clear that therapy that targets the HPV genome or HPV-related protein products will be useful in reversing the fully transformed phenotype.

The observation that, in a large portion of HPV-infected women, invasive carcinoma never develops suggests that the preinvasive neoplastic cells can be cleared by the immune system. Recent studies identified T cells that specifically identify peptide epitopes of the E6 and E7 proteins. Certain human leukocyte antigen (HLA) DR2 and TAP genes have been associated with invasive cervical carcinoma. Understanding the biology of cervical cancer initiation and propagation requires an understanding of HPV biology and its interaction with its epithelial cell target, as well as an understanding of cervical immunity. The HPV virus is epithelial trophic. Unlike that in other oncogenic viruses (such as the hepatitis viruses), systemic exposure to the virus is not required for infection of the target organ. Analysis has demonstrated that E6-specific T cells in the majority of healthy women are responsible (at least in part) for eradication of infection. Tetramer analysis in patients with cervical CIS or invasive cervical cancer have in general demonstrated few HPV-16 E7-reactive T cells, typically representing less than 0.1% of the $CD8^+$ T cells in the systemic circulation. Recent attempts to generate productive and/or long-term HPV-16 infection have been accomplished by using an HPV-16 virus-like particle vaccine. In a recent randomized, placebo-controlled study, the delivery of three vaccinations at day 0, month 2, and month 6 reduced the risk of persistent new HPV-16 infection from 3.8 cases per 100 women-years at risk to 0 per 100 woman-years in the group that were vaccinated, for a 100% efficacy rate. In this study, involving 2392 young women between the ages of 16 and 23 years, nine cases of HPV-16-related CIN were noted, all in the placebo recipients.[28] Further study with this and other vaccines is ongoing.

Maiman, Fruchter, and associates[29–32] investigated the disease characteristics, recurrence risks, and survival rates of HIV-seropositive patients with CIN and invasive cervical cancer. HIV-infected women had significantly higher rates of recurrence of CIN after standard therapies than did seronegative women. HIV-infected women with cervical cancer had significantly more advanced disease than did those who were not infected. Only 3 (19%) of 16 HIV-seropositive patients were first seen with an early-stage disease (defined as stage Ia or nonbulky Ib) compared with 35 (52%) of 68 in the HIV-seronegative group. When upstaged based on surgicopathologic findings, only 1 (6%) HIV-infected patient had early-stage disease compared with 40% of uninfected patients. The response to therapy and prognosis were poorer among HIV-seropositive women, with higher recurrence and death rates. The majority of seropositive women had lymph node metastases and high-grade tumors. They generally were asymptomatic with respect to their HIV disease, but died of cervical cancer. The significant impact of immune status on disease progression was made evident by prolonged disease-free follow-up in seropositive patients with CD4 counts greater than

500/mm^3, in contrast to those with CD4 counts less than 500/mm^3. The observed marked increased risk of invasive cervical carcinoma in women infected with the HIV virus and the demonstration that highly effective antiretroviral therapy (HEART) is capable of doubling the CIN regression rates in women infected with HIV, as compared with those women not receiving HEART, provides suggestive, indirect clinical evidence supporting the critical importance of the intact immune system in limiting the progression of HPV infection to invasive cancer in healthier populations.

PATHOLOGY

The epithelium of the cervix is composed of squamous epithelium that covers the exocervix and glands and columnar epithelial cells that line the endocervix. The border between the squamous and columnar epithelium is called the *squamocolumnar junction*, the site of ongoing squamous metaplasia believed to be most vulnerable to viral neoplastic transformation. With increasing age, the squamocolumnar junction migrates from the exocervix into the distal endocervical canal (Fig. 91-2), with the region between the original and subsequent locations termed the *transformation zone*. The transformation zone is the most common location for detection of early cervical cancers (Fig. 91-3) Tumors arising on the ectocervix typically are squamous cell carcinomas, whereas adenocarcinomas are more likely to have their epicenter in the endocervix.

A continuum appears to exist from CIN to frankly invasive squamous cell carcinoma (Fig. 91-4). The mean age of women with CIN is 15.6 years younger than that of women with invasive cancer, suggesting slow progression of CIN to invasive carcinoma.[18] The natural history of HPV infection and CIN in part reflects the host immune system response to the virus. Seventy-five percent of CIN 1 lesions will spontaneously regress or persist as CIN 1, without progression to invasive carcinoma.[18–21]

Miller[22] reported, in a 13-year observational study, that only 14% of CIN 3 lesions had progressed, whereas 61% persisted, and the remainder disappeared. Patients taking corticosteroids or other immunosuppressive drugs and patients with HIV infection are at higher risk of progressing to invasive cancer and may have a shorter transit time for this progression.

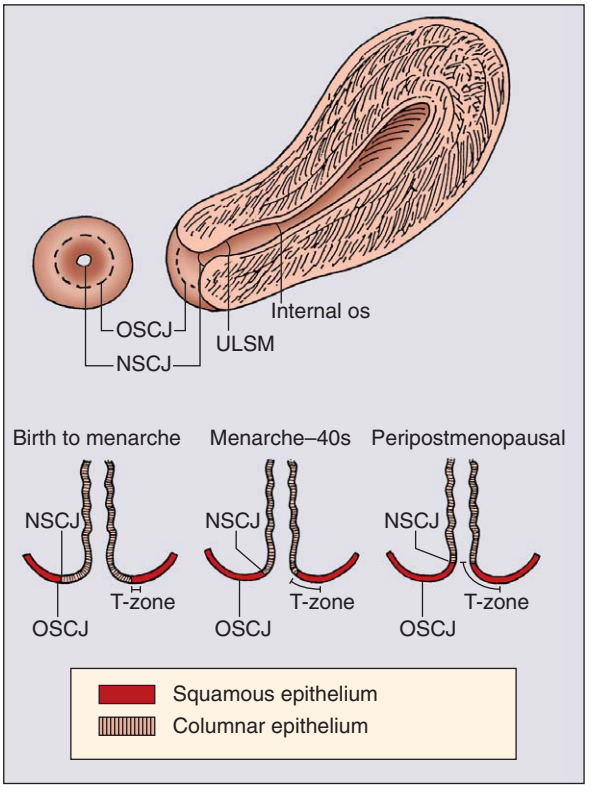

Figure 91-2 • The transformation zone and squamocolumnar junction. NSJC, new squamocolumnar junction; OSJC, original squamocolumnar junction; T-zone, region between original and new squamocolumnar junctions. (From Wright TC Jr, Richart RM: Pathogenesis and diagnosis of preinvasive lesions of the lower genital tract. In Hoskins WJ, Perez CA, Young RC [eds]: Principles and Practice of Gynecologic Oncology, 2nd ed. Philadelphia, Lippincott, 1997, p 678 and Berek JS, Hacker NF: Practical Gynecologic Oncology, 2nd ed. Baltimore, Williams & Wilkins, 1994.)

Figure 91-3 • Invasive squamous cell carcinoma. A mass is present on the external os. (Clement PB, Young RH: Atlas of Gynecologic Surgical Pathology. Philadelphia, WB Saunders, 2000, p 103.)

Squamous Cell Carcinomas of the Cervix

Approximately 75% of invasive cervical carcinomas are squamous cell carcinomas. Tumor histology differs between well, moderately, or poorly differentiated tumors. Squamous carcinomas (Fig. 91-5) may be keratinizing (sometimes containing characteristic keratin pearls) or nonkeratinizing. Large cell and small cell variants exist. True verrucous cancers of the cervix are rare.

Cervical Adenocarcinomas

Adenocarcinomas account for 15% to 25% of invasive cervical carcinomas. Typically arising in the endocervix, adenocarcinomas can be more difficult to detect on visual inspection of the cervix. These tumors may infiltrate deeply into the stroma of the cervix, sometimes with parametrial extension and nodal metastases without gross destruction of the exocervix. In addition to the classic endocervical type, histologic variants of adenocarcinoma include endometrioid carcinoma, villoglandular, mesonephric, serous, intestinal-type, and signet-ring morphologies.

Clinically important subtypes also include clear cell adenocarcinomas of the cervix associated with in utero diethylstilbestrol (DES) exposure, which tend to be diagnosed at a younger age than most other adenocarcinomas, and so-called "adeno malignum" or minimal deviation adenocarcinoma (Fig. 91-6), an entity associated with deceptively bland or benign-appearing cells, which may be cause for undertreatment of a true malignancy, with a significant likelihood of recurrence even when diagnosed at an early stage.[33,34]

Adenosquamous Carcinomas

Adenosquamous carcinomas consist of a malignant glandular component and a malignant squamous component and make up approximately one third of cervical carcinomas with glandular differentiation. Opinions vary regarding the prognosis of adenosquamous carcinoma compared with pure adenocarcinoma or pure squamous carcinoma when prognosis is adjusted for clinical stage at diagnosis. A clinically important variant of adenosquamous carcinoma is the so-called "glassy cell" carcinoma, thought to represent a very poorly differentiated adenosquamous carcinoma, the name of which derives from the ground-glass or granular appearance of the cytoplasm seen in many cases. Additional features may include an intense stromal inflammatory infiltrate composed predominantly of eosinophils and plasma

cells. Some patients may have accompanying eosinophilia in their circulating blood, with elevated absolute eosinophil counts. This histologic type is associated with a rapid clinical rate of growth, proclivity for early regional dissemination, and increased risk of recurrence after surgical therapy or radiation therapy, even in the absence of other recognized adverse prognostic factors.[35–38]

NEUROENDOCRINE TUMORS OF THE CERVIX

Neuroendocrine tumors arising in the cervix include typical and atypical carcinoid tumors, and large cell, small cell neuroendocrine carcinomas, and undifferentiated small cell carcinoma. Both large cell and small cell neuroendocrine tumors resemble similar carcinomas arising in the lung and other aerodigestive sites.[39,40] Undifferentiated small cell carcinoma is a very poorly differentiated carcinoma with neuroendocrine features, histologically similar to anaplastic small cell carcinoma of the lung.[41] Neuroendocrine carcinomas tend to behave very aggressively, with frequent widespread metastasis to multiple sites, including bone, liver, skin, and other sites. Brain metastases may occur when disease is advanced but usually are preceded by lung metastases.[43] Efforts to treat these tumors by using approaches typically used for small cell carcinomas of the lung have had mixed results.[42]

Clinical Presentation

Preinvasive neoplastic disorders of the cervix usually are asymptomatic, hence the need for regular screening by cytologic evaluation of cells collected from the exocervix and endocervix. Early invasive cancers also may be asymptomatic, although some women will notice postcoital, intermenstrual, or postmenopausal spotting. Other symptoms may include malodorous vaginal discharge, dyspareunia, or cramping pelvic pain from uterine contractions caused by the accumulation of blood and uterine deciduas in menstruating patients with occlusion of the endocervical canal. Chronic blood loss may result in symptomatic anemia in some patients. Major hemorrhage is unusual

except in locally advanced disease. Pelvic pain, lower extremity swelling (from occlusion of pelvic lymphatics or thrombosis of the external iliac vein), or problems with micturition or defecation indicate advanced regional disease and portend an ominous prognosis. Metastatic disease involving supraclavicular nodes, bones, or lungs can be the cause of presenting symptoms, but rarely in the absence of pelvic symptoms. Constitutional symptoms, including anorexia, dysgeusia, and weight loss, are seen most often in patients with very advanced disease.

Screening

Screening for cervical cancer and its precursors with the Pap smear and pelvic examination has resulted in dramatic reductions in cervical cancer mortality in every country where this has been widely used, and is arguably the most effective screening program in effect for any neoplastic disease, in either gender. Current screening guidelines of the American Cancer Society are outlined in Table 91-1. The false-negative rate of the Pap smear is about 10% to 15% in women with invasive cancer, but the sensitivity, as defined by the detection of biopsy-proven CIN, is 51%.[43–45] The sensitivity of the test may be improved by ensuring adequate sampling of the squamocolumnar junction and the endocervical canal. Smears without endocervical or metaplastic cells may be inadequate and possibly should be repeated.[46]

Factors contributing to abnormal cytologic smears include the presence of hemorrhage, necrosis, and intense inflammation. Thus gross symptomatic lesions should be sampled with biopsy rather than assessed with exfoliative cytology.

In the 1980s, cytology laboratories began reporting an increasing number of smears with changes of "squamous atypia" in response to concerns from clinicians over an unacceptably high false-negative cytology rate and increased recognition by cytopathologists of the cytologic changes associated with HPV infection. The use of multiple classification systems with inconsistently defined numeric grading conventions added further imprecision. In an attempt to eliminate confusion among clinicians and cytopathologists, a uniform system for reporting epithelial cell abnormalities was established in 1988 at a National Cancer Institute (NCI) workshop for reporting cervical and vaginal cytologic diagnoses.[47]

The Bethesda System has since been revised, in 1991 and again in 2001 (Table 91-2),[48] to reflect laboratory and clinical experience gained since the original implementation, as well as the increased utilization of new technologies and results from interval research studies. An important contribution of the Bethesda System was the creation of a standardized format and nomenclature for cytology laboratory reports that includes both a descriptive diagnosis and an evaluation of specimen adequacy.

With the formulation of Bethesda 2001, a specimen is designated "satisfactory for evaluation" or "unsatisfactory for evaluation." The category "satisfactory but limited by . . ." has been eliminated as confusing. Minimal cellularity requirements for a specimen to qualify as satisfactory depend on specimen type, with an estimated 8000 to 12,000 well-visualized squamous cells for conventional smears and 5000 squamous cells for liquid-based preparations. Comments on partially obscuring inflammation or blood may be added to the "satisfactory" designation, with a specimen considered "partially obscured" when 50% to 75% of the epithelial cells cannot be visualized. When more than 75% of epithelial cells are obscured, a specimen is designated "unsatisfactory." A notation is made regarding the presence or absence of an endocervical/transformation zone component for specimens with adequate squamous cellularity, with the numeric criterion being at least 10 well-preserved endocervical or squamous metaplastic cells. Cell clusters are not required.

Squamous atypia is a mild cellular abnormality characterized by slight nuclear enlargement and minimal changes of the nuclear chromatin. Cellular changes that show morphologic features of papillomavirus infection or mild CIN (grade 1) are termed low-grade

Table 91-2 2001 Bethesda System

SPECIMEN ADEQUACY

Satisfactory for evaluation (note presence of endocervial/transformation zone component)

Unsatisfactory for evaluation (specify reason)

Specimen rejected/not processed (specify reason)

Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (specify reason)

GENERAL CATEGORIZATION (OPTIONAL)

Negative for intraepithelial lesion or malignancy

Epithelial cell abnormality

Other

INTERPRETATION/RESULT

Negative for intraepithelial lesion or malignancy

- Organisms
  - *Trichomonas vaginalis*
  - Fungal organisms consistent with *Candida* sp.
  - Shift in flora suggestive of bacterial vaginosis
  - Bacteria morphologically consistent with *Actinomyces* sp.
  - Cellular changes consistent with herpes simplex virus

Other nonneoplastic findings (Optional. List not comprehensive)

- Reactive cellular changes associated with inflammation (includes typical repair)
  - Radiation
  - Intrauterine contraceptive device
- Glandular cells after hysterectomy
- Atrophy

Epithelial cell abnormalities

- Squamous cell
  - Atypical squamous cells (ASC) of undetermined significance (ASC-US), cannot exclude high-grade squamous intraepithelial lesion (HSIL [ASC-H])
  - Low-grade squamous intraepithelial lesion (LSIL) encompassing human papillomavirus, mild dysplasia, cervical intraepithelial neoplasia (CIN) 1
  - HSIL encompassing moderate and severe dysplasia, carcinoma in situ; CIN 2 and CIN 3
  - Squamous cell carcinoma
- Glandular cell
  - Atypical glandular cells (AGCs) (specify endocervical, endometrial, or not otherwise specified)
  - Atypical glandular cells, favor neoplastic (specify endocervical or not otherwise specified)
  - Endocervical adenocarcinoma in situ (AIS)
  - Adenocarcinoma
- Other (list not comprehensive)
  - Endometrial cells in a woman 40 yr or older

AUTOMATED REVIEW AND ANCILLARY TESTING

(Include as appropriate)

EDUCATIONAL NOTES AND SUGGESTIONS

(Optional)

Adapted from Soloman D, Davey D, Kurman R, et al: The 2001 Bethesda System: terminology for reporting results of cervical cytology. JAMA 2002;287:2114.

squamous intraepithelial lesions or LSILs. Cellular changes consistent with moderate (CIN 2) or severe (CIN 3) dysplasia are termed high-grade squamous intraepithelial lesions or HSILs. The division of SILs into high- and low-grade strata reflects accumulating evidence that LSIL generally is indicative of transient infection with HPV, particularly in young women, and does not routinely require colposcopy or treatment, whereas HSIL cytology detects precursor lesions that require further evaluation and treatment. Important refinements in the 2001 Bethesda System relate to the reporting of equivocal results. Atypical squamous cells (ASCs) are now further qualified as "of undetermined significance" (ASC-US) or "cannot exclude HSIL" (ASC-H). The qualifier "undetermined significance" was retained, as some cases of ASC-US are associated with underlying CIN 2 or CIN 3. All ASCs are considered to be suggestive of SILs, and thus the category "ASC-US favor reactive" has been eliminated, with a portion of cases previously so designated being downgraded to "negative for intraepithelial lesion or malignancy." The new term ASC-H includes true HSIL and its mimics and is thought to have a positive predictive value for CIN 2 or CIN 3 intermediate between ASC-US and HSIL. The term *atypical glandular cells of undetermined significance* (*AGUS*) has been eliminated to avoid confusion with ASC-US. Glandular cell abnormalities now are classified as atypical endocervical, endometrial, or glandular cells. The term *atypical epithelial cells* may be used when a squamous versus glandular origin cannot be ascertained.

DIAGNOSIS

Management of the patient with an abnormal Pap smear with respect to further diagnostic assessments, therapeutic intervention, and subsequent surveillance follow-up is a complex arena in which guidelines continue to evolve. The American Society for Colposcopy and Cervical Pathology (ASCCP) has developed contemporary guidelines for management of cervical cytologic abnormalities and CIN based on current reporting terminology (Bethesda 2001).[49,50] Techniques for further evaluation can include colposcopy, endocervical curettage or brushing, and cervical conization by cold knife or loop electrodiathermy excision procedure (LEEP).

Testing for high-risk, oncogenic HPV DNA[51–57] synchronously, or subsequent to cytologic screening, is proving to be a useful complementary tool in triage of patients with ASC-US smears and in determining the need for colposcopy and the intervals for repeated screening. It may be helpful in the follow-up of younger patients with LSIL smears, and a useful tool in identifying older women who can safely be screened at 3-year intervals instead of annually.

HPV triage of patients with an ASC-US smear is at least as sensitive as immediate colposcopy for ultimately detecting CIN 3 and results in referral of about half as many women to colposcopy. A follow-up strategy that uses repeated cytology is sensitive at an ASCUS referral threshold, but requires two follow-up visits and ultimately more colposcopic examinations than does HPV triage.[58]

Cytologic and HPV screening in women older than 30 years (after which most sexually active women have been exposed to HPV and have, or have not, spontaneously cleared the infection) may be a mechanism through which low-risk HPV-negative and cytologically negative patients can be identified for whom screening at 3-year intervals is prudent and appropriate.

Colposcopy

Patients with a gross lesion of the cervix should undergo cervical biopsy. For patients with an abnormal cytologic evaluation, without a gross lesion, a colposcopic examination with directed punch biopsies is required. Colposcopy allows the clinician to identify areas suggestive of dysplasia. A 3% acetic acid solution is applied to the cervix for 30 to 90 seconds, which causes a transient reaction with the envelope proteins of the papillomavirus, in addition to producing an osmotic dehydration of the dysplastic cells, thereby accentuating the optically dense chromatin to produce a whitish area. The skilled colposcopist can further distinguish between grades of dysplasia based on aceto-whitening and types of vascular patterns (Fig. 91-7). An additional technique to help visualize abnormal areas is the application of quarter-strength Lugol's iodine after the initial inspection for aceto-whitening. High-grade lesions turn mustard yellow.

Endocervical Curettage or Endocervical Brush

Study of the endocervical canal is required when no abnormalities are found on colposcopic examination, when the entire squamocolumnar junction cannot be visualized, or when atypical endocervical cells are present on Pap smear. Some experts advocate the use of endocervical curettage (ECC) as part of every colposcopic examination to safeguard against missing occult cancer within the endocervical canal. Others reserve ECC for patients with recurrent cytologic atypia after therapy. A sleeved endocervical brush is an alternative to ECC that is less uncomfortable for many patients. Recent, prospective comparison of ECC specimens with sleeved endocervical brush specimens (both obtained from the same patient sequentially after randomization with respect to the order of obtaining specimens) before cervical conization or hysterectomy revealed a higher rate of inadequate specimens from ECC, comparability of the two techniques with respect to sensitivity and specificity in unmatched analysis, and superior sensitivity of the sleeved endocervical brush in matched analysis. As the sleeved endocervical brush is at least isoeffective and possibly better than ECC but more comfortable for the patient, many clinicians prefer this maneuver, which may serve to increase patient compliance with subsequent surveillance follow-up and repeated assessment.[59]

Excisional Biopsy

Diagnostic cervical conization (cone biopsy) leads to an accurate diagnosis and decreases the incidence of inappropriate therapy in the following situations: (1) the squamocolumnar junction is not visualized on colposcopy; (2) dysplastic epithelium extends into the endocervical canal; (3) cytology is suggestive of high-grade dysplasia or worse; (4) microinvasive carcinoma is found on directed biopsy; (5) sampling of the endocervical canal shows high-grade intraepithelial neoplasia; and (6) cytology is suggestive of adenocarcinoma in situ.

Loop Electrodiathermy Excision Procedure

LEEP uses wire-loop electrodes in conjunction with a radiofrequency alternating current to excise the entire transformation zone and distal canal under local anesthesia (Fig. 91-8). Compared with ablative procedures, LEEP has the major advantage of obtaining tissue for histologic evaluation. At many centers, LEEP has become the preferred treatment for CIN that can be assessed adequately with colposcopy.[60–72]

Complications include bleeding, with a reported incidence of 1% to 8%,[73,74] cervical stenosis (1%), and, rarely, pelvic cellulitis or adnexal abscess. In some cases, LEEP may not be an adequate alternative to formal excisional conization, such as in those patients in whom microinvasive or invasive cancer is suspected, or in those with adenocarcinoma in situ, as it may treat disease within the cervical canal inadequately and complicate pathologic interpretation of the specimen. Appropriate application of this technique will yield tissue suitable for pathologic study and reliable diagnosis. Excess heat may result in thermal artifact that can compromise interpretation of margins and the therapeutic adequacy of the LEEP procedure.

Diagnostic or Therapeutic Excisional Conization (Cone Biopsy)

Diagnostic or therapeutic excisional conization (cone biopsy) must be performed under general or regional anesthesia. Complications,

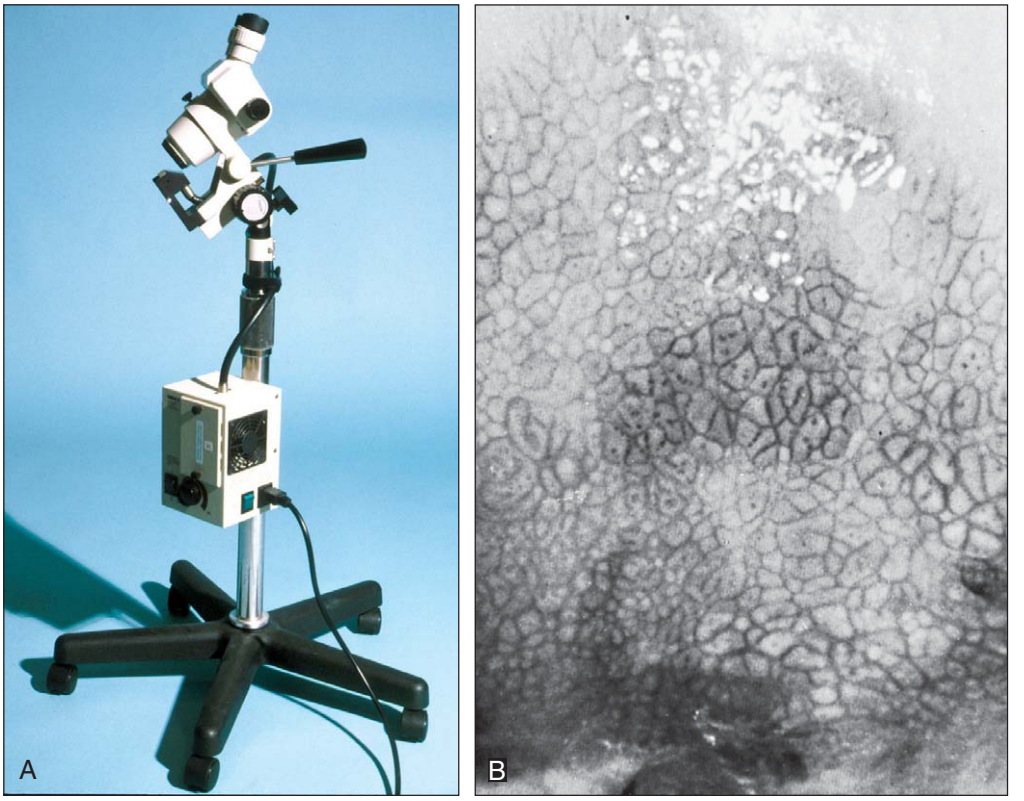

Figure 91-7 • A, Colposcope. **B,** Colposcopic discovery of high-grade cervical dysplasia. (**A** From Apgar B, Brotzman G, Spitzer M [eds]: Colposcopy: Principles and Practice, 2nd ed. which include hemorrhage, sepsis, infertility, stenosis, and cervical incompetence, occur in 2% to 12% of patients, depending on depth and geometry of excision.[73–75] Width and depth of the cone should be tailored to the topography of the lesion, to produce the least amount of injury while providing clear surgical margins. Conization may be performed with a cold knife or with the carbon dioxide laser.

Patient Evaluation in Patients with Invasive Disease

A thorough history should be obtained before diagnostic assessments are initiated, because skilled questioning will elicit information that will serve to guide subsequent evaluation. A sexual history should be obtained from all patients, which may alert the physician to screen for HIV and other sexually transmitted diseases. This also will serve to establish a baseline for sexual function and expectations that may be helpful in the post-treatment counseling and sexual rehabilitation of patients after completion of therapy. A complete history and systems review also should assess comorbid conditions (e.g., neurologic, cardiovascular, pulmonary, gastrointestinal, endocrine) that may affect the selection and implementation of treatment strategy.

A social assessment should be routinely obtained and will assist in determining supportive interventions that may be necessary to facilitate patient compliance with complex diagnostic programs and multimodality treatment programs. In the United States, patients with advanced cervical cancer may be uninsured or underinsured, often will have cultural or language barriers to obtaining and complying with care, may have limited educational attainment and medical sophistication, and will have variable degrees of familial or other social support.

A general physical examination should be carried out, with attention to accessible lymph node groups, including the supraclavicular nodes and the inguinal nodes. Physical examination also should assess the heart, lungs, and large vasculature (i.e., the carotid, dorsalis pedis, posterior tibial, and femoral arteries; the aorta; and the veins of the lower extremities). Pelvic examination must include meticulous inspection of all potentially visible sites and palpation of the perineum, the vulva, the full length of the vaginal barrel, and the anorectum. Some patients will manifest areas of preinvasive disease at multiple separate sites along the lower reproductive tract or synchronous invasive primary cancers of the lower reproductive tract and the anus, representing "field cancerization" consequent to exposure to a common etiologic agent. Typically tumors arising from the ectocervix

or transformation zone are easily visualized and sampled with biopsy. Occasionally tumors arising in the uterine corpus or lower uterine segment can invade the uterine cervix or protrude through the cervical os, causing confusion in the diagnosis. Often this can be sorted out by histopathology and by diagnostic imaging, with magnetic resonance imaging (MRI) being most useful in this context. Once the diagnosis of cervical carcinoma is established, staging includes careful clinical evaluation of the vagina, cervix, uterus, and parametria. The adenexal areas should be palpated as well, because some patients will harbor adenexal pathology (tubo-ovarian abscesses or, less commonly, adenexal metastases) that optimally are diagnosed and addressed before initiation of cancer treatment.

Conventionally, pelvic examinations in the setting of invasive cancer are performed under general or regional anesthesia (EUA) to assist in the most accurate possible physical evaluation of disease extent. Relaxation of the muscles of the pelvic floor and the opportunity to conduct vigorous and prolonged examination without inflicting discomfort or pain may identify disease extension that may be missed in an outpatient clinic examination. For example, EUA may be critical in very anxious, young, nulliparous women, as well as in elderly patients who may not be regularly sexually active and in whom the vagina may be stenotic. EUA also affords the opportunity to perform cystoscopy and proctosigmoidoscopy when indicated. However, in an era of cost containment and constrained health care resources, EUA may be omitted when a cooperative patient is amenable to satisfactory examination in the clinic or in rare circumstances in patients with locally extensive disease requiring rapid initiation of treatment.

Staging

The revised 1995 staging criteria (Table 91-3) of the International Federation of Obstetrics and Gynaecology (FIGO) are a mixture of histopathologic, clinical, and radiographic assessments that reflect the fact that invasive cervical cancer is most prevalent in less-developed portions of the globe where sophisticated and expensive imaging modalities may not be widely available. Cervical cancer is clinically staged, and staging is based primarily on inspection and palpation of the cervix, vagina, parametrium, and pelvic sidewalls. Only the subclassification of stage I (Ia1, Ia2) requires pathologic assessment. The FIGO staging system permits assessment through biopsy, physical examination, cystoscopy, proctoscopy, excretory urography (intravenous pyelography or IVP), and plain film radiography of the chest and skeletal system. Results of lymphangiography (LAG), computed tomography (CT), MRI, and positron emission tomography (PET) may be of great value in planning treatment, but do not influence assignment of clinical stage in the FIGO formalism. When findings are equivocal, by convention, a patient is assigned to a lower stage. Once clinical stage has been assigned, it cannot be altered by subsequent events or findings. Findings from surgical evaluation (by laparoscopy or by surgical assessment of retroperitoneal lymph nodes via extraperitoneal or transperitoneal node dissection) will not alter assignment of clinical stage. However, these findings may profoundly influence subsequent treatment. Similarly, evidence of nodal or other spread discerned at the time of hysterectomy does not alter clinical stage.

A staging system based largely on findings from clinical pelvic examination is inherently imprecise and somewhat subjective, with over- and understaging of the parametria being the most problematic issue and the one most likely to alter management. However, FIGO stage does correlate with prognosis and does permit cautious interinstitutional and intrainstitutional comparisons of treatment outcomes.

Diagnostic Imaging Evaluation of Cervical Cancer

The goals of clinical staging in patients with invasive disease include determining the appropriateness and extent of initial surgical treatment, as opposed to initial treatment with combined radiation therapy and synchronous chemotherapy. Although not formally part of clinical staging, modern sophisticated diagnostic imaging can enhance clinical assessment of disease volume and extent in women with cervical carcinoma, thus refining both selection of treatment and technical implementation of treatment modalities.

The FIGO staging system is based predominantly on clinical EUA, ultrasonography, intravenous urography, cystoscopy, proctoscopy, and chest radiography. Significant inaccuracies occur in this staging because of possible errors in gynecologic examination (24% to 39%).[76] The various imaging modalities have a complementary role in the accurate staging and complete evaluation of the cancer that have important therapeutic implications.

Today, clinicians most often obtain a contrast-enhanced CT scan of the abdomen and pelvis for patients with disease of stage Ib2 or greater (Fig. 91-9).[77] Lymph nodes larger than 1.0 to 1.5 cm in diameter are suspicious for tumor involvement and should be biopsied. Unfortunately, microscopic metastases are not readily detected with CT, and the inflammation commonly associated with advanced disease may cause enlargement of nodes that do not contain metastases. The sensitivity of MRI in the detection of regional metastases is similar to that of CT. However, MRI provides better anatomic delineation and accurate estimation of the tumor size, volume, and local extent within the pelvis, which can influence the choice of therapy (Fig. 91-10). Involvement of the vagina, parametrium, pelvic wall muscles, ureter, bladder, and rectum can be better assessed for accurate staging (Fig. 91-11).[76] MRI before and after vaginal opacification with contrast medium can be used if imaging evaluation of the vaginal wall or fornices is required.[78] T_2-weighted images obtained by using phased-array coil, fast-spin-echo or conventional spin-echo techniques are accurate in local staging and lymph nodal assessment; the former technique is faster with increased resolution.[79] Dynamic contrast-enhanced T_1-weighted images are helpful in identifying smaller tumors, fistulous tracts, and invasion into bladder and rectum.[74] Dynamic contrast-enhanced imaging is useful in differentiating areas composed predominantly of tumor cells (well-enhanced areas) from those of fibrous tissue with scattered cancer cells (poorly enhanced areas). This information can be helpful, as radiation therapy is more effective in well-enhancing tumors.[80]

MRI is very useful in the evaluation of tumor volume and enlarged lymph nodes, inherently important prognostic factors as well as determinants of the design of radiation treatment ports and selection of radiation dose. However, MRI cannot identify micrometastases to lymph nodes and differentiate malignant from nonmalignant enlargement. MRI with newer contrast agents like ultrasmall

Table 91-3 American Joint Committee on Cancer and International Federation of Gynecology and Obstetrics Staging Systems for Cancer of the Uterine Cervix

AJCC TNM Categories	FIGO Stages	
TX	—	Primary tumor cannot be assessed
T0	—	No evidence of primary tumor
Tis	0	Carcinoma in situ
T1	1	Cervical carcinoma confined to uterus (extension to corpus should be disregarded)
T1a	Ia	Invasive carcinoma diagnosed only by microscopy. All macroscopically visible lesions—even with superficial invasion—are T1b/Ib. Stromal invasion with a maximum depth of 5.0 mm measured from the base of the epithelium and a horizontal spread of 7.0 mm. Vascular space invasion, venous or lymphatic, does not affect classification
T1a1	Ia1	Measured stromal invasion ≤3.0 mm in depth and ≤7.0 mm in horizontal spread
T1a2	Ia2	Measured stromal invasion >3.0 mm and ≤5.0 mm with a horizontal spread ≤7.0 mm
T1b	Ib	Clinically visible lesion confined to the cervix or microscopic lesion greater than T1a2/Ia2
T1b1	Ib1	Clinically visible lesion ≤4.0 cm in greatest dimension
TIb2	Ib2	Clinically visible lesions >4.0 cm in greatest dimension
T2	II	Cervical carcinoma invades beyond uterus but not to pelvic wall or to the lower third of vagina
T2a	IIa	Tumor without parametrial invasion
T2b	IIb	Tumor with parametrial invasion
T3	III	Tumor extends to the pelvic wall, and/or involves the lower third of the vagina, and/or causes hydronephrosis or nonfunctioning kidney
T3a	IIIa	Tumor involves lower third of the vagina, no extension to pelvic wall
T3b	IIIb	Tumor extends to pelvic wall and/or causes hydronephrosis or nonfunctioning kidney
T4	IVa	Tumor invades mucosa of the bladder or rectum, and/or extends beyond true pelvis (bullous edema is not sufficient to classify a tumor as T4)
M1	IVb	Distant metastasis

REGIONAL LYMPH NODES (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis

DISTANT METASTASIS (M)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Table 91-3 American Joint Committee on Cancer and International Federation of Gynecology and Obstetrics Staging Systems for Cancer of the Uterine Cervix—cont'd

NOTES ABOUT THE STAGING SYSTEM

Stage 0 cases have full-thickness involvement of the epithelium with atypical cells but with no signs of invasion into the stroma. (Case of stage 0 disease should not be included in any therapeutic statistics for invasive carcinoma.)

As a rule, it is impossible to estimate clinically whether a cancer of the cervix has extended to the corpus. Extension to the corpus should therefore be disregarded.

A growth fixed to the pelvic wall by a short and indurated but not nodular parametrium should be assigned stage IIb. It is impossible at clinical examination to decide whether a smooth and indurated parametrium is truly cancerous or only inflammatory, and thus such cases should be classified as stage III only if the parametrium is nodular to the pelvic wall or if the growth itself extends to the pelvic wall.

The presence of hydronephrosis or nonfunctioning kidney caused by stenosis of the ureter by cancer permits a case to be classified as stage III even if, according to the other findings, the case should be classified as stage I or stage II.

The presence of bullous edema, as such, should not permit a case to be classified as stage IV. Ridges and furrows into the bladder wall should be interpreted as signs of submucous involvement of the bladder if they remain fixed to the growth at palposcopy (i.e., examination from the vagina or the rectum during cystoscopy). A finding of malignant cells in cytologic washings from the urinary bladder requires further examination and biopsy from the wall of the bladder.

RULES FOR CLINICAL STAGING

Staging should be based on careful clinical examination and should be performed before any definitive therapy. Ideally, the examination should be performed under anesthesia by an experienced examiner.

The clinical stage must under no circumstances be changed on the basis of subsequent findings.

When doubt exists as to the assignment of stage, the case must be classified as the earlier stage. For staging purposes, the following examination methods are permitted: palpation, inspection, colposcopy, endocervical curettage, hysteroscopy, cystoscopy, proctoscopy, intravenous urography, and X-ray examination of the lungs and skeleton. Suspected bladder or rectal involvement should be confirmed by biopsy and histologic evidence.

Findings on examinations such as lymphangiography, arteriography, venography, laparoscopy, and so forth are valuable for planning therapy, but because such studies are not yet generally available and because interpretation of the results is variable, the findings of such studies should not be the basis for changing the clinical staging.

Infrequently, hysterectomy is performed in the presence of unsuspected extensive invasive cervical carcinoma. Such cases cannot be clinically staged or included in therapeutic statistics, but they should be reported separately.

Only strict observance of the rules for clinical staging will allow meaningful comparison of results between clinics and modes of therapy.

superparamagnetic iron oxide has been useful in distinguishing benign from malignant nodes.[81] The shape, volume, and direction of the growth of the tumor can be well assessed, and these are crucial for planning brachytherapy and external-beam radiotherapy.[74] MRI also is useful in the follow-up evaluation of the tumor, its response to treatment, and identification of recurrences. However, benign conditions like edema or inflammation sometimes cannot be differentiated from tumor. Dynamic contrast-enhanced MRI is useful in differentiating malignant lesions that usually have shorter and stronger enhancement than benign conditions in patients who have abnormalities after treatment for cervical cancer.[82]

Recent studies have suggested that [(18)] fluorodeoxyglucose positron emission tomography (FDG-PET) is more sensitive and specific than more standard radiographic studies in the detection of lymph node involvement by cervical cancer.[83–85] Grigsby and colleagues[86] have reported a strong correlation between abnormal post-therapy FDG uptake and tumor recurrence. Inconsistent reimbursement for the study continues to be a barrier to widespread use in U. S. patients with cervical cancer, and the cost of the study currently prevents its widespread international use in this generally medically underserved group of patients.

Laboratory Evaluation

Routine laboratory assessment should include complete blood counts with differential counts and red cell indices. Many patients with advanced disease will be anemic at the time of diagnosis, often reflecting chronic blood loss and iron deficiency. Anemic patients treated with radiation or chemoradiation have poorer outcomes than do patients with near-normal hemoglobin levels.[87–90] Anemia at diagnosis (before treatment) correlates significantly with reduced pelvic control and survival with univariate analysis, but not always when data are subjected to multivariate analysis. In contrast, multivariate analysis reveals that hemoglobin level during the course of radiation therapy or chemoradiation is a robust predictor of local outcome and survival.[87–90] Transfusion for anemic patients with maintenance of average weekly nadir hemoglobin levels at or above 11 to 12 g/dL through radiation therapy is associated with improvement in prognosis to that associated with patients with near-normal or normal hemoglobin levels at diagnosis.[87,89] This effect may be partially mediated through better tumor oxygenation and oxygen-enhanced radiation lethality to clonogenic cells as well as reduced angiogenesis in better-oxygenated tumors. With pelvic or extended-field radiation that will encompass a substantial percentage of adult bone marrow, hemoglobin may decline slowly, even when adequate iron stores are present and patients are supported with hematinics. Concurrent administration of cisplatin further aggravates this problem, and can result in clinically significant reduction in hemoglobin levels over the course of a 6- to 8-week program of chemoradiation, even in patients with normal hemoglobin levels at the time of diagnosis. Frequent monitoring of hemoglobin levels as well as white cell counts and platelets should be performed throughout a course of chemoradiation, and hemoglobin level should be supported, either by transfusion or through the use of recombinant erythropoietin. The minimal hemoglobin level required is uncertain, but it seems prudent to target a minimum of 10 g/dL.

Neutropenia may indicate supportive treatment with granulocyte-colony-stimulating factor (G-CSF) to avoid prolonged treatment interruptions that are known to adversely affect local tumor control in patients treated with radiation.[91,92] Absolute neutrophil counts should be monitored at least weekly in patients undergoing chemoradiation.

An elevated platelet count has been associated with advanced malignancy and is considered a consequence of increased platelet production.[93] Hernandez and associates[94] identified this effect in advanced cervical cancer, and Rodriguez and coworkers[95] identified the preoperative platelet count as an adverse prognostic factor, even for patients with stage Ib cervical carcinoma. The cumulative 5-year survival of women with a platelet count greater than 300,000 (85 women) was 65%, compared with 84% for the group with a normal value (134 women). At issue was the question of whether the value could have been elevated simply because of bleeding from the primary tumor, but no association was found with the preoperative hematocrit. This study of surgically treated patients with early disease also demonstrated that the effect was not a consequence of metastatic disease and did correlate with tumor volume, with nearly half of the patients with platelet counts in excess of 300,000 having "large" lesion size, in contrast to only 28% (32 of 114) patients with normal counts.[96] In a multivariate analysis, adjusting for age, race, tumor size, and presence of lymph node metastases, high platelet count was still associated with an adverse prognosis.

Additional laboratory tests should include a complete chemistry panel with serum electrolytes and measurements of renal and hepatic function. Electrolytes and renal function should be monitored repeatedly through a course of chemoradiation. Creatinine may be elevated secondary to hydroureter/hydronephrosis that may require ureteral stent placement or nephrostomies before radiation therapy, particularly if cisplatin chemotherapy is anticipated. Serum sodium and potassium may become abnormal during the course of chemoradiation, particularly in elderly patients, consequent to diarrhea with potassium loss, inadequate oral replenishment, and inadequate or inappropriate fluid intake.

PROGNOSTIC FACTORS

Prognostic factors fall into two groups, tumor-related factors and patient-related factors. Probably the most important tumor-related factor is tumor size, and this is true both for patients treated with hysterectomy[96,97] and for patients treated with radiation therapy.[98–100] In fact, FIGO, in 1995, divided stage Ib into two groups according to size; other stage categories act, in part, as surrogates for tumor size. For patients treated with surgery, histologic evidence of extracervical spread is associated with a poorer prognosis. Parametrial extension is associated with a higher rate of lymph node involvement, local recurrence and death from cancer.[101,102] Uterine body involvement is associated with an increased rate of distant metastases in patients treated with radiation therapy or surgery.[103,104]

Lymph node involvement is another important tumor-related factor. After radical hysterectomy, reported-year survival rates usually are about 35% to 40% lower when the pelvic lymph nodes are involved.[105,106] However, recent studies suggest that postoperative chemoradiation improves these results.[107] Several reports suggest that survival decreases with increasing size of the largest involved nodes,[108,109] increasing number of nodes involved,[106,110] and the increasing level of regional involvement and with extent of central disease in the cervix. Overall, the survival rates for patients with positive para-aortic nodes are about half those of patients who have similar stages of disease without para-aortic lymph node involvment.[111–113] LVSI also is correlated with an increased risk of recurrence. This reflects, in part, the strong correlation between LVSI and lymph node involvement; however, in a large number of postoperative studies, LVSI is an independent predictor of prognosis.[106,114–116]

Investigators have compared the outcome of patients with adenocarcinomas with squamous carcinomas and have reached varying conclusions about the relative prognoses of the two histologic types of cervical cancer.[117–119] In a review of 1767 patients with stage Ib disease (229 with adenocarcinoma), Eifel and colleagues[120] found that patients with adenocarcinoma had a significantly higher risk of recurrence and death from disease, independent of age, tumor size, or tumor morphology. The rate of distant metastasis for patients with bulky (>4 cm) adenocarcinomas was almost twice that for patients with squamous carcinoma (37% vs. 21%, $P < 0.01$). Several investigators have reported high recurrence rates after radical hysterectomy

for adenocarcinomas. In a recent subset analysis of a randomized Gynecologic Oncology Group study, Rotman and associates[121] reported a high recurrence rate (11 of 25 patients [44%]) after treatment with radical hysterectomy alone for adeno-adenosquamous carcinomas of the cervix; in contrast, only 3 of 31 patients (10%) who received postoperative radiation therapy had recurrences. However, it is important to remember that all of these comparisons are compromised by the relatively small number of patients treated with cervical adenocarcinomas.

Other tumor factors include correlation between the serum concentration of squamous cell carcinoma antigen and the extent of squamous carcinoma of the cervix.[122–124] Increased tumor vascularity has been associated with a relatively poor prognosis,[125,126] and a strong inflammatory response in the cervical stroma tends to predict a good outcome.[125] Some authors have reported a correlation between HPV subtype and prognosis.[27] Several investigators have reported a higher recurrence rate in patients with histologically negative lymph nodes when a polymerase chain reaction assay of the lymph nodes was strongly positive for HPV DNA.[127,128] Other authors have correlated poor prognosis with the presence of HPV mRNS[128] or HPV-related proteins[129] in the peripheral blood of cervical cancer patients.

Patient-related factors have been discussed in different sections of this chapter and include age, hemoglobin, platelet counts, race, and smoking.[130] Several studies have demonstrated that in the United States, women of color with invasive cervical cancer present with higher-stage disease[131–133] and lower hemoglobin levels[134,135] than white women. Differences in socioeconomic status may influence minority patients' access to care and ability to comply with treatment recommendations.[135] In a study of 1304 women treated with radiation for cervical cancer, Kucera and colleagues[130] reported that smokers with cervical cancer had a poorer 5-year survival rate than nonsmokers. This difference was statistically significant for patients with stage III disease (5-year survival 20.3% vs. 33.9%, $P < 0.01$). However, in their analysis, the authors did not analyze the possible influence of smoking-related deaths from causes other than cervical cancer.

TREATMENT OVERVIEW

The treatment of patients with cervical cancer is determined primarily by the stage and extent of disease. As a general rule, CIS and microinvasive cervical cancer with no more than 3 mm of stromal invasion and no more than 7 mm breadth (FIGO stage Ia1) are managed with conservative surgery (excisional conization or extrafascial/simple hysterectomy). Microinvasive cervical cancer with 3 to 5 mm of stromal invasion and no more than 7 mm breadth (FIGO stage Ia2) may be managed with modified radical hysterectomy. Stages Ib1 and small-volume IIa may be managed with either radical surgery (generally radical hysterectomy or modified radical hysterectomy), radiation alone, or chemoradiation. Controversies surround the optimal management of patients with bulky stage Ib2 (>4 cm) cancer, who may be treated with triple-modality therapy in selected instances (surgery, radiation, chemotherapy in a variety of possible sequences).

After initial radical surgical therapy, patients with adverse histopathologic factors may be advised to undergo adjuvant pelvic radiation or adjuvant chemoradiation. Risk factors for recurrence include metastatic disease in regional nodes, positive surgical margins, parametrial extension, deep cervical stromal invasion, lymphovascular space invasion, and large tumor size.

Patients with large FIGO stage IIa or with stages IIb through IVa usually are managed with chemoradiation. Some patients with an incomplete response to chemoradiation may benefit from a combined approach using adjunctive hysterectomy to clear persistent central disease after chemoradiation. Patients with bulky Ib2 or IIa disease and rare patients with bulky central stage IIb lesions with minimal, medial parametrial invasion may be considered for this approach. For patients in whom disease recurs centrally in the pelvis after maximal chemoradiation, radical exenterative surgery can be performed, provided that no distant disease is present. Optimal candidates have mobile central disease without lymph node involvement.[136–138] Intraoperative radiation therapy (IORT) may be part of salvage surgery when lateral or posterior surgical margins will be predictably inadequate.[139,140] Recurrent disease after initial radical surgery historically has been treated with salvage radiation, but currently should be treated with chemoradiation.[141]

Superficial Ablative Therapy

A major deficiency of all ablative therapies is the absence of full histopathologic assessment of the lesion treated, and the hazard of undertreatment of an occult invasive lesion. For this reason, use of ablative techniques is declining appropriately. Three superficial ablative techniques used historically are electrocoagulation diathermy, cryosurgery, and CO_2 laser therapy.

Hysterectomy

Hysterectomy involves the removal of the uterus and varying amounts of surrounding tissue (Fig. 91-12). Because the risk of ovarian metastases is low (0.5%), ovarian preservation usually is recommended in premenopausal women, obviating the need for hormone replacement therapy.[142] An important exception is when nodal metastases from a primary cervical adenocarcinoma are detected intraoperatively, when the risk of ovarian metastasis escalates steeply, perhaps to as high as 25%.[143] Five types of hysterectomy have been described.[144]

Extrafascial or Simple Hysterectomy (Type I)

Extrafascial or *simple hysterectomy* involves the removal of the cervix, adjacent tissues, and a small cuff of the upper vagina in a plane outside the pubocervical fascia; it is appropriate treatment for stage Ia1 disease. Minimal disturbance occurs to the bladder and ureters, which decreases the risk of urinary complications.

Modified Radical Hysterectomy (Type II)

Modified radical or *Wertheim's hysterectomy*, less extensive than the radical hysterectomy, removes the cervix and proximal 1 to 2 cm of vagina, including the paracervical and parametrial tissues. The ureters are dissected to the point of entry to the bladder to allow safe removal of parametrial and paracervical tissue. The medial half of the cardinal ligaments and the uterosacral ligaments also are removed.

Radical Hysterectomy (Type III)

A *radical* (*Meigs'*) *hysterectomy* includes removal of the uterus, cervix, and paracervical, parametrial, and paravaginal tissues to the pelvic sidewalls bilaterally in continuity, with as much of the uterosacral ligaments as possible. The uterine vessels are ligated at their origin, and the proximal one fourth to one third of the vagina and paracolpos is resected. This operation usually is performed in conjunction with bilateral therapeutic pelvic lymphadenectomies. Acute complications include blood loss (average, 800 mL), ureterovaginal fistula (1% to 2%), vesicovaginal fistula (<1%), pulmonary embolus (1% to 2%), small bowel obstruction (1%), and febrile morbidity (25% to 50%). Subacute complications include transient bladder dysfunction lasting 1 to 7 weeks (30%) and lymphocyst formation (<5%). Chronic complications include bladder hypotonia and atonia in about 3% of patients and, uncommonly, ureteral strictures. Rare patients may have transient or permanent lower extremity lymphedema.

Extended Radical Hysterectomy (Type IV)

In addition to the tissue removed in the type III, *extended radical hysterectomy* removes the periureteral tissue, the superior vesicle artery, and up to three fourths of the vagina. This procedure is rarely done, because patients with the anatomic extent of disease that would warrant such treatment generally should be treated with chemoradiation.

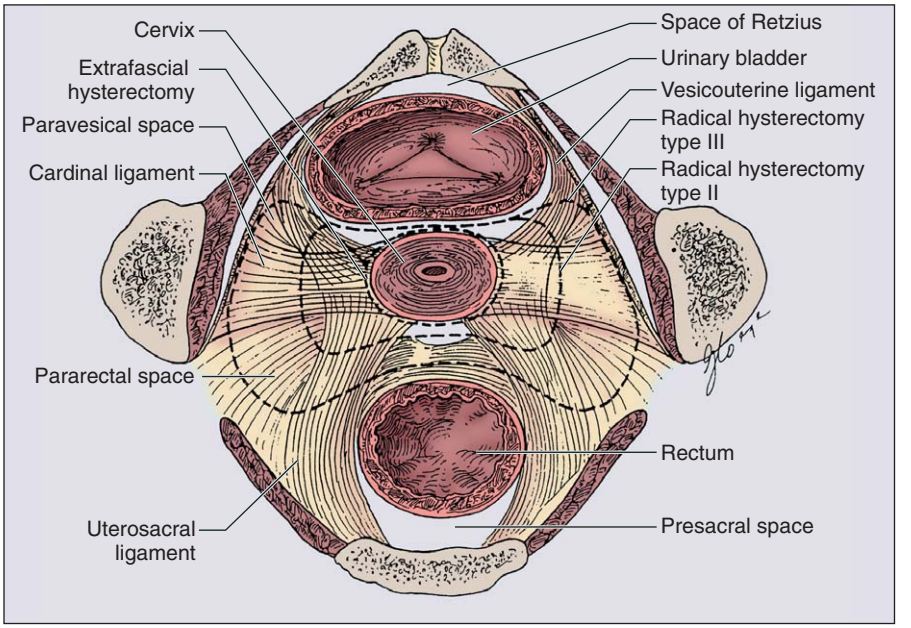

Figure 91-12 • Diagram of pelvic anatomy and types of hysterectomy. (From Berek JS, Hacker NF: Practical Gynecologic Oncology, 2nd ed. Baltimore, Williams & Wilkins, 1994.)

Partial Exenteration (Type V)

Partial exenteration is rarely performed, because radiation therapy should be used for patients with the extent of disease that would require surgery of this extent for gross anatomic clearance. Parts of the distal ureters and bladder are resected in this procedure. This may be appropriate initial surgery for patients with FIGO stage IVa cancer with large vesicovaginal fistulae and incontinence. However, vesicovaginal fistulae may scar closed in some patients after high-dose radiation therapy if the upper vagina is permitted to fuse shut, thus restoring urinary continence.

Surgical Alternatives to Conventional Radical Abdominal Hysterectomy

The late 1980s and the 1990s witnessed a proliferation of surgical techniques consequent to the availability of the sophisticated instruments and optical equipment required for laparoscopic surgery, a resurgence of interest in vaginal hysterectomy, and concerns about preserving reproductive potential in young women with early cervical cancer.

Radical vaginal hysterectomy carried out by the methods of Schauta-Stoeckel (less radical) or Schauta-Amreich (more radical) is a surgical alternative to radical or modified radical abdominal hysterectomy (types II and III) that may be associated with shorter hospital stays and more rapid recuperation. Laparoscopic radical hysterectomy performs an operation comparable to a radical hysterectomy (type III hysterectomy) entirely through the laparoscope, including the vaginal closure.

Laparoscopy has been coordinated with vaginal hysterectomy, with varying amounts of surgery being carried out via the laparoscopic approach, ranging from pelvic and para-aortic lymphadenectomy to lymphadenectomy plus important components of the radical hysterectomy.[145–147]

Radical cervicectomy is an operation suitable for selected patients with small, generally exophytic squamous tumors (usually <2 cm, although some patients with larger tumors have been treated in this fashion) involving primarily the exocervix who desire conservation of reproductive capacity. In this surgery, the main trunk of the uterine artery is preserved, although branches to the cervix and vaginal fornices are sacrificed before amputation of the cervix at a point approximately 5 mm caudal to the uterine isthmus. The uterus is suspended from the lateral stumps of the transected paracervical ligaments. Isthmic cerclage is performed in a fashion similar to that used as prophylaxis against miscarriage, and an anastomosis between the vaginal mucosa and the isthmic mucosa is performed. Variations on this surgery can be performed vaginally with laparoscopy, or abdominally. The margin between the superior extent of the tumor and the uterine isthmus must be a minimum of 1.5 cm, but 2 cm is preferable. MRI can be used preoperatively to assist in patient selection for this procedure. Intraoperative assessment by inspection of the trachelectomy specimen and frozen-section pathologic study are done to ensure an adequate surgical margin, and patients must be prepared for hysterectomy in the eventuality that a satisfactory margin cannot be obtained. Numerous successful pregnancies have been reported after such surgery, although the risk of miscarriage is increased. In carefully selected patients, the risk of cancer recurrence is very small.[148–150]

Damage to the pelvic autonomic nerves during radical hysterectomy is responsible for much of the late morbidity after surgical treatment of FIGO stages Ia2 to IIa cervical cancer, including problems with bladder function, defecation, and sexual dysfunction. Nerve-sparing radical abdominal hysterectomy[151] endeavors to spare important components of the autonomic innervation of the true pelvis by identification and preservation of the hypogastric nerves, which carry sympathetic fibers; the inferior hypogastric plexus formed from the fusion of the hypogastric nerves with fibers of the pelvic splanchnic nerves derived from sacral roots S2 to S4, which carry parasympathetic fibers; and the most distal part of the hypogastric plexus, which extends to the lateral vaginal wall and the base of the bladder. In aggregate, these structures are important in controlling bladder compliance, urinary continence, vaginal lubrication and genital engorgement during sexual arousal, small muscle contractions with orgasm, and some rectal functions. This recent surgical innovation is intended not to compromise the efficacy of the cancer surgery, while preserving important components of quality of life in cancer survivors. Precise criteria for patient selection have not been defined.

Radiation Therapy

Radiation therapy for cervical cancer usually consists of a combination of external radiation (teletherapy) and intracavitary or interstitial radioisotope therapy (brachytherapy). Roentgen discovered r-rays in 1895. Radium was discovered by the Curies in 1898. Biologic effects of so-called "Roentgen rays" on skin soon were appreciated after

prolonged exposures had occurred. Serendipitous discovery of the acute biologic effect of exposure to radium came when the discoverer of radioactivity, Becquerel, carried a 200-mg sample in his vest pocket for 6 hours and experienced an ulcerating burn as a result.

Roentgen rays were first applied to the cervix in 1901 using a transvaginal cone. Intracavitary brachytherapy for cervical cancer with radium first was described around 1902. Interstitial brachytherapy with radium was first proposed by Alexander Graham Bell in 1903. In the past 100 years, the discipline of radiation oncology has evolved as a medical specialty because of continuous refinements in medical radiation dosimetry, increasing sophistication of equipment, and progress in understanding the biologic consequences of radiation exposure in both cancer and normal tissues and cell lines (radiobiology).

Patients with very-small-volume cervical tumors of stages Ia1 to Ib1 (Ib1, <1 cm in diameter) can be treated successfully with intracavitary brachytherapy alone, with results that parallel the efficacy of surgery.[152] Brachytherapy alone, particularly if conducted on an outpatient basis with high-dose-rate (HDR) technology, may serve as suitable alternative therapy for medically compromised patients for whom operative intervention implies more than minimal risk of intraoperative or perioperative morbidity. At the other end of the spectrum of invasive disease, patients with very extensive stage III or IVa cervical cancer may not have geometry compatible with brachytherapy, and cure sometimes may be accomplished with teletherapy administered alone (or, more commonly, in combination with chemotherapy) by using progressively smaller teletherapy treatment volumes carried to progressively higher cumulative radiation dose ("shrinking fields technique"). However, radiation-based therapy with curative intent is accomplished for most patients with a combination of external beam (teletherapy) and intracavitary or interstitial isotope therapy (brachytherapy).

Conventional teletherapy is given in a fractionated course by using daily doses of 1.8 to 2 Gy per fraction, five fractions weekly. Selected patients may benefit from twice-daily fractionation by using a "field within a field" concurrent boost to limited volumes of nodal or parametrial disease. Altered fractionation may serve to keep the overall duration of treatment as short as possible, which has been correlated with improved local control and survival. It should be emphasized that target volumes and teletherapy dose distributions are not standardized and should be based on pretreatment imaging studies that define disease extent rather than on FIGO stage. Depending on the presence or absence of nodal metastases and the anatomic level of nodal disease, teletherapy ports may encompass only nodes caudal to the bifurcations of the common iliac arteries (approximately at the interspace between the fifth lumbar vertebra and the first sacral segment), nodes to the level of the aortic bifurcation (approximately at the level of the third lumbar vertebra), or to a volume extending to encompass para-aortic nodes to the level of the cisterna chyli (approximately at the level of the 12th thoracic vertebra). Treatment of such widely differing volumes, particularly when done with synchronous chemotherapy, implies substantial variability in acute symptomatic tolerance, hematologic tolerance, and potential delayed sequelae of treatment. Routine treatment of standard volumes is not a substitute for appropriate diagnostic assessment of disease extent and treatment tailored in consideration of both tumor and patient factors.

The brachytherapy dose conventionally has been calculated and prescribed at points A and B (Fig. 91-13). Doses to the bladder neck and anterior rectal wall (dose-limiting normal structures) usually are specified as well (Fig. 91-14).[153] Brachytherapy usually is accomplished by using one or two intracavitary or interstitial inpatient applications LDR (40 to 60 cGy/hr) technologies. Most applicators for intracavitary brachytherapy resemble the apparatus in Figure 91-15, and consist of intrauterine tandem and paired colpostats or ovoids, which are placed in the lateral vaginal fornices, resulting in a classic pear-shaped isodose distribution. The customary strategy is intracavitary brachytherapy supplemented by tailored teletherapy

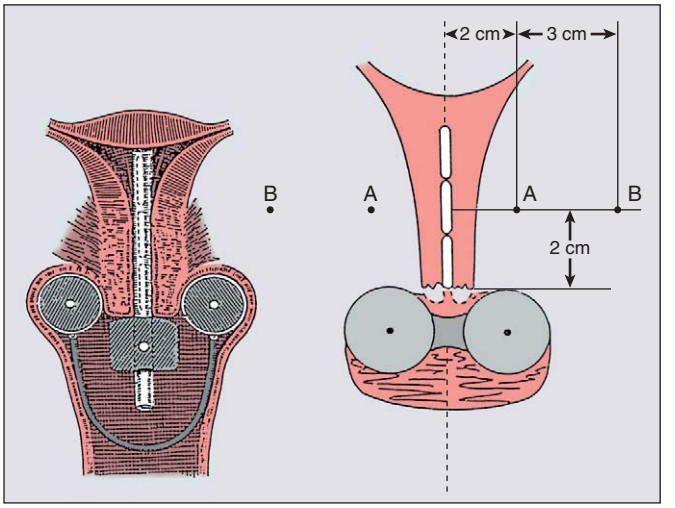

Figure 91-13 • Points A and B for cervical radiation therapy. (From Hoskins WJ, Perez CA, Young RC [eds]: Principles and Practice of Gynecologic Oncology, 2nd ed. Philadelphia, Lippincott, 1997, p 678.)

treatment to boost volumes, generally lateral and posterior to the cervix and medial parametria. In patients whose vaginal anatomy does not accommodate tandem and colpostat devices (a so-called "conical vagina" with flush or ablated fornices and a narrowed upper vagina) or patients with extensive, lateral parametrial invasion, interstitial implantation may provide more satisfactory dose distribution when gross tumor extends beyond the traditional pear-shaped dose envelope provided by intracavitary brachytherapy (Fig. 91-16). Interstitial templates have been used to treat cervical cancer for many years; however, reported series have been small, and patient follow-up rarely has been sufficient to permit calculation of long-term survival rates.[154–156] One of the largest series is from University of California—Irvine, where they described 5-year survival rates of 21% and 29%, respectively, for patients with stage IIB and IIIB disease with high complication rates.[157] (Therefore, at present, there is no definite evidence to indicate that interstitial therapy improves the outcome of patients with advanced intact cervical lesions.)

LDR brachytherapy procedures require insertion under anesthesia and hospitalization for radiation safety and patient immobilization. Alternatively, multiple outpatient intracavitary insertions may be per-

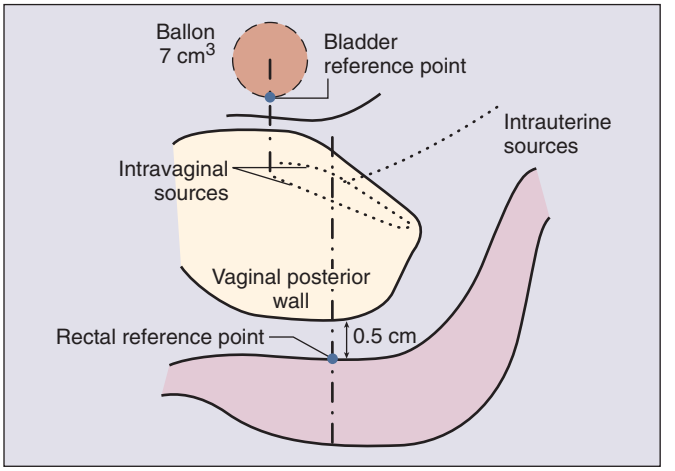

Figure 91-14 • Rectal and bladder reference points according to the International Commission on Radiation Units and Measurements Report 38. (From Cox JD [ed]: Radiation Oncology, 8th ed. St. Louis, Mosby, 2003, Fig. 28-16.)

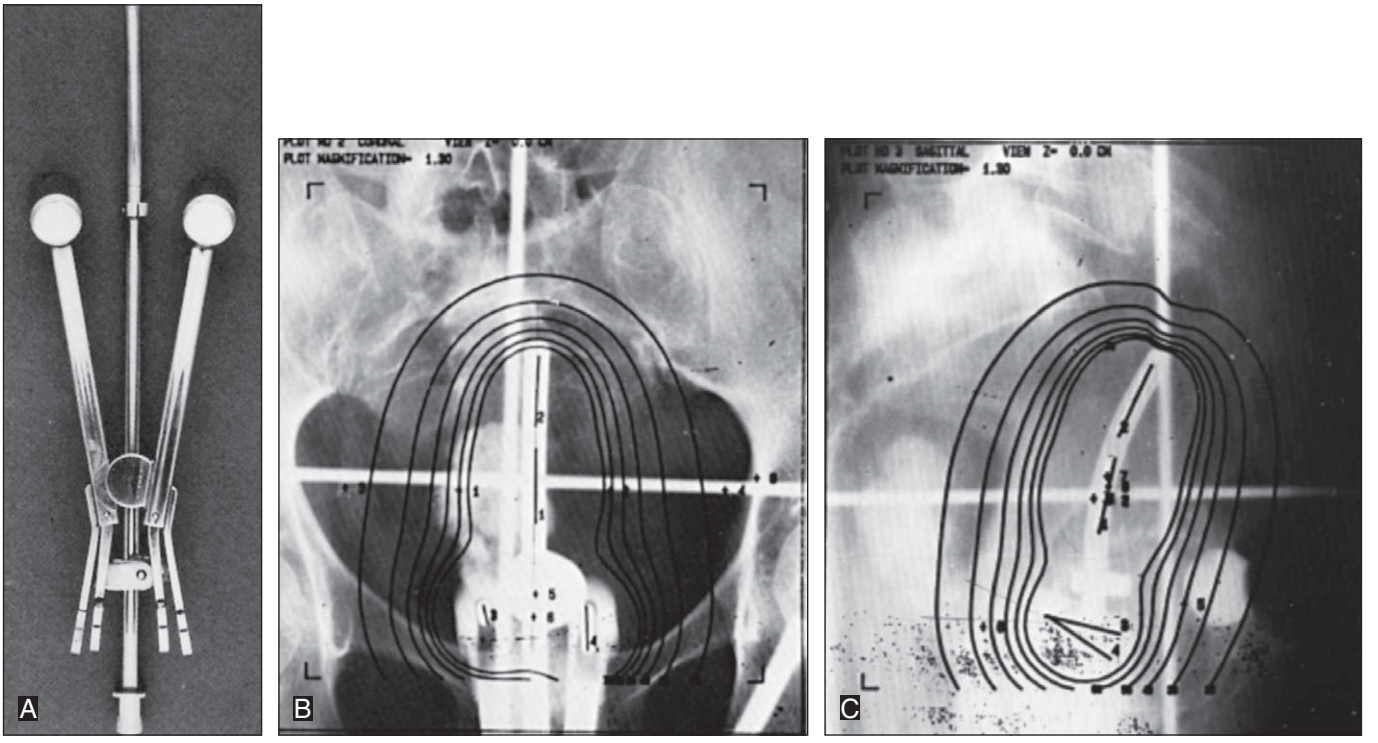

Figure 91-15 • **A,** Intracavitary device for brachytherapy. **B** and **C,** Treatment plan for cervical carcinoma showing a radiograph of the intracavitary irradiation in situ with its isodose distribution in cGy/hr. formed by using HDR (100 cGy/min) remote afterloading technology. Most commonly, five intracavitary insertions are performed when HDR technology is used. Because of miniaturization of the high-activity source and the hardware used for treatment, these insertions may be accomplished under conscious sedation when cooperative patients with favorable vaginal anatomy are selected. Because of inherent biologic disadvantages associated with HDR brachytherapy, substitution of this technology for conventional LDR systems has been controversial. More tailored dose distributions often can be designed with the inherently more flexible HDR systems than with historically used LDR equipment employing multiple sources with fixed physical dimensions and a limited spectrum of source strengths. The comparative data that exist suggest that HDR and LDR technologies are approximately isoeffective for tumor control and roughly equivalent with respect to complications when appropriate dose-rate corrections have been applied.[158,159]

It seems increasingly clear that either approach (LDR or HDR) in the hands of seasoned physicians with substantial brachytherapy experience is likely to be superior to the other approach in the hands of the clinician who is inexperienced or treats only a limited number of patients. Brachytherapy often has been defined as an art and not a science. The American Brachytherapy Society is attempting to place brachytherapy on a more rational, scientific basis by developing guidelines grounded in established practice and data driven to replace what has often been based on subjective criteria and intuition coupled with the hard lessons of experience.[160,161] Improvements in diagnostic

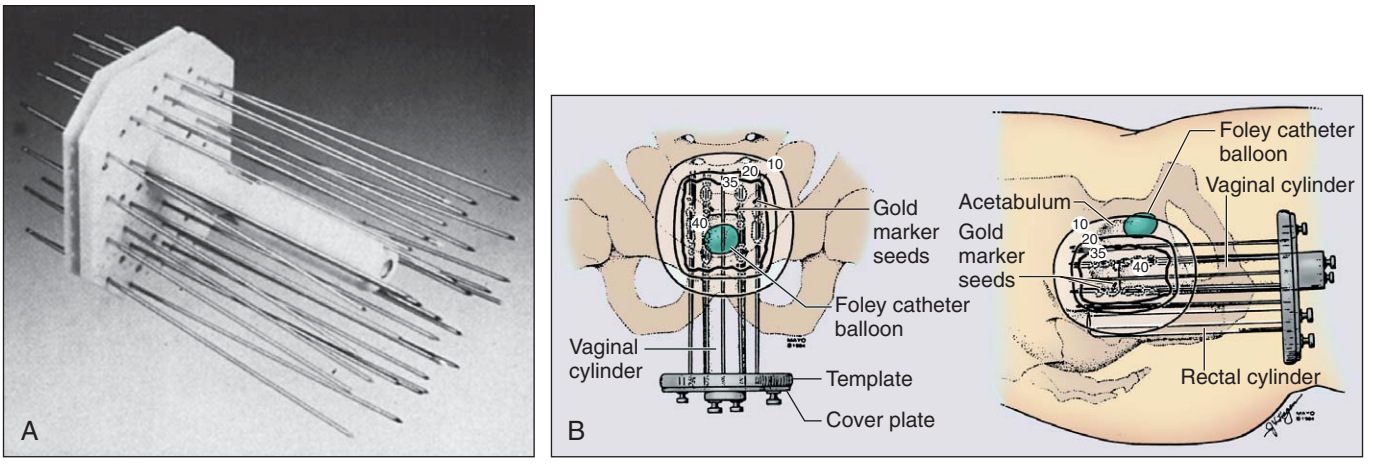

Figure 91-16 • **A,** Device for interstitial brachytherapy. **B,** Diagrams of the same device in coronal and sagittal planes. (From Hoskins WJ, Perez CA, Young RC [eds]: Principles and Practice of Gynecologic Oncology, 2nd ed. Philadelphia, Lippincott, 1997, p 678.)

imaging (MRI, CT, PET, and combination, hybrid, or fusion studies) are anticipated to facilitate these efforts by providing improved understanding of the spatial relations of brachytherapy sources and both cancer and dose-limiting normal tissues. This effort, however, remains a work in progress.

In its definition as partially art rather than pure science, brachytherapy is similar to surgery. Skills atrophy unless used regularly. Understanding that fact should stimulate consideration of referral of patients requiring brachytherapy to centers of excellence where the annual volume provides greater assurance that the requisite skills and experience will be available.

The side effects of radiation therapy include both immediate and late effects. Acute reactions of radiation are seen in tissues with the most rapid cell turnover rates such as skin, intestinal mucosa, urothelium, vaginal mucosa, and bone marrow. Acute side effects of pelvic irradiation include diarrhea, abdominal cramps, tenesmus, urinary frequency, urgency, and dysuria. Some women experience vaginal bacterial overgrowth consequent to alterations in the integrity of the vaginal mucosa, causing symptoms of discharge and pruritus. Occasionally small-volume bleeding from the bladder or rectum may occur. Aggravation of hemorrhoidal disease is common. Older patients with extensive diverticular disease are vulnerable to development of diverticulitis under the influence of pelvic radiotherapy, which may result in pain, bleeding, perforation, and significant delay in completion of treatment. Rare patients experience bacterial overgrowth with *Clostridium difficile*, even in the absence of antecedent antibiotic exposure. Severe, prolonged diarrhea poorly responsive to standard medications and dietary modification should arouse the clinician's suspicion. Not uncommonly, pelvic radiation will provoke a recrudescence of herpes simplex virus type II, usually manifest as focal, discrete, well-marginated ulcerations on the labia caudal to the irradiated volume, although lesions may affect the urethra, bladder, and vagina. It is important for the radiation oncologist to recognize the labial lesions, the pattern of which tends to be discrete ulcerations, usually quite different from the more confluent, irregularly bordered, moist desquamative reaction seen with acute radiation dermatitis, because treatment for these conditions is quite different.

Late complications (onset months to years after radiation therapy) can be due to intimal proliferation in small arteries/arterioles with decreased blood supply and subsequent fibrosis or focal infarction. The larger the dose per treatment fraction, the greater the risk of late complications in normal tissues unavoidably included within the treatment volume. Most late complications of radiation therapy involve the rectum, bladder or small bowel. Although most serious gastrointestinal complications occur with the first 3 years, serious side effects also may occur several decades after treatment. The average time to onset of major urinary tract complications tends to be somewhat longer than that of intestinal complications. Late effects of pelvic irradiation may include chronic radiation cystitis with urothelial atrophy, irritative symptoms, and bleeding. In rare patients, vesicovaginal fistulae may develop, usually at the level of the bladder neck, where the brachytherapy dose often is highest. Vaginal stenosis with dyspareunia and compromised ability to perform surveillance follow-up is a somewhat avoidable consequence of radiation therapy if informed and compliant patients are provided with vaginal dilators and instructed in their use, as well as provided with vaginal estrogen cream. Chronic radiation proctitis or sigmoiditis with pain and small-volume bleeding can occur in some patients, with focal injury to the anterior rectal wall consequent to brachytherapy being the most common site for this late complication. Major hemorrhage is unlikely, except in patients with portal hypertension or therapeutic anticoagulation for medical comorbidities. Distressing bleeding often can be controlled through conservative, judicious laser ablation of bleeding telangiectatic vessels. Symptomatic large bowel stricture is uncommon, but may require fecal diversion in severe instances. Rectovaginal fistulae may be the consequence of severe injury to the rectovaginal septum and anterior rectal wall. This complication usually requires permanent fecal diversion, but occasional patients can have segmental resection with re-establishment of intestinal continuity. Most intestinal injury is to small intestine, commonly manifested by obstructive symptoms. The usual site is in the terminal ileum, but focal jejunal injury may be seen, particularly in patients undergoing extended-field treatment to encompass para-aortic lymph nodes. If the ovaries are in the treatment field, ablation of both endocrine and reproductive function will be the inevitable consequence of pelvic radiation therapy administered in cancerocidal dose to premenopausal women. Symptoms of estrogen deprivation may take several months to develop after pelvic radiation, depending on the age of the patient and endogenous body stores of estrogen. Usually the endometrium is ablated consequent to high mucosal dose from intracavitary brachytherapy. Occasional patients will have remnants of functioning endometrium. With the almost inevitable occlusion of the endocervical canal after brachytherapy, painful hematometra may develop in such patients if unopposed estrogen replacement therapy or cyclical hormone replacement is instituted. Generally, combined hormone replacement therapy will avoid this complication, which may necessitate hysterectomy in severe cases.

Chemoradiation

Synchronous administration of radiation and cytotoxic chemotherapy will enhance acute radiation reactions within all tissues included in the treatment volume, resulting in more severe acute symptoms. Impact on chronic radiation injuries is less predictable. Anxiety regarding normal tissue tolerance, both immediate and late, has delayed extrapolation of successful chemoradiation strategies for anal cancer to the larger volumes of vulnerable tissues routinely irradiated in the treatment of cervical cancer.

Multiple clinical trials have investigated the sequential use of neoadjuvant chemotherapy followed by conventional radical radiation therapy for patients.[162–165] In several of these studies, patients treated with neoadjuvant chemotherapy followed by radiation had worse survival probability than did patients treated with radiation alone. This has been attributed to selection of cross-resistant tumor clonogens as well as delay in initiation of the potentially curative therapy.

In dramatic contrast to the manifest failure of sequential chemotherapy and radiation, the large majority of recent prospective, randomized controlled trials investigating radiation and synchronous chemotherapy have demonstrated improvements in both local control and survival. Data from five phase III randomized clinical trials sponsored by the National Cancer Institute have shown that the addition of concurrent cisplatin-containing chemotherapy to radiation results in a reduction in risk of recurrence by 21%.[102,166–169] Four of these trials pertained to women with locally advanced cervical cancer, stages Ib2 to IVa. The fifth studied high-risk postoperative patients stages Ib to IIa with cancer extension to parametrium, surgical margins, or regional lymph nodes.

The optimal drug regimen is uncertain. Four of these trials had an experimental arm containing 5-fluorouracil (5-FU); however, the Gynecologic Oncology Group (GOG) prospectively compared weekly cisplatin with continuous-infusion 5-FU at 225 mg/m^2 for 5 days weekly (a lower daily dose than the 1000 mg/m^2/24 hr for 96 hours used in the previous positive studies) and terminated the study (GOG protocol 165) when it became clear that no possibility existed that the 5-FU arm might ultimately prove superior. Weekly cisplatin at a dose of 40 mg/m^2 for six doses has become the most commonly used regimen for concurrent chemotherapy with radiation for advanced cervical cancer.

However, the National Cancer Institute of Canada (NCIC) prospectively compared radiation alone with radiation plus weekly cisplatin in 259 patients with squamous cancers with bulky (≥5 cm) stage Ib2 to IIa, or smaller tumors with positive nodes, and patients with stages IIb to IVa cancers. The study was designed to have an 80% probability of detecting a 15% survival difference at 5 years.

Although patients receiving the cisplatin regimen did marginally better, the study failed to find a statistically significant difference.[170]

The Radiation Therapy Oncology Group (RTOG) prospectively compared radiation alone administered to extended volumes (pelvis plus para-aortic nodes) with pelvic radiation with three synchronous cycles of 5-FU and cisplatin, with one cycle administered synchronously with intracavitary brachytherapy. 5-FU was administered at 1000 mg/m^2/24 hr for 96 hours with each cycle, and cisplatin at 75 mg/m^2. The population of 403 patients composing the study population were identified and selected with entry criteria similar to those of the NCIC study (except that nonsquamous cancers were included). The relative risk of recurrence was 0.48 (90% confidence interval) in the chemoradiation arm compared with radiation alone.[171]

Further complicating this issue are the three additional prospective, randomized studies that have found relapse-free survival benefit from the synchronous administration of epirubicin with radiation,[171] mitomycin-C with radiation,[172] or 5-FU plus mitomycin-C with radiation,[173] and a fourth prospective randomized trial that failed to detect benefit from synchronous administration of cisplatin, vincristine, and bleomycin with radiation compared with radiation alone.[174]

Most studies have demonstrated that the use of combined chemotherapy and radiation therapy has been associated with statistically significant increase in gastrointestinal and hematologic toxicity that, although significant, has been tolerable. Data suggest that synchronous administration of chemotherapy potentiates radiation effect in cycling, immediately responding cell systems, in both cancer and normal tissue. Thus both immediate normal tissue reactions and side effects are potentiated. Importantly, an increase in catastrophic late complications such as bowel obstruction, fistula formation, or second malignancies, has not been seen. Given the preponderance of evidence, which now suggests that synchronous radiation with radiopotentiating chemotherapy favorably affects probability of cancer-free survival, clinical research into the optimal drugs and schedule of administration is likely to play a central role in clinical investigation for the foreseeable future.

TREATMENT OF LOCOREGIONAL DISEASE BY STAGE

Stage Ia1 and Ia2 (Microinvasion)

The purpose of defining microinvasion is to identify a group of patients who are not at risk for lymph node involvement and therefore are treatable with conservative therapy. In the current staging classification, stage Ia1 is defined as a tumor with stromal invasion no greater than 3 mm in depth beneath the basement membrane and no wider than 7 mm. Stage Ia2 is defined as a tumor with stromal invasion greater than 3 mm, no greater than 5 mm in depth, and no wider than 7 mm. Patients at highest risk for metastases or recurrence in this group appear to be those with evidence of tumor in the lymphovascular spaces.[106,175]

Patients with stage Ia1 disease can be adequately treated with therapeutic conization if conservation of reproductive capacity is desired, or extrafascial hysterectomy. The risk of pelvic lymph node metastases with 1 to 3 mm of stromal invasion is less than 1%.[176,177] For patients opting for therapeutic conization, the following histopathologic criteria should be met: (1) depth of stromal invasion 3 mm or less, (2) diameter of lesions less than 7 mm, (3) no lymphovascular invasion, and (4) clear margins. Patients treated with conization should be followed up closely with cytologic, colposcopic, and endocervical curettage evaluation every 3 months for the first year.[178] A vaginal or a type I abdominal hysterectomy (extrafascial) is appropriate treatment if future childbearing is not desired.

Microinvasive carcinoma with stromal invasion 3.1 to 5 mm is associated with a 5% risk of nodal metastases.[179] The preferred treatment for stage Ia2 is a modified radical (type II) hysterectomy with bilateral pelvic lymphadenectomy. Treatment with radiation also will have a high probability of success and may be preferable therapy in patients who are compromised surgical candidates based on age and comorbidities.

Stage Ib1, Ib2, and IIa

Stage Ib is defined as a clinically evident lesion confined to the cervix or preclinical lesions greater than those of Ia2. Patients with IIa disease have extension to the upper vagina without parametrial involvement. The incidence of pelvic nodal metastases is approximately 15% to 25% for patients with stage Ib disease.[179] Treatment must be directed toward the lymph nodes, cervix, parametrial tissue, paravaginal tissue, and upper vagina; therefore, a radical (type III) hysterectomy with bilateral pelvic lymphadenectomy and para-aortic lymph node evaluation has historically been the treatment of choice. Radiation therapy is as effective as surgery based on a prospective, randomized comparison conducted in Italy.[180] In that study, 337 analyzed patients (FIGO Ib1, Ib2, and IIa) were randomly assigned treatment with initial type III hysterectomy or with radiation therapy using a radiation dose (cumulative teletherapy and brachytherapy dose of 76 Gy at point A) that is substantially lower than the 85 to 90 Gy used in leading centers in the United States. Postoperative pelvic radiation therapy was administered to patients with positive nodes, positive margins, positive parametria, or less than 3 mm surgical margin. Forty-six of 55 patients (84%) with tumors larger than 4 cm in diameter received postoperative radiation therapy. Chemotherapy was not used. Five-year survival and disease-free survival were identical in both groups (83% and 74%, respectively). Serious complications occurred in 28% of the group treated initially with surgery, and 12% of the radiation therapy group. Theoretically, results with chemoradiation might well be superior to those with surgery, but the benefit for synchronous administration of chemotherapy has been documented only in patients with tumors larger than 4 cm (Ib2) or more advanced stages of disease.

Given that surgery and radiation therapy are approximately isoeffective with respect to cancer control, treatment generally is selected on the basis of physician and patient preference and differences in treatment-related morbidity. Surgery provides important prognostic information and offers premenopausal women the option of ovarian conservation, because the risk of ovarian metastases is only 0.5%.[142] Considerable debate concerns whether sexual function is more feasible or better after surgical treatment or radiation therapy. Both forms of treatment carry some risk of urologic injury or bowel injury. However, the nature of those complications, the ability to remedy those complications, and the impact of chronic complications on quality of life are both challenging to quantitate and vulnerable to quite subjective interpretation. Radiation carries a small but not trivial risk of late induction of second malignancies.

For patients with stage Ib1 who are young and free of major comorbid conditions, surgery tends to be the preferred option. In patients who are poor surgical risks or elderly, radiation therapy is more sensible. Radiation therapy usually is a combination of teletherapy intended to encompass the primary, microscopic regional extensions, and regional lymph nodes, supplemented by intracavitary brachytherapy intended selectively to take the gross disease in the uterus and cervix to a much higher dose while sparing normal tissues including bladder and rectum. When disease is very small (<1 cm in diameter), the risk of nodal metastases is low, and the treatment approach may be modified to intracavitary brachytherapy therapy alone with excellent results.[152]

The treatment of patients with stage Ib2 disease remains a source of continued controversy. With either surgery or radiation therapy, progressive decrements in survival probability are found as tumor size increases. In some centers, patients with stage Ib2 disease continue to undergo initial surgery, recognizing that most will have indications for postoperative radiation therapy, but that surgery will clear gross central disease, which is the most likely site of pelvic failure in

patients treated with radiation. Because the morbidity of combined therapy is greater, some surgeons limit the radicality of surgical extirpation in anticipation of postoperative radiation therapy in a sensible effort to limit morbidity.[181] Neoadjuvant chemotherapy with cisplatin, vincristine, and bleomycin for three cycles at 10-day intervals before attempted radical hysterectomy has been used with encouraging results in Ib2 cancers reported by Sardi and colleagues in Argentina.[182] Pathologic downstaging was observed in patients operated on after neoadjuvant chemotherapy compared with patients undergoing initial surgery. These results have not been reproduced in the context of a multi-institutional trial, when tested by the GOG.

Alternatively, radiation has been used as initial therapy supplemented by type I adjuvant hysterectomy to clear central disease. The GOG compared radical radiation therapy with attenuated preoperative radiation therapy supplemented by extrafascial hysterectomy.[183] A lower cumulative incidence of local relapse was noted in the radiation therapy plus hysterectomy group (at 5 years, 27% vs. 14%). No statistical differences were observed in outcomes between regimens, except for the adjusted comparison of progression-free survival, although all indicated a slightly lower risk in the adjuvant hysterectomy regimen (unadjusted relative risk [URR] of progression, 0.77; $P = 0.07$; URR of death, $P = 0.26$; both one-tailed). Because preliminary analysis of this trial suggested benefit from surgery in improved local control, the GOG carried out a successor trial in which all patients had attenuated preoperative radiation therapy, followed by extrafascial hysterectomy. Half of the patients were randomized to receive weekly cisplatin at 40 mg/m^2 during teletherapy. The rates of both progression-free survival ($P < 0.001$) and overall survival ($P = 0.008$) were significantly higher in the combined-therapy (chemoradiation) group at 4 years.[166]

Although interpretations of the outcomes of these studies vary, it has become less common to carry out adjunctive hysterectomy routinely in patients undergoing chemoradiation for Ib2 or bulky IIa disease. However, selected patients may benefit who have poor response to teletherapy and chemotherapy assessed at the time of intracavitary insertion, or who have poor vaginal anatomy, limiting the dose of brachytherapy that can be prudently prescribed.

Patients undergoing primary surgery for stage Ib and IIa cancer who are found to have adverse clinicopathologic prognostic factors may be advised to undergo adjuvant postoperative pelvic radiation therapy or adjuvant chemoradiation. Much effort has been expended in attempting to define clinicopathologic factors that reliably identify patients at high risk for failure after initial surgical therapy. Primary tumor size, depth of cervical invasion, and lymph-vascular space invasion (LVSI) are thought to be independent prognostic factors in node-negative patients with surgically treated Ib squamous carcinoma of the cervix.[106] Parametrial extension[184] and parametrial node metastasis,[185] independent of retroperitoneal lymph node status,[102] predict an increased risk of recurrence in surgically treated patients. Positive or insecure margins including vaginal margins,[186] extension of cancer to the lower uterine segment,[187,188] and adverse histopathology[37] are additional parameters that may correlate with a more ominous outlook. Controversies persist concerning the relative importance of some of these factors in multivariant analysis. However, with consensus approaching unanimity, metastasis to pelvic lymph nodes is recognized as a dominant prognostic indicator.[189]

Two cooperative NCI-sponsored intergroup studies have been carried out prospectively evaluating adjuvant therapy for patients with adverse histopathologic features after radical hysterectomy. Sedlis[190] reported on 277 "intermediate risk" node-negative patients who were identified based on combinations of tumor size, depth of cervical stromal invasion, and lymphatic space invasion. Based on historic outcomes, these patients were estimated to have an approximate 25% to 27% probability of recurrence after surgery, with the pelvis being the most probable site of relapse. Patients were randomized to observation versus adjuvant pelvic teletherapy. In recent update of this series by Rotman[121] there was a 46% reduction in the risk of recurrence ($P = 0.007$) and a significant improvement in recurrence or death (HR = 0.58) when postoperative pelvic irradiation was given. Although there was a 30% reduction in the risk of death for patients who received radiation therapy, this difference was not statistically significant ($P = 0.07$).

Peters[107] reported on 243 analyzable "high-risk" patients who had positive nodes, parametrial extension, or positive surgical margins. After radical hysterectomy, these patients were randomized to receive adjuvant pelvic radiation therapy, or the same adjuvant radiation regimen with two cycles of synchronous 5-FU and cisplatin followed by two further cycles of sequential 5-FU and cisplatin. Cisplatin was administered at 70 mg/m^2, and 5-FU was administered at 1000 mg/m^2/24 hr for 96 hours with each cycle. The projected progression-free survival at 4 years was 80% for the patients in the radiation-plus-chemotherapy arm compared with 63% in patients receiving adjuvant radiation alone. Analysis of pattern of treatment failure at the time of initial recurrence reveals that 11 of 127 patients receiving chemoradiation had a component of pelvic recurrence compared with 25 of 116 patients receiving radiation, suggesting that the addition of chemotherapy resulted in a 60% reduction in the rate of pelvic failure. A component of distant metastatic spread was seen in 13 of 127 patients in the chemoradiation group and 18 of 116 patients in the radiation group, suggesting that the addition of chemotherapy resulted in a 34% reduction in distant spread. Paradoxically, the effect of the chemotherapy appears to have been greater on local disease than on distant dissemination, suggesting that the primary benefit may have been as a potentiator of local radiation effect.

In a small, randomized trial, Tattersall[191] reported that the addition of three cycles of cisplatin, vinblastine, and bleomycin before adjuvant pelvic radiation produced no benefit compared with immediate postoperative radiation therapy in patients with Ib to IIa disease with pelvic node metastases. In a complementary, randomized trial in which all patients received adjuvant postoperative chemotherapy, Curtin[192] reported that the addition of delayed adjuvant radiation produced no benefit in either pelvic control or survival.

Stages IIb and III

In the United States, patients with advanced disease are treated with chemoradiation. Teletherapy with synchronous chemotherapy is supplemented with intracavitary brachytherapy whenever feasible. The Syed-Neblett or Martinez interstitial templates are alternative brachytherapy approaches that have the theoretic advantage of extending the brachytherapy isodoses laterally to treat pelvic side walls and parametrium.[193,194] However, it is unclear that this provides any advantage compared with conventional intracavitary brachytherapy supplemented by teletherapy boost treatments to limited volumes.

It is important to remember that even patients with very large tumors (even tumors measuring 7 cm or more in diameter) have a chance of being cured with radiation therapy alone, particularly if the patient is not found to have extensive regional metastases. Prior to the use of concurrent chemoradiation, 5-year survival rates for patients with stage IIb disease usually were reported to be between 50% and 75%.[100,195,196] The broad range probably reflects differences in staging, patient selection, and treatment technique between reporting institutions. For patients with stage IIIb disease, reported survival rates after treatment with radiation therapy alone ranged between 30% and 50%.[99,196–198] However, in recent years, prospective trials with concurrent chemotherapy and radiation have improved survival even more[167,168] and have become the standard of care in this group of patients.

Although the preliminary finding of RTOG 90-01, first published in 1999, demonstrated a highly significant overall survival benefit from chemotherapy among patients with stage Ib to IIb (79% vs. 55% at 5 years, $P < 0.0001$), no significant difference was found in survival among patients with stages III to IVa disease; at the time, follow-up was incomplete and the total number of patients with the more advanced stage[114] was small, contributing to large confidence intervals on the results.[168] Nevertheless, an update in 2004[199] did show a significant difference in disease free-survival (54% vs 37%,

$P = 0.05$) and a trend toward improved overall survival (59% vs 45%, $P = 0.07$). A recent update of GOG 120, in which a greater percentage of patients enrolled had III-IV disease, found a significant improvement in PFS and OS in patients receiving concurrent cisplatin-based chemotherapy with radiation therapy compared with patients receiving hydroxyurea and radiation, and the results were analogous in patients with Stage IIb and III (each $P < 0.025$).[200]

Stage IVa

Fewer than 5% of cases of invasive cervical cancer are truly stage IVa. Most of these are classified as IVa because of bladder involvement; rectal involvement very rarely is seen at initial diagnosis. The management of stage IVa disease is challenging because the tumors usually are large, often fixed to pelvic structures, and usually regionally metastatic. Brachytherapy often is compromised or impossible to perform because vesicovaginal fistulae develop before diagnosis or during treatment. However, at least 10% to 20% of stage IVa tumors are curable with radiation therapy alone.

Regional Disease

Most patients treated with radical hysterectomy who are found to have lymph node metastases require postoperative radiation therapy. On the basis of the findings of Peters and colleagues,[107] concurrent chemotherapy also is recommended if no medical contraindications are present.

Patients with para-aortic node involvement can be treated effectively with extended-field irradiation. Five-year survival rates range between 25% and 50%. Some investigators have advocated prophylactic irradiation of the aortic nodes for patients with an increased risk of metastases to this region. The value of prophylactic extended-field irradiation was tested in two randomized trials. In RTOG 79–20[201] patients with stage Ib2 to IIb disease were randomly assigned to receive brachytherapy plus external-beam radiation therapy to the pelvis or to the pelvis and para-aortic nodes. The absolute 5-year survival rate was significantly better for those who had para-aortic treatment, but no difference was found in disease-free survival. A European trial[202] done at the same time had a similar randomization but included patients with more advanced disease (e.g., with pelvic lymph node metastases or bulky stage IIb or IIIb disease). No significant difference was found in the 4-year disease-free survival rates between the two arms, but the rate of para-aortic node recurrence was significantly higher for patients in whom that area was not treated.

In several phase II studies, concurrent chemotherapy has been given with extended field irradiation.[203,204] Although side effects are more significant when treatment fields are enlarged, combined therapy may be tolerable if careful consideration is given to the chemotherapy regimen, the volume of tissue irradiated, and other factors that might increase the risk of serious toxicity. However, new imaging techniques such as PET and safer methods of surgical evaluation of lymph nodes (e.g., retroperitoneal or laparoscopic lymphadenectomy), may increase the precision with which the extent of regional disease can be estimated, decreasing the margin for improvement to be gained by treating large volumes prophylactically. However, it is important to remember that there is no evidence that chemotherapy given concurrently with radiation can prevent recurrence in nonirradiated nodal sites (the rate of aortic recurrence in patients treated on RTOG 90–01 with pelvic chemoradiation was 9%).[199]

Some bulky nodal metastases can be difficult to control with external beam radiation therapy alone. Some investigators have suggested resections of nodes larger than 2.0 cm prior to radiation therapy. Several investigators have reported high local control rates in patients treated with excision of bulky nodes and radiation; however, the numbers of patients in these series are small.[205,206] With standard radiation therapy, it is difficult to deliver a high enough dose to the node without exceeding normal tissue tolerance limits; however, with modern conformal or intensity-modulated radiation therapy (IMRT) techniques, this may be possible.

TREATMENT OF METASTATIC DISEASE AND SALVAGE CHEMOTHERAPY

Cervical cancer is not considered curable with chemotherapy. Chemotherapy traditionally has been reserved for patients with extrapelvic metastatic disease or recurrent disease who are not candidates for radiation therapy or exenterative surgery. In an important GOG study, Thigpen and colleagues[207] found that cisplatin has the greatest antitumor activity in advanced squamous carcinoma of the cervix, with a response rate of 20% to 25%. Unfortunately, in most series, responses to cisplatin are short-lived (3 to 6 months). The median duration of response for complete responders is 6 months, and the median survival is only 9 months.[208,209] Other agents reported to achieve partial responses (15% to 25%) include carboplatin, iphosphamide, 5-FU, doxorubicin, methotrexate, hexamethylmelamine, mitomycin-C, vinblastine, bleomycin, paclitaxel, topotecan, vinorelbine, and irinotecan. Little objective evidence suggests that combination chemotherapy is superior to single-agent cisplatin.

A small portion of patients are first seen with advanced disease that is not amenable to radiation therapy with curative intent. In women in whom recurrent or persistent disease develops in the central pelvis after radical hysterectomy, a cure may be achieved on occasion with radical salvage radiation or chemoradiation. A second small subset of patients with central pelvic recurrence after radiation therapy can be salvaged with aggressive surgical therapy, which often involves removal of the bladder or rectum, or both. For patients with distant disease, the principle goal of therapy is palliation with the aim of reducing pain and suffering associated with metastatic lesions. No convincing data indicate that the delivery of systemic therapy in this clinical setting improves overall survival.

Numerous platinum combination-based regimens incorporating drugs such as doxorubicin, iphosphamide, bleomycin, and, most recently, paclitaxel, have demonstrated higher response rates (typically in the 20% to 40% range) with the combinations with greater toxicity. A limited number of reasonably well powered randomized trials comparing these doublets with either triplet regimens or singlet regimens have demonstrated that combination therapy leads to a slightly higher response rate and a longer progression-free survival that does not appear to affect overall survival.[210,211] Recently the GOG compared paclitaxel and cisplatinum with single-agent cisplatinum. In this study of 241 eligible women, the response rate to single-agent cisplatin was 19%. The response rate to the doublet was 36%. The median time to progression was prolonged from 2.8 months with cisplatin alone to 4.8 months for the doublet. Overall survival for the two arms was equivalent, with an 8.8-month median for cisplatin and a 9.7-month median for the doublet.[212]

The potential role of drugs such as epidermal growth factor-receptor inhibitors, angiogenesis inhibitors, and other molecularly targeted therapies, remains largely unexplored in this disease. Preliminary evaluation of geftinib demonstrates only minimal activity in cervical cancer.

When interpreting clinical trials evaluating the efficacy of chemotherapy in cervical cancer, it is important to recall the patient population under study. Chemotherapy- and radiation therapy-naïve women receiving neoadjuvant therapy for bulky cervical tumors typically demonstrate response rates in excess of 50%. As discussed earlier, this response rate has not reproducibly translated into improved survival or cure. Response rates for recurrent disease outside of the radiation ports (such as pulmonary metastases or high para-aortic nodal recurrences) typically range between 10% and 20% for single-agent therapy and 20% and 45% for multiagent therapy. Finally, response rates for measurable tumors in the previously irradiated pelvis tend to be much lower, with complete responses rare, and response rates generally no higher than 10% to 15%. Evaluation is complicated in the irradiated pelvis, with either physical examination or radiologic studies, both of which are, at times, unable to distinguish postsurgical and postradiation changes from tumor recurrences, which often are infiltrating distorted tissue planes in the post-treatment pelvis.

VULVAR CANCER

SUMMARY OF KEY POINTS

Epidemiology
- The American Cancer Society estimates that there were 3490 new cases of invasive vulvar cancer diagnosed in the United States in 2007, with 880 deaths.
- Vulvar cancers account for 4% of malignancies of the female genital tract.
- Squamous cell carcinoma and its variants are the most prevalent histologies, accounting for 90% of invasive lesions.
- Vulvar melanoma, basal cell cancer, and rare sarcomas constitute most of the remaining tumors.
- Adenocarcinoma and adenoid cystic carcinoma of the vestibular glands (Bartholin's gland) are less common than the squamous cancers arising from these structures.
- Age-adjusted incidence increases steeply after age 70.

Etiology
- An association is found with human papillomavirus (HPV) in approximately one third of cases, primarily in younger patients.
- Vulvar cancer in older patients commonly arises in association with lichen sclerosus or squamous hyperplasia (hyperplastic dystrophy or lichen simplex chronicus), although these conditions are not clearly premalignant.
- Chronic immunosuppression has been implicated in some cases.

Differential Diagnosis
- Paget's disease of the vulva and vulvar intraepithelial neoplasia (VIN) are in the differential diagnosis of a vulvar lesion.
- Giant condylomata may mimic vulvar neoplasia, and vulvar neoplasia may coexist with condyloma accuminata.

Evaluation
- Complete history and physical examination including a thorough pelvic examination and careful palpation of groin lymph nodes.
- Diagnosis must be confirmed by vulvar biopsy.

Treatment of Squamous Cell Carcinoma of the Vulva
- Treatment should be individualized on the basis of disease volume and anatomic extent, histology, age, comorbidities, and patient preference.
- Stage I lesions may be treated with radical local excision alone, or combined with inguinofemoral lymphadenectomy if depth of invasion exceeds 1 mm.
- Surgery for stage II vulvar cancer usually consists of modified radical vulvectomy and inguinofemoral lymphadenectomy.
- Locally extensive (T3,4) vulvar cancers, or cancers invading or encroaching on functionally important midline structures can be managed with synchronous preoperative chemotherapy and radiation (chemoradiation) followed by conservative excision of residual disease, or by radical chemoradiation alone.
- Management of inguinofemoral nodes may consist of surgical dissection alone, or surgery coordinated with preoperative or postoperative radiation if nodes harbor metastatic deposits.
- Surgery of the primary and the groin nodes may be conducted through separate incisions (triple incisions) to reduce both acute and late surgical morbidity.
- Elective radiation or chemoradiation may be an alternative to surgical treatment of inguinofemoral nodes in selected patients with clinically and radiographically negative groin nodes.
- Sentinel lymph node biopsy may be a useful discriminator to guide the selection and sequencing of modalities used to treat the groin nodes.

EPIDEMIOLOGY

Vulvar cancer is predominantly a disease of postmenopausal women, most commonly observed in the seventh and eighth decades, and with a mean age at diagnosis of 65 years. Age-specific incidence rates in the United States increase steeply at age 70 and continue to increase beyond age 80 years.[213] The coexistence of vulvar intraepithelial neoplasia (VIN) or invasive squamous carcinoma of the vulva with in situ or invasive epidermoid carcinoma of the cervix has long been known, and synchronous or sequential (usually antecedent) cervical lesions may be present in as many as 20% of women with primary vulvar lesions. This observation suggests a common etiology in at least some patients.[214–220]

VIN, a precursor lesion, often is multifocal. After conservative local excision of invasive vulvar cancer with preservation of clinically normal vulva, cancer may develop at anatomically distinct structures within conserved vulvar tissues. Rather than recurrence, this phenomenon may be a manifestation of the so-called "field change" model of oncogenesis, representing metachronous appearance of independent primaries.[221]

ETIOLOGY

Risk factors for the development of invasive vulvar cancer include a history of condyloma acuminatum, VIN, smoking, and chronic vulvar dystrophies including lichen sclerosus and squamous hyperplasia (hyperplastic dystrophy).[222–225]

Vulvar carcinoma often coexists with vulvar dystrophy, particularly in older women, with dystrophic changes in adjacent skin in up to 50% of patients with invasive vulvar cancer.[226,227]

However, it is unknown whether lesions such as lichen sclerosus or squamous hyperplasia are true precursor lesions. Detection of human papillomavirus (HPV) in VIN or invasive disease is most common in young patients and less frequent in older patients.[228,229] These observations have led to the hypothesis that patients with vulvar cancer may be segregated into two broad groups: an older population with cancer arising in association with vulvar dystrophy and unassociated with HPV, and a younger population with HPV-associated tumors often adjacent to areas of VIN.[225,230]

An increasing incidence of VIN and reports of invasive vulvar cancer in young patients may be consequences of the sexual revolu-

tion and transmission of HPV. Invasive vulvar cancer has been reported in young patients with both naturally occurring and iatrogenic immune compromise.[231–236] Patients infected with the human immunodeficiency virus-1 (HIV-1) are much more likely to have HPV infection than are women who are not infected with HIV and may be more vulnerable to development of VIN than are HIV-negative controls. VIN may be more difficult to clear in HIV-infected women and may progress to invasive disease with greater rapidity.[237,238]

Detection of HIV in very young patients with vulvar cancer raises the specter of increasing rates of vulvar as well as cervical cancer as the acquired immunodeficiency syndrome (AIDS) epidemic unfolds.[239]

NATURAL HISTORY

Vulvar Dystrophy

A patient with any degree of cellular atypia associated with vulvar dystrophy is at risk of invasive vulvar cancer. Patients with cellular atypia compose approximately 10% of those patients with histopathology-proven vulvar dystrophy, and vulvar cancer will develop in fewer than 5% of these patients.[240] The International Society for the Study of Vulvar Disease (ISSVD) established a classification for vulvar dystrophies and atypias based on histopathology[241] (Table 91-4). The ISSVD now advises that "dystrophy" is no longer an acceptable term and recommends use of specific terminology (e.g., lichen sclerosus, lichen planus, lichen simplex chronicus, psoriasis), although these recommendations have not been adopted uniformly.[242–244]

Paget's Disease

Vulvar Paget's disease was first reported in 1901 by Dubreuilh.[245] The disease is seen predominantly in postmenopausal women, with common presenting symptoms of vulvar pruritus and soreness, sometimes accompanied by persistent oozing. Grossly, Paget's disease may have an eczematoid appearance. With extensive disease, it may appear raised and velvety. Under the light microscope, the presence of large, pale Paget's cells that are rich in mucopolysaccharide and that are periodic acid-Schiff (PAS)-positive and diastase resistant are pathognomonic of this disorder (Fig. 91-17). Paget's cells stain for carcinoembryonic antigen (CEA), cytokeratin 7 (CK-7), and gross-cystic-disease fluid protein.[246,247] Paget's cells rarely express CA-125, and testing for estrogen receptors usually is generally negative.[248,249] Many cases express c-erB2 (HER-2/neu), which is not believed to influence the risk of metastatic spread.[250,251] Nondiploid tumors are more likely to recur. Electron microscopic studies have demonstrated that Paget's cells are derived from the stratum germinativum of the epidermis.[252] Squamous keratinocytes, sweat gland cells, and hair follicles also are derived from this epidermal layer, possibly explaining the characteristic finding of more Paget's cells in juxtaposition to the basal layer of cells in the epidermis, as opposed to within higher strata.

In approximately one sixth of cases, Paget's disease involving the vulva has been associated with an underlying adenocarcinoma of the vulva, often arising in apocrine glands or within Bartholin's glands. Paget's disease also has been associated with a synchronous primary invasive cancer in another female genital tract site in approximately one fourth of patients.[253–255]

Wide local excision is recommended as treatment, with verification of surgical margins by frozen section.[256,257] Repeated excision sometimes is required for marginal recurrence.[258]

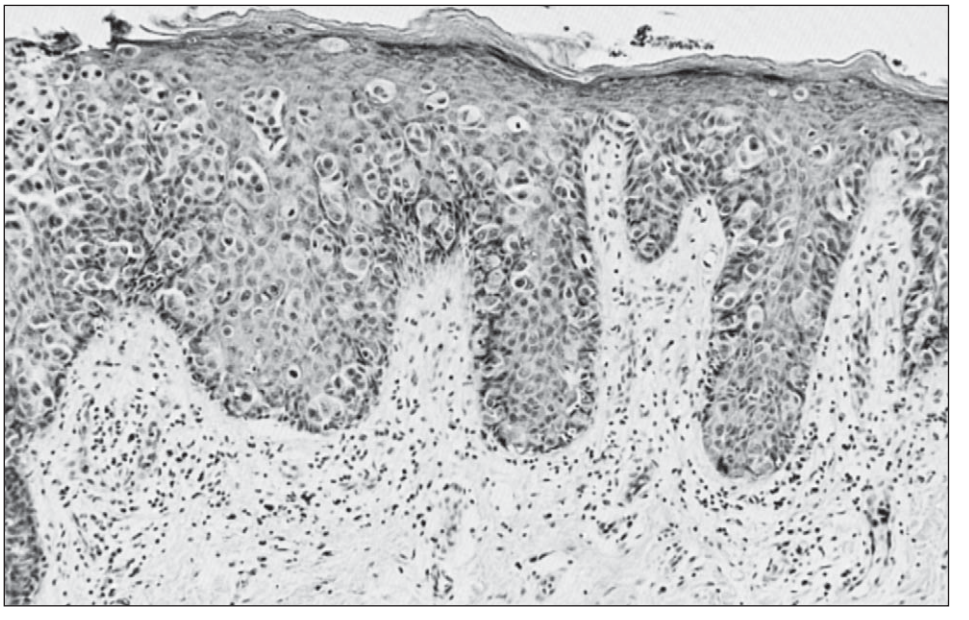

Figure 91-17 • Histologic portrait of Paget's disease of the vulva. (From Wilkinson EJ, Hassanein AM: The vulva and vagina. In Silverberg SG [ed]: Silverberg's Principles and Practice of Surgical Pathology and Cytopathology, 4th ed. New York, Churchill Livingstone, 2006.)

Intraepithelial Squamous Cell Neoplasia of the Vulva

The term *VIN* now replaces such terms as Bowen's disease, erythoplasia of Queyrat, carcinoma simplex, bowenoid papulosis, bowenoid dysplasia, hyperplastic dystrophy with atypia, and condylomatous dysplasia. The ISSVD recognizes squamous cell carcinoma in situ. VIN is appearing with increasing frequency in women under the age of 40 years and seems to be associated with high-risk strands of the HPV virus. Histopathologically, these lesions are characterized by varying degrees of cytoplasmic and nuclear maturation, giant cells with abnormal nuclei, and disruption of the normal epithelial architecture (Fig. 91-18). On rare occasions, pearl formation at the base of the rete pegs can be seen, without significant abnormality in the overlying epithelium. Buscema and colleagues[259] reported that invasive vulvar cancer developed in approximately 4% of patients with VIN. Fu and colleagues[260] observed that all intraepithelial lesions analyzed had an aneuploid DNA pattern when associated with HPV. The term *bowenoid papulosis* historically has been used as a synonym for multifocal intraepithelial neoplasia of the vulva. This lesion also is associated with HPV infection. The invasive potential of this entity appears to be very low. Therapy for VIN usually consists of surgical excision. Laser vaporization may be useful as an alternative when large areas would require excision or functionally important areas are involved, but carries a small risk of failure to detect areas of true invasion. The risk of occult invasion may be as high as 20% in patients with VIN 3.[261] Cavitational ultrasonic surgical aspiration (CUSA) provides another conservative surgical modality to treat VIN with minimal loss of functionally important tissue and provision of tissue for histologic study.[262] Laser excision, by providing tissue for histologic evaluation, is less likely to miss a clinically occult area of invasion.[263]

Invasive Squamous Cell Carcinoma of the Vulva

Clinical Features

Histologically, squamous cell carcinoma accounts for more than 90% of cases of malignancy involving the vulva. Common presenting symptoms include chronic vulvar pruritus; a mass, lump, or sore; and small-volume bleeding. About two thirds of the lesions involve the labia majora, whereas lesions originating on the labia minora and the clitoris occur less commonly. Lesions arising in the vestibular (Bartholin's) glands are first seen as a swelling or mass, sometimes without invasion of overlying skin. Tumors arising in the Bartholin's glands tend to be adenocarcinomas. In 10% of cases, the lesion will be too extensive to determine the site of origin, and in 5% of cases, the lesions are multifocal.[264] From the site of origin, carcinomas of the vulva can extend to invade the vagina, urethra, or anus; advanced vulvar carcinoma can invade adjacent pelvic bones, particularly the pubis.

Routes of Spread

Direct extension occurs to adjacent structures including the vagina, perineum, clitoris, and anus. The vulva is richly supplied with lymphatic vessels that often cross the midline. As a result, the risk of regional spread is significant for any vulvar carcinoma that has invaded to a depth of more than 1 mm. The lymphatics of the vulva consist of a network that covers the entire labia minora, fourchette, prepuce, and distal vagina below the hymenal membrane. These coalesce anteriorly, forming larger trunks, which run laterally to the clitoris to the mons veneris, acquiring tributaries from the lymphatics of the labia majora, which run in a parallel fashion anteriorly from the perineal body. The vulvar lymphatics run through the vulva and do not cross the labiocrural fold. The lymphatics of the perineum, however, course lateral to the labiocrural fold through the superficial tissues of the upper medial thigh. In the treatment of patients with advanced vulvar cancer that extends beyond the vulva to the perineal skin, these more lateral channels must be taken into consideration. Similarly, direct proximal extension of an advanced vulvovaginal cancer along the vaginal cylinder may spread through vaginal lymphatics directly to pelvic nodes. At the mons veneris, the vulvar lymphatic trunks diverge laterally to the primary regional nodes, the ipsilateral or contralateral inguinal nodes. Study of the localization of dye or radiolabeled tracer in regional lymph nodes after focal injection of discrete sites in the vulva and on the perineum reveals that the lymphatic drainage of the perineum, clitoris, and anterior labia minora is bilateral, whereas the lymph flow from well-lateralized sites in the vulva is, predominantly, to the ipsilateral groin.[265,266] Discrete (≤2 cm diameter), well-lateralized primary cancers limited to the vulva and not approaching midline structures rarely manifest spread to contralateral groin nodes in the absence of spread to ipsilateral nodes.[267–272]

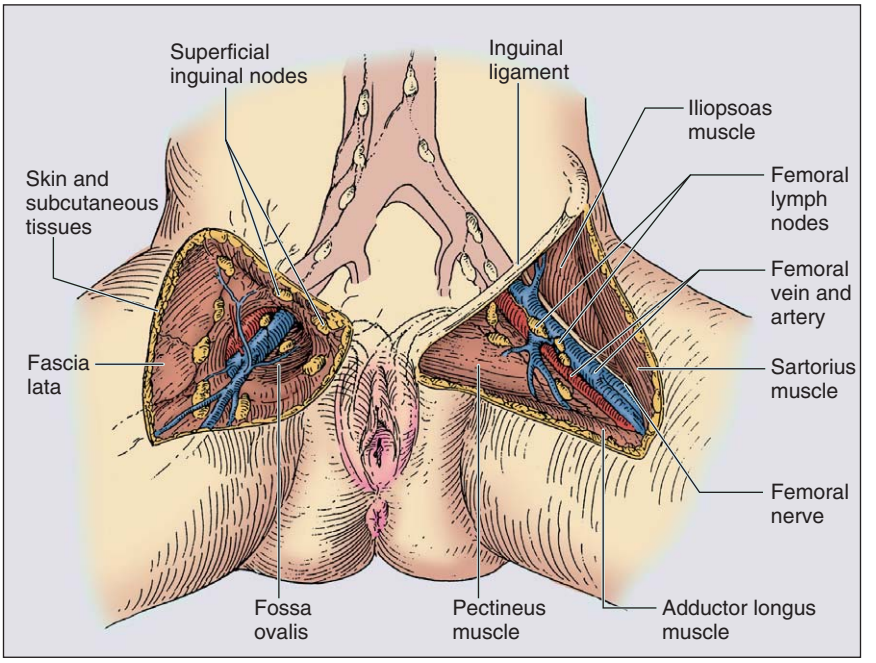

Figure 91-19 • Regional lymph nodes in vulvar carcinoma: inguinal and femoral. (From Berek JS, Hacker NF: Practical Gynecologic Oncology, 2nd ed. Baltimore, Williams & Wilkins, 1994.)

From the superficial inguinal nodes, secondary lymphatic drainage is through the cribriform fascia to the femoral nodes (Fig. 91-19), with subsequent tertiary flow under the inguinal ligaments to the external iliac nodes. However, metastases have been reported to the femoral lymph nodes without involvement of the superficial inguinal lymph nodes, especially from carcinomas of the clitoris and Bartholin's gland.[273,274] A recent GOG study also found an unexpectedly high incidence of ipsilateral groin recurrences secondary to presumed involvement of lymph nodes deep to the cribriform fascia, despite having negative superficial nodes.[275] Levenback and colleagues[276] further supported these data by lymphatic mapping studies.

The frequency of lymph node metastases to the inguinofemoral nodes is related to the lesion size and depth of stromal invasion.[268,277] For lesions smaller than 1 cm in diameter, the incidence is approximately 5%. For lesions exceeding 4 cm, the rate of inguinofemoral lymph node metastases is 30% to 50%.[269,278] The overall incidence of metastases to the pelvic lymph nodes is 5% and is rare in the absence of three or more positive inguinofemoral lymph nodes. Hematogenous spread is rare in the absence of inguinofemoral lymph node involvement and usually occurs late in the course of the disease. However, in patients with three or more positive lymph nodes, the ultimate risk of hematogenous spread is 66%. By contrast, patients with fewer than three positive lymph nodes have only a 4% risk of hematogenous spread.[279,280] Sites of hematogenous spread include lung and bone.

Staging

Staging of invasive vulvar cancer is based on clinicopathologic measurement and assessment of anatomic extent of the primary lesion; the presence, laterality, and extent of regional lymph node metastases; and the presence or absence of distant metastases including pelvic lymph nodes. Historically, staging evaluation of the inguinal lymph nodes was based on palpation and clinical impression. Because the clinical assessment of inguinal lymph nodes is associated with false-positive and false-negative rates of approximately 20%[281–286] (Table 91-5), a surgical staging system for vulvar cancer initially was adopted by FIGO in 1988 and has been revised several times since[287] (Table 91-6). However, many locally advanced vulvar lesions are being treated with initial radiation or chemoradiation; consequently, the absence of a complete surgical specimen may interfere with accurate staging, particularly of the inguinal lymph nodes.

Diagnosis

Diagnosis of vulvar lesions requires a biopsy, which should include some surrounding skin and underlying dermis and connective tissue so that the pathologist can assess the depth and nature of stromal invasion. This procedure usually can be performed under local anesthesia. For lesions of 1 cm or less in diameter, excisional biopsy is preferable. All patients with invasive disease should be evaluated with a careful physical examination, including a detailed pelvic examination, chest radiography, a complete blood count, and a biochemical profile. Computed tomography (CT) or magnetic resonance imaging (MRI) scans should be done to evaluate deep and pelvic lymph nodes.

Treatment

Treatment of Preinvasive Disease

Small VIN lesions are treated with local excision. More extensive VIN can be treated with carbon dioxide (CO_2) laser vaporization. However, careful inspection and biopsies to rule out invasive disease should be done before laser treatment. Extensive disease may require wide local excision or excision of the superficial skin of the vulva (skinning vulvectomy). Although the morbidity of excision may be greater than that of laser vaporization, the ability to examine the surgical specimen is a relative advantage of surgical excision. VIN

Table 91-5 Clinical Assessment of Inguinofemoral Nodes by Palpation

	Histologically (–)	Histologically (+)
Clinically (–) ($N = 451$ patients)	363 (80.5%)	88 (19.5%)
Clinically (+) ($N = 243$ patients)	53 (21.8%)	190 (78.2%)

TNM CLASSIFICATION	
T	Primary tumor
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ (preinvasive carcinoma)
T1	Tumor confined to the vulva and perineum* ≤2 cm in greatest dimension
T1a	Tumor confined to the vulva or vulva and perineum, ≤2 cm in greatest dimension, and with stromal invasion ≤1 mm
T1b	Tumor confined to the vulva or vulva and perineum, ≤2 cm in greatest dimension, with stromal invasion >1 mm
T2	Tumor confined to the vulva and perineum >2 cm in greatest dimension
T3	Tumor of any size with adjacent spread to the lower urethra and/or vagina and/or anus
T4	Tumor of any size invading any of the following: the upper urethral mucosa, the bladder mucosa, the rectal mucosa, or tumor fixed to the bone
N	Regional lymph nodes†
N0	No nodal metastases
N1	Unilateral regional lymph node metastasis
N2	Bilateral regional lymph node metastasis
M	Distant metastasis
M0	No evidence of distant metastasis
M1	Any distant metastasis including pelvic lymph nodes
STAGE GROUPING

*The depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

†Note that assessment of inguinofemoral nodes is histologic.

often is a multicentric disease, and local recurrences often occur even after extensive surgical resection.

Surgical Treatment of Invasive Carcinoma

The operative approach to the treatment of vulvar carcinoma, consisting of a radical en bloc resection of the vulva, was developed at the beginning of the 20th century in response to the combination of patients first seen with regionally advanced disease and the poor results (approximately 20% to 25% 5-year survival) achieved with limited surgical excision.[288]

Basset[289] first reported an en bloc operative removal of the vulva along with the regional lymph nodes, resulting in considerable improvement in 5-year survival (60% to 70%). Three decades later, Taussig[290] of the United States and Way[281,291] of the United Kingdom popularized this radical en bloc dissection, which remained the standard of surgical care for vulvar cancer until the early 1980s. At that time, Hacker and others[292,293] introduced the concept of individualized and conservative surgery, proposing the use of separate groin incisions for women with stage I disease and demonstrating no difference in the incidence of recurrence between those women undergoing a radical vulvectomy compared with those undergoing a radical local excision (modified radical vulvectomy). The trend over the past 20 years has been toward less radical surgery for early-stage vulvar cancer in an attempt to decrease the significant physical and psychological morbidity associated with en bloc dissection (Fig. 91-20). Historically, exenterative procedures were undertaken to clear central disease in patients first seen with locally advanced disease.[294] Increasingly, treatment has evolved to include combinations of preoperative radiation or preoperative chemoradiation to reduce tumor volume sufficiently to permit clearance of central disease without sacrifice of functionally important midline structures.[292–296]

Surgical Techniques

RADICAL LOCAL EXCISION. Radical local excision involves a wide and deep excision of the lesion with the goal of clearing the lesion by 2 cm at all margins, except for posteriorly with perineal lesions in which the distance to the anus is limited. The incision should be carried down to the inferior fascia of the urogenital diaphragm, which is in a parallel plane to the fascia lata and the fascia over the symphysis pubis. The surgical defect is closed in two layers. Limitations to this conservative approach are encountered when cancer is in close proximity to functionally important midline structures (e.g., clitoris, urethra, anus). A histopathologic margin of 8 millimeters or greater (approximately equivalent to 1-cm clinical margin in tissue before fixation) serves as a useful discriminating boundary between patients who are likely to have excellent prospects for local control with surgery alone, as opposed to patients who have a substantial risk of local recurrence and who might require more extensive surgery initially or postoperative adjuvant radiation therapy[297–299] (Table 91-7).

RADICAL VULVECTOMY. The radical vulvectomy may be performed through an incision separate from the groin dissection or in an en bloc fashion. The en bloc technique was based on the concern that leaving tissue between the primary tumor and the regional lymph nodes might leave microscopic foci tumor in the draining lymphatics. However, squamous carcinoma most often spreads by embolization and not by permeation. Although rare instances of recurrence within the skin bridge have been reported, the experience with separate groin incisions has shown that very little chance of recurrence exists in the skin bridge without clinically suggestive groin nodes.[292] Wound seroma, the most common acute complication, occurs in approximately 15% of cases.[292,293] Other acute complications include urinary tract infection, wound cellulitis, temporary anterior thigh anesthesia from femoral nerve injury, thrombophlebitis, and, rarely, pulmonary embolus. The most common chronic complication now is leg edema, and with the use of separate groin incisions, its incidence has decreased from 31% to 14%.[292,293] Other chronic complications include genital prolapse, urinary stress incontinence (10%), temporary weakness of the quadriceps muscle, and introital stenosis. Rare late complications include pubic osteomyelitis, femoral hernia, and rectoperineal fistula. Farias-Eisner and associates[300] and Hacker and colleagues[268] observed a further reduction in acute and chronic morbidity when radical local excision of the primary lesion is used instead of radical vulvectomy.

Groin Lymph Node Dissection

The appropriate application of groin dissection is the single most important factor in decreasing the mortality of early vulvar cancer. The technique for groin dissection involves the removal of an ellipse

of skin 1 cm below and parallel to the groin crease. The incision is carried down, with incising and dissecting, to the fascia lata and 2 cm above the inguinal ligament to remove the inguinal nodes. The saphenous vein is tied off, the fascia lata is then split, and the femoral nodes are dissected. Some surgeons conserve the saphenous vein in an effort to decrease both acute and chronic morbidity. A suction drain is placed, and the wound closed in two layers.

Surgical specimens from patients with primary tumors 2 cm or smaller in diameter (T1) clearly show escalating risk of node metastasis with progressive depth of invasion (Table 91-8).[268,270,271,277,301,302] The probability of finding groin node metastasis is related to the size of the primary tumor (Table 91-9).[303,304] An infiltrative pattern of growth correlates with nodal spread,[305,306] and the presence of vascular or lymphatic space invasion substantially escalates the probability of finding metastases in dissected nodes.[303] Metastatic spread to contralateral groin nodes in the absence of disease in ipsilateral nodes occurs in 15% or fewer of all patients with metastases to groin nodes,[307] generally in patients with larger lesions. The risk of contralateral nodal spread in the absence of ipsilateral metastasis is less than 1%,[219,278,282,283,307–312] although it has been described in two patients with lateralized T1 lesions.[166] When metastatic disease is present in multiple groin nodes, pelvic lymphadenectomy will detect disease in 15% to 25% of patients, but rarely when only one groin node is microscopically contaminated.[313,314]

A thoughtful appraisal of the risk of nodal spread and the anatomic level of potential contamination is an essential part of planning surgical therapy and determining target volume, dose, and technique for a course of radiation therapy. Diagnostic imaging may be helpful in the assessment of regional nodes in patients with vulvar cancer and tailoring the extent of surgery or radiation accordingly. MRI is highly specific for the detection of inguinal nodal involvement (97% to 100%). CT scanning also is useful in detecting nodal involvement (Fig. 91-21) that may be deeper in tissue than can be readily detected on physical examination. Fluorodeoxyglucose-positron emission tomography (FDG-PET) has a sensitivity of 67% to 80% in predicting lymph node metastasis. It also is more specific (90% to 95%) and is useful in planning radiation therapy and as an adjunct to lymphatic mapping and sentinel lymph node dissection.[315] Lymphoscintigraphy with technetium-99 m (Tc-99 m) sulfur colloid may be useful in the identification of sentinel nodes.[316]

Given the results of the Gynecologic Oncology Group (GOG) prospective randomized trial demonstrating better efficacy for adjuvant node radiation compared with pelvic node dissection, the

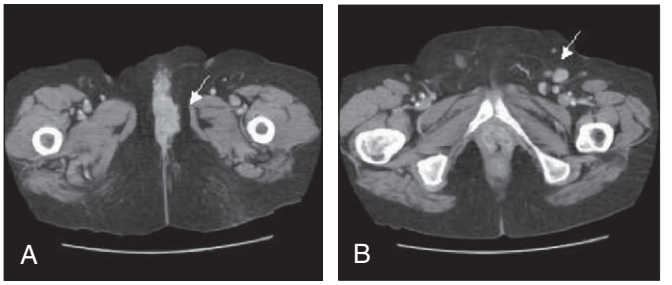

Figure 91-21 • CT of vulvar cancer. **A,** Irregular thickening and growth involving the left vulva with distortion of contour *(arrow)*. **B,** Enlarged left inguinal node *(arrow)*.

indications for extending surgery proximal to the inguinal ligament are diminishing.[310]

RADIATION THERAPY

Radiation therapy is increasingly used in the curative management of vulvar cancer,[317–322] often in conjunction with synchronous administration of radiation potentiating chemotherapy (chemoradiation).[296,323–334]

Radiation salvages some patients with locoregional recurrence after radical vulvectomy and regional node dissection.[334] Postoperative radiation directed to the groins and pelvic nodes improves disease-free survival in patients with metastatic spread to two or more inguinofemoral nodes[310] and may further improve results if residual vulva and perineum (operative bed) are included within the irradiated volume.[335]

Preoperative radiation and chemoradiation have reduced the indications for exenterative surgery and may permit a substantial decrease in the volume of normal tissue that must be removed in patients with tumors invading or intimately approximating the anus, clitoris, urethra, and distal vagina.[317,321,329,334]

Postsurgical, central, limited-volume, local recurrence in the residual vulva, at the introital margin, or on the perineum often is salvaged with secondary surgery, radiation, or combined-modality therapy.[336] A disease-free interval of 2 or more years and lack of involvement of regional nodes portend a favorable outcome with salvage therapy, although most disease recurs within 2 years of initial surgery.[337,338] Under circumstances in which the anticipated surgical margin is less than that of the original surgery, when recurrence approaches or involves critical structures, or when the pattern of recurrence is multifocal, it is prudent to plan for delivery of radiation as at least a component of the salvage strategy. Regional relapse in the groin or in pelvic nodes is much less likely to be salvaged, regardless of the combination of modalities used.[336,338–340] Salvage radiation alone, in doses ranging from 63 Gy to 72 Gy with progressive volume reductions or partial treatment with brachytherapy, often controls small-volume recurrence. Preoperative radiation ranging in dose from 45 Gy to 54 Gy followed by local excision may be less injurious in terms of delayed normal tissue effects than a high radiation dose to a large perineal volume in the absence of surgery.[336]

Adjuvant Postoperative Radiation Therapy

Postoperative radiation therapy usually is indicated in the following situations: more than one positive inguinal node, one grossly positive inguinal node or extracapsular extension of nodal disease, small tumors in patients with medical problems that prohibit radical inguinofemoral lymph node dissection, and a vulvar resection margin of less than 8 to 10 mm.

The GOG conducted a randomized trial comparing pelvic lymphadenectomy with radiation therapy directed to the bilateral groins and pelvic nodes (but not the tumor bed or perineum) in patients who were found to have groin node metastasis. A total of 114 eligible patients were randomized, of whom 40 had only one positive groin node. In 15 (28.3%) patients of 53 undergoing pelvic lymphadenectomy, disease had spread to pelvic nodes; 9 (60%) of these patients died of cancer within 1 year of study entry. The overall survival advantage for radiation at 2 years (68% for radiation, 54% for pelvic node dissection) was limited to patients with two or more involved groin nodes (63% for radiation, 37% for pelvic node dissection) and was attributable to a decrease in recurrence in the groin among the irradiated patients (5.1%) compared with those patients treated with surgery alone (23.6%). Lymphedema was reported in 19% of irradiated patients compared with 11% of patients treated with surgery alone. Of the 44 patients who had recurrence, only 11 patients failed with a component of "distant" disease (including three patients with relapse in the thigh, periaortic nodes, and abdominal skin), whereas 75% of relapsing patients failed with locoregional disease alone (vulvar area, groins, or pelvis). Eleven (25%) patients experienced recurrence in the unirradiated vulvar area; 10 of these had no other apparent sites of failure. As a consequence of this study, pelvic lymphadenectomy is less likely to be performed, and regional adjuvant radiation has become the standard of additional care for patients with metastasis to two or more regional nodes.[310] Katz and coworkers[341] recently found a higher rate of inguinal recurrence when patients started radiation therapy more than 50 days after their operation, and therefore concluded that postoperative radiation therapy should begin whenever possible within 4 to 6 weeks of surgery.

Areas of controversy in the postoperative adjuvant therapy of resected, node-positive vulvar cancer include whether patients with only one node contaminated should receive adjuvant therapy, whether patients with only unilateral groin node metastasis should have radiation delivered to the contralateral groin and pelvis, and whether synchronous administration of chemotherapy might further improve outcomes. Retrospective outcomes analysis of node-positive patients undergoing adjuvant groin and pelvic radiation suggests the wisdom of including the operative bed of the primary lesion within the treatment volume.[335]

Preoperative Chemoradiation

Under circumstances in which the extent of the primary disease suggests that postoperative radiation will be indicated, it is reasonable to consider preoperative radiation if it has the potential to reduce the scope of surgery and to conserve normal tissue structure and function or to convert the patient's status from unresectable to operable.[296,317–321,329] An anticipated margin of 1 cm or less from structures that will not be surgically removed is a useful guide for selecting patients for preoperative radiation.[297–299] Tumors that encroach on the anal sphincter, abut the pubic arch, or involve more than the distal urethra should be considered for preoperative radiation therapy. Patients with tumors that approach the clitoris or extend more than minimally past the vaginal introitus also should be considered for preoperative irradiation if conservation of sexual function is desired. Moderate-dose radiation (36 Gy to 54 Gy) has been given, followed by excision of residual palpable abnormalities that revealed no evidence of persistent cancer in 50% of cases (Table 91-10).

External-beam radiation is used most commonly, but interstitial or intracavitary brachytherapy may apply a higher dose to a discrete tissue volume where a surgical margin is anticipated to be inadequate.[317]

The GOG studied 73 patients with stage III to IV squamous cancers of the vulva who were judged not amenable to resection because of local disease extent beyond the conventional boundaries of radical vulvectomy. Preoperative chemoradiation, consisting of 47.6 Gy delivered in fractions of 1.7 Gy coordinated with two cycles of synchronous cisplatin and 5-fluorouracil (5-FU), converted 69 of 71 patients medically fit for surgery to having lesions considered

*Includes one patient who received additional 24 Gy by intravaginal mould.

amenable to resection. Ultimately, urinary and fecal continence was conserved in all but 3 patients. With the use of this approach, local tumor control has been excellent, with conservation of normal tissue integrity in many patients who otherwise would have required exenterative surgery for tumor clearance.[296] By using the identical regimen (Fig. 91-22) in 46 patients with extensive (matted, fixed, or ulcerated) and unresectable groin metastases, physicians of the GOG were ultimately able to resect groin nodes in 37 patients, of whom 15 had histologically negative groin specimens.[342] The observation of complete histologic clearance of malignancy after moderate-dose preoperative radiation (alone or coordinated with synchronous chemotherapy) serves to encourage efforts to control vulvar cancer with radiation-based therapy under circumstances in which surgery is either technically unfeasible or medically contraindicated.

Figure 91-22 • Time/dose/fractionation schedule: Phase II evaluation of preoperative chemoradiation for advanced vulvar cancer. Patients who are judged to be unresectable following completion of 47.6 Gy preoperative chemoradiation receive additional 20 Gy in fractions of 1.7–2 Gy with reduced treatment volume encompassing gross residual disease, or may receive additional radiation dose via brachytherapy. A third cyle of chemotherapy is recommended if teletherapy is employed. The authors would suggest restricting the cumulative dose to 59.5 Gy/35 Fx in the interest of avoiding severe late skin effects. 0, a day without radiation treatment; F, 5-fluorouracil by continuous intravenous infusion; P, bolus cisplatin administration; R, a fraction of external radiation—a 4-hour minimum intertreatment interval is mandatory, but 6 or more hours are suggested when practical. GOG Protocol 101.[296]

Radical Radiation and Chemoradiation

Definitive radiation has been used to treat medically inoperable or technically unresectable patients. Historically, results have been poor, in terms of both tumor control and normal tissue sequelae, although the tumor-control probability for patients with disease of limited volume has approached that of surgery.[321,343,344] Results with radiation alone in recent years have improved with better technique and dosimetry.[322]

The favorable experience with chemotherapy and reduced-dose radiation in the treatment of cancers of the anal canal has prompted increasing utilization of this approach in the treatment of advanced vulvar cancer. Most published experiences have used 5-FU, with or without cisplatin or mitomycin.[325–327,331,333,345–348] Retrospective comparison[348] suggests the superiority of chemoradiation compared with radiation alone, but prospective randomized data do not exist to validate the clinical impression of better results. Unquestionably, the administration of concurrent chemotherapy augments the acute reaction in normal tissues. Moist desquamation of the vulva necessitates treatment interruption in most patients. Hybrid dose/fractionation regimens have been developed to preserve dose intensity and to maximize potential synergistic effects. Twice-daily fractionation has become a popular strategy to exploit the radiation/drug interaction while minimizing the theoretical disadvantages of split-course radiation that is made mandatory by the enhanced effects in normal tissue.[296,332,333] Because of potential enhancement of late normal tissue effects, and because full radiation dose must be administered to some skin when treating what is fundamentally a skin cancer, it is advisable that total dose not exceed approximately 54 Gy in 30 fractions, 59.5 Gy in 35 fractions, or 64 Gy in 40 fractions to gross disease when chemoradiation is used, and that the volume receiving the full dose be as small as possible, while including all areas of initial measurable clinical involvement.

Elective Groin Radiation

A contributing factor to perioperative complications and chronic morbidity is the dissection of the inguinofemoral nodes.[349] In selected patients with limited primary tumors (T1a with ≤1 mm of invasion), omission of the node dissection is prudent. In others, limiting the groin dissection to superficial inguinal nodes (if histopathologically negative) has been an effective strategy for reducing acute and chronic morbidity. Preoperative identification of sentinel nodes may further enhance the safety of this approach. Elective irradiation of the clinically and radiographically negative groin nodes is an alternative strategy that has the theoretical advantage of treating all of the regional nodes rather than leaving some portion untreated. This approach also is applicable in patients with locally advanced primary tumors, in whom less than radical (superficial and deep) bilateral groin dissection would constitute less than adequate surgical treatment. Several series[350–353] have reported favorable results with elective or prophylactic groin irradiation (Table 91-11), but frequently in the setting in which groin nodes would be expected to be histologically uninvolved if treated surgically (T1 or T2 primary tumors of limited extent; Table 91-12).[354]

The GOG conducted a randomized trial comparing groin irradiation with groin dissection in otherwise operable patients with resectable vulvar primaries.[355] The study was terminated early because of an unacceptable rate of groin relapse (5 of 27 patients [18.5%]) and subsequent death from cancer (all 5 patients) in the group of women randomized to radiation. Technical inadequacies in the radiation treatment that may have led to inadvertent underdosage of the nodes could have contributed to this outcome.[356]

*Patients with FIGO 1969 N0,1 negative groin nodes by clinical evaluation.

At the Radiation Oncology Centers of Sacramento[357] and at Loma Linda University,[358] patients have undergone prophylactic chemoradiation to the groin nodes, generally as a component of preoperative or definitive chemoradiation for locally advanced primary cancers. Among 37 such patients treated, no groin relapses occurred (see Table 91-11). It remains unclear whether the better results reflect better radiation technique or the radiopotentiating effect of synchronous chemotherapy.

Radiation Techniques, Volumes, and Doses

No standard approach is found to the treatment of vulvar cancer with radiation. The circumstance of radiation (postoperative, preoperative, or as definitive treatment) will influence the designation of target volume, fractionation, and dose. Clinical and histopathologic characteristics of the primary and regional nodes may independently affect the selection of treatment parameters, which depends further on the scope of any coordinated surgery and whether chemotherapy is to be administered with radiation. Comorbidities in elderly patients may constrain the volume and intensity of treatment. Conservation of ovarian function and possible reproductive integrity in younger patients also may affect the technique of treatment.[359] No substitute can be found for comprehensive assessment of disease extent followed by tailored, individualized therapy that takes into account the intent of treatment (i.e., preoperative, definitive, adjuvant postoperative), patient comorbidities, and patient preference. A guideline for radiation doses and fractionation is found in Table 91-13.

CHEMOTHERAPY

Chemotherapy to potentiate the effectiveness of locoregional radiation is rapidly becoming the standard of care for patients receiving radiation as all or part of treatment for the vulvar primary and regional nodes. Prospective randomized data for chemoradiation versus radiation alone do not exist. However, it is the clinical impression of experienced clinicians that tumor control within the irradiated volume appears to be better than that historically achieved with radiation alone. Additionally, late radiation sequelae in normal tissues may be milder consequent to the use of lower total dose and lower dose per treatment fraction. Most chemoradiation has been done with 5-FU alone or in combination with cisplatin or mitomycin-C. Representative results of treatment are depicted in Table 91-14. Experience with radiation and concurrent bleomycin has been disappointing as both preoperative treatment[360] and as treatment for extensive, inoperable disease,[361] with most patients treated for locoregionally advanced disease manifesting persistent or recurrent disease within the irradiated volume.

Chemotherapy for Recurrent, Persistent, or Metastatic Vulvar Carcinoma

Recurrent or persistent vulvar carcinoma after surgical therapy typically is treated with surgical resection or radiation-based therapy or

Table 91-13 Dose Guidelines

	CANCER VOLUME			
	RADIATION ALONE		CHEMORADIATION	
Treatment Intent	**Microscopic**	**Gross**	**Microscopic**	**Gross**
Preoperative	45–56	45–56	36–48	36–48
Postoperative	45–56	54–64 (+ margin)	36–48	45–56 (+ margin)
Radical	45–56	63–72	36–48	45–64

All doses expressed in Gy. Dose guidelines assume that treatment will be administered in fractions of 1.6 Gy to 1.8 Gy and that multiple daily fractions may be used for all or a part of the treatment. Higher total doses imply fraction size of 1.6 Gy, and lower total doses imply fraction size of 1.8 Gy. Dose guidelines should be interpreted in the contexts of tumor bulk, health of normal tissues unavoidably included within the treatment volume, tolerance, and response to treatment. Use of doses in the lower end of the range for gross disease is predicated on a biopsy at the completion of treatment confirming histologic clearance. Doses for gross disease should be applied with progressively shrinking volumes that confine high dose to not more, and possibly less, than the original volume of measurable disease.

both. Vulvar carcinoma that recurs in a local or regional area of prior radiation often is considered for surgical resection. Tumors that are not controlled or amenable to surgical or radiotherapeutic approaches are difficult to manage because of a lack of active systemic agents; these tumors often are first seen in elderly patients with major comorbidities, and sometimes in individuals with altered immunity due to chronic immunosuppression. Because recurrent tumors are rare, no randomized phase III trials have evaluated systemic therapy. Very few phase II studies have been reported to guide clinicians in selecting treatment. The effectiveness of chemotherapy also is limited by the fact that many treatment failures are local, or locoregional,[268,337–339,362,364] and typically within a prior radiation field (Table 91-15). These radiation-resistant tumors typically are also resistant to chemotherapy. Responses to treatment may be difficult to evaluate because of extensive anatomic abnormalities associated with prior surgery and radiation. Only six agents have been evaluated as single agents, with trials including only 4 to 22 patients, with most of these trials done in the early 1980s. Doxorubicin (Adriamycin) and bleomycin have demonstrated some single-agent activity.[365–367] An anecdotal response has been reported with liposomal doxorubicin.[368] Unfortunately, the

Table 91-15 Pattern of Recurrence* in 267 Patients for Whom Regional Therapy† Failed for Carcinoma of the Vulva

Vulva/Perineum No. (%)	Groin No. (%)	Pelvis No. (%)	Distant No. (%)
162 (60.7)	62 (23.2)	42 (15.7)	51 (19.1)

*Because some patients manifested recurrence at more than one site, the total recurrences exceed 267, and the total of the percentages exceeds 100.

†The majority of patients underwent radical surgery. Adjunctive radiation was administered in some, and a small number were treated with radiation alone.

Pooled data, seven series.[268,337–339,362–364]

duration of response in most instances is disappointing and is measured in months.

Combination chemotherapy regimens that have been evaluated have included bleomycin together with a variety of agents (Table 91-16).[369–373] The largest experience is with the regimen of bleomycin, methotrexate, and N-(2-chloroethyl)-N′-cyclohexyl-N-nitrosourea (CCNU).[369,370] Activity has been seen in two separate phase II studies that included 53 patients and demonstrated 5 complete responses and 27 partial responses, for an overall response rate of 60%, in a group of patients with locally advanced squamous cell carcinoma of the vulva.

In vitro studies with squamous cell cancer lines of the vulva demonstrate high expression of the epidermal growth factor receptor and efficacy of ZD1839 in vitro, either alone or in combination with chemotherapy.[374,375] The role of this targeted agent in the clinic awaits formal testing.

Other Histologic Types

Adenosquamous Carcinoma

The pathogenesis of adenosquamous carcinoma of the vulva remains controversial, as it has been since it was first described by Lever 45 years ago.[376] Initially, it was thought to arise from solar keratoses. However, this theory later was discounted, as cases were described in which vulvar sun exposure was not a factor.[376,377] A currently accepted theory is that the involved glandular elements produce mucin and have their origin from mucin-producing cells of the skin appendages.[378]

Adenosquamous cell carcinoma of the vulva appears to be a biologically distinct tumor. These lesions involving the vulva are highly aggressive, are first seen at a more advanced stage, and are associated with a higher incidence of lymph node metastases than are their corresponding squamous cell counterparts. Five-year survival rates reflect this trend, at 5% and 62% for adenosquamous and squamous cell carcinomas, respectively.[379]

Melanoma

Malignant melanoma of the vulva is the second most common cancer of the vulva, accounting for approximately 10% of primary vulvar neoplasms and representing 0.05% to 0.5% of all malignancies of the female genital tract. Even large, tertiary cancer referral centers see only one or two patients annually.[380–383]

Malignant melanoma occurs predominantly in postmenopausal white women, with a peak incidence between the 6th and 7th decades. These lesions may arise de novo or from pre-existing junctional or compound nevi. Three basic histologic types exist: (1) superficial spreading melanoma, the most common type, which tends to remain superficial in its early course; (2) lentigo malignant melanoma, a "flat freckle" that has a tendency to remain superficial; and (3) nodular melanoma, which is the most aggressive variety, carries the worst prognosis, and tends to invade deeply early.[381]

Amelanotic varieties of these lesions are very rare. These lesions tend to be asymptomatic and insidious. Any pigmented lesions on the vulva should be sampled with biopsy. Melanomas typically contain melanoma antigen and S-100 antigen and lack carcinoembryonic antigen (CEA). These immunohistochemical tests may be required to differentiate superficial spreading melanoma from Paget's disease.[384]

STAGING. The prognosis for vulvar melanoma appears to correlate most closely with the level of skin involvement. Chung and colleagues[381] (Table 91-17) proposed a modified leveling system, retaining Clark's definitions[385] for levels I and V. Levels II, III, and IV are arbitrarily defined by using measurements in millimeters. Breslow's[386] measurements also may be used, but in the vestibule and perineum, because no keratin or granular layers exist, the system must be modified.

Table 91-16 Combination Chemotherapy in Squamous Cell Carcinoma of the Vulva

Table 91-17 Stages of Melanoma of the Vulva According to Three Different Systems of Criteria

Stage	Clark's Levels	Chung	Breslow
I	Intraepithelial	Intraepithelial	<0.76 mm
II	Into papillary dermis	≤1 mm from granular layer	0.76–1.50 mm
III	Filling dermal papillae	1.1–2 mm from granular layer	1.51–2.25 mm
IV	Into reticular dermis	>2 mm from granular layer	2.26–3.0 mm
V	Into subcutaneous fat	Into subcutaneous fat	>3 mm

From Berek JS, Hacker NF: Practical Gynecologic Oncology, 2nd ed. Baltimore, Williams & Wilkins, 1994.

TREATMENT. For level I or II lesions (superficial), the risk of nodal spread is low, and wide local excision is adequate therapy. For deeper lesions, radical vulvectomy with en bloc bilateral inguinofemoral lymphadenectomy should be performed if the inguinofemoral nodes are positive. Estrogen receptors have been demonstrated in human melanomas, and a response to tamoxifen has been reported.[387] PET and sentinel-node groin biopsies may be tools to aid in selecting the extent of regional surgery. Systemic adjuvant therapies for vulvar melanoma parallel adjuvant strategies for cutaneous melanomas arising at other primary sites.

PROGNOSIS. Melanomas of the vulva tend to spread earlier than squamous cell carcinoma and carry a worse prognosis overall. Chung and colleagues[386] reported corrected 5-year survival rates of 100%, 40%, and 20% for patients with level II, III or IV, and V lesions, respectively. The overall 5-year survival rate with negative and positive nodes is 38% and 13%, respectively.[388]

Basal Cell Carcinoma

Basal cell carcinomas represent approximately 2% of vulvar cancers. They usually affect postmenopausal white women and are locally aggressive, although nonmetastasizing. They are commonly seen on sun-exposed skin, but also can be seen rarely on the vulva. Their common appearance is a "rodent" ulcer with rolled edges and central ulceration. Wide local excision is the treatment of choice. Not unlike CIS and Paget's disease of the vulva, basal cell carcinomas are associated with a high incidence of antecedent or concomitant malignancy elsewhere in the body; a thorough search for other primary malignancies is always warranted.

Bartholin's Gland Carcinoma

Bartholin's gland is situated inferior to the bulbocavernosus muscle and superior to the deep perineal muscles. The gland is composed of columnar epithelium, and ducts are lined by stratified squamous epithelium and transitional cell epithelium. Therefore, adenocarcinomas, squamous cell carcinomas, and, rarely, transitional cell carcinomas may arise from Bartholin's gland. Most primary adenocarcinomas of the vulva arise within these glands. The median age at diagnosis is 57 years. In 10% of patients, a history of preceding inflammation of Bartholin's gland is obtained. Malignancy arising from Bartholin's gland constitutes approximately 4% to 7% of vulvar malignancy.

The criteria established by the Armed Forces Institute of Pathology for the diagnosis of Bartholin's gland carcinoma enjoy the broadest contemporary acceptance.[389] A primary Bartholin's cancer should show areas of apparent transition from normal elements to neoplastic elements on histologic study, should be histologically compatible with origin from Bartholin's gland, and should exist without evidence of primary cancer elsewhere. The Bartholin's complex consists of a duct that is lined by squamous epithelium as it enters the distal vagina. The more proximal portions of the ductal system are lined by transitional epithelium and may be lined by columnar epithelium before arborization into secretory glandular elements. Squamous carcinoma constitutes approximately 35% to 50% of cases, with adenocarcinoma only slightly less common.[389–393] Adenosquamous carcinomas and transitional cell carcinomas make up a small minority of cases. Adenoid cystic carcinoma represents a distinct subset thought to be less likely to spread to regional nodes and associated with a long natural history and late recurrences, which may be either local or hematogenous.[394] Bartholin's gland carcinomas have been reported in younger women and in association with pregnancy,[389,390] although an etiologic relation is not apparent. Often first seen with a mass deep in the labia with intact overlying skin, Bartholin's gland carcinomas may be confused with a Bartholin's cyst or abscess, particularly if the patient is young. No persuasive evidence exists that squamous carcinomas of Bartholin's gland behave differently or should be managed differently from squamous cancers arising from other vulvar structures. However, it may be more difficult to accomplish conservative excision with adequate surgical margins in patients with Bartholin's gland cancers, and most patients for whom surgical therapy fails have a component of locoregional recurrence.[392,393] The use of adjuvant postoperative radiation is common.[395,396] A retrospective review of 36 nonrandomized patients at M.D. Anderson Cancer Center revealed that in 6 (27%) of 22 patients treated with surgery alone local recurrence developed, whereas only 1 (7%) of 14 higher-risk patients selected to receive adjuvant radiation manifested local failure.[393]

Sarcoma

Vulvar sarcomas constitute 1% to 2% of vulvar malignancies and include leiomyosarcomas, rhabdomyosarcomas, angiosarcomas, neurofibrosarcomas, and epithelioid sarcomas. The prognosis appears to depend on three main determinants: lesion size, tumor contour, and mitotic activity. Lesions greater than 5 cm in diameter, with infiltrating margins, and demonstrating more than five mitotic figures per 10 high-power fields (HPFs) are most likely to recur. Wide local excision is the usual treatment.

Verrucous Carcinoma

Verrucous carcinoma of the vulva represents a variant of squamous cell carcinoma. These lesions originally were described as occurring in the oral cavity but also have been described involving the vagina, cervix, and vulva. The lesion grossly appears cauliflower-like. Microscopically, the papillary fronds lack the connective tissue core that characterizes condyloma acuminata. These features are very similar to those of the giant condylomata Buschke-Loewenstein, possibly representing successive stages of the same pathologic process. Clinically, these tumors are very slow growing and carry a favorable prognosis. As metastasis to regional lymph nodes is rare, radical local excision is the standard treatment.[397–400] If suggestive groin nodes are present, fine-needle aspiration (FNA) or excisional biopsy should be carried out. Enlarged nodes usually are caused by inflammatory hypertrophy, but if they do contain metastases, radical vulvectomy and bilateral groin lymph node dissections are indicated. Verrucous carcinoma has the reputation of being radioresistant, and reports of favorable outcomes after radiation are uncommon. Surgery remains the treatment of choice whenever feasible.

CANCER OF THE VAGINA

SUMMARY OF KEY POINTS

Epidemiology
- For 2007, 2140 new cases of invasive vaginal cancer in the United States are estimated, with 790 deaths
- Primary vaginal cancer constitutes only 1% to 2% of malignancies of the female genital tract and 0.1% to 0.2% of all cancers.
- The majority of vaginal malignancies (≤90%) are metastatic.
- Squamous cell carcinomas compose approximately 80% of primary vaginal malignancies, with adenocarcinomas, melanomas, sarcomas, and lymphomas accounting for most of the remainder.

Etiology
- The role of human papillomavirus (HPV) in vaginal carcinoma has been the subject of much speculation, but no conclusive etiologic link has been identified. Low socioeconomic status, a history of genital warts, a prior abnormal Papanicolaou (Pap) smear, early hysterectomy, and prior vaginal trauma may be associated risk factors.
- The frequency with which vaginal intraepithelial neoplasia (VAIN) progresses to invasive malignancy is unknown, but the percentage is thought to be small.

Evaluation
- Up to 20% of patients are asymptomatic, with disease being diagnosed on routine pelvic examination and Pap smear.
- Most patients initially have postcoital or postmenopausal painless bleeding or discharge.
- Patients also may have symptoms related to the location of the tumor, such as urinary frequency or dysuria from anterior tumors, or constipation or tenesmus from posterior tumors.
- Vaginal carcinoma may be identified by colposcopy in the setting of an abnormal Pap smear.
- Diagnosis is established by tissue biopsy of a gross or colposcopically detected lesion.
- Vaginal cancer is staged clinically based on findings of physical examination, cystoscopy, proctoscopy, and chest radiography. Additional diagnostic assessments will not alter staging, but may be important in the design of a treatment program.

Treatment
- Depending on the location of cancer within the vagina, tumor size, and extent of invasion, surgery may be effective primary therapy in selected circumstances Patients with stage I disease that can be excised with negative surgical margins without compromising the function of the urinary bladder or rectum are appropriate candidates, as are patients with stage IVa disease in whom urinary or fecal continence has already been destroyed by direct invasion of the cancer through the wall of adjacent viscera.
- Radiation therapy is the treatment of choice for most other patients. Combined chemoradiation, similar to the approach used in anal, vulvar, and cervical cancers, has been reported in a limited number of patients, but has not been established as superior to radiation alone.
- Patients with central recurrence after radiation may be candidates for surgical salvage, which usually entails pelvic exenteration.

EPIDEMIOLOGY

Primary vaginal cancers are rare, accounting for only 1% to 2% of malignant neoplasms involving the female genital tract. By convention, with International Federation of Gynecology and Obstetrics (FIGO) criteria for classification and staging, any tumor that has extended to the cervix and has reached the external os should be classified as a cervical carcinoma. Similarly, any tumor extending to involve the vagina and vulva simultaneously is classified as vulvar carcinoma. In addition, if a patient has been previously treated for a cervical cancer, a subsequent vaginal cancer within 5 years (or 10 years, depending on the author) is considered a recurrence of the cervical cancer rather than a new primary cancer. Thus, some tumors with their epicenters in the vagina will be classified as cervical or vulvar neoplasms by using the FIGO formalism, and other patients, who may have second primary vaginal malignancy as part of a "field cancerization" of the lower genital tract, will be classified as patients with recurrence of prior malignancy. These factors account for some of the rarity of primary vaginal cancer. Over 60% of primary apical vaginal tumors are diagnosed in women who have undergone hysterectomy. Speculation occurs that the lack of a transformation zone and glandular tissue in the vagina (compared with the cervix) makes the vagina less likely to develop neoplasia.

Most cancers involving the vagina are metastatic. Vaginal involvement may occur by direct extension or by lymphatic or hematogenous spread. Primary tumors that most commonly are the source of metastases involving the vagina include cancers of the endometrium, cervix, vulva, ovary, breast, colon and rectum, and kidney.[401–404]

Only 10% of vaginal cancers are primary in the vagina, and most of these are of squamous histology. The nonsquamous primary vaginal malignancies account for a heterogeneous group of histologies (Table 91-18).[405–414] Metastatic tumors are treated according to their primary site of origin, and not as vaginal cancers.

Most women with vaginal squamous cancer are postmenopausal, and more than 75% of patients are older than 50 years at diagnosis. Most single-institution series report average age in the fifth through seventh decades, with ages ranging from the 20s to the 90s. No correlation is found between age and stage of disease or survival. Squamous tumors may be nodular, ulcerative, indurative, or exophytic plaques of any size. Histologically, they are similar to squamous tumors from other sites. Approximately one third of these tumors are keratinizing, and more than one half are nonkeratinizing, moderately differentiated lesions. The degree of histologic differentiation of these tumors has not been shown to correlate with survival.[407,415–418]

Verrucous carcinoma is an uncommon variant of squamous cell carcinoma, morphologically similar in the vagina to verrucous lesions of the vulva (Fig. 91-23). Grossly, it appears as a warty fungating mass. Histologically, it is composed of large papillary fronds covered by dense keratin. Its deep margin creates a pushing border of well-oriented rete ridges. This tumor rarely metastasizes but can infiltrate

Table 91-18 Primary Vaginal Cancer: Reported Incidence of Histologic Types

Histology	No.	Percentage
Squamous	627	83.4
Adencarcinoma	70	9.3
Sarcoma	20	2.6
Melanoma	20	2.6
Undifferentiated	8	1.0
Small cell	5	0.7
Lymphoma	2	0.3
Carcinoid	1	0.1
Total	753	100.0

Modified from Berek JS, Hacker NF: Practical Gynecologic Oncology, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2000, p 598.

extensively into surrounding tissues, including the rectum and coccyx. This histologic variant of squamous cancer has the reputation of being resistant to control by conventional doses of radiation. Thus surgery is favored as a treatment modality when clinically feasible.

Adenocarcinomas occurring in the vagina include papillary, mucinous, adenosquamous, small cell, and clear cell variants. The variants that have been best described are the clear cell malignancies, primarily because of their reported occurrence in young women who had been exposed to diethylstilbestrol (DES) in utero.[419,420] Clear cell carcinomas of the vagina usually are polypoid masses. Histologically, well-described patterns are noted: tubulocystic, solid, or papillary. They usually are diagnosed at an earlier clinical stage than is seen with squamous cell carcinomas; 74% of Registry patients were stage I, and 26% were stage II.

ETIOLOGY

The association of vaginal, vulvar, and cervical intraepithelial neoplasia (CIN) and human papillomavirus (HPV) has caused speculation as to the role of HPV in multifocal carcinoma of the lower female genital tract. Ikenberg and coworkers[421] were able to demonstrate the presence of HPV DNA in tumor tissue in 10 of 18 patients (56%) with vaginal cancer, suggesting a possible etiologic role for HPV in the development of vaginal neoplasia. Many women are first seen with multifocal disease of the genital tract, including dysplasias of vulva, vagina, and cervix. Unlike the cervix, where disease usually is present in the transformation zone, vaginal dysplasia can occur anywhere in the vaginal mucosa and often is multifocal. The natural history of vaginal intraepithelial neoplasia (VAIN) is not well understood, and the potential of VAIN to progress to invasive squamous malignancy is not known with precision. Aho and colleagues[422] identified 23 patients with VAIN followed up for at least 3 years without treatment. The mean age was 41 years. Half of the VAIN lesions were multifocal, and half were associated with either cervical intraepithelial neoplasia (CIN) or vulvar dysplasia. The spontaneous regression rate of VAIN was high (78%), including four of five VAIN 3 patients, but two cases (9%) progressed to invasive cancer. Studies by Benedet and Saunders[423] and by Lenehan and associates[424] have shown that only 3% to 5% of patients with VAIN treated with various methods actually progressed to having invasive vaginal carcinoma. Invasive vaginal carcinoma has also been associated with chronic irritant vaginitis, particularly that type caused by chronic use of a vaginal pessary.

The clear cell variant of vaginal adenocarcinoma has been clearly linked to in utero exposure to DES. The Registry for Research on Hormonal Transplacental Carcinogenesis had accessioned more than 580 cases of clear cell carcinoma of the vagina and cervix. In utero exposure to synthetic estrogens accounted for only two thirds of reported cases. Work by Herbst and coworkers[425–427] suggests that the age distribution for clear cell adenocarcinoma of the vagina has two separate peaks. The first peak included women with a mean age of 26 years, and the second peak contained women with a mean age of 71 years. The first peak contained all DES daughters, and the second peak contained women born before 1950 and thus not exposed to DES. However, even when the DES daughters were excluded, a bimodal pattern still was observed. The authors suggested that this pattern might imply a genetic predisposition. The age range of DES-related clear cell adenocarcinoma is 7 to 42 years. The actual risk of clear cell adenocarcinoma developing in DES-exposed women is estimated at only 1 in 1000, with the highest risk in those women exposed before 12 weeks' gestation.[419] Although the risk of clear cell carcinoma of the vagina is small in DES-exposed women, 45% of these patients will have areas of vaginal adenosis, and 25% will have structural abnormalities of the uterus, cervix, or vagina. Thus it is recommended that women exposed to DES in utero be examined initially at menarche (approximately age 14 years) and that a careful examination of the cervix and the vagina be performed in addition to cytologic examinations. Colposcopy is unnecessary if the clinical and cytologic examinations are normal.

Figure 91-23 • Locally recurrent verrucous cancer following radical vulvectomy. Warty, exophytic, cauliflower morphology is characteristic. This patient had persistent local disease, despite salvage chemoradiation consisting of 54 Gy in 30 fractions with twice-daily fractionation over 7 weeks with three cycles of synchronous 5-fluorouracil and cisplatin. (Reproduced with permission from Russell AH: Vulva. In Leibel SA, Phillips TL [eds]: Textbook of Radiation Oncology. Philadelphia, WB Saunders, 1998, pp 907–925.)

PATTERNS OF SPREAD

Vaginal cancer may spread by several routes:

- Direct extension to adjacent soft tissue structures such as the paracolpos/parametria, bladder, urethra, and rectum, with eventual involvement of the bony structures of the pelvis.
- Lymphatic dissemination, the pattern of which will depend on the location of the primary tumor. The lymphatics of the upper vagina communicate with those of the cervix and drain into the pelvic nodes and then to the para-aortic nodes. The posterior vaginal wall drains into lymphatics that anastomose with the inferior gluteal, sacral, and deep pelvic nodes. The anterior wall is drained by lymphatics that drain to the lateral pelvic walls. The lymphatics of the distal one third of the vagina drain into the inguinofemoral nodes and then secondarily to the pelvic nodes.

- Hematogenous dissemination to other organs, including the lungs, liver, and bone, usually is a late manifestation in the natural history of this disease.

SIGNS AND SYMPTOMS

Presenting symptoms commonly associated with vaginal cancer include painless spontaneous or postcoital vaginal bleeding or vaginal discharge. Because of the close proximity of the urethra to the vagina, anterior vaginal tumors may cause symptoms of urinary frequency or dysuria or both. Similarly, advanced posterior vaginal tumors may cause symptoms of tenesmus or constipation. Pelvic pain may be present when disease has extended beyond the vagina. Up to 20% of patients are asymptomatic, with disease detected on routine examination or Papanicolaou (Pap) smear. In a review of the literature by Plentl and Friedman[428] and colleagues in 1971, 51% of vaginal carcinomas arose in the upper vagina, 19% from the middle third, and 30% from the distal third. Fifty-seven percent of the tumors originated from the posterior wall, 27% from the anterior wall, and 16% from the lateral wall.[406] The most common site of occurrence of vaginal carcinoma is along the posterior wall in the upper one third of the vagina. Because the posterior blade of the speculum often obscures this area, the speculum must be rotated to view the vaginal tube in its entirety.

DIAGNOSIS

The diagnosis of carcinoma of the vagina may be missed on initial examination, especially if the tumor is located anteriorly or posteriorly where the blades of a duckbill speculum may obscure a lesion. Thus the speculum must be rotated as it is withdrawn to allow circumferential visualization of all areas of the vaginal mucosa, and the speculum may require multiple insertions and withdrawals to accomplish this goal. If no lesion is detected in the setting of an abnormal Pap smear, use of Lugol's iodine to stain the vaginal mucosa and colposcopy may be helpful to direct biopsies. Diagnosis requires biopsy confirmation of a suspected lesion, as benign lesions such as vaginal warts (condyloma) may mimic the gross appearance of malignancy. An examination under anesthesia with directed biopsies may be necessary if the patient is elderly or has significant vaginal stenosis precluding a satisfactory office examination, or if cystoscopy or proctoscopy is indicated to evaluate the patient adequately because of the location and extent of the vaginal lesion.

STAGING

Vaginal cancers are staged according to criteria set forth by FIGO or by the American Joint Committee on Cancer (Table 91-19). The staging of vaginal cancers is primarily clinical and is based on findings on physical and pelvic examination, cystoscopy, proctoscopy, chest radiography, and skeletal radiography (if indicated for bone pain). Assignment of FIGO stage is necessary, but alone may be insufficient to direct therapy optimally. Rubin and colleagues[408] studied patients with vaginal cancer spanning the years 1958 through 1980. In this study, 18% of patients had stage I tumors, and 46% had stage II tumors. Stock and colleagues[429] reviewed patients spanning the years 1962 through 1992. In this study, 23% of patients had stage I disease, and 58% had stage II disease; the remaining patients had more advanced disease.

In addition to the standard staging investigation, an abdominopelvic computed tomography (CT) scan or pelvic magnetic resonance imaging (MRI) or both may be helpful to evaluate the extent of the primary tumor, confirm patency of the ureters, and screen for the possible presence of metastases to deep femoral, pelvic, and paraaortic lymph nodes.[430] Precise delineation of local disease extent may be helpful in planning intracavitary or interstitial brachytherapy. Positron emission tomography (PET) may be a clinically useful tool to assess for regional (lymphatic) and remote (hematogenous) dissemination, but its value has not been prospectively evaluated in this context (Fig. 91-24).

Table 91-19 Vaginal Cancer: Staging Systems

Type	TNM	FIGO	Definition
Primary tumor	TX		Primary tumor cannot be assessed
	T0		No evidence of primary tumor
	Tis	0	Carcinoma in situ
	T1	I	Tumor confined to the vagina
	T2	II	Tumor invades paravaginal tissues but not to the pelvic wall
	T3	III	Tumor extends to the pelvic wall
	T4	IVa	Tumor invades mucosa* of the bladder or rectum and/or extends beyond the true pelvis
		IVb	Distant metastasis
Regional lymph nodes	NX		Regional lymph nodes cannot be assessed
	N0		No regional lymph node metastasis
Upper $^2/_3$ vagina	N1		Pelvic node metastasis
Lower $^1/_3$ vagina	N1		Unilateral inguinal node metastasis
	N2		Bilateral inguinal node metastases
Distant metastasis	MX		Presence of distant metastasis cannot be assessed
	M0		No distant metastasis
	M1		Distant metastasis

FIGO, International Federation of Gynecology and Obstetrics; TNM, tumor-node-metastasis.

*Presence of bullous edema is not sufficient evidence to classify as T4 or FIGO IVa.

A refinement of the AJCC/FIGO staging system that has been proposed by Perez and colleagues[431] is commonly used by radiation oncologists, both in selection of radiation technique and in the reporting of outcomes after treatment. Patients with stage IIa have paravaginal extension only, whereas patients with stage IIb have extension to parametria. This distinction has both prognostic significance and a potential impact on the volume and technique of teletherapy and brachytherapy (intracavitary vs. interstitial).

TREATMENT

Therapy for vaginal carcinoma must be highly individualized based on tumor location, size, extent, and the functional status of both the vagina and adjacent organs. The close proximity of the bladder, urethra, and rectum limits the doses of radiation that can be given and restricts the surgical margins that can be obtained without performing an exenterative procedure. Up to 50% of patients with primary vaginal cancer may have had prior hysterectomy for malignant or benign indications.[429,432,433] In such patients, the presence of adhesions with fixed loops of small bowel or sigmoid colon above the vaginal apex also may affect selection of treatment modalities and techniques.

Additionally, psychosexual issues and the attempt to maintain a patent and functional vagina in patients desirous of preserving the option of vaginal intercourse should be an important part of treatment planning.

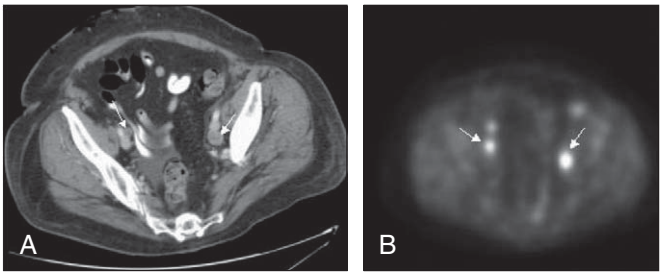

Figure 91-24 • Vaginal cancer with lymphadenopathy. **A,** CT of pelvis showing mildly enlarged bilateral external iliac nodes suggestive of metastases *(arrows)*. **B,** Axial FDG-PET scan showing hypermetabolic nodes as hyperintense spots confirming metastases *(arrows)*.

Surgery

Surgery in vaginal cancer is limited by the propensity of this cancer to spread to adjacent organs because of the lack of anatomic boundaries around the vagina.[406,434] The use of surgery as a primary modality is limited to those cases in which negative margins can be achieved without significant loss of function of bladder and rectum. Surgery also can be used to salvage central pelvic recurrence after radiation.

In the past, many authors have considered radiation to be the primary treatment modality for vaginal cancer. Contributing to this recommendation has been the age of most patients with vaginal cancer and the complicating presence of multiple medical comorbidities. With improved anesthetic techniques and better postoperative care, surgery may be an option available to more women with vaginal cancer.

Surgery for vaginal cancer can be primary therapy or can be used as an adjunct to radiation therapy. Stage I vaginal cancer involving the upper vagina in a young woman can be treated with radical hysterectomy and radical upper vaginectomy with pelvic lymph node dissection. This approach in most cases allows preservation of both vaginal and ovarian function, particularly if no risk factors are found during surgery that would require postoperative radiation therapy.

Traditionally, later-stage vaginal cancers, particularly those in elderly women, have been treated primarily with radiation therapy. However, several recent series have suggested that judicious use of surgery may increase disease-free survival in carefully selected patients.

Tjama and associates[435] reported their experience treating 84 patients with primary invasive vaginal cancers in the Northern Gynecological Oncology Centre, where the policy tended toward operative management. In this series, the treatment was individualized based on patient age, medical status, size of tumor, location of lesion, and stage. Large lesions that did not permit negative margins were treated primarily with radiation, and adjuvant radiation was used postoperatively to treat patients who had positive retroperitoneal nodes or incomplete excision. Forty patients in this series were treated with surgery alone. Fifty-eight patients underwent exploratory laparotomy for either treatment or staging. Primary surgical treatment included radical vaginectomy, partial vaginectomy, wide local excision, and exenteration. This study demonstrated a significantly increased disease-free survival in patients who had surgery as part of their therapy or as their only therapy compared with patients who were treated with radiation alone. When stratified by stage, this difference was significant in those patients with stage II disease. In a multivariate analysis, surgical treatment and FIGO stage were the only significant predictors of improved disease-free survival. Unknown selection biases may have contributed substantially to these results, influencing treatment modality choice and, therefore, outcomes.

The National Cancer Data Base study[436] reported that surgery was used to treat 49% of patients with stage I disease, 28% of patients with stage II disease, and 25% of patients with advanced stage disease. Women with stage I disease treated with surgery only had a 5-year survival of 90%, compared with 63% for women with stage I disease treated with radiation therapy only. Although this difference was statistically significant, differences among these patients with respect to age and medical comorbidities could not be assessed. Similar findings were demonstrated in stage II disease, in which surgery alone gave a 5-year survival rate of 70% compared with 57% for patients treated with radiation therapy alone. Nine women with advanced-stage disease had surgery, radiation therapy, and chemotherapy; remarkably, the 5-year survival for this group was 71%. These findings suggest that in selected cases, surgery may play a role in improving 5-year survival in all stages of disease.

Radiation Therapy

Radiation therapy using various combinations of teletherapy as well as interstitial and intracavitary therapy generally is considered the treatment of choice for most patients with more than small-volume stage I and II cancers of limited extent. The exact combinations of treatment again depend on the tumor location, volume and thickness, and depth of invasion beyond the vagina. Almost all patients with stage I lesions that are larger than 2 cm, and all patients with stage II to IV disease, require initial treatment with external-beam radiation therapy of approximately 45 to 50.4 Gy, both to shrink the primary tumor and to address potential sites of microscopic or clinically occult dissemination. Inclusion of pelvic or inguinofemoral lymph nodes, or both, in the field depends on the tumor location. Tumors extending to involve the distal third of the vagina should have inclusion of the inguinofemoral nodes as well as the pelvic nodes. Extended-field treatment to include the para-aortic lymph nodes is appropriate if these nodes have been found to contain metastatic disease by surgical excision or image-guided fine-needle aspiration. External-beam therapy usually is followed by interstitial or intracavitary brachytherapy to a total tumor dose of approximately 75 to 85 Gy. For tumors involving the upper third of the vagina with intact uterus, intrauterine tandem and vaginal ovoids/colpostats may be used to obtain proper dose distributions encompassing the vaginal wall, paravaginal tissues, and parametria. For a patient in this category whose uterus previously has been surgically removed, a vaginal cylinder or colpostats may be used. The use of intracavitary vaginal brachytherapy generally is restricted to patients with tumor thickness of 5 mm or less because of the rapid fall-off of dose with distance from intracavitary isotope sources. For carcinomas with more than 5 mm thickness after teletherapy, the use of interstitial technique in addition to a vaginal cylinder will increase the depth of the radiation-dose distribution without delivering an excessive dose of radiation to the vaginal mucosa.[442] The treatment of small, superficial, stage I lesions may be satisfactory with brachytherapy alone, involving intracavitary cylinders with or without single-plane interstitial implants.[437,438]

The concomitant use of chemotherapeutic agents such as cisplatin and 5-fluorouracil (5-FU) as radiosensitizers for vaginal cancer has not been extensively studied. As the combination of radiation with synchronous chemotherapy (chemoradiation) has increasingly become the mainstay of therapy for locally advanced cervical cancer, anal cancer, and advanced vulvar cancer, extrapolation to squamous carcinoma of the vagina seems logical. The shared etiology suspected in many patients with primary squamous cancers of the anogenital area supports the notion that a successful treatment strategy used for one disease site also could be expected to be effective at adjacent disease sites. However, because of the rarity of vaginal cancer, the use of chemoradiation in this context has not been prospectively evaluated in randomized cooperative group studies comparable to protocols that have been feasible in patients with cervical and anal cancers.

Intervention by Stage

Stage I Disease

For disease involving the proximal vagina, if the uterus is still in situ, a radical hysterectomy, partial vaginectomy, and bilateral pelvic lymphadenectomy can be performed. In a patient with a prior hysterectomy, a radical upper vaginectomy and bilateral lymphadenectomies can be performed. For disease in proximity to the bladder neck or urethra in the anterior vagina, radiation generally is preferable. Posterior tumors may be more amenable to a surgical approach. Lateral tumors in the middle or distal vagina with minimal invasion may be considered for wide local excision. Radiation therapy with brachytherapy alone may be considered for very small tumors less than 2 cm in largest diameter. Radiation usually consists of a combination of teletherapy and brachytherapy. In a recent review of the M.D. Anderson Cancer Center experience, Frank and associates[439] reported that of the nine patients who received brachytherapy alone, three recurred within the pelvis, resulting in a pelvic control rate of only 67%. Therefore, the authors concluded that patients with invasive disease, no matter what size, should be treated with a combination of external beam radiation and brachytherapy; however, it is not necessary to treat the whole pelvis in all patients. They found that there were no pelvic recurrences in 11 patients who received local external beam irradiation (to the lower pelvis only) combined with brachytherapy.

Stage II or III Disease

Before radiation, exploratory laparotomy may allow precise detailing of the areas of involvement, resection of bulky metastatic adenopathy, and ovarian transposition in premenopausal patients. Radiation therapy will consist of both teletherapy and brachytherapy in most patients, with treatment volume and techniques contingent on the location and extent of the primary, the presence and level of metastatic involvement of regional lymph nodes, and patient comorbidities. Although brachytherapy is an important tool in the treatment of vaginal cancer, it should be used only if the entire tumor can be encompassed with adequate margin. Even very small tumors probably will recur if a portion of the tumor receives less than 60 to 70 Gy. Some patients may be treated successfully with progressively shrinking teletherapy treatment volumes designed to deliver a tumor dose of 60 to 66 Gy as an alternative to large-volume interstitial brachytherapy treatment. Three-dimensional conformal therapy or IMRT may improve the ability to deliver high doses to the tumor with external-beam therapy alone. At the M.D. Anderson Cancer Center, we found IMRT to be particularly helpful for tumors that extensively involve the periurethral space, infiltrate the entire vagina, or involve the rectovaginal septum. However, great care must be taken to consider the influence of internal organ motion and the complex regional lymphatic drainage of the vagina in designing target volumes. With IMRT, careful immobilization, attention to organ motion, and set-up verification, the gross target volume sometimes can be taken to an effective total dose of 70 Gy.

Stage IVa Disease

For patients with a rectovaginal or vesicovaginal fistula or extensive bladder or rectal involvement who are in otherwise good medical condition, a pelvic exenterative procedure with vaginal reconstruction using a gracilis myocutaneous flap or rectus abdominis myocutaneous flap may be the procedure of choice.[440,441] Rarely, in patients with fistulae who are not sexually active, the vagina may be allowed to fuse/scar shut after high-dose radiation therapy, thus effectively sealing the fistula and restoring continence. Treatment for most patients involves radiation therapy, either as primary therapy or as adjuvant treatment after surgical clearance of central disease.

Patients with a Central Recurrence after Previous Surgery or Radiation Therapy

Radiation treatment usually is the most appropriate intervention in patients previously treated with surgery. Surgery for local failure after radiation therapy usually requires anterior, posterior, or total pelvic exenteration. Repeated irradiation rarely is feasible.

Complications of Therapy

Complications from the use of radiation or surgery occur in 10% to 15% of patients. Frank and colleagues[439] reported major complication rates of 4%, 9%, and 21% at 5 years for patients treated definitively with radiation for stage I, II, or III-IVA disease, respectively. The close proximity of other organs to the vagina predisposes them to injury. These complications include rectovaginal or vesicovaginal fistulae, radiation cystitis, radiation proctitis, rectal and vaginal strictures, and vaginal necrosis. To decrease the degree of vaginal stenosis after radiation therapy, patients should use a vaginal dilator, preferably on a daily basis. After radiation therapy, the vaginal mucosa may become thin and atrophic. Topical application of estrogen cream stimulates thickening of the vaginal mucosa after radiation and decreases symptoms of vaginal mucosal atrophy, which can include pruritus, discharge, and dyspareunia.[442,443]

PROGNOSIS

Because of the rarity of vaginal cancer, even large referral centers have only limited experience treating vaginal cancers, and thus data with respect to treatment and survival are scarce and based on retrospective series that may span multiple decades, during which both diagnostic assessments of treatment extent and treatment techniques have changed and evolved. Additionally, some published series have pooled patients with squamous cancers together with patients with other histologic types. Others have included patients with noninvasive disease. Thus precision in assignment of prognosis remains elusive. Although the natural history and biologic behavior of vaginal squamous cancer mimics squamous cancer of the cervix,[349] the cure rates of vaginal neoplasms remain lower, and the morbidity associated with treatment may be higher because of the close proximity of functionally important organs, which limit the intensity of treatment and account for most of the late morbidity consequent to therapy.

The most important variable affecting prognosis is the clinical stage at presentation, which reflects the size and depth of tumor penetration.[438,444] Five-year survival estimates for all patients with this malignancy range from 42% to 56%. Rates of survival according to stage are as follows: stage I, 75% to 95%; stage II, 50% to 80%; stage III, 30% to 60%; and stage IV, 15% to 50%.[439]

Adenocarcinoma

Fewer than 15% of primary vaginal neoplasms are adenocarcinomas. Adenocarcinomas occurring in the vagina include papillary, mucinous, adenosquamous, small cell, and clear cell variants. As glandular tissue is not normally present in the vagina, patients with adenocarcinoma must be carefully evaluated to exclude the probability that adenocarcinoma found in the vagina represents metastatic spread from another primary site. Potential primary sites are most likely to include endometrium, cervix, vulva (Bartholin's gland), ovary, breast, colon and rectum, and kidney.[401,404] The treatment for vaginal adenocarcinoma is similar to that for squamous cell carcinoma of the vagina. Because most women afflicted with clear cell cancer of the vagina are young, efforts should be made to preserve vaginal and ovarian function. Surgical treatment of stage I and II disease has consisted of radical hysterectomy; vaginectomy, with formation of a split thickness of skin graft neovagina; and lymphadenectomy or local surgical excision followed by local irradiation to the tumor bed.[445] With use of local irradiation to a stage I lesion, consideration should

be given to performing a pelvic lymphadenectomy, because 17% of stage I lesions have pelvic nodal metastases.[446] If treatment of larger or more advanced lesions with whole pelvic irradiation is to be undertaken, ovarian transposition before radiation should be considered. Prognosis with clear cell vaginal cancers, if correlated with DES, is favorable. The overall actuarial 10-year survival rate is 79%, improving to 90% for patients with stage I vaginal tumors. However, if not associated with DES, the prognosis of primary adenocarcinoma of the vagina is poorer than squamous carcinomas; at 5 years, Frank and coworkers[447] reported an overall survival rate of only 34% for 26 patients treated with radiation for non-DES-related adenocarcinomas of the vagina.

Sarcomas

Vaginal sarcomas make up 3% of primary vaginal carcinomas. Of the 68 cases of vaginal sarcoma reported by Peters and colleagues,[448] leiomyosarcomas accounted for 46 (68%) of the reported cases. Other reported sarcomas include endometrial stromal sarcoma, malignant mixed müllerian tumor, and rhabdomyosarcoma, among others.[449] Surgical resection is the treatment of choice. The benefit of chemotherapy or radiation therapy is unclear in the treatment of adult vaginal sarcomas. Embryonal rhabdomyosarcoma (sarcoma botryoides) is a highly malignant sarcoma that occurs in children aged 6 years or younger (mean age, 1.8 years). This sarcoma generally appears as soft nodules that fill and protrude from the vagina or as abnormal bleeding. The prognosis for patients with this malignancy has improved with the use of multimodality therapy including surgery, polyagent chemotherapy, and radiation.[450]

Endodermal Sinus Tumors

Endodermal sinus tumors are rare germ cell malignancies that occur primarily in the ovary but have been reported to occur at extragonadal sites, including the vagina. This vaginal malignancy, which occurs in children younger than 2 years, appears as abnormal bleeding or discharge in addition to the presence of a vaginal mass. As in its ovarian counterpart, α-fetoprotein can be detected in this malignancy and can be used as a serum tumor marker. Treatment consists of chemotherapy (vincristine, actinomycin D, and cyclophosphamide), as well as surgical excision, and, occasionally, radiation therapy.

Melanoma

Vaginal melanomas are rare but account for 2.7% of vaginal malignancies.[451–453] Three percent of malignant melanomas involve the female genital tract, with the vulva the most common site of occurrence. Melanomas arising in the vagina are thought to originate from in situ melanocytes in areas of melanosis or atypical melanocytic hyperplasia. These malignancies occur at a mean age of 55 years, with an age range of 22 to 83 years. Patients typically are first seen with abnormal vaginal bleeding, discharge, or a mass. These tumors most commonly occur in the lower one third of the vagina on the anterior wall and appear as a blue-black or black-brown mass or plaque. They have a poor prognosis, with 5-year survival rates of 15% to 20%.[451–453] Management is surgical and, depending on the position of the lesion, may require exenterative procedures to obtain adequate margins. No established curative role is found for radiation, which generally is reserved for circumstances in which surgery either is not feasible or is refused. Local radiation may provide palliation and growth restraint in patients with proven metastatic deposits for whom exenterative surgery may not be appropriate. Adjuvant systemic therapy and treatment for disseminated melanoma parallels the treatment of melanoma arising at other sites.

CHEMOTHERAPY FOR PERSISTENT, RECURRENT, OR METASTATIC VAGINAL CANCER

Most cases of recurrent or persistent vaginal carcinoma occur in the vaginal vault, or pelvic, inguinal, and supraclavicular nodes.[454] Dermal metastasis and lung and bone metastases also have been reported.[455,456] Very limited data exist on the treatment of vaginal cancer, with only few phase II studies describing single-agent experiences with squamous cell carcinoma of the vagina. Even fewer data are available for therapies for clear cell or adenocarcinomas of the vagina. Responses to single-agent cisplatin and doxorubicin have been reported, and a single case reports a complete response to the combination of bleomycin, methotrexate, and cisplatin.[457–460]

92 Cancer of the Endometrium

Catherine K. Park, Sachin Apte, Geza Acs, and Eleanor E. R. Harris

SUMMARY OF KEY POINTS

Incidence
- There are 39,080 estimated new cases of endometrial cancer in the United States, and 7400 deaths each year.
- Endometrial adenocarcinomas account for 95% of cases, and 5% are uterine sarcomas.

Etiology and Epidemiology
- The median age for endometrial cancer is 63 years; the majority of these cancers occur after menopause.
- Hormonally dependent subtypes arise in hypertrophic endometrium.
- Lifetime estrogen exposure contributes to risk.
- Hormonally independent types occur at an older age and arise in atrophic endometrium.
- Other risk factors include family history, certain systemic diseases, and tamoxifen use.

Pathology and Biology
- Atypical hyperplasia confers a 25% risk of invasive cancer.
- Aggressive subtypes include uterine serous, clear cell, and sarcomas.
- Estrogen and progesterone receptor expression influence biologic behavior.
- Uterine serous pathogenesis is p53-mediated.

Clinical Findings
- Abnormal uterine bleeding and discharge are present in 90% of cases.
- Endometrial biopsy or dilation and curettage is generally required for diagnosis.

Differential Diagnosis and Staging
- Other causes of uterine bleeding include atrophy, infection, medications, coagulopathy, polyps and fibroids, cervical cancer, and nongynecologic malignancies.
- Staging is surgical and is based on whether disease is confined to the uterus.
- Clinical staging is used for inoperable patients.

Primary Therapy
- Surgery, including hysterectomy, bilateral salpingo-oophorectomy, lymph node sampling, and pelvic washings, is performed in all operable patients. Lymph node sampling may be omitted in patients with grade II tumors that are limited to the endometrium or grade I tumors with less than 50% invasion.
- Adjuvant radiation to the pelvis is indicated for high-risk factors, including high grade, deep myometrial invasion, and lymph node spread.
- Systemic doxorubicin, cisplatin, ifosfamide, carboplatin, paclitaxel, and cyclophosphamide are used for metastatic disease.
- Radiation alone is used for inoperable patients and for palliation.

Salvage Therapy
- Failure after surgery alone is treated with radiation therapy.
- Salvage after surgery and radiation is seldom successful, although systemic therapy may be used.

Complications
- Surgical and radiation complications include bladder or bowel dysfunction.

Prognosis
- Survival is strongly correlated with stage and extent of disease as defined by depth of invasion, lymph node metastases, adnexal spread, and peritoneal cytology.
- Survival is worse when the tumor is higher grade or has aggressive histology.

INTRODUCTION

Endometrial cancer is a malignancy that arises from the endometrium, the lining of the uterus. It may also be referred to as uterine cancer. Endometrial cancer is the fourth most common malignancy among women, ranking after breast, lung, and colon cancer, and is the most common gynecologic cancer in the United States. Women have an approximately one in forty lifetime risk of being diagnosed with uterine cancer.[1] The majority of endometrial cancers are stage I (confined to the uterus) at diagnosis as most women present with postmenopausal bleeding. Ninety-five percent of uterine carcinomas arise from endometrial glands and are referred to as carcinomas, the remaining 5% of cases are uterine sarcomas.

ANATOMY

Anatomically, the uterus is contiguous with the cervix, and the two structures are separated at a narrowing called the isthmus, at which point the epithelium begins to transition from endometrial glands to mucus-secreting columnar epithelium.[2] The body, or corpus, of the uterus is typically 7 to 8 cm in length, 5 to 7 cm wide, and 2 to 3 cm in thickness. The corpus is located superior to the bladder, from which it separated by the vesicouterine pouch, and normally projects anteriorly, but in some women, it may be retroverted. Posteriorly, it is separated from the sigmoid colon by peritoneum and from the rectum by the rectouterine pouch (pouch of Douglas). The fallopian tubes extend laterally from the cornu of the fundus, the superiormost

portion of the corpus, and open into the peritoneal cavity adjacent to the ovaries. The corpus and adnexae are enclosed in the broad ligaments, which are folds of the peritoneum that hold the uterus in position, although it is mobile enough to move with the filling and emptying of the adjacent bladder. The round and uterosacral ligaments also extend from the uterine wall to the pelvic wall through the broad ligaments. The round ligaments course toward the deep inguinal ring, and the uterosacral ligaments course posteriorly toward the sacrum.

The main blood supply to the uterus is via the uterine arteries, which are branches of the internal iliac arteries. They enter the broad ligaments near the lateral vaginal fornices and cross the ureters superiorly adjacent to the uterine cervix. The uterine fundus is also supplied by the ovarian arteries, which are branches of the aorta. These vessels form a vascular plexus and anastomose with each other. The uterine venous plexus drains to the uterine veins. The lymphatics follow the vascular structures. The lymphatics that supply the fundus drain to the aortic lymph nodes, and those that supply the lower portions of the uterus drain to the internal and external iliac nodes. Lymphatics may also run along the round ligaments toward the superficial inguinal nodes. The uterus is innervated by the inferior hypogastric plexus.

EPIDEMIOLOGY

According to Cancer Statistics for 2007, there were 39,080 estimated new cases of endometrial cancer in the United States and 7400 deaths attributable to this disease.[3] The median age of diagnosis for endometrial cancer is 63 years and most patients are postmenopausal.[3] Table 92-1 shows the distribution of endometrial cancer by age as reported by the Surveillance, Epidemiology, and End Results program.

The Surveillance, Epidemiology, and End Results Program of the National Cancer Institute, reported stage distribution from 1996 to 2003 that showed that 70% of patients are diagnosed with localized disease, regional spread represented 17%, distant disease only 9%, with 4% unstaged.[1] In this survey, the 5-year overall survival rate for all stages of endometrial cancer from 1996 to 2003 was 82.9%. The 5-year relative survival rates were 95.3% for localized, 67.4% for regional, 23.1% for distant, and 55.8% for unstaged.[1]

Table 92-1 Incidence by Age, 2000–2004

Age	Incidence per 100,000 Females
20–24	0.3
25–29	1.3
30–34	3.4
35–39	6.8
40–44	12.8
45–49	23.1
50–54	42.5
55–59	66.9
60–64	81.8
65–69	89.1
70–74	86.5
75–79	86.6
80–84	81.8
85+	61.4

Surveillance Epidemiology, and End Results Program Incidence Data, Cancer Statistic Review, 1975–2004.

RISK FACTORS

Hormones

For the cancers that arise in hypertrophic or active endometrium, the risk factors are related to the lifetime estrogen exposure, known as the unopposed estrogen effect. According to this hypothesis, exposure to unopposed estrogens leads to increased proliferative activity of the endometrial cells, resulting in increased DNA replication errors and somatic mutations. Table 92-2 lists some of the known risk factors for endometrial adenocarcinomas. Higher endogenous estrogen exposure associated with nulliparity, lower gravidity, early menarche, late menopause, estrogen-producing ovarian tumors, and obesity are all associated with an increased risk of endometrial cancer.[4–6] High circulating blood levels of androstenedione, estrone, and estradiol are associated with a threefold to fourfold increased risk.[7] Exogenous estrogen sources such as hormone replacement therapy without progestins also increase the risk. Taking unopposed estrogens for 3 or more years is associated with a fivefold increased risk of invasive endometrial cancer.[8] Pathologic comparison between cancers that occur in women who did or did not use estrogen replacement has shown that in the nonusers, the cancers are more likely to be of lower grade, while those in users were more likely to be clear cell or adenosquamous.[9] The use of progesterones in a hormone replacement regimen may actually decrease the risk of cancer through downregulation of hormone receptors.[10] Cancers that occur in women who used combined estrogen and progestin hormone replacement tend to be tumors of low stage and grade.[11] A study of endometrial sarcomas and reproductive factors notes that leiomyosarcomas (LMS) are associated with early menarche, induced abortions, and breast-feeding, and both LMS and endometrial stromal sarcomas (ESS) are associated with later menopause.[12]

A potential causal link between the treatment of breast cancer with the selective estrogen receptor modulator drug tamoxifen and the development of endometrial cancer was first suggested in 1985.[13] This link was later confirmed by the results of large series from the Netherlands Cancer Institute and the National Surgical Adjuvant Breast Project (NSABP). The Netherlands Cancer Institute identified 98 patients who developed endometrial cancer after treatment for breast cancer and performed a matched case-control study among women who did not develop endometrial cancer.[14] Among patients with endometrial cancer, 24% had taken tamoxifen, compared to 20% of the controls, and for a longer median duration. The risk of developing endometrial cancer increased with the duration of tamox-

Table 92-2 Risk Factors for Endometrial Adenocarcinoma

Risk Factor	Relative Risk
Nulliparity[5]	1.4
Endogenous estrogen levels[34]	2.0–3.8
Estrogen use[8]	5
Obesity[31]	
High body mass index	3.2
Substantial weight gain	3.5

Tamoxifen[15]	2.2
Oral contraceptives[19]	0.5

ifen use. Those who were treated for 5 years or more had a 3.0 risk of endometrial cancer compared to controls. The NSABP analyzed data from their B-14 study in which 2834 women with node-negative, estrogen receptor-positive breast cancers were randomized to placebo or tamoxifen (20 mg/day).[15] Twenty-three of 24 cases of endometrial cancers that occurred in women entering this trial occurred in the tamoxifen arm. These were mostly favorable cancers: 88% were stage I at diagnosis, and 78% were of low or intermediate grade. The authors calculated the annual hazard rate of endometrial cancer development to be 1.6 per 1000 patient-years in women taking tamoxifen and 0.2 per 1000 patient-years in the placebo group. However, the use of tamoxifen results in a 38% improvement in disease-free survival for breast cancer, which far outweighed the risk of endometrial cancer, from which there were only four deaths. Another study by the NSABP analyzed data from their P-1 study for patients receiving tamoxifen for chemoprevention of breast cancer and found that patients receiving tamoxifen had a 2.53 times greater risk of developing an invasive endometrial cancer compared to placebo.[16] This risk was predominantly in women 50 years of age or older, with an incidence of about 2 per 1000 women, and regular gynecologic follow-up in women who receive the drug was recommended.

Genetics

Endometrial cancer is uncommon in young women (younger than 50 years at age of diagnosis).[17] A family history of endometrial cancer in a first-degree relative or of hereditary nonpolyposis colorectal cancer syndrome (HNPCC) is associated with a relative risk of 1.5 for development of endometrial cancer in the premenopausal years, although only about 1% of endometrial cancers are attributable to genetic factors.[18] Endometrial cancer is part of the spectrum of cancer predisposition in families with HNPCC syndrome, which results from mutations in DNA mismatch repair genes. Carriers of the HNPCC mutation have a 50% to 60% lifetime risk of developing endometrial cancer, with a median age of less than 50 years.[19] Other risk factors for younger women include use of unopposed estrogen replacement therapy, nulliparity, and other reproductive factors similar to those seen in older women.[20] Compared with older women, young women have a similar stage distribution at diagnosis, the majority of cancers presenting as stage I. Younger women are actually more likely to have lower-grade, less deeply invasive cancers and have an overall survival similar to that of older women.[21,22]

In contrast, elderly patients (older than 75 years) have a higher incidence of poorly differentiated cancers, aggressive histologies, and lack of steroid receptor expression, consistent with nonendometrioid patterns of tumorigenesis.[23] When outcomes are examined by race, African-American women have a somewhat lower incidence of endometrial cancer but a worse overall survival compared to Caucasian women.[24] African-American women are diagnosed more often with aggressive histologies, with higher-grade tumors, and at later stages.

For the uterine serous subtype, women are at increased risk for also developing a concurrent or subsequent breast cancer.[25] In women with uterine serous carcinoma, breast cancers are diagnosed in 25%, compared to 3% of those with endometrioid carcinoma, implicating a genetic or biologic link.

Previous Irradiation

The etiology of uterine sarcomas is not well understood. One factor is prior exposure to pelvic irradiation. Secondary uterine sarcomas and carcinomas have been reported after irradiation for cervix and rectal cancers,[26,27] with a median latency of 17 years and an absolute risk range of 0.03% to 0.8%.[28] Radiation-associated uterine cancers tend to be of higher grade and stage and to have a more unfavorable histology.[29]

Other Comorbidities

Other systemic diseases and lifestyle factors influence the risk of endometrial cancer. Obesity, diabetes and hypertension all increase the risk. Hypertension and diabetes may be associated with an increased risk, though mainly in women who are also obese. Overall nearly 40% of endometrial cancer risk can be attributed to obesity.[30] Obesity from an early age, substantial weight gains over time, and marked obesity all confer higher risks than moderate obesity.[31] When examined by degree of obesity as measured by body mass index (BMI) in comparison to lean women, women who are overweight (BMI: 28 to 29.9) have a relative risk of 1.5 compared to women with a lower BMI, women who are obese (BMI: 30 to 33.9) have a 2.9 relative risk, and women who are markedly obese (BMI: ≥34) have a relative risk of 6.3.[32] Some studies show an association between endometrial cancer and dietary intake of fat, suggesting that healthier diets and reduction of dietary fat could reduce the risk.[33,34] Diabetes confers a relative risk of around 4.0,[35] and the risk is highest for women who are obese and diabetic.[36,37] There may be a link between ovarian hyperandrogenism leading to progesterone deficiency, lifetime weight gain, and chronic hyperinsulinism, which all interact to increase the endometrial cancer risk.

Protective Factors

Known protective factors against endometrial cancer include full-term pregnancy, multiparity or incomplete pregnancies, older age of menarche, older age at first birth, and oral contraceptive use. Use of oral contraceptives for 1 to 5 years is associated with a relative risk of 0.2, and use for at least 1 year reduces endometrial cancer risk by about 45%.[19] Increasing physical activity decreases the risk of endometrial cancer independently of weight and parity.[38] Interestingly, cigarette smoking decreases the risk of endometrial cancer, but this effect might be limited to postmenopausal women or those taking hormone-replacement therapy.[39] It has been postulated that components of cigarette smoke might suppress endogenous estrogens or be associated with lower body weight as a potential mechanism for the protective effect. Clearly, the adverse risks of smoking greatly outweigh any potential benefit with respect to endometrial cancer.

PATHOGENESIS

The most common pathologic subtype is endometrioid adenocarcinoma, which arises from the endometrium and accounts for about 80% of malignant endometrial neoplasms. There are aggressive variants of adenocarcinomas, including uterine serous and clear cell histologies, which have a much poorer prognosis. Less common are the uterine sarcomas, which arise from the myometrium or other mesenchymal elements of the uterine wall, comprising only 2% to 5% of all uterine malignancies.[40] Of the uterine sarcomas, carcinosarcoma (or mixed malignant müllerian tumors) is the most common (8.2 per million women per year), followed by LMS (6.4 per million), both of which are somewhat more common in African-American women than Caucasian women. The incidence of carcinosarcomas rises in incidence with age, while the incidence of LMS peaks in middle age and then declines. Next most common is ESS (1.8 per million). The final group is known as unclassified (0.7 per million); it includes rhabdomyosarcoma, angiosarcoma, fibrosarcoma, chondrosarcoma, and liposarcoma.

Endometrial adenocarcinomas appear to have two distinct mechanisms of pathogenesis.[41] Most adenocarcinomas (type I) arise in normal, functioning endometrium; are associated with hyperplasia; tend to be well differentiated and express steroid hormone receptors; and are hormonally responsive. Others (type II) arise in atrophic endometrium, are associated with endometrial intraepithelial carcinoma without high levels of steroid receptor expression, and do not appear to be related to hormonal exposures. Type I tumors have a better prognosis overall than do type II tumors.

Pathology

Hyperplasia

Proliferative diseases of the endometrium represent a broad continuum of morphologic and cellular changes ranging from simple hyperplasia to invasive carcinoma. Hyperplasia is an abnormal proliferation of the endometrial glands and in some cases precedes endometrial cancer as a premalignant phase. According to the World Health Organization and International Federation of Gynecologic Oncologists (FIGO), hyperplasia is classified as simple or complex with or without atypia.

Simple hyperplasia is the most common type and is a benign change that causes diffuse thickening of the endometrium, with dilation and increased number of endometrial glands but minimal crowding or glandular complexity. Such changes are rarely associated with malignant progression. Complex hyperplasia is characterized by increased endometrial thickness due to increased numbers and crowding of the endometrial glands. The glands have irregular contours and markedly diminished stromal spaces. Epithelial pseudostratification in two to four layers can occur with a variable amount of mitotic activity. These lesions are associated with a 3% rate of malignant progression.[42] The majority of both types of lesions without atypia will regress.

Atypical hyperplasia is characterized by an increased number of cells with cellular atypia, whether the glandular morphology appears simple or complex (although usually complex), including loss of the normal orientation of the epithelial cells, nuclear enlargement, increased nucleus-to-cytoplasmic ratio, nuclear hyperchromatism, and prominent nucleoli. If atypia is present in an endometrial biopsy or curettage, the reported risk of finding adenocarcinoma after hysterectomy ranges from 14% to 57%, with an average risk of about 25%.[43] Among such cancers, myometrial invasion is common, and up to 20% of them will be grade II or III. While Pap smear is not a reliable screening test for endometrial cancer, findings on Pap smears known as atypical glandular cells of undetermined significance may be of endometrial origin. Among patients undergoing biopsy for atypical glandular cells of undetermined significance, 13% have endometrial cancers, 11% have endometrial hyperplasia, and 7% have squamous lesions, so one-third of women with this finding on Pap smear will have a significant endometrial lesion.[44] Table 92-3 lists the risk of progression to malignancy based on the type of hyperplasia.

Endometrioid Adenocarcinoma

Adenocarcinomas arising from hypertrophic endometrium or associated with atypical hyperplasia are typically endometrioid type (Fig. 92-1). For this histologic subtype, the median age of diagnosis is around 65 years. Table 92-4 lists the various types of endometrial carcinomas classified by the International Society of Gynecologic Pathologists. Endometrioid adenocarcinomas are the most common type arising from the endometrium, representing about 75% of cases and are usually designated NOS (not otherwise specified).[45] In addition to NOS, there are four other variants: villoglandular, secretory,

- Mixed epithelial-stromal
  - Adenosarcoma
  - Carcinosarcoma (mixed malignant müllerian tumor)
    - Without heterologous elements
    - With heterologous elements

ciliated cell, and adenocarcinoma with squamous differentiation. The villoglandular variant of endometrioid adenocarcinomas makes up about 7% of all adenocarcinomas. They are low grade and lack the anaplasia that is associated with uterine serous carcinomas. They otherwise have a similar median age, depth of invasion, and frequency of nodal spread compared to the usual endometrioid type.[46] Secretory carcinomas are found in only 2% of cases and tend to be low grade and well-differentiated with a favorable outcome. Progesterone administration may cause a secretory appearance of atypical hyperplasia or low-grade adenocarcinoma. Ciliated cell carcinomas are composed primarily of ciliated cells, which are typically confined to benign endometrial lesions but rarely form cancers that invade the myometrium.[47] Approximately 25% of endometrial adenocarcinomas display focal squamous differentiation. In the late 1960s, distinction was made between tumors in which the squamous component appeared bland and well differentiated (adenoacanthoma) and those in which it appeared frankly malignant and often poorly differentiated (adenosquamous carcinoma). Numerous studies have confirmed the significantly better prognosis that is associated with adenoacanthoma than with adenosquamous carcinoma. However, in large studies in which the glandular and squamous component were graded separately, differentiation of the squamous component was shown to closely parallel that of the endometrial component. Thus, the prognosis can be predicted by the grade of the glandular component alone. Accordingly, the International Society of Gynecologic Pathologists and the World Health Organization recommends the use of the term *adenocarcinoma with squamous differentiation* for these tumors, and grading is based solely on the glandular component.

Adenocarcinomas are further characterized by grade and depth of invasion. Grade 1 or low-grade lesions are well differentiated; grade II lesions are moderately differentiated; and grade III lesions are poorly differentiated. Histologic grading according to FIGO uses a combination of architectural patterns and nuclear features. Grade I tumors are composed of cells and glands that closely resemble those of normal endometrium and show well-preserved glandular growth patterns with 5% or less solid growth pattern; grade II contains 6% to 50% solid growth pattern; grade III tumors are composed of more than 50% nonsquamous solid growth pattern.[48] Although this system relies predominantly on the architectural pattern of the glands, FIGO recommends that in cases in which there is severe nuclear atypia, inappropriate for the architectural grade, the overall grade of the tumor should be raised by one grade. In addition, in cases of serous and clear cell carcinomas, nuclear grading takes precedence. In the nuclear grading system, grade I has uniform oval nuclei with evenly distributed chromatin; grade III has large pleomorphic nuclei with prominent nucleoli and clumped chromatin; grade II is intermediate between these features.[49] Higher grade is associated with myometrial invasion, lymph node metastases, and a poorer overall prognosis. The Gynecological Oncology Group (GOG) found that high-grade tumors made up 42% of those with deep myometrial invasion, compared to 7% of tumors with no myometrial invasion.[50] Depth of invasion is determined by measuring the extension of cancer into the myometrium divided by the total width of the myometrium. Depth of myometrial invasion has been categorized by both thirds and halves. For staging purposes, FIGO classifies depth of invasion as limited to the endometrium, less than one half of the myometrium, or greater than one half of the myometrium. Deeper invasion has a higher risk of nodal metastases.

Uterine Serous Carcinoma

Uterine serous carcinoma (USC) represents 5% to 10% of endometrial carcinomas (Fig. 92-2). The median age of diagnosis is 63 years.[51] This subtype arises in atrophic endometrium from a putative precursor lesion that is designated endometrial intraepithelial carcinoma (Fig. 92-3), and is not hormonally mediated. These cancers are considered high grade; however, depth of invasion might not always be deep. Morphologic features include a papillary or solid growth pattern with slitlike spaces, marked nuclear pleomorphism, multinucleated cells, hobnail cells, psammoma bodies, uneven gland borders, and inflammation.[52] Most have lymphovascular invasion, and lymph node metastases are present in 36% of women with no myometrial invasion, in 50% with inner one half invasion, and in 40% with outer one half invasion.[53] These cancers have a high rate of spread to peritoneal surfaces and to omentum and distant metastases.[54] Because of these features, uterine serous cancers are upstaged postoperatively from clinical stage I to II to clinical stage III to IV in nearly 50% of patients. Survival rates are only 30% to 50% even when disease is confined to the uterus, and median survival is significantly shorter than that for endometrioid carcinoma.

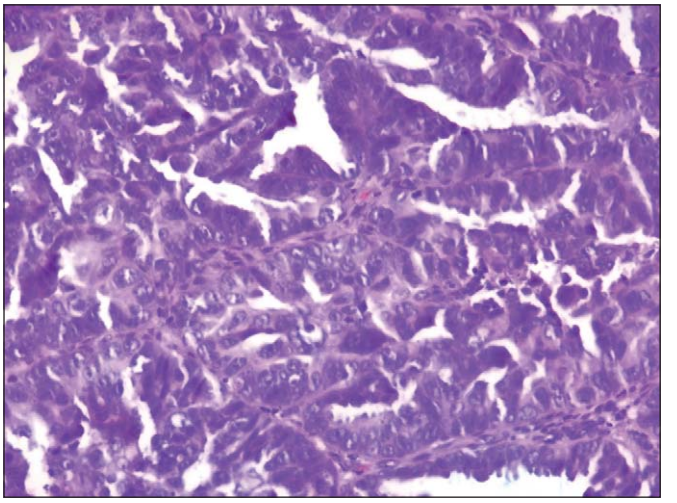

Figure 92-2 • Serous carcinoma. Uterine serous carcinoma composed of highly atypical tumor cells forming irregular, slitlike glandular spaces and solid sheets of cells.

Clear Cell Carcinoma

Carcinomas with clear cell features arise in the uterus, ovary, vagina, and cervix, all of which have been associated with in utero exposure to the synthetic estrogen diethylstilbestrol (DES). DES was prescribed to women during pregnancy between 1940 and 1971 for certain complications. The overall risk to a woman who received DES

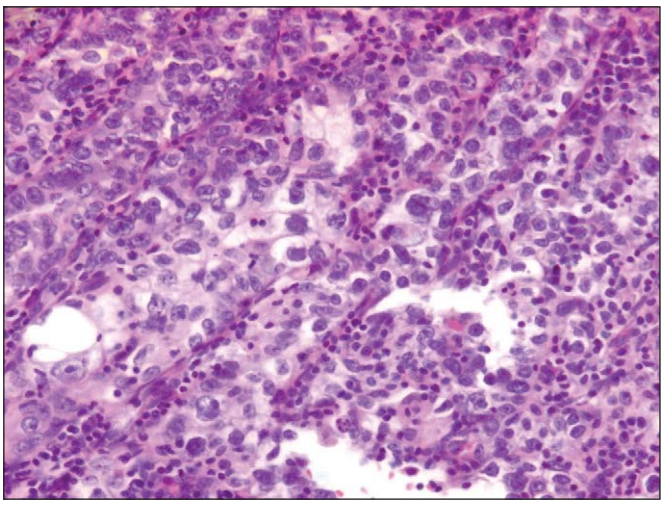

Figure 92-4 • Clear cell carcinoma. Endometrial clear cell carcinoma showing a solid growth pattern. The tumor cells have moderate amounts of clear cytoplasm and show moderate to severe nuclear pleomorphism.

in utero of developing clear cell carcinoma (CCC) of the gynecologic tract is estimated at 0.1%.[55] Clear cell endometrial cancers make up about 5% of adenocarcinomas (Fig. 92-4). The median age at diagnosis is 66 years.[56] Cells form cystic solid or tubular cellular patterns whose cytoplasm appears clear or light pink on hematoxylin-eosin staining. Papillary formations, when present, often have a characteristic hyalinized core, and hobnail cells are frequently seen. This cytoplasmic material is glycogen positive. Nucleic size varies, but high mitotic count is often present, and the cells are generally considered high grade. Although pelvic failures occur in about one third of patients postoperatively without adjuvant radiation, unlike serous carcinoma, this subtype has only a 15% rate of intra-abdominal failure. Relapse in the lung, liver, and bone occurs in 25% of patients. The 5-year disease-free survival rate is about 40%.[57] For stage I, the survival rate is 72%, and for stage II, the survival rate is 60%, which is more favorable than that for serous cancers.[58]

Other Carcinomas (Mucinous, Squamous, Undifferentiated, Mixed, Metastatic)

There are a variety of other relatively rare subtypes of endometrial cancer. Mucinous cancers contain more than 50% cells with periodic acid-Schiff-positive diastase-resistant mucin.[59] These cells have abundant cytoplasmic mucin, and the tumors produce large amounts of mucopolysaccharides. Morphologically similar tumors may occur in other abdominal organs such as the gastrointestinal tract or ovary, so metastasis should be ruled out. For primary cases, the prognosis appears to be similar to that of endometrioid carcinoma. Primary squamous cell cancer of the endometrium is exceedingly rare, reported in only about 100 cases. The median age at diagnosis is 67 years.[60] Chronic pyometria may be a predisposing factor, and these are associated with nulliparity. If the cervix is involved, the tumor should be considered a primary cervical cancer; thus, no stage II squamous carcinomas of the endometrium can be reported. Survival appears to be similar to adenocarcinoma (80% for stage I at 3 years). Undifferentiated carcinomas demonstrate no clear glandular or squamous differentiation, and some may be small cell neuroendocrine carcinomas. They may stain for epithelial or neurosecretory antigens. Mixed cell carcinomas comprise at least 30% each of two or more pure cell types. If serous or undifferentiated components are present, the prognosis is worse than that for pure high-grade endometrioid cancers.[61] Other extragenital cancers may metastasize to the endometrium or myometrium. One study found that primary tumors originated in the breast (43%), colon (18%), stomach (11%), pancreas (11%), gallbladder (5%), lung (5%), cutaneous melanoma (3%), urinary bladder (3%), and thyroid (2%).[62] Among those, the metastatic disease in the uterus was the first indicator of the primary cancer in 25%.

Uterine Sarcomas

Uterine sarcomas arise primarily from the mesenchymal or muscle elements of the uterus. They may be composed of pure mesenchymal elements or of mixed mesenchymal and epithelial elements. The classification that has been proposed by the GOG is shown in Table 92-4. The most common types are carcinosarcoma or mixed malignant müllerian tumors, LMS, and ESS. All of the subtypes combined occur rarely, uterine sarcomas making up only 5% of all malignant uterine neoplasms.

Carcinosarcoma (Malignant Mixed Müllerian Tumor)

Carcinosarcoma represents about 50% of all uterine sarcomas, or 3% of all uterine neoplasms. They occur at a median age of 66 years.[63] These tumors contain mixed epithelial and mesenchymal elements (Fig. 92-5). Adenosarcoma is a tumor with malignant mesenchymal stroma and benign epithelial elements. Carcinosarcomas contain both malignant mesenchymal and epithelial elements, typically adenocarcinoma. The stromal component is usually high grade. The mesenchymal component is classified as either homologous (composed of cell types that are normally found in the uterus, such as endometrial stromal sarcoma, fibrosarcoma, leiomyosarcoma, and undifferentiated sarcoma) or heterologous (composed of cell types that are not normally found in the uterus), each making up about half of carcinosarcomas. The heterologous elements are found in association with overt sarcoma and may comprise rhabdomyosarcoma, chondrosarcoma, liposarcoma, and osteosarcoma, in order of decreasing frequency. Although these tumors are heterogeneous, in general depth of invasion and stage correlate with prognosis. Other prognostic factors may include extensive tumor involvement of the uterus, lymphovascular invasion, extrauterine disease, and heterologous elements.[64] Nodal metastases are seen in about 35% of cases and tend to arise from the epithelial component. However, recurrences are often secondary to the sarcomatous elements. The overall 5-year survival rate is 40% to 50%.[65]

Leiomyosarcomas

LMS makes up about 25% of uterine sarcomas, or 1% of malignant uterine neoplasms (Fig. 92-6). The median age at diagnosis is 52

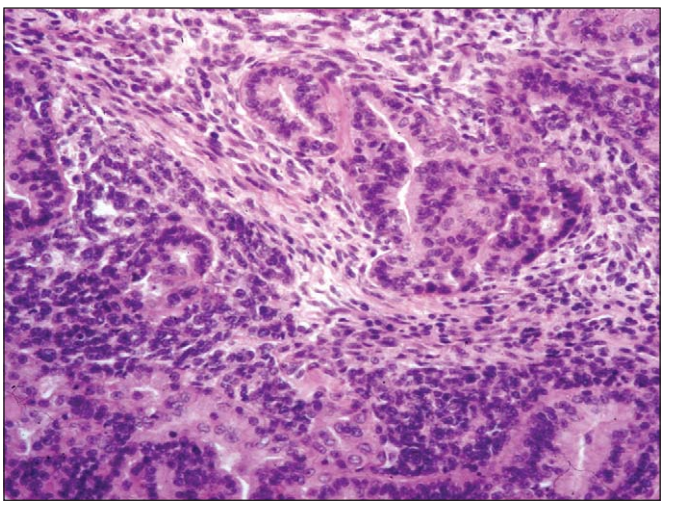

Figure 92-5 • Carcinosarcoma. Mixed malignant müllerian tumor (carcinosarcoma) composed of an admixture of glandular carcinomatous and sarcomatous elements.

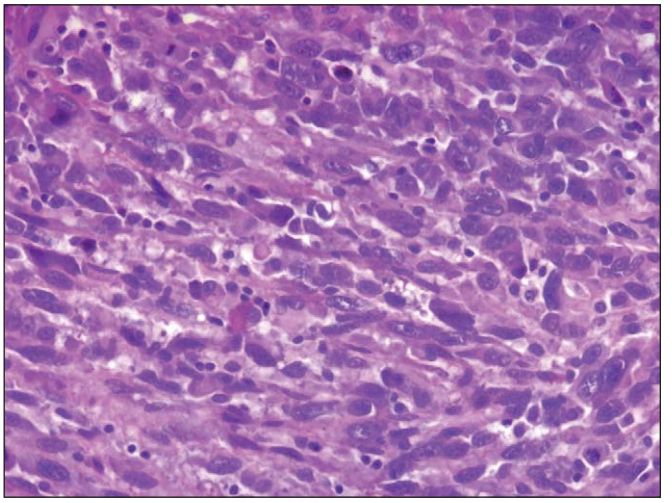

Figure 92-6 • Leiomyosarcoma. Uterine leiomyosarcoma composed of malignant spindled cells with prominent eosinophilic cytoplasm, moderate to marked cytologic atypia, and mitotic activity.

years. Benign leiomyomas occur commonly in the uterus with rare malignant transformation; LMSs are thought to arise independently. LMSs are typically solitary and irregularly permeate the adjacent myometrium and may show areas of hemorrhage and necrosis. The tumor arises from the myometrium and thus may be located deep in the uterine wall. Histologically, the tumors are more densely cellular and are composed of bundles of spindle cells. The degree of smooth muscle differentiation is variable. Nuclear and cellular pleomorphism, nuclear hyperchromasia, and multinucleate giant cells are common. To differentiate leiomyosarcoma from benign leiomyoma, the following factors should be considered: age of the patient; size, gross appearance, and invasiveness of tumor margins; vascular invasion; cytologic atypia; coagulative tumor cell necrosis; and mitotic activity. About 27% of LMSs metastasize to lymph nodes, and 50% recur, the lung being the most common site of metastasis.[66]

Endometrial Stromal Sarcoma

Endometrial stromal tumors are usually defined as neoplasms composed of stromal cells similar to those of normal proliferative phase endometrium. Classically, endometrial stromal tumors have been divided into two categories: benign stromal nodule if the margins are smooth, and ESS if the margins are infiltrating or lymphovascular permeation is present (Fig. 92-7). Sarcomas were further subdivided into those with fewer than 10 mitoses per 10 high-power fields (low grade) and those with 10 or more mitoses per 10 high-power fields (high grade).[67] The tumors that were formerly regarded as high-grade stromal sarcomas, however, are a heterogeneous group, composed partly of tumors made up of endometrial stromal cells but also of anaplastic tumors composed of tumor cells that show marked cytologic atypia. The latter tumors occur at an older age and are associated with a much worse prognosis. Histologically, they more closely resemble the sarcomatous components of a carcinosarcoma than an endometrial stromal tumor. On the basis of these features, endometrial stromal tumors have recently been reclassified as endometrial stromal nodule, endometrial stromal sarcoma, and undifferentiated uterine sarcoma.[68,69]

Endometrial stromal sarcomas are malignant tumors with infiltrative margins that are composed of cells similar to those of endometrial stroma. Histologically, the tumor cells are uniform with scant cytoplasm. A striking feature of many endometrial stromal sarcomas and the origin of their older name of "endolymphatic stromal myosis" are serpentine processes of the tumor that infiltrate between muscle fibers and into lymphatic spaces. Nuclear atypia is typically mild, and mitotic activity is usually less than 10 per 10 high-power fields; mitotic count is not a criterion for diagnosis, however. These tumors generally express estrogen and progesterone receptors and are responsive to progesterone therapy.[70] The clinical course is indolent, characterized by long disease-free intervals, although 36% of patients even with stage I will relapse and 10% will die of disease.

Undifferentiated Uterine Sarcoma

Undifferentiated uterine sarcoma is a rare malignant tumor composed of pleomorphic mesenchymal cells with a high mitotic index that do not resemble cells of endometrial stroma. These tumors are found in older women (median age: 58 to 61 years).[71] These tumors behave aggressively; 55% of patients who have disease that is confined to the uterus develop recurrent disease at a median of 5 months, in both the pelvis and abdomen.[72]

Molecular Pathology and Biology

Endometrioid Adenocarcinoma

About 57% of endometrial adenocarcinomas express estrogen receptors (ER) and progesterone receptors (PR), while 24% are negative for either receptor.[73] Expression correlates with tumor differentiation and stage. Both ER and PR are expressed in about 80% of grade I cancers and 60% to 70% of grade II cancers; for grade III cancers, ER is expressed in 46%, and PR is expressed in 59%.[74] Expression also differs among histologic types, with much lower levels in higher-grade histologies such as uterine serous carcinomas than in endometrioid carcinomas. In patients whose tumors are ER-positive/PR-positive or ER-negative/PR-positive, survivals are significantly better than for patients with either ER-negative/PR-negative or ER-positive/PR-negative tumors.[75] Some studies have also found ER status to be prognostic.[76,77] When tumors metastasize, loss of PR expression is more common than is loss of ER expression.[78] In vitro studies have shown that the PR isoform PRB is downregulated in more poorly differentiated cancers that do not respond to progesterone therapy.[79] For ER isoforms, a higher ratio of ER-β expression correlates significantly with deeper myometrial invasion and more advanced disease.[80] Genetic analysis of DNA from human endometrial cancers has shown that certain polymorphisms on the ER-α gene are present at different frequencies, suggesting that inherited alterations in the ER gene could either predispose or protect against the development of endometrial cancer.[81] More information about the

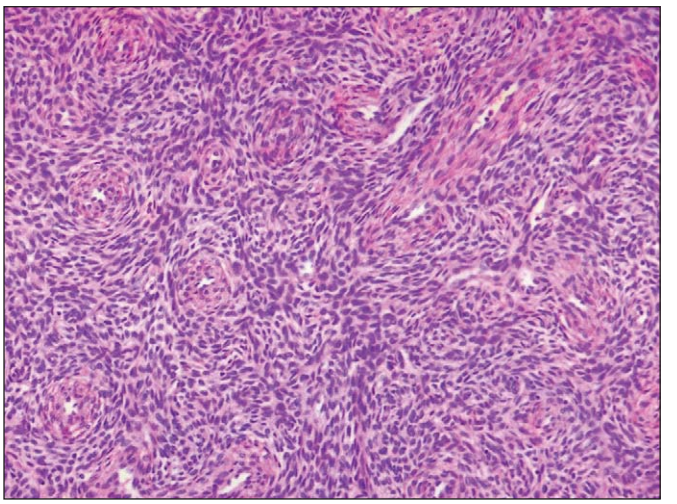

Figure 92-7 • Endometrial stromal sarcoma: Low-grade endometrial stromal sarcoma. The tumor is cellular and shows a solid growth pattern of uniform, bland endometrial stromal-type cells. The tumor cells focally show a whirled arrangement around prominent arterioles.

role of specific steroid receptor isoforms in uterine tissues and how they are expressed in different stages of disease may lead to the development of selective receptor modulators, thereby potentially improving treatment outcomes.

The endometrial hormonal pathways interact with other molecular pathways, further explicating potential mechanisms for tumorigenesis and progression. The proto-oncogene transmembrane receptor Her2/neu (c-erbB2) is a member of the epidermal growth factor family of receptor tyrosine kinases and is overexpressed in about one third of breast cancers. A monoclonal antibody therapy that targets the gene expression has been developed. Her2 is overexpressed in about 10% to 20% of endometrial cancers, correlating with higher grade, advanced disease, and loss of ER expression.[82–85] Her2 overexpression is seen in 27% of patients with metastatic disease compared to only 4% with early-stage disease. One study has shown that Her2 overexpression correlates with poorer overall survival and that the use of radiation therapy or chemotherapy in these patients is associated with improved survival.[86] Overexpression of the oncogene p53, found in about 15% of endometrial cancers, may also correlate with worse prognosis and might predict for recurrence.[87] P53 is almost never overexpressed in endometrial hyperplasia, suggesting that this particular mutation occurs late in the course of tumorigenesis.[88]

Serous and Clear Cell Carcinoma

USC and CCC have often been studied together, both for clinical outcomes and for biologic parameters. Unlike endometrioid, both subtypes are associated with lack of hormonal dependence and arise in atrophic endometrium. Immunohistochemical profiles comparing endometrioid and USC subtypes for ER, PR, and the expression of p53 and HER-2/neu reveal that USC cancers are generally negative for ER and PR, while 80% overexpress p53, and 45% overexpress Her2/neu.[85,89] Another study has found that 80% of USC cancers highly express Her2 and that USC cancer cell lines express Her2 at higher levels than either breast or ovarian cells do.[90] These cell lines are resistant to chemotherapy, but exposure to Herceptin, the monoclonal antibody that targets Her2, is cytotoxic, suggesting that Herceptin might be a useful therapy for USC cancers.

Overexpression of the p53 oncogene appears to play an important role in the biology of USC cancers, which demonstrate a significantly higher p53 expression than endometrioid subtypes (75% to 85%).[91,92] Unlike endometrioid carcinomas, p53 mutations occur early in USC tumorigenesis. USC cancers and their putative precursor, endometrial intraepithelial carcinoma, both commonly have abnormal p53 overexpression.[93] P53 mutation is associated with loss of ER and PR expression confers a poorer overall survival even among USC cancers.[94]

Clear cell carcinoma has a distinctive molecular profile. While demonstrating low expression of ER and PR similarly to USC, CCC has immunoreactivity for p53 significantly less frequently compared to USC.[95] CCC without any serous features is associated with hyperplastic endometrium in 40% of cases. Such findings suggest that CCC is a biologic subtype that is distinct from both USC and endometrioid cancers.

Other molecular markers have been investigated for both endometrioid and USC/CCC types. Overexpression of the epidermal growth factor receptor, which occurs in 50% of endometrial cancers, strongly correlates with squamous differentiation,[96] nonendometrial subtypes, and metastasis (76%) and predicted for a poorer survival in patients with endometrioid subtypes.[97] DNA aneuploidy is associated with higher pathologic stage, higher grade, and more frequent lymph node involvement and is found in the majority of USC and CCC.[98] Metallothioneins are small molecular weight proteins associated with metastatic potential that are expressed in endometrial carcinomas. They are associated with higher grade, higher stage, and uterine serous subtypes.[99] High levels of the cathepsin D protease, another metastatic marker, correlate with high-grade tumors, uterine serous carcinoma subtype, positive nodal status, and deep myometrial invasion.[100] Microsatellite instability has been found in about one third of endometrioid carcinoma, but does not correlate well with other prognostic factors.[101] Early use of gene microarrays has identified 24 transcripts that distinguish USC from endometrioid cancers, promising to expand the knowledge base regarding molecular differences that could lead to targeted therapies.[102] The prognostic or therapeutic usefulness of these markers remains to be determined.

Sarcoma

Little is known about the biology of uterine mesenchymal tumors, owing to their rarity and heterogeneity. Most studies have combined the different types of sarcomas. Histologic grade is a prognostic factor. Mitotic count also predicts for outcome in some sarcomas.[103] Sarcomas express ER and PR less frequently than carcinomas do, with an overall ER positivity of 48% and PR positivity of 30%[104]; however, most sarcomas do not respond to hormonal therapy. Aneuploidy, found in about half of sarcomas, and high S-phase fraction occur more often in sarcomas that are higher-stage, more poorly differentiated tumors and with a higher mitotic index.[105] Histology does not clearly correlate with outcome, as survival rates are similar among the three main subtypes: LMS, carcinosarcoma, and ESS.

CLINICAL PRESENTATION AND PATIENT EVALUATION

The majority (80%) of patients with either uterine carcinomas or sarcomas present with abnormal postmenopausal uterine bleeding. Endometrial cancer may also present as menorrhagia or other abnormal bleeding patterns in premenopausal women. Profuse serous or serosanguinous discharge is a presenting symptom in 10% of cases. Sarcomas may present as a rapidly enlarging uterine mass or be associated with symptomatic fibroids. The differential diagnosis of bleeding symptoms includes other types of gynecologic cancers, such as cervical or vaginal cancers or gastrointestinal or bladder cancers.[106] Nonmalignant causes of bleeding or discharge include atrophy, infection or pyometria, traumatic lesions or foreign bodies, polyps or fibroids (leiomyomas), adenomyosis, and endometriosis. Iatrogenic causes include use of hormonal medications, hypothalamic depressants, digitalis, phenytoin, and anticoagulants. Systemic diseases that may cause abnormal bleeding include liver disease and coagulation disorders.

Less commonly, patients present with more advanced disease in the absence of uterine bleeding in which symptoms are related to a large tumor mass, such as pelvic pain, hematuria or hematochezia, rectal obstruction, renal failure secondary to hydronephrosis, or abdominal discomfort and distension. Advanced cases will present with a pelvic mass on examination. Metastatic disease commonly occurs in the lungs, and there may be associated pulmonary symptoms.

Symptoms should be routinely evaluated with pelvic examination and endometrial biopsy or dilation and curettage. Although Pap smear is not an effective screening or diagnostic test for endometrial cancer, it should be performed to assess cervical pathology. Biopsies are subject to sampling error. If biopsy is negative for cancer but symptoms persist, a fractional dilation and curettage should be performed. A biopsy finding of atypical hyperplasia also needs further sampling, since 15% to 25% of patient with this finding on biopsy will have carcinoma.[107] Samples should be taken separately from the cervix and the uterus so that an endocervical lesion may be differentiated from a lesion in the lower uterine segment. Any suspicious masses that are visible in the uterine cavity at the time of the procedure should be biopsied as well. Sarcomas, leiomyosarcoma in particular, may be located submucosally.

After pathologic diagnosis, a thorough history and physical examination should be obtained to document any signs of local or metastatic disease and to determine risk factors for cancer as well as

comorbidities, which could affect the patient's ability to tolerate surgery and other cancer therapy. An examination under anesthesia might be indicated for patients who have apparent locally advanced disease, during which time cystoscopy and proctoscopy may be performed to document any invasion of the bladder or rectosigmoid colon.

Endometrial cancer screening should be considered in special populations. Women who take tamoxifen for treatment for breast cancer have twice the risk of developing endometrial cancer as the general population. Analysis of the NSABP data shows that the average annual hazard rate of endometrial cancer within 5 years of follow-up is 1.2 per 1000 patient-years, with a cumulative hazard rate of 6.3 per 1000 patient-years.[15]

In a randomized study of ultrasonography or office hysteroscopy for endometrial assessment in asymptomatic women who are using tamoxifen, the sensitivity and specificity of transvaginal ultrasonography for cancer detection were 85% and 100%, respectively, and those for office hysteroscopy were 77% and 92%, respectively.[108] Transvaginal ultrasound detects a high percentage of cases of endometrial thickening. Women who are on tamoxifen have a significantly thicker endometrium than do those who are not, and this correlates with duration of exposure.[109] However, nearly half of women who have undergone follow-up hysteroscopy and sampling have benign or atrophic endometrium, resulting in a high false-positive rate even with up to 10 mm of endometrial thickening.[110] Despite concerns regarding cost effectiveness, it is reasonable to perform an annual pelvic examination and transvaginal ultrasound in women who are taking tamoxifen, as the benefit of early cancer detection is significant. Hysteroscopy and biopsy may be performed as indicated on the basis of the findings of these examinations.

Women with HNPCC have a 50% lifetime risk of developing endometrial cancer, which is the most common noncolonic cancer occurring in these families. While optimal screening protocols in this population have not been established, routine annual screening with pelvic examination and transvaginal ultrasound is recommended.[111] A recent study suggests that prophylactic hysterectomy might be an effective strategy in preventing endometrial cancer in women with HNPCC.[112]

LABORATORY AND IMAGING STUDIES

Routine tests including complete blood count, liver function tests, electrolytes and renal function are obtained for presurgical clearance. The tumor marker CA-125 is elevated preoperatively in the serum of about 20% of patients with endometrial carcinomas and is correlated with stage.[113] Elevated CA-125 levels predict for occult extrauterine or metastatic disease.[114]

Since the lung is a common site of metastasis, a chest x-ray is part of the initial evaluation. Abnormalities on chest x-ray should be further evaluated by computed tomography (CT) scan of the chest with contrast. A mammogram should be performed if a screening study has not been performed in the past year. Imaging of the brain is performed only if indicated by history or examination. Patients who are undergoing surgery also need cardiac evaluation, including an EKG and further studies as indicated for surgical clearance. Further evaluation of the gastrointestinal tract, including colonoscopy and upper endoscopy, is indicated for mucinous tumors, which may be of gastrointestinal origin, or those with symptoms related to the upper bowel.

To assist with preoperative staging and management decisions, imaging of the urogenital tract may include intravenous pyleogram or CT scan of the abdomen and pelvis with contrast. Since endometrial cancer is a surgically staged disease, routine preoperative CT scan is often omitted. In cancers of grade II to III or high-risk histology on biopsy, surgical staging including nodal sampling is performed; therefore, CT scan is not needed to assess lymph nodes. However, for patients who are medically inoperable or in whom more advanced or metastatic disease is suspected, a CT scan may be useful to evaluate the extent of abdominopelvic and nodal disease. Magnetic resonance imaging scans improve on the evaluation of myometrial and cervical invasion and may be warranted in medically inoperable patients or other specific situations.[115] Transvaginal ultrasound is also useful for assessing myometrial invasion and tumor size. Accurate prediction of myometrial invasion by ultrasound compared to pathologic assessment ranges from 70% to 100%.[116,117] The role of positron emission tomography (PET) and CT in uterine cancer has not been clearly defined. A recent report suggests that PET might be useful in determining depth of invasion.[118] PET has been utilized in the early detection of recurrence of uterine sarcomas[119] and endometrial cancers.[120]

STAGING

The system that is used to stage most cancers is the TNM system developed by the American Joint Committee on Cancer[121]; however, the main staging system that is used for endometrial cancer is the FIGO system. The T category from TNM staging corresponds to the FIGO stage. In the TNM system, lymph nodes are designated NX if nodes cannot be assessed, N0 if there is no regional lymph node metastasis, or N1 if there is metastasis to pelvic and/or para-aortic nodes. Distant metastases are categorized as MX if distant metastasis cannot be assessed, M0 for no evidence of metastasis, and M1 if there is any distant metastasis.

In 1988, FIGO instituted a surgical staging system for endometrial cancer. Prior to this system, FIGO utilized a clinical staging system based upon the extent of disease within the uterus that could be assessed primarily by physical exam (Table 92-5). The surgical

Table 92-5 International Federation of Gynecology and Obstetrics Staging Systems for Endometrial Cancer

Stage	Description
1988 STAGING FOR CARCINOMA OF THE CORPUS UTERI	
Stage IA G123	Tumor limited to the endometrium
Stage IB G123	Invasion to less than one half of the myometrium
Stage IC G123	Invasion to more than one half of the myometrium
Stage IIA G123	Endocervical glandular involvement only
Stage IIB G123	Cervical stromal invasion
Stage IIIA G123	Tumor invades serosa and/or adnexa and/or positive peritoneal cytology
Stage IIIB G123	Vaginal metastases
Stage IIIC G123	Metastases of pelvic and/or para-aortic lymph nodes
Stage IVA G123	Tumor invasion of bladder and/or bowel mucosa
Stage IVB	Distant metastases including intra-abdominal and/or inguinal lymph nodes
1971 STAGING OF CORPUS CANCER	
I	Confined to the corpus
Ia	Length of uterine cavity ≤8 cm
Ib	Length of uterine cavity >8 cm
II	Carcinoma involves corpus and cervix
III	Carcinoma extends outside the corpus but not outside the true pelvis (may involve vaginal wall or parametrium but not bladder or rectum)
IV	Carcinoma involves bladder or rectum or extends outside the true pelvis

staging system should be used for all patients who undergo hysterectomy for treatment of their endometrial cancer. Because this system requires specific assessment of the adnexae, lymph nodes, and peritoneal cytology, appropriate surgery for endometrial cancer includes a total abdominal hysterectomy, bilateral salpingo-oophorectomy, pelvic and para-aortic lymph node sampling, and pelvic washings. Biopsies of any suspicious nodules in the abdomen or pelvis should be obtained. However, for superficial grade I or noninvasive grade II cancers, the risk of lymph node involvement is sufficiently low that the nodal sampling is sometimes omitted. Surgery may be significantly modified in patients with known metastatic disease when surgery is used for debulking or palliation of symptomatic disease, in which case thorough staging is not indicated. Generally, the pelvic and para-aortic nodes should be sampled whether they appear grossly suspicious or not. Adequate nodal sampling of the obturator, external iliac, and para-aortic regions suffices. Pathologic assessments included in the staging system are grade, depth of myometrial invasion, peritoneal cytology, cervix invasion, serosal or adnexal involvement, vaginal invasion, and lymph node metastases. The FIGO 1971 clinical staging system is used for any patients who are not surgical candidates. Whether the staging is based on surgical or clinical staging systems should be clearly documented. These staging systems may also be used for uterine sarcoma, for which there is no specific system.

The use of surgical staging has become the standard after a GOG study by Creasman and colleagues, who reviewed the patterns of spread in surgically staged patients.[50] Of patients with clinical stage I (disease confined to the uterus), 9% were found to have pelvic node metastasis, and 6% were found to have para-aortic node metastasis. Three factors that predict the risk of nodal metastasis, which can be assessed at the time of surgery, are grade ($P = 0.03$), depth ($P = 0.0001$), and the presence of intraperitoneal metastasis ($P = 0.001$).[50] The risk of pelvic nodal metastases in clinical stage I patients is less than 10% in all tumors with superficial invasion or invasion of up to two thirds of the myometrium only, regardless of grade (range 0% to 9%). Tumors that invade more than two thirds of the myometrial depth have a higher risk of pelvic node metastases, depending on the grade: grade I = 11%, grade II = 19%, and grade III = 34%. Furthermore, grade and depth of invasion are strongly correlated; 58% of grade III tumors demonstrate deep invasion. Para-aortic nodal metastases are present in 14% of grade II deeply invasive tumors and in 23% of grade III deeply invasive tumors. Approximately 20% of patients with clinical stage I disease will have occult extrauterine disease in the nodes or washings. Downstaging in clinical stage I is uncommon.

PROGNOSIS

The most important prognostic factors in endometrial carcinoma are stage or extent of disease, grade, depth of invasion, and histologic subtype. The prognosis for uterine confined, stage I disease is excellent, so survival is highly correlated with the presence of extrauterine disease. These factors influence the risk of extrauterine spread and recurrence and therefore influence survival.

Stage

The stage at the time of diagnosis is an important prognostic indicator; patients with more advanced stage have less favorable outcomes. Overall survival rates are approximately 90% for stage I to II, 60% for stage III, and 25% for stage IV. Surgical staging more accurately predicts for survival than does clinical staging. In one study, survival rates for clinical stages I, II, and IV were 83%, 64%, and 8%, respectively; survival rates for surgical stages I, II, III, and IV were 89%, 100%, 58%, and 24%, respectively.[122]

Histologic Subtype

The most common histology, and one of the most favorable, is endometrioid adenocarcinoma. Other adenocarcinomas, including USC and CCC, have a much higher propensity for both nodal and extrauterine spread; therefore, their prognosis is much poorer. Squamous carcinomas and undifferentiated subtypes also behave aggressively. The overall survival rate among patients with endometrioid adenocarcinoma is over 90%, compared to only 33% for all unfavorable histologies combined.[123] High-grade sarcomas also have a poorer prognosis than does endometrioid adenocarcinoma.

Depth of Invasion

Depth of invasion of the myometrium is the most influential pathologic feature with respect to lymph node metastases. Pelvic node metastases are found in 1% of superficial tumors, in 5% of tumors with invasion of the inner one third of the myometrium, in 6% of tumors with middle one third invasion, and in 25% of tumors with deep outer one third invasion.[50] Para-aortic nodal metastases are seen in 1%, 3%, 1%, and 17% of tumors, respectively. Depth of invasion correlates with the grade, and over half of cancers that are grade III have deep invasion.

Grade

Histologic grade is one of the primary predictors for extrauterine spread. Higher grade is associated with both deeper myometrial invasion and lymph node metastases. Grade I cancers have a 3% risk of pelvic lymph node spread, compared to 9% for grade II and 18% for grade III.[50] Para-aortic nodes are involved in 2% of grade I, 5% of grade II and 11% of grade III tumors. The presence of both high grade and deep myometrial invasion conveys the highest risk of nodal spread: 34% to pelvic nodes and 23% to para-aortic nodes. The correlation is not absolute, however, and 10% of grade I tumors will demonstrate deep invasion, while 7% of grade III are endometrium only.

Adnexal Involvement

Only 5% to 6% of surgically staged patients with clinical stage I disease have isolated adnexal involvement.[50] This pathologic finding is associated with a 32% risk of pelvic lymph node metastases, and 23% have para-aortic lymph node spread, compared to only 8% and 5% risk of pelvic or para-aortic nodal spread, respectively, without adnexal involvement.

Positive Peritoneal Cytology

Positive peritoneal washings are often a marker for other extrauterine spread. Over half of patients with positive pelvic washings will have adnexal or other areas of pelvic spread of disease. About 10% of patients with FIGO stage I endometrial cancer have positive peritoneal washings. This finding is associated with depth of invasion, high grade, and positive nodes, appearing to place these patients at higher risk for recurrence.[124] In a series of 270 patients with stage I disease, 5% demonstrated positive washings, which correlates with tumor grade and depth of invasion.[125] Peritoneal cytology was found to predict for survival; however, peritoneal cytology can fail to identify any additional patients whose prognosis is not apparent from grade and depth of invasion.

Lymphovascular Invasion

Lymphovascular invasion is present in 15% of endometrial cancers, conferring a 27% risk of pelvic nodal spread and a 19% risk of para-aortic nodal spread, compared to 7% and 9%, respectively, if the feature is absent.[50] Lymphovascular invasion correlates with poorer disease-free survival.[126]

Age

Older age is associated with a worse prognosis.[127] Age is also associated with a higher risk of presenting with high-risk histologies such as uterine serous, higher grade, deep invasion, and higher stage, possibly reflecting a more aggressive biologic behavior of hormone-independent cancers that occur at a higher median age. However, when endometrial cancers with similar pathologic features are compared, survivals are not significantly different by age (less than 60 years: 74%, 60 to 69 years: 70%, ≥70 years: 60%).[128]

TREATMENT OF EARLY-STAGE ENDOMETRIAL CANCER

FIGO stage I and II endometrial carcinomas consists of tumors that are confined to the uterus or that extend to the uterine cervix only. Five-year overall survival rates of 76% to 100% and 46% to 85% for stage I and II patients, respectively, have been reported (Tables 92-6 and 92-7). Treatment mainly consists of surgical resection with adjuvant radiation therapy reserved for patients who have risk factors for pelvic recurrence (Box 92-1). If recurrences do occur after early-stage endometrial carcinoma, they are predominantly local in nature, and the addition of radiation therapy to the management of early-stage endometrial carcinoma, has been shown to decrease the rate of local recurrence. Definitive radiation is largely reserved for patients who are medically inoperable or who refuse surgical resection.

Surgery

Surgical Technique

Surgery should be performed by utilizing an incision that allows for adequate examination of the abdomen and pelvis as well as retroperitoneal lymph node sampling if indicated. Upon entry into the abdominal cavity, pelvic washings should be obtained for cytologic analysis. Next, a thorough inspection of all peritoneal surfaces should be performed, with biopsy of any suspicious lesions. Prior to removal of the uterus, the fallopian tubes should be clamped or occluded with clips to prevent retrograde spillage of tumor. Extrafascial hysterectomy with bilateral salpingo-oophorectomy may then be completed. The specimen should be bivalved and examined for depth of myometrial invasion and other features that are indicative of high-risk disease in the pathology laboratory as part of intraoperative consultation and frozen section evaluation. (Specimens should never be opened or cut into in the operating room because that compromises pathologic evaluation.) In cases of deep myometrial invasion, grade II or III disease, nonendometrioid histologic type, or obvious extrauterine tumor, pelvic and para-aortic lymph nodes should be sampled.

For selected patients who are at high risk for perioperative complications whose tumors appear clinically confined to the uterus, vaginal hysterectomy may be an alternative.[129] Although this approach might offer reduced surgical morbidity, it has several disadvantages. A vaginal approach can render removal of the ovaries difficult. In

Box 92-1. ADJUVANT RADIATION THERAPY FOR EARLY-STAGE ENDOMETRIAL CANCER

One of the most controversial aspects of clinical management in endometrial cancer involves the use of adjuvant postoperative radiation therapy for stage I disease, including determining who benefits from it and who may safely avoid it. The recommendations for adjuvant radiation are influenced by the risk of nodal metastases and the rate of vaginal recurrence. According to a GOG pathologic study, patients with deep myometrial invasion and grade II or III tumors have a 19% to 34% risk of pelvic lymph node metastases.[50] The risk is also increased by positive peritoneal cytology, location in the lower uterine segment or cervix, adnexal involvement, and capillary space invasion. The risk of vaginal recurrence after surgery alone is greater with grade II or III histology, deep myometrial invasion, lymphovascular space invasion, large tumor size, location in the lower uterine segment or cervix, and close or positive margins. Adjuvant radiation is extremely effective at preventing pelvic and vaginal recurrence but is associated with an increased risk of late side effects. It can also be argued that radiation therapy for isolated vaginal recurrence is relatively effective salvage treatment and therefore may be reserved for those that do recur.

Although three randomized trials have addressed the question of postoperative radiation in early-stage disease, all have been criticized. All three trials entered patients who were predominantly at low or intermediate risk for recurrence. The PORTEC study excluded high-risk patients from eligibility, including those with high-grade or deeply invasive tumors.[50] In the Norwegian Radium Hospital (NRH) trial, 50% of the patients entered had stage IB grade I or II adenocarcinomas, and only 18% had stage IC grade 3 tumors.[164] In GOG Protocol 99, only 18% of patients entered had grade III disease, and only 20% had deep myometrial invasion (outer one third).[166] Two trials (NRH and PORTEC) did not include surgical lymph node staging. Although GOG Protocol 99 did require surgical staging, the median number of lymph nodes that were recovered was relatively low. The therapeutic benefit of nodal sampling and its role in reducing pelvic recurrence are controversial. Therefore, all three randomized trials addressing the role of adjuvant radiation in early-stage endometrial cancer included a preponderance of intermediate-risk patients, diluting the ability to detect a benefit in the patients who are at highest risk for pelvic recurrence: those with high-grade and deep myometrial invasion. In addition, none of these trials has adequately assessed the benefit of adjuvant radiation after comprehensive surgical staging. Not surprisingly, no overall survival benefit for adjuvant radiation has been reported in these trials. GOG Protocol 99 showed an estimated hazard of recurrence that was 58% less in the irradiated arm ($P = 0.007$) and a 4-year overall survival rate of 92% in the radiation arm versus 86% in the observation arm ($P = 0.09$).

What is not controversial is that adjuvant radiation has been consistently shown to significantly reduce the pelvic and vaginal recurrence rates in stage I endometrial cancer patients. In the NRH trial (in which all patients received vaginal brachytherapy and were randomized to pelvic radiation or no further treatment), the vaginal and pelvic recurrence rate in the observation arm was 6.9% compared to 1.9% in the radiation arm ($P = 0.01$). The PORTEC trial reported locoregional recurrences rates of 14% in the observation arm compared to 4% in the radiation arm ($P < 0.001$). GOG Protocol 99 reported a crude vaginal and pelvic recurrence rate of 8.9% in the observation arm and 1.6% in the radiation arm (three patients, two of whom refused radiation after randomization). When risk factors for recurrence were examined in the NRH trials, it was noted that the greatest benefit of adjuvant radiation was for patients with high-grade and deeply invasive tumors.

Complications are increased by the use of both surgery and pelvic radiation. The NRH reported a crude grade III or IV complication rate of 0.7% after postoperative vaginal brachytherapy alone (one fistula and one urethral stricture) and 0.7% after postoperative pelvic radiation and brachytherapy (including one death due to postoperative infection after a bowel obstruction, and one bladder necrosis). The PORTEC trial included no vaginal brachytherapy and reported treatment-related complications (grades I to IV) of 25% in the radiation arm compared to 6% in the observation arm, of which 68% overall were grade I toxicities. Grade III toxicity occurred in seven patients (0.09%), six of whom received radiation therapy. Grade IV toxicity occurred in one patient from the radiation arm who had Crohn's disease and therefore should not have been offered adjuvant irradiation.

On the basis of the patterns of nodal metastases and patterns of recurrence, a management algorithm has been developed for the use of postoperative radiation therapy stage I and II endometrial cancer patients. A multidisciplinary approach is recommended, involving gynecologic oncologists and radiation oncologists in the patients' care. Low-risk patients have a sufficiently small risk of nodal or vaginal recurrence that they require no adjuvant therapy, including stage IA grade I to II and stage IB grade I. The recurrence pattern in intermediate-risk patients is predominantly vaginal. These patients may be offered observation versus vaginal brachytherapy alone after a discussion of the risks and benefits of both approaches and the salvage rates after recurrence. This category includes stage IA grade III, stage IB grade II or III and stage IC grade I or II. The recurrence pattern for high-risk patients includes both vaginal and pelvic relapses; therefore, they should be offered pelvic radiation with or without vaginal brachytherapy. This category includes stage IC grade III and stage II. Vaginal brachytherapy in addition to pelvic radiation is considered for stage II patients (those with extension to the cervix) unless they have undergone a radical hysterectomy and margins are widely negative and for some stage IC grade III patients, including those with large tumors (>4 cm) in the lower uterine segment or extensive lymphovascular invasion. The fraction size for vaginal brachytherapy when given in combination with external beam pelvic irradiation should not exceed 500 cGy. Any patient with very close or positive margins postoperatively should be offered vaginal brachytherapy at a minimum. Patients who have not undergone an adequate pelvic lymph node sampling (several nodes from each side of the pelvis) should be offered pelvic irradiation, even if they have only intermediate-risk features.

addition, peritoneal cytology, thorough abdominal exploration, and lymphadenectomy are not feasible. To overcome these obstacles, some clinicians have advocated use of laparoscopic-assisted vaginal hysterectomy combined with laparoscopic lymphadenectomy.[130] The laparoscopic surgery consists of initial laparoscopic examination of the abdominal cavity followed by sampling of the para-aortic and pelvic lymph nodes through the same incisions. The hysterectomy may be performed vaginally with laparoscopic assistance to ensure ovarian removal (Box 92-2). The procedure is converted to an open laparotomy if the laparoscopy proves to be too difficult or inadequate or if excessive blood loss occurs. Although laparoscopy has been shown to increase the total time of the operation, the length of post-surgical hospital stay is shorter.[131] While rates of complications, lymph node counts, and recurrence and survival rates are reportedly equivalent to those of traditional total abdominal hysterectomy, the technique has yet to be validated over the long term.[132–135] There have been reports of increased need for blood transfusion and increased operative times for the laparoscopic approach, as well as a small

Box 92-2. LAPAROSCOPIC SURGERY FOR ENDOMETRIAL CANCER

Total abdominal hysterectomy and bilateral salpingo-oophorectomy, with lymph node sampling in selected patients, is the standard surgical approach for management of early endometrial cancer. Although vaginal hysterectomy has been utilized in women who are at high risk for perioperative morbidity, the technique does not allow for adequate peritoneal exploration or for lymphadenectomy. However, laparoscopic-assisted vaginal hysterectomy may be combined with laparoscopic lymph node sampling to provide a means of adequate staging as well as to potentially decrease the length of patients' postoperative stay. The Gynecologic Oncology Group (GOG) has completed a phase III randomized study comparing laparoscopy with laparotomy.[137] Laparoscopic surgical staging could be performed in 76.3% of cases. No difference in stage, positive cytology, or lymphatic metastasis could be attributed to the laparoscopic approach. Quality of life and physical functioning improved 6 weeks postoperatively following laparoscopy, but these differences were not significant by 6 months.[137] The role of robotics in minimally invasive surgery for uterine cancer is under investigation. While laparoscopic staging could be a technically feasible option for surgical management, long-term data regarding recurrence and survival have yet to be characterized.

number of deaths directly related to complications associated with laparoscopy. Vaginal cuff recurrence associated with laparoscopic-assisted vaginal hysterectomy has also been reported.[136]

For patients with disease spread outside of the uterus, more aggressive surgical options exist. Radical hysterectomy with removal of the uterus, cervix, parametria, and upper vagina may be an option for those with disease involving the cervix.[138] Fewer than 10% of patients will present with stage IV disease.[139] While the overall survival rate for these patients is less than 10%, aggressive surgical cytoreduction may improve survival.[140–142]

Surgical removal of the uterus not only provides a therapeutic benefit, but is also important for accurately staging the patient. Surgical staging can result in upstaging 12% of patients with clinical stage I disease and 27% with clinical stage II disease as well as downstaging 59% of patients with clinical stage II disease.[143] In addition, surgical staging allows for full evaluation of histologic grade. Histologic grade from the biopsy specimen differs from the histologic grade from the surgical specimen after hysterectomy in over 20% of cases, mainly owing to tumor heterogeneity.[144,145] Surgical staging is also vital for assessing the depth of myometrial invasion and presence of lymph-vascular invasion, all of which are critical in guiding adjuvant therapy.

Surgical Staging of the Lymph Nodes

Surgical staging, including sampling of the pelvic and para-aortic lymph nodes, may be performed at the time of the surgery. When the tumor is limited to the uterine corpus, occult metastases to the lymph nodes most frequently occur to the external iliac and obturator lymph node chains.[146] Spread to the common iliac lymph nodes is more frequent when there is cervical extension of the primary disease. Isolated involvement of the para-aortic lymph nodes can occur, although it is uncommon in the absence of associated pelvic lymph node spread. The presence of lymph node metastases can significantly alter the treatment plan, and removal of the lymph nodes has a strong role in improving staging.[147] However, lymphadenectomy has not been shown to improve survival, other than in small retrospective studies[146,148,149] A review of over 9000 women with endometrial cancer who were registered into the National Cancer Institute's Surveillance, Epidemiology and End Results database revealed that the 5-year relative survival of 2831 women with stage I endometrial cancer who underwent sampling of their pelvic lymph nodes was nearly identical to that of 6363 women with stage I disease who did not undergo lymph node sampling.[150]

Risk factors for metastases to clinically uninvolved lymph nodes include myometrial invasion to the outer one third of the myometrium, lymph-vascular space involvement, cervical involvement, and high-grade histology. Stage I carcinomas without any of these adverse risk factors have histologically involved lymph nodes less than 10% of the time, and lymph node sampling may be omitted in these cases.[151,152] In a nonrandomized, prospective trial of 332 patients with endometrial carcinoma who did not have significant risk factors for lymph node metastases, treatment with hysterectomy and adjuvant postoperative vaginal brachytherapy alone without lymphadenectomy resulted in a 30-year disease-free-survival rate of 96.7%.[153] Involvement of any of these risk factors can increase the risk of pelvic or para-aortic lymph node involvement to 14% to 31%; therefore, sampling of the pelvic and para-aortic lymph nodes to allow for complete pathologic staging is indicated.[152,154] To identify the patients who are at high risk for lymph node involvement, frozen section of the uterine specimen may be performed at the time of surgery to determine the grade, depth of invasion, and presence of lymph-vascular invasion. Such algorithms must be used with caution. Currently, there are no proven methods to definitively predict which patients are at low risk for lymph node metastases.[155,156] Therefore, some surgeons will perform retroperitoneal lymph node staging on all patients with endometrial cancer.

Surgery as a Single Modality

Several series, listed in Table 92-8, have examined the outcomes of patients with stage I/II endometrial cancer who have undergone hysterectomy without adjuvant treatment. Berchuck and colleagues reviewed a series of 354 patients with stage I/II endometrial adenocarcinoma from Duke University who underwent postsurgical surveillance.[157] Twelve percent of patients developed recurrent disease. Of the patients with recurrence, 27% had isolated vaginal recurrences, 27% had pelvic recurrences with vaginal or abdominal involvement, 29% had pelvic recurrences with other distant sites, 10% had isolated lung recurrences, and 7% had recurrences at other distant sites. Another study from the University of Alabama–Birmingham reviewed 613 patients with stage I endometrial carcinoma who underwent primary surgery.[158] The 5-year overall survival rate was 98%, and the 5-year disease-free survival rate was 93%. For stage IB patients, 99% did not receive adjuvant treatment, and only 5% of those patients experienced recurrent disease. All patients who recurred within the pelvis or vagina were successfully salvaged with radiation therapy. For stage IC patients, 69% did not receive adjuvant therapy. Recurrence was seen in only 8% of those patients. A small, prospective series of 33 patients with stage I endometrial carcinoma who had poor prognostic features, including deep myometrial invasion and/or histologic grade III tumors, utilized surgery alone as primary treatment for their endometrial cancer.[159] All 18 patients who presented with disease that was confined to the uterus were without evidence of disease at their latest follow-up. However, 73.3% (11 of 15) of patients with spread beyond the uterus had recurrences. Larson and colleagues reviewed 207 women with uterine-confined endometrial carcinoma who underwent surgery without adjuvant radiation therapy.[160] Forty-five percent were considered to be in a low-risk group with grade I tumors and invasion through less than 50% of the myometrium. The 5-year recurrence-free survival rate was 95% in these patients. Forty-seven percent of patients with additional risk factors, but who had histologically confirmed negative nodes, had a 5-year recurrence-free survival rate of 89%.

A factor that favors the use of surgery only in some patients is the high rate of salvage for recurrences. Patients who experience recur-

rence after surgery alone can often be successfully salvaged with external beam radiation therapy (EBRT) to the pelvis, vaginal brachytherapy, or, most commonly, a combination of both. The 5-year disease-free survival rate after salvage radiation therapy ranges from 62% to 92% for these patients.[161,162] The long-term grade II or III complication rate from salvage radiation therapy is 10% to 15%.[163]

External Beam Radiation Therapy for Early-Stage Endometrial Cancer

Endometrial carcinoma is a radiosensitive tumor, and the addition of radiation can result in very high rates of locoregional control. The presence of adverse risk factors such as extension beyond the corpus to the uterine cervix, deep myometrial invasion, or high-grade histology significantly increases the risk of locoregional recurrence following surgery alone. In these patients, adjuvant radiation therapy has been used successfully to significantly reduce the risk of local recurrence. In addition, radiation has been used with some success as the primary treatment of patients who are poor surgical candidates, who are medically inoperable, or who refuse surgical removal of the uterus.

Postoperative External Beam Radiation Therapy for Stage I

Several randomized studies, reviewed in Table 92-6, have explored the benefit of adjuvant EBRT. A study by Aalders and colleagues randomized 540 patients with clinical stage I endometrial adenocarcinoma who underwent hysterectomy and received 60 Gy of postoperative radiation delivered via intravaginal radium implants to either no further treatment or an additional 40 Gy to the pelvis via EBRT.[164] The results showed a significant reduction in the 5-year local recurrence rate in the group that received pelvic radiation (1.9% versus 6.9%, $P < 0.01$); however, no overall survival advantage was seen, owing to an increase in the rate of distant metastases in the group receiving additional radiation. On subgroup analysis, the patients who experienced the greatest reduction in local recurrence were those patients with grade III tumors as well as those with more than 50% myometrial invasion.

Another prospective, randomized trial supporting the use of adjuvant radiation for early-stage endometrial cancer was conducted by the Post-Operative Radiation Therapy in Endometrial Cancer (PORTEC) Study Group in the Netherlands.[165] Only patients with intermediate-risk, stage I endometrial carcinoma were enrolled. Eligibility included grade I tumors with 50% or more myometrial invasion, grade II tumors with any depth of invasion, or grade III tumors with less than 50% myometrial invasion. Treatment consisted of a total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO) with or without EBRT (46 Gy, 2 Gy/day) delivered to the whole pelvis following surgery. Overall, 715 patients were randomized to postoperative radiation therapy versus no further treatment. Patients were followed for a median of 52 months. The 5-year local and regional recurrence rate was 4% in the group that received postoperative radiation therapy compared to 14% in the group that underwent no further treatment ($P < 0.001$). The overall incidence of distant metastases was similar in both groups (8% versus 7% for the radiation and observation arms, respectively). Despite this improvement in locoregional control, there was no difference in overall survival, largely owing to the high rate of salvage for patients who experienced a recurrence. The 5-year overall survival was 81% in the radiotherapy group compared to 85% in the observation group ($P = 0.31$). Deaths from endometrial cancer were also similar between the two groups (9% versus 6% for the radiotherapy group and the observation group, respectively, $P = 0.37$). On multivariate analysis, the only factors predicting for locoregional recurrence were patient age and the use of postoperative radiation therapy. The histologic grade and depth of myometrial invasion both showed a trend toward predicting recurrence; however, neither reached statistical significance. In terms of patterns of failure, 75% of patients who experienced a local recurrence recurred within the vaginal vault. An increase in late toxicity was associated with the radiation therapy. Twenty-five percent of patients receiving radiation therapy experienced grade I to IV late toxicity compared to 6% of the observation group ($P < 0.001$). However, only seven patients experienced any grade III toxicity, and one patient who had Crohn's disease experienced grade IV GI toxicity.

The study GOG Protocol 99 is the first postoperative radiation trial that required comprehensive surgical staging. They randomized 392 patients with surgical stage IB, IC, or occult IIA or IIB endometrial cancer to treatment with surgery alone versus surgery with 50.4 Gy of postoperative EBRT.[166] The majority of patients had stage IB (60%) disease, and most had grade I or II disease (80%), representing a group without high-risk factors overall. The median follow-up was 69 months. The results estimated that the hazard of recurrence was 58% less in patients who were randomized to the irradiated arm compared to those who were randomized to the observation arm ($P = 0.007$). Importantly, all patients in this study were required to undergo surgical lymph node staging, and this benefit in progression-

free survival was seen even in patients who were found to have pathologically uninvolved lymph nodes. In addition, while 18 patients failed in the pelvis or vagina in the observation arm, only three patients in the radiation arm experienced a locoregional failure; and two of those three patients did not actually receive radiation treatment. At 48 months, the overall survival rate was higher in the radiation arm than in the observation arm (92% versus 86%), though this difference was not statistically significant ($P = 0.09$); however, this trial was not adequately powered to reliably detect overall survival differences. Subgroup analysis identified a high-intermediate-risk group that showed a trend toward a lower overall death rate in the radiation arm, suggesting a possible benefit of adjuvant radiation in patients that have a combination of advanced age, moderate to poorly differentiated rumors, presence of lymphovascular invasion, or outer third myometrial invasion.

A number of retrospective series have examined the efficacy of postoperative radiation therapy in stage I endometrial cancer. In one series, 124 patients with stage IB endometrial carcinoma were reviewed at Massachusetts General Hospital.[167] All patients underwent hysterectomy, and 62 patients did not receive any adjuvant therapy. Only 3% (4 of 124) of the patients developed a recurrence. One of the four patients who relapsed had received adjuvant therapy, and that patient had a grade III tumor. In another retrospective series from Washington University, 858 patients with clinical stage I endometrial cancer were treated with TAH-BSO and radiation therapy.[168] The study included a wide variety of radiation techniques, including EBRT and intracavitary brachytherapy as well as both preoperative and postoperative radiation, and included patients who were treated over a long time period. The 5-year progression-free survival rate was 92% for patients with stage IA disease and 86% for patients with stage IB disease.

A series from Princess Margaret Hospital compared 228 patients who underwent surgery alone for stage I endometrial carcinoma to 217 patients who received adjuvant EBRT with intracavitary boost and 97 patients who received adjuvant EBRT only.[169] Overall, the local control rate was the same among the three groups (93% to 95%); however, the patients who received radiation were more likely to have more than 50% myometrial invasion and grade III tumors. Another series reviewed 300 patients with endometrial cancer confined to the uterus who had undergone hysterectomy.[170] Patients with high-risk features for local recurrence received adjuvant radiation therapy. Treatment with radiation resulted in a pelvic control rate of 95%, and recurrences were more likely to be distant than local in this population. The use of radiation therapy was found to correlate with patient prognosis. A smaller series from the University of Chicago reviewed the outcomes of women with stage IC endometrial carcinoma who were treated with EBRT to the whole pelvis without the addition of intracavitary brachytherapy.[171] No patient developed local recurrence, and the 5-year disease-free and overall survival rates were 87% and 98%, respectively.

A multi-institution review by Straughn and colleagues examined 220 patients with surgical stage IC and compared patients who were managed with and without adjuvant radiation. Forty-five percent of patients were treated with adjuvant radiation on the basis of physician preference. Six percent of patients recurred in the radiation arm, and 12% of patients recurred in the observation arm. Though there were fewer recurrences in the radiation arm, the results were not statistically significant ($P = 0.20$). The 5-year disease-free survival rate was significantly improved in the adjuvant radiation group (93% versus 75%, $P = 0.013$). Overall survival was similar in both groups. The overall salvage rate was 64%.[172]

For patients who are good candidates for postoperative radiation, the time interval between completion of surgery and the initiation of radiation appears to significantly affect local control. In a retrospective study by Ahmad and colleagues, patients with endometrial cancer who were treated with postoperative radiation were found to have significantly decreased 5-year disease-specific survival rates, from 89% to 81% ($P < 0.005$ on multivariate analysis), when the interval between surgery and radiation was greater than 6 weeks.[173] In addition, an increased surgery-to-radiation interval showed a trend to worsened local control (88% for interval less than 6 weeks versus 84% for interval greater than 6 weeks, $P = 0.06$ on multivariate analysis).

Postoperative Radiation Therapy for Stage II

The presence of cervical invasion in endometrial cancer results in an increased risk of local recurrence, particularly at the vaginal cuff. In the setting of known cervical extension, a wider resection, such as a radical hysterectomy, is often performed at the time of surgery. Often, occult cervical involvement is seen only on pathologic examination of the surgical specimen. In either case, postoperative radiation therapy is usually indicated to reduce the risk of local recurrence.

Aside from the inclusion of patients with occult stage IIA or IIB in the GOG Protocol 99 trial, there are no randomized trials that specifically address the role of adjuvant radiation therapy with stage II endometrial carcinoma. Nevertheless, several retrospective series support its use in these patients (see Table 92-7). Greven and Olds reported a 5-year overall survival rate of 86% for patients with stage II disease treated with surgery and adjuvant radiation.[174] Lanciano and colleagues reviewed 184 patients with stage II carcinoma of the endometrium who received a variety of treatments, including TAH-BSO with preoperative RT, postoperative RT, or both, or who received RT alone or radical hysterectomy alone.[175] The overall 5-year disease-free survival and overall survival rates were 79% and 70%, respectively. The only predictors of recurrence on multivariate analysis were histologic subtype and grade. There was no difference in disease-free survival on subgroup analysis with respect to the timing of radiation to surgery. In a series at the University of Vermont, 48 women with stage II endometrial carcinoma were treated with TAH followed by pelvic EBRT and/or vaginal cuff radiation or with radical hysterectomy alone.[176] The 5-year overall survival rate was 92%, and the 5-year disease-free survival rate was 90%. None of the 31 patients who were treated with both EBRT and vaginal cuff boost or with radical hysterectomy recurred. Seventeen percent of patients who received total abdominal hysterectomy with only pelvic radiation or vaginal cuff radiation experienced local recurrence. The authors concluded that use of both pelvic EBRT and vaginal cuff radiation was warranted in this group of patients. Sartori and colleagues reviewed 203 patients with stage IIA and stage IIB endometrial carcinoma among whom 66% underwent simple hysterectomy while 34% underwent radical hysterectomy.[177] Adjuvant radiation was delivered to 59% of stage IIA patients and to 73% of stage IIB patients. Overall survival was better in patients who underwent radical hysterectomy (10-year overall survival rate: 74% versus 94%, $P < 0.05$) compared to simple hysterectomy. Overall survival did not differ between the two treatment groups (10-year overall survival rate: 73% for irradiated patients versus 75% for observation patients). However, the overall recurrence rate was lower in the patients who received adjuvant radiation (11.3% versus 18.6%).

Preoperative Radiation for Early-Stage Endometrial Carcinoma

An alternative approach to postoperative radiation therapy for early-stage carcinoma is the administration of radiation therapy prior to surgical resection of the uterus, either via EBRT, brachytherapy, or a combination of both. Preoperative radiation has the potential advantages of sterilizing the tumor prior to surgery and increasing the ease of resection by decreasing tumor bulk, particularly in patients with extensive involvement of uterine cervix. There are no randomized studies comparing the relative efficacy of preoperative radiation

therapy to postoperative radiation; however, several retrospective studies indicate that preoperative radiation is a reasonable option for patients with early-stage endometrial cancer (Table 92-9). One retrospective study of patients with stage I endometrial carcinoma compared treatment with hysterectomy alone to hysterectomy with preoperative radiation with cesium implants.[178] The 5-year disease-free survival rate was similar for the two groups (94% versus 91%); however, the treatment groups were unbalanced. Patients who received preoperative radiation were more likely to have adverse prognostic features that placed them at higher risk for local recurrence. A study from the Mallinkrodt Institute of Radiology reviewed the results of 90 stage II patients with endometrial cancer, most of whom were treated with a combination of preoperative EBRT and intracavitary low-dose-rate brachytherapy.[179] The 5- and 10-year disease-free survival rates for these patients was 78% and 75%, respectively. Bruckman and colleagues reported the results of 40 patients with stage II endometrial cancer treated with 40 Gy of EBRT with an additional 40 mgh Ra Eq of radiation delivered via intracavitary brachytherapy followed by surgery.[180] In these patients, the 5-year relapse-free survival rate was 78% and the 5-year overall survival rate was 80%. Overall, for stage I or II disease, the addition of preoperative radiation has resulted in a reported 5-year disease-free survival rate of 80% to 88% and a 5-year overall survival rate of 82% to 95%.[181–183]

Grigsby and colleagues[168] reported a decrease in progression-free survival with doses less than 3500 mgh Ra Eq delivered via intracavitary cesium implants. This decrease was greatest for high-grade tumors, though doses greater than 3500 mgh Ra Eq resulted in equivalent results (a 5-year progression-free survival rate of 87%) for all grades. The results of these retrospective series for preoperative radiation are similar to historical results for early-stage endometrial cancer treated with hysterectomy followed by adjuvant radiation. Preoperative radiation remains a viable option for the treatment of stage I/II patients; however, care must be taken to deliver adequate doses, particular in patients with risk factors for recurrence such as high-grade disease or deep myometrial invasion.

Postoperative Radiation Therapy for Early-Stage High-Risk Histology

Several histologic subtypes of endometrial carcinoma have a significantly higher risk of extrauterine spread and propensity for local recurrence, most notably uterine serous and clear cell variants. These histologic subtypes have shown a propensity for distant spread and, when compared to other stage-matched endometrial carcinomas, have significantly worse outcomes. The propensity of uterine serous tumors to spread can be seen even in the absence of definitive evidence of local invasion. Lymph node metastases can be seen in more than 35% of patients with uterine serous tumors who do not have any evidence of myometrial invasion on pathologic examination. Patients with stage I/II uterine serous carcinoma have a recurrence rate of 38% compared to 22% for CCC and 20% for grade III adenocarcinoma.[183] Survival is also worse for these variant histologies with an estimated 5-year overall survival rate of 32% to 44% for patients with uterine serous histology and a 5-year overall survival rate of 59% to 72% for those with clear cell histology.[184]

Owing to the probability of intraperitoneal spread with uterine serous and clear cell histologies, the use of whole-abdominal irradiation has been explored in several studies. At Stanford University, eight patients with stage I or II uterine serous or clear cell histology endometrial cancers were treated with adjuvant whole-abdominopelvic irradiation.[185] The 3-year disease-free and overall survival rates were both 87% for these patients. Another study reviewed the results of 78 patients with stage I to IIIA (positive washings only) endometrial cancer who had tumors with uterine serious histology.[186] Fifty-eight patients received whole-abdominal radiotherapy and had a significantly better 5-year disease-specific survival rate than did those who received either less extensive radiation therapy or no adjuvant therapy (75% versus 41%). These studies indicate that the use of whole-abdominal radiation therapy can improve disease control in patients with these aggressive histologies and should be considered as part of treatment for all patients with these variant histologies, even when they present with early-stage disease. Alternative approaches to the treatment of these high-risk histologies include the use of chemotherapy.

Brachytherapy for Early-Stage Endometrial Cancer

Intravaginal brachytherapy has been used both alone as the primary means of radiation treatment or in conjunction with EBRT. For early-stage disease, brachytherapy offers the advantage of delivering a high dose of radiation locally while minimizing the volume of surrounding normal structures that receives a high dose of radiation. Previously, brachytherapy consisted mainly of low-dose rate (LDR) intracavitary insertions; however, this requires in-patient hospitalizations and lengthy insertion times that increase the risk of exposure to medical personnel. Increasingly, high-dose rate (HDR) techniques with remote afterloading of the radiation source have been used, forgoing the need for hospitalization and minimizing exposure to medical personnel. In appropriately selected patients, brachytherapy offers results similar to those of EBRT, and it appears that HDR brachytherapy offers rates of control similar to those of LDR techniques.[187] The PORTEC-2 trial is currently under way, which randomizes patients to EBRT versus vaginal brachytherapy to compare rates of vaginal relapse and overall survival.

Low-Dose-Rate Brachytherapy

In addition to the preoperative use of LDR brachytherapy with or without EBRT that was described previously, LDR brachytherapy

has been used in the postoperative setting to decrease the risk of local recurrence at the vaginal cuff (Table 92-10). In the randomized trial by Aalders and colleagues, all patients were treated postoperatively with 60 Gy of intracavitary radium and then were randomized to either an additional 40 Gy of EBRT to the pelvis or no further therapy.[164] Although the addition of EBRT resulted in improved vaginal and pelvic control, the patients who benefited the most from pelvic irradiation were those with high-grade lesions and deep myometrial invasion. Patients without these features who were treated with brachytherapy only had excellent rates of local control without the addition of external beam radiation. For patients who had less that 50% myometrial invasion and received only intracavitary radiation, the vaginal and pelvic recurrence rate was 4.3%. In addition, patients receiving brachytherapy only who had grade I tumors had a vaginal and pelvic recurrence rate of 3.6%, whereas those with grade II tumors had a local recurrence rate of 3.2%. High rates of local control with postoperative LDR brachytherapy alone in appropriately selected patients have also been seen retrospectively. In one study, 68 patients with grade I or II tumors and less than 50% myometrial invasion were treated with postoperative intracavitary radium only. At a median follow-up of 4.8 years, none of the patients experienced a vaginal recurrence.[188] For patients without significant risk factors for nodal dissemination, postoperative LDR brachytherapy alone provides excellent local control.

The role of adding a brachytherapy boost to EBRT in patients who are at risk for nodal dissemination but at low risk for local recurrence is less clear. A retrospective study from Princess Margaret Hospital described 550 patients with stage I endometrial carcinoma who were treated with surgery alone, surgery followed by EBRT, or surgery with external beam and intracavitary brachytherapy.[189] Local control rates were similar among all three groups (93% versus 94% versus 95%). Grade III or IV toxicity was higher in the patients who received both EBRT and intracavitary brachytherapy. The rate of grade III or IV bowel toxicity was 9.7% when patients received both compared to 5% when they received EBRT as their only postoperative adjuvant therapy. Vaginal stenosis was also worse for patients who received EBRT and brachytherapy (21%, grade III or worse) compared to those who received postoperative EBRT only (3%). Although the authors concluded that neither the addition of EBRT nor the addition of brachytherapy improved local control, patients who received EBRT were more likely to have greater than 50% myometrial invasion than were patients who underwent surgery alone. In addition, the majority of patients who received brachytherapy had lower uterine segment involvement, increasing their risk of local recurrence. Greven and colleagues retrospectively reviewed the outcomes of 270 patients with stage I or II endometrial carcinoma who received either EBRT alone or EBRT with the addition of a brachytherapy boost.[190] Of the 97 patients who received a brachytherapy boost, LDR was used in 41 patients. Five-year pelvic control rates were similar for those who received a brachytherapy boost and those who did not (96% versus 94%). Pelvic control rates remained similar when patients were analyzed separately by stage. In addition, a nonstatistically significant increase in grade III and IV small bowel complications was seen in the group that received brachytherapy. Other retrospective studies have also failed to demonstrate improved local control but show increased complication rates from adding intracavitary radiation to external beam radiation for patients with low risk of nodal spread.[191] Currently, it appears that for patients who are at risk for nodal spread, EBRT alone provides adequate regional and local control. For patients who are at low risk for nodal spread but have risk factors for vaginal recurrence, such as lower uterine segment involvement, the addition of postoperative brachytherapy alone provides excellent local control.

High-Dose-Rate Brachytherapy

Although there are no prospective, randomized data utilizing HDR brachytherapy, a number of retrospective and institutional studies indicate that HDR brachytherapy is an effective means of providing local control for selected patients with an acceptable level of toxicity (Table 92-11). A series from Memorial Sloan-Kettering Cancer Center examined 233 patients with stage IB grades I or II endometrial carcinoma who were treated with simple hysterectomy followed by postoperative HDR intravaginal brachytherapy consisting of 21 Gy in 7-Gy fractions at 2-week intervals.[192] The 5-year vaginal/pelvic control rate was 96%, and the 5-year overall survival rate was 94%. The actuarial rate of grade III or higher complications at 5 years was 2%. Another series from Memorial Sloan-Kettering Cancer Center examined 382 patients with stage IB to IIB endometrial carcinoma who were treated with simple hysterectomy followed by postoperative HDR intravaginal brachytherapy with a median dose of 21 Gy given in three fractions at 2-week intervals. The 5-year vaginal/pelvic control rate was 95%, and the 5-year overall survival rate was 93%. The 5-year actuarial rate of complications was 1%.[193] Noyes and colleagues performed a phase II trial on 63 patients with stage IA grade III or stage IB grade I to II disease, all of whom received HDR brachytherapy alone postoperatively.[194] Most received a total of dose of 32.4 Gy in two fractions delivered to the surface of vaginal ovoids. With a median follow-up of 1.6 years, no patient had developed a vaginal cuff recurrence. Solhjem and colleagues reviewed 100 surgically staged patients with stage I endometrial carcinoma (94% were stage IB or IC) treated with HDR brachytherapy with 21 Gy in three fractions of 7 Gy following hysterectomy.[195] At a median follow-up of 23 months, there were no pelvic or vaginal recurrences. The 3-year estimated disease-free survival rate was 93.3%. On subgroup analysis, grouping patients according to comprehensive surgical staging and stage/grade subgroups provided better predictors of pelvic control than did the GOG-99 high-risk features. For patients with stage IB grade III to IIB disease and no comprehensive surgical staging, the 5-year pelvic control rate was 86% compared to 97% in those who had undergone comprehensive surgical staging; for patients with stage IB grades I to II, the 5-year pelvic control rate was 97% without comprehensive surgical staging and 100% with comprehensive surgical staging ($P = 0.027$).[195] Anderson and colleagues reviewed 102 patients with stage IB and IC endome-

trial carcinoma who were treated postoperatively with a relatively lower dose of HDR brachytherapy, using 15 Gy in three fractions of 5 Gy per fraction following hysterectomy.[196] Five-year locoregional control was 97% with only one patient experiencing a failure at the vaginal cuff, comparable to that found with higher doses. A number of other institutional series have demonstrated similar excellent local control with postoperative HDR brachytherapy only for appropriately selected patients. These results are similar to historical results that have been seen with LDR brachytherapy.[196]

The use of HDR brachytherapy following EBRT has been described in a number of nonrandomized series. Several studies have included both patients who received postoperative external beam radiation alone and those who received postoperative external beam with an HDR intracavitary brachytherapy boost. However, direct comparisons between these two groups is difficult in these retrospective studies, as patients receiving both modes of radiation therapy frequently have independent risk factors for local recurrence. Mandell and colleagues reviewed 330 endometrial cancer patients with either high-risk stage I or stage II endometrial carcinoma who were treated with a combination of 40 Gy EBRT and a vaginal vault boost of 21 Gy.[197] The overall pelvic and vaginal recurrence rate was 3.7%. Nori and colleagues reviewed 300 patients with stage I or II endometrial carcinoma who were treated with hysterectomy and HDR brachytherapy.[198] EBRT was given to patients with high-risk features. With a median follow-up of 12 years, the actuarial progression-free survival rate was 96.6%. Importantly, on long-term follow-up, no grade III or IV toxicities were seen in any patient. Another retrospective study examined the results of 86 stage I and occult stage II endometrial cancer patients who were treated with surgery followed by EBRT in one of three different fractionation schedules with or without intracavitary brachytherapy.[199] No difference was seen in rates of local recurrence, and on multivariate analysis, the addition of brachytherapy did not affect survival. A retrospective series from Fox Chase Cancer Center looked at 98 patients with pathologic stage I/II endometrial cancer.[200] Most patients received postoperative EBRT with an HDR brachytherapy boost; however, 17 patients received postoperative brachytherapy only. The 5-year freedom from pelvic recurrence rate for the entire population was 89%.

As with LDR brachytherapy, it remains unclear whether the addition of HDR brachytherapy to EBRT adds any benefit to local control. In addition, intravaginal brachytherapy might lead to an increased incidence of complications such as vaginal stenosis, particularly when combined with EBRT. The long-term incidence of this may be decreased with physical adhesiolysis either via use of a dilator, by stent, or through sexual intercourse. These patients require close, appropriate follow-up. Overall, these series indicate that the addition of HDR brachytherapy alone after hysterectomy results in high rates of local control in patients who are at low risk for nodal spread. There is some indication that rates of acute toxicity might be somewhat higher with the use of HDR brachytherapy.[201] The dose that is received by the surrounding normal tissue is critically dependent on positioning of the applicator and in one study was found to result to in a change in the distance from the rectal wall to the applicator of a median of 10.5 mm between two consecutive placements of the applicator.[202] It is critical that the treatment be appropriately planned and that the position of the applicator for each treatment be verified to minimize radiation dose to the surrounding normal tissues.

Radiation Therapy in the Medically Inoperable

Patients who are medically inoperable or who refuse surgery may be treated with primary radiation therapy alone. EBRT with or without vaginal brachytherapy is often used; however, in patients who are at low risk for spread beyond the uterus, vaginal brachytherapy alone may be used. Table 92-12 reviews results for radiation alone. In the work of Patanaphan and colleagues, 5-year overall survival was 46% for all patients receiving radiation alone, and the 5-year overall survival for stage I, grade I patients was only 75%.[203] Langren and colleagues retrospectively reviewed 124 stage I and II endometrial cancer patients who were treated with radiation alone.[204] Although 5-year overall survival was low, owing to the medical comorbidities of this patient population (77% for stage I, 65% for stage II), radiation alone was able to achieve acceptable rates of local control. The 5-year freedom from pelvic recurrence rate was 78% for stage I patients and 82% for stage II patients. Several institutional series have demonstrated the effectiveness of radiation alone for stage I and II endometrial carcinoma. Kupelian and colleagues reviewed 152 patients who were treated with radiotherapy alone.[205] The majority of patients (116 out of 152) were treated with brachytherapy alone. For patients with stage I and stage II disease, the 5-year disease-specific survival rate was 87% and 88%, respectively. Intrauterine recurrence was seen in 14% of patients with stage I or II disease, and extrauterine recurrence was seen in 3%. Chao and colleagues reviewed 101 patients who were treated with primary radiation therapy at Washington University.[206] All patients were either stage IA (18 patients) or stage IB (83 patients). The majority of patients were treated with both whole-pelvic irradiation and intracavitary boost, although a wide range of techniques was used. Pelvic control was achieved in 100% of stage IA patients and in 88% of stage IB patients. The 5-year disease-free survival rate was 80% for stage IA patients and 84% for stage IB.

In another series from Yale University, 54 patients with medically inoperable stage I or II endometrial adenocarcinoma were treated with radiation alone.[207] These patients were matched 2:1 by age, stage, and grade with patients who underwent surgical treatment for their endometrial cancer. The cancer-specific survival rate was somewhat worse for patients who underwent primary radiation treatment. For stage I patients, the 5-year actuarial cancer-specific survival rate was 80% for patients who were treated with radiation alone compared to a 5-year cancer-specific survival rate of 98% for those who underwent surgery. For stage II patients, the 5-year actuarial cancer-specific survival rate was 85% and 100% for inoperable and operable patients, respectively. A significant difference in the 5-year overall survival rate was seen between inoperable and operable patients (30% and 24%, respectively, for stage I and stage II inoperable patients versus 88% and 85%, respectively, for stage I and stage II operable patients). However, for patients receiving radiation only who did not die of intercurrent illness, there was no significant difference in medial survival between inoperable and operable patients.

For patients who are not good candidates for surgical removal of the uterus owing to coexisting medical conditions and who are at low risk for nodal spread, brachytherapy alone may be used as the primary treatment for their endometrial cancer. Although LDR brachytherapy may require anesthesia, it can also be performed with an epidural anesthesia in some patients. It is less invasive than hysterectomy and is generally well tolerated with a low procedural complication rate.[208] Grigsby and colleagues reviewed the outcomes of 26 stage II patients who were treated with LDR intracavitary brachytherapy alone.[179] The 5-year disease-free survival rate was found to be 53% in this group with a high major complication rate of 19%. In another retrospective study, the 5-year disease-free survival rates for stage IA, IB, and II disease treated with HDR brachytherapy alone were reported to be 85%, 73%, and 69%, respectively.[209] Another study reported a 3-year disease-free survival rate of 85% in stage I medically inoperable endometrial cancer patients who were treated with HDR brachytherapy alone; however, complication rates were again high at 21%.[210] Overall survival is low in these patients, owing to their medical comorbidities and complication rates higher than those in medically operable patients. The results of brachytherapy alone are worse than those of treatment that includes surgical resection, even for very early-stage disease; however, it does offer a reasonable option for treatment in patients who are poor surgical candidates.

No studies have been conducted in a randomized fashion that directly compare radiation alone and surgery alone for early-stage endometrial cancer. Surgery remains the treatment of choice for patients who are medically fit; however, for patients who are medically inoperable, radiation therapy alone offers a viable alternative for treatment and provides adequate rates of local control.

TREATMENT OF ADVANCED ENDOMETRIAL CANCER

Although the majority of patients who are diagnosed with endometrial cancer present with early-stage disease, 10% to 15% have advanced disease at presentation. This includes patients with positive pelvic and para-aortic lymph nodes, local invasion into other pelvic organs, pelvic recurrence at the vaginal cuff or in pelvic lymph nodes, and distant metastases. Patients may be categorized as having pathologic stage or clinical stage III and IV disease. Hysterectomy remains the primary treatment for any operable advanced-stage cancers. Radiation therapy is often used postoperatively to reduce the risk of local recurrence, to treat areas of residual disease or to palliate symptoms related to recurrent cancer. It may also be used preoperatively in technically inoperable patients or even as the primary therapy in patients with medically inoperable disease. While radiation therapy has not been shown to improve overall survival in these situations, it is very effective therapy for both locoregional control and palliation. Adjuvant radiation has a particularly important role in endometrial cancer, given relatively low response rates to chemotherapeutic agents.

The GOG has conducted a phase III randomized trial for advanced endometrial cancer patients. GOG Protocol 122 randomized 422 patients with stage III or IV endometrial carcinoma with maximal postoperative residual disease of 2 cm to whole-abdominal irradiation versus cisplatin and doxorubicin systemic chemotherapy every 3 weeks for eight cycles.[211] The radiation arm was treated to 30 Gy and included a pelvic boost (15 Gy) to the true pelvis or to an extended field encompassing pelvic and para-aortic lymph nodes. An extended field boost was used in the case of positive para-aortic nodes or in patients whose para-aortic lymph nodes were not sampled. The median dose was 45 Gy for whole-abdominal irradiation plus the boost. Approximately 84% of patients completed radiation therapy, and 63% completed the eight cycles of chemotherapy. Fifty-four percent of patients in the radiation arm and 50% in the chemotherapy arm had a documented tumor recurrence. The hazard ratio for progression adjusted for stage was 0.71 favoring the chemotherapy arm ($P < 0.01$). At 60 months, 50% of patients who received chemotherapy were predicted to be alive and disease free compared with 38% of patients who received radiation, when adjusted for stage. The most common acute toxicities were grade III to IV toxicities—hematologic followed by gastrointestinal—and were significantly more common in the chemotherapy arm. There were eight treatment-related deaths in the chemotherapy arm and five deaths in the radiation arm. The GOG Protocol 184, which has completed accrual but for which results are pending, included a similar patient cohort, all of whom received pelvic radiation with or without para-aortic

fields and then were randomized to cisplatin and doxorubicin with or without paclitaxel.

Treatment of Advanced Endometrial Cancer by Stage

Pathologic Stage III Endometrial Cancer

Results of therapy for stage III disease depend on whether patients have pathologic stage III diagnosed after surgical staging or present with clinical stage III disease. Surgically staged III disease includes those with stage IIIA due to positive washings alone or microscopic extension to the serosa or adnexae, IIIB due to vaginal metastasis, or IIIC due to microscopic lymph node involvement. Clinical stage III disease involves gross extrauterine extension, pelvic adenopathy that is detectable on preoperative scans, or clinically evident vaginal extension. Thus, clinical stage III disease comprises bulkier tumors by definition and often includes patients who require radical surgery, such as an exenteration, or those who are technically inoperable. Inevitably, outcomes are poorer for these patients. For surgically treated pathologic stage III patients overall who are treated with hysterectomy and postoperative radiation, a 5-year disease-free survival rate of 64% and a pelvic recurrence rate of 21% have been reported.[212] Predictors of survival include grade, depth of invasion, number of extrauterine sites of disease, and uterine serous or clear cell histology. Grade is the strongest predictor of pelvic recurrence; histology and number of extrauterine sites predict for abdominal recurrence.

Pathologic Stage IIIA

Surgical stage IIIA represents a heterogeneous group of disease. The most favorable subgroup of stage IIIA patients are those with positive peritoneal washings as their sole criterion of advanced disease, which occurs in about 5% of patients. Such patients have a favorable outcome, with or without adjuvant therapy.[213] The selection of adjuvant treatment of these patients is controversial, and the prognostic significance of this finding remains uncertain. About 10% of patients with FIGO stage I endometrial cancer have positive peritoneal washings. Over half of all patients with positive pelvic washings will also have adnexal or other areas of pelvic spread of disease. This finding is associated with depth of invasion, high-grade and positive nodes, and positive cytology and is predictive of survival.[214,215] Table 92-13 shows the results from series examining the impact of positive cytology, with recurrence rates ranging from 0% to 46% and disease-free survival rates of 17% to 100%, highlighting the difficulty in interpreting positive cytology as a prognostic marker. Overall, peritoneal cytology often fails to identify any additional patients who are candidates for postoperative therapy that are not identified by grade and depth of invasion.

Despite data suggesting a poorer prognosis for these patients, only a few series have reported exclusively on outcomes in pathologic stage IIIA patients. In a series by Creasman and colleagues, 26 patients with stage I disease and positive peritoneal washings had a 34% recurrence rate compared to 9% among women with negative washings.[216] Of thirteen patients with no extrauterine disease and positive cytology, 46% died of disseminated intraperitoneal recurrence. Thus the investigators subsequently treated 23 patients with malignant washings with intra-abdominal P-32 colloid postoperatively. They concluded that P-32 therapy was efficacious, as none of these patients had any pelvic or abdominal recurrence, although three developed distant disease. In a report by Soper and colleagues, 65 women with clinical stage I to III endometrial cancer with malignant cytology were treated with intraperitoneal radioactive P-32 suspension demonstrated an 8% intraperitoneal recurrence rate, most with simultaneous extraperitoneal metastases.[217] Chronic bowel problems were not seen in patients who received P-32 alone but occurred in 29% of women who also received external irradiation to the pelvis, including two deaths. Potish has described 5-year relapse free survival rate

of 77% of women with microscopic peritoneal spread treated with whole-abdominal radiation and an overall 4% rate of bowel obstructions.[218] The use of adjuvant radiation in patients with positive cytology as the only evidence of extrauterine spread remains controversial, although it is frequently offered. Whether to offer pelvic or whole-abdominal radiation remains unclear.

Hormonal therapy with progestins or systemic chemotherapy has also been used as an adjuvant treatment in small groups of patients with isolated positive washings. These small series report relapse rates of 0% to 25% and a disease-free survival rate of 67%, compared to 85%.[219,220] Piver conducted a pilot study of 25 patients with surgical stage I disease and malignant pelvic washings who were treated with progesterone.[221] Twenty-two patients underwent a second-look laparoscopy, and 95% had no evidence of disease with negative washings. One patient with persistent positive washings was treated with an additional year of progestins and remained free of disease. Although these data are intriguing, too few patients have been treated exclusively with hormonal therapy to assess the efficacy of this therapy compared to adjuvant radiation, although either treatment appears superior to no adjuvant therapy. Most patients will have other risk factors for pelvic or distant recurrence that guide treatment decisions, including grade, depth of invasion, and lymphovascular space invasion.

Patients with pathologic stage IIIA disease due to isolated adnexal involvement also make up a more favorable subset among stage III patients. Invasion may occur by direct transtubal invasion or may be due to lymphatic spread. Some of these patients might have concurrent early-stage ovarian cancers as well; therefore, careful pathologic assessment is warranted. The GOG reported that 5% of surgically staged patients with clinical stage I disease had adnexal involvement.[50] This pathologic finding is associated with a 32% risk of pelvic lymph node metastases, and 23% of patients have para-aortic lymph node spread. In the largest reported subgroup of 42 patients with isolated adnexal involvement, Greven and colleagues noted a 5-year survival rate of 60%, compared to 54% for the entire group of pathologic stage III patients.[212] The grade and depth of myometrial invasion further defined the prognosis for these patients, in whom high grade reduced the survival rate to 40% and invasion through greater than one third of the myometrium resulted in a 47% survival rate. Most patients had received postoperative pelvic irradiation with or without a boost. Isolated abdominal failure in this series was uncommon, at 7%. Nori and colleagues analyzed a group of patients who were treated with surgery and either preoperative or postoperative pelvic irradiation with an intravaginal boost, which included 21 patients with microscopic involvement of the adnexae and 12 patients with gross adnexal involvement.[222] The 5-year survival rate was better for those with microscopic invasion (80%) than for those with gross invasion of the adnexae (40%), even though this was the only extrauterine disease. Several other smaller series that analyzed this subset of patients have reported 5-year relapse free survival rates from 60% to 90% in patients who were treated postoperatively with either pelvic[223,224] or whole-abdominopelvic radiation.[225,226] Overall, the small patient numbers in these reports preclude any conclusion as to the relative efficacy of pelvic versus whole-abdominal radiation in this subset. Adjuvant pelvic therapy is generally offered to patients who do not have significant comorbidities.

Pathologic Stage IIIB

Stage IIIB is a very uncommon presentation. It is generally treated with a combination of EBRT and intracavitary or interstitial brachytherapy.

Pathologic Stage IIIC

The patients who are at highest risk for recurrence are those with positive pelvic or para-aortic lymph nodes. The GOG examined pathologic factors in clinical stage I to II endometrial cancer patients.[50] In their series of 1180 women, 13% (3% grossly positive) overall had positive pelvic nodes, and about one third of patients with positive pelvic nodes were also documented to have para-aortic nodal metastases. Lymph nodes were involved in 51% of women with extrauterine disease, 32% with adnexal invasion, and 25% with deep myometrial invasion. Patients with positive pelvic nodes who were treated with postoperative pelvic irradiation had a 5-year disease-free survival rate of 72%. The presence of positive pelvic lymph nodes only was more favorable than was involvement of the para-aortic nodes as well. There was a recurrence rate of 28% for those with positive pelvic nodes compared to 40% for those with positive aortic nodes. Of patients with positive para-aortic nodes, 77% received postoperative radiation with a 5-year disease-free survival rate of 36%. A small study of 17 patients with nodal spread confined to the pelvic nodes, all of whom received postoperative radiation, reported a 5-year overall survival rate of 72%.[227] Better survivals have been reported for patients who present with microscopically positive lymph nodes versus grossly involved nodes. One series reported a mean survival greater than 60 months if nodes were microscopically involved compared to 35 months for macroscopically involved nodes.[228]

Outcomes with adjuvant radiation (with or without systemic therapy) have been retrospectively reviewed, although treatment techniques have varied significantly. Table 92-14 reviews the results of various series. In a recent study of 47 patients with stage IIIC disease, 36% had whole-abdominal radiation, 19% had extended pelvic and para-aortic nodal irradiation, and 17% had pelvic irradiation alone.[229] In addition, 17% were treated with chemotherapy and 11% with progestins. The 5-year overall survival rate was 65%, with distant metastases seen in 21% and pelvic recurrence in 9%. Predictors of failure included depth of invasion and positive cytology or adnexal involvement. The role of the various adjuvant treatments used, however, could not be clearly defined. Patients in whom nodal disease is confined to the pelvic lymph nodes and whose para-aortic lymph node sampling is negative are still at risk for para-aortic recurrence. Mundt and colleagues reported on 30 stage IIIC patients, all with positive pelvic nodes, and 54% with positive para-aortic lymph nodes, all treated with TAH-BSO followed by pelvic or extended field radiation.[230] They noted a 5-year disease-free survival rate of 34%, with 23% of patients experiencing pelvic failure (including four vaginal failures), 13% experiencing abdominal failures, and 13% experiencing para-aortic failures; 40% developed distant metastases. No patient who was treated with extended field irradiation developed a para-aortic nodal recurrence, although 8 of 10 had positive para-aortic nodes at the time of surgery. Treatment was well tolerated, with only two late sequelae (one chronic enteritis and one bowel obstruction).

For patients with positive para-aortic nodes and no other abdominal disease, the optimal radiation field arrangement remains uncertain. Potish and colleagues reported on 48 women who were treated with extended para-aortic fields, half of whom had abnormal lymphangiograms and half of whom had pathologically documented nodal metastases. They found that 88% of recurrences were outside the radiation fields, including 44% of first failures in the abdomen.[231] In this series, the survival rate was better in clinically staged patients than in surgically staged patients (57% versus 47%), suggesting an uncertainty in clinical staging of nodal disease. Corn and colleagues examined outcomes in 50 women, 26 with pathologically staged para-aortic nodal involvement and 24 who had been diagnosed with lymphangiography, who were treated preoperatively and postoperatively or primarily with extended field radiation.[232] Para-aortic lymph node dissection significantly decreased the para-aortic failures, and the authors noted only three abdominal failures. Two other series looked at the impact of extended field irradiation in patients all with pathologically documented para-aortic nodal spread. In one group of 26 patients, 17 received extended field radiation treatment, most with adjuvant megestrol acetate (Megace), and the remaining 9 patients received megestrol acetate or chemotherapy alone.[233] The overall

Table 92-14 Results for Stage IIIC Patients with Positive Pelvic or Para-aortic Lymph Nodes

survival rate was significantly improved in the irradiated group (53% versus 22%). In the second series, 20 patients with para-aortic metastases received three cycles of postoperative chemotherapy followed by extended field irradiation.[234] The 5-year survival rate was 75% for positive para-aortic nodes, compared to 100% if only the pelvic nodes were positive. Reported series of patients treated with whole-abdominal radiation have represented heterogeneous stage and histologic groups and generally included small numbers of patients with para-aortic metastases as the primary reason for whole-abdominal radiation fields. Adjuvant therapy with combination chemotherapy combined with involved field radiation has been reported in advanced endometrial cancer.[235–237] These protocols were well tolerated. Additional trials are required to determine long-term survival.

Clinical Stage III and IV Disease
